AMERICAN SOCIETY OF CLINICAL ONCOLOGY

2017 EDUCATIONAL BOOK

"Making a Difference in Cancer Care WITH YOU"

A PEER-REVIEWED, INDEXED PUBLICATION

53rd Annual Meeting | June 2-6, 2017 | Chicago, Illinois | Volume 37

ASCO®

Making a world of difference in cancer care

American Society of Clinical Oncology Educational Book

The 2017 *ASCO Educational Book* (Print ISSN: 1548-8748 37; Electronic ISSN: 1548-8756) is published by American Society of Clinical Oncology, Inc. ("ASCO").

All other questions should be addressed to ASCO Educational Book Managing Editor, American Society of Clinical Oncology, Inc., 2318 Mill Road, Suite 800, Alexandria, VA 22314. Tel: (571) 483-1300; fax: (571) 366-9550; or email: edbook@asco.org.

Single issues, both current and back, exist in limited quantities and are offered for sale subject to availability. For further information, email edbook@asco.org or call (888) 273-3508.

American Society of Clinical Oncology Educational Book

Editor in Chief: Don S. Dizon, MD

Associate Editor: Nathan Pennell, MD, PhD

Guest Editor: Hope S. Rugo, MD

Managing Editor: Lindsay F. Pickell, MFA

Editorial Coordinator: Christine Melchione

Production Manager: Donna Dottellis

American Society of Clinical Oncology

2017 ASCO Educational Book Expert Panel xiii

Letter From the Editor in Chief 1

INVITED ARTICLES

Can Cancer Truths Be Told? Challenges for Medical Journalism
Elaine Schattner 3

Future Genetic/Genomic Biomarker Testing in Non–Small Cell Lung Cancer
David Planchard, Jordi Remon, Frédérique Nowak, and Jean-Charles Soria 12

Making the Case for Improving Oncology Workforce Diversity
Karen M. Winkfield, Christopher R. Flowers, and Edith P. Mitchell 18

Minimizing Minimally Invasive Surgery for Endometrial Carcinoma
Melissa K. Frey, Stephanie V. Blank, and John P. Curtin 23

The Road to Addressing Noncommunicable Diseases and Cancer in Global Health Policy
Heath Catoe, Jordan Jarvis, Sudeep Gupta, Ophira Ginsburg, and Gilberto de Lima Lopes Jr. 29

POINTS OF VIEW

How Should We Intervene on the Financial Toxicity of Cancer Care? One Shot, Four Perspectives
S. Yousuf Zafar, Lee N. Newcomer, Justin McCarthy, Shelley Fuld Nasso, and Leonard B. Saltz 35

Practice Model for Advanced Practice Providers in Oncology
Jamie Cairo, Mary Ann Muzi, Deanna Ficke, Shaunta Ford-Pierce, Katrina Goetzke, Diane Stumvoll, Laurie Williams, and Federico A. Sanchez 40

BREAST CANCER

Breast Cancer in the Central Nervous System: Multidisciplinary Considerations and Management
Nancy U. Lin, Laurie E. Gaspar, and Riccardo Soffietti 45

Lifestyle Interventions to Improve Cardiorespiratory Fitness and Reduce Breast Cancer Recurrence
Mark J. Haykowsky, Jessica M. Scott, Kathryn Hudson, and Neelima Denduluri 57

Novel Targeted Agents and Immunotherapy in Breast Cancer
Ingrid A. Mayer, Rebecca Dent, Tira Tan, Peter Savas, and Sherene Loi 65

Optimal Management of Early and Advanced HER2 Breast Cancer
Sara A. Hurvitz, Karen A. Gelmon, and Sara M. Tolaney 76

The 2017 *ASCO Educational Book* is published online at asco.org/edbook. Articles that are only available online are denoted with an "e" ahead of the page number.

Optimizing Breast Cancer Adjuvant Radiation and Integration of Breast and Reconstructive Surgery
Henry M. Kuerer, Peter G. Cordeiro, and Robert W. Mutter 93

Standard and Genomic Tools for Decision Support in Breast Cancer Treatment
N. Lynn Henry, Philippe L. Bedard, and Angela DeMichele 106

Therapeutic Bone-Modifying Agents in the Nonmetastatic Breast Cancer Setting: The Controversy and a Value Assessment
Michael Gnant, Catherine Van Poznak, and Lowell Schnipper 116

CANCER PREVENTION, HEREDITARY GENETICS, AND EPIDEMIOLOGY

European/U.S. Comparison and Contrasts in Ovarian Cancer Screening and Prevention in a High-Risk Population
Marian J. Mourits and G. H. de Bock 124

Social Media and Mobile Technology for Cancer Prevention and Treatment
Judith J. Prochaska, Steven S. Coughlin, and Elizabeth J. Lyons 128

CARE DELIVERY AND PRACTICE MANAGEMENT

Challenges in Opening and Enrolling Patients in Clinical Trials
Julie M. Vose, Meredith K. Chuk, and Francis Giles 139

mHealth: Mobile Technologies to Virtually Bring the Patient Into an Oncology Practice
Nathan A. Pennell, Adam P. Dicker, Christine Tran, Heather S. L. Jim, David L. Schwartz, and Edward J. Stepanski 144

Perspectives on the Use of Clinical Pathways in Oncology Care
Anne C. Chiang, Peter Ellis, and Robin Zon 155

Precision Oncology: Who, How, What, When, and When Not?
Lee Schwartzberg, Edward S. Kim, David Liu, and Deborah Schrag 160

CENTRAL NERVOUS SYSTEM TUMORS

American Society for Radiation Oncology 2016 Annual Meeting: Central Nervous System Abstracts
Samuel Chao 171

Beyond Alkylating Agents for Gliomas: *Quo Vadimus*?
Vinay K. Puduvalli, Rekha Chaudhary, Samuel G. McClugage, and James Markert 175

Practice-Changing Abstracts From the 2016 Society for Neuro-Oncology Annual Scientific Meeting
Marta Penas-Prado 187

DEVELOPMENTAL THERAPEUTICS AND TRANSLATIONAL RESEARCH

Adoptive T-Cell Therapy for Solid Tumors
Oladapo Yeku, Xinghuo Li, and Renier J. Brentjens 193

Biomarkers for Checkpoint Inhibition
Jeffrey S. Weber 205

Pharmacokinetic/Pharmacodynamic Modeling for Drug Development in Oncology
Elena Garralda, Rodrigo Dienstmann, and Josep Tabernero 210

Strategies to Maximize Patient Participation in Clinical Trials
Eric H. Rubin, Mary J. Scroggins, Kirsten B. Goldberg, and Julia A. Beaver 216

Tissue-Agnostic Drug Development
Keith T. Flaherty, Dung T. Le, and Steven Lemery 222

GASTROINTESTINAL (COLORECTAL) CANCER

Personalizing Adjuvant Therapy for Stage II/III Colorectal Cancer
Nadine Jackson McCleary, Al B. Benson III, and Rodrigo Dienstmann 232

Systemic Therapy for Metastatic Colorectal Cancer: From Current Standards to Future Molecular Targeted Approaches
Chloe E. Atreya, Rona Yaeger, and Edward Chu 246

GASTROINTESTINAL (NONCOLORECTAL) CANCER

Best Practices and Practical Nuances in the Treatment of Gastric Cancer in High-Risk Global Areas
Federico A. Sanchez 258

Gastric Cancer in Southern Europe: High-Risk Disease
Ramon Andrade De Mello 261

Deploying Immunotherapy in Pancreatic Cancer: Defining Mechanisms of Response and Resistance
Gregory L. Beatty, Shabnam Eghbali, and Rebecca Kim 267

Gastric Cancer in Asia: Unique Features and Management
Tomoyuki Irino, Hiroya Takeuchi, Masanori Terashima, Toshifumi Wakai, and Yuko Kitagawa 279

Immunotherapy for Esophageal and Gastric Cancer
Ronan J. Kelly 292

Pancreatic Adenocarcinoma: Improving Prevention and Survivorship
Davendra P. S. Sohal, Field F. Willingham, Massimo Falconi, Kara L. Raphael, and Stefano Crippa 301

The Promise of Immunotherapy in the Treatment of Hepatocellular Carcinoma
Anthony El-Khoueiry 311

GENITOURINARY (NONPROSTATE) CANCER

Evolving Treatment Paradigm in Metastatic Renal Cell Carcinoma
David M. Gill, Neeraj Agarwal, and Ulka Vaishampayan 319

New Developments and Challenges in Rare Genitourinary Tumors: Non-Urothelial Bladder Cancers and Squamous Cell Cancers of the Penis
Jeanny B. Aragon-Ching and Lance C. Pagliaro 330

Systemic Therapy for Non–Clear Cell Renal Cell Carcinoma
Tian Zhang, Jun Gong, Manuel Caitano Maia, and Sumanta K. Pal 337

GENITOURINARY (PROSTATE) CANCER

Diagnosis and Treatment of Prostate Cancer: What Americans Can Learn From International Oncologists
Nicholas James, John Graham, Tobias Maurer, Matthias Eiber, and Jürgen E. Gschwend 344

Personalizing Therapy for Metastatic Prostate Cancer: The Role of Solid and Liquid Tumor Biopsies
Terence W. Friedlander, Colin C. Pritchard, and Himisha Beltran 358

Screening and Treating Prostate Cancer in the Older Patient: Decision Making Across the Clinical Spectrum
Alicia K. Morgans, William Dale, and Alberto Briganti 370

GERIATRIC ONCOLOGY

Improving Quality and Value of Cancer Care for Older Adults
Erika E. Ramsdale, Valerie Csik, Andrew E. Chapman, Arash Naeim, and Beverly Canin 383

GLOBAL HEALTH

Global Health Initiatives of the International Oncology Community
Sana Al-Sukhun, Gilberto de Lima Lopes Jr., Mary Gospodarowicz, Ophira Ginsburg, and Peter Paul Yu 395

Biomarker Testing for Personalized Therapy in Lung Cancer in Low- and Middle-Income Countries
Fred R. Hirsch, Bojan Zaric, Ahmed Rabea, Sumitra Thongprasert, Nirush Lertprasertsuke, Mercedes Liliana Dalurzo, and Marileila Varella-Garcia 403

Cancer Care and Control as a Human Right: Recognizing Global Oncology as an Academic Field
Alexandru E. Eniu, Yehoda M. Martei, Edward L. Trimble, and Lawrence N. Shulman 409

Thinking Differently in Global Health in Oncology Using a Diagonal Approach: Harnessing Similarities, Improving Education, and Empowering an Alternative Oncology Workforce
Natalia M. Rodriguez, Jeannine M. Brant, Dinesh Pendharkar, Hector Arreola-Ornelas, Afsan Bhadelia, Gilberto de Lima Lopes Jr., and Felicia M. Knaul 416

Wedge Resection Versus Anatomic Resection: Extent of Surgical Resection for Stage I and II Lung Cancer
Hisao Asamura, Keiju Aokage, and Masaya Yotsukura 426

GYNECOLOGIC CANCER

Endometrial Cancer: Is This a New Disease?
Kathleen Moore and Molly A. Brewer 435

Whence High-Grade Serous Ovarian Cancer
Elise C. Kohn and S. Percy Ivy 443

HEALTH SERVICES RESEARCH, CLINICAL INFORMATICS, AND QUALITY OF CARE

More Medicine, Fewer Clicks: How Informatics Can Actually Help Your Practice
Debra A. Patt, Elmer V. Bernstam, Joshua C. Mandel, David A. Kreda, and Jeremy L. Warner 450

The Oncology Care Model: Perspectives From the Centers for Medicare & Medicaid Services and Participating Oncology Practices in Academia and the Community
Ron Kline, Kerin Adelson, Jeffrey J. Kirshner, Larissa M. Strawbridge, Marsha Devita, Naralys Sinanis, Patrick H. Conway, and Ethan Basch 460

HEMATOLOGIC MALIGNANCIES—LEUKEMIA, MYELODYSPLASTIC SYNDROMES, AND ALLOTRANSPLANT

Chronic Myeloid Leukemia: What Every Practitioner Needs to Know in 2017
Hanna Jean Khoury, Loretta A. Williams, Ehab Atallah, and Rüdiger Hehlmann 468

New Insight Into the Biology, Risk Stratification, and Targeted Treatment of Myelodysplastic Syndromes
Mintallah Haider, Eric J. Duncavage, Khalid F. Afaneh, Rafael Bejar, and Alan F. List 480

Novel Therapeutics in Acute Myeloid Leukemia
Courtney D. DiNardo, Richard M. Stone, and Bruno C. Medeiros 495

HEMATOLOGIC MALIGNANCIES—LYMPHOMA AND CHRONIC LYMPHOCYTIC LEUKEMIA

Age and Sex in Non-Hodgkin Lymphoma Therapy: It's Not All Created Equal, or Is It?
Michael Pfreundschuh 505

Current Approaches to Mantle Cell Lymphoma: Diagnosis, Prognosis, and Therapies
Jonathon B. Cohen, Jasmine M. Zain, and Brad S. Kahl 512

Health Disparities and the Global Landscape of Lymphoma Care Today
Adrienne A. Phillips and Dominic A. Smith 526

Understanding the New WHO Classification of Lymphoid Malignancies: Why It's Important and How It Will Affect Practice
Elaine S. Jaffe, Paul M. Barr, and Sonali M. Smith 535

HEMATOLOGIC MALIGNANCIES—PLASMA CELL DYSCRASIA

Established and Novel Prognostic Biomarkers in Multiple Myeloma
Mark Bustoros, Tarek H. Mouhieddine, Alexandre Detappe, and Irene M. Ghobrial 548

Hematologic Malignancies: Plasma Cell Disorders
Madhav V. Dhodapkar, Ivan Borrello, Adam D. Cohen, and Edward A. Stadtmauer 561

Integration of Genomics Into Treatment: Are We There Yet?
Gareth J. Morgan and John R. Jones 569

Myeloma in Elderly Patients: When Less Is More and More Is More
Ashley Rosko, Sergio Giralt, Maria-Victoria Mateos, and Angela Dispenzieri 575

LUNG CANCER

Caring for the Older Population With Advanced Lung Cancer
Carolyn J. Presley, Craig H. Reynolds, and Corey J. Langer 587

Clinical Pathways and the Patient Perspective in the Pursuit of Value-Based Oncology Care
Jennifer L. Ersek, Eric Nadler, Janet Freeman-Daily, Samir Mazharuddin, and Edward S. Kim 597

Managing Resistance to EFGR- and ALK-Targeted Therapies
Christine M. Lovly, Puneeth Iyengar, and Justin F. Gainor 607

Pathology Issues in Thoracic Oncology: Histologic Characterization and Tissue/Plasma Genotyping May Resolve Diagnostic Dilemmas
Ibiayi Dagogo-Jack, Andreas Saltos, Alice T. Shaw, and Jhanelle E. Gray 619

Role of Chemotherapy and Targeted Therapy in Early-Stage Non–Small Cell Lung Cancer
Shirish M. Gadgeel 630

MELANOMA/SKIN CANCERS

Advances in the Treatment of Advanced Extracutaneous Melanomas and Nonmelanoma Skin Cancers
Kimberly M. Komatsubara, Joanne Jeter, Richard D. Carvajal, Kim Margolin, Dirk Schadendorf, and Axel Hauschild 641

Operable Melanoma: Screening, Prognostication, and Adjuvant and Neoadjuvant Therapy
Ahmad A. Tarhini, Paul Lorigan, and Sancy Leachman 651

Systemic Therapy Options for Patients With Unresectable Melanoma
Melinda Yushak, Paul Chapman, Caroline Robert, and Ragini Kudchadkar 661

PATIENT AND SURVIVOR CARE

Addressing the Survivorship Care Needs of Patients Receiving Extended Cancer Treatment
Paul B. Jacobsen, Ryan D. Nipp, and Patricia A. Ganz 674

Bench-to-Bedside Approaches for Personalized Exercise Therapy in Cancer
Lee W. Jones, Neil D. Eves, and Jessica M. Scott 684

Improving Cancer Care Through the Patient Experience: How to Use Patient-Reported Outcomes in Clinical Practice
Kathi Mooney, Donna L. Berry, Meagan Whisenant, and Daniel Sjoberg 695

Pain and Opioids in Cancer Care: Benefits, Risks, and Alternatives
Mike Bennett, Judith A. Paice, and Mark Wallace 705

Using the New ASCO Clinical Practice Guideline for Palliative Care Concurrent With Oncology Care Using the TEAM Approach
Cardinale B. Smith, Tanyanika Phillips, and Thomas J. Smith 714

PEDIATRIC ONCOLOGY

Advances in the Treatment of Pediatric Bone Sarcomas
Patrick J. Grohar, Katherine A. Janeway, Luke D. Mase, and Joshua D. Schiffman 725

Breast Cancer After Childhood, Adolescent, and Young Adult Cancer: It's Not Just About Chest Radiation
David Hodgson, Flora van Leeuwen, Andrea Ng, Lindsay Morton, and Tara O. Henderson 736

Data Commons to Support Pediatric Cancer Research
Samuel L. Volchenboum, Suzanne M. Cox, Allison Heath, Adam Resnick, Susan L. Cohn, and Robert Grossman 746

New Classification for Central Nervous System Tumors: Implications for Diagnosis and Therapy
Christine E. Fuller, David T. W. Jones, and Mark W. Kieran 753

PROFESSIONAL DEVELOPMENT

Collaborating With Advanced Practice Providers Impact and Opportunity
Heather M. Hylton and G. Lita Smith e1

For Our Patients, for Ourselves: The Value of Personal Reflection in Oncology
Lidia Schapira, Jane Lowe Meisel, and Ranjana Srivastava 765

Mastering Resilience in Oncology: Learn to Thrive in the Face of Burnout
Fay J. Hlubocky, Miko Rose, and Ronald M. Epstein 771

Social Media for Networking, Professional Development, and Patient Engagement
Merry Jennifer Markham, Danielle Gentile, and David L. Graham 782

The Road of Mentorship
Kelly J. Cooke, Debra A. Patt, and Roshan S. Prabhu 788

SARCOMA

Bone Sarcoma Pathology: Diagnostic Approach for Optimal Therapy
Andrew E. Rosenberg 794

Fertility, Cardiac, and Orthopedic Challenges in Survivors of Adult and Childhood Sarcoma
Emma R. Lipshultz, Ginger E. Holt, Ranjith Ramasamy, Raphael Yechieli, and Steven E. Lipshultz 799

The Current Landscape of Early Drug Development for Patients With Sarcoma
Breelyn A. Wilky, Robin L. Jones, and Vicki L. Keedy 807

TUMOR BIOLOGY

Higher-Level Pathway Objectives of Epigenetic Therapy: A Solution to the p53 Problem in Cancer
Vamsidhar Velcheti, Tomas Radivoyevitch, and Yogen Saunthararajah 812

Metabolic Alterations in Cancer and Their Potential as Therapeutic Targets
Jamie D. Weyandt, Craig B. Thompson, Amato J. Giaccia, and W. Kimryn Rathmell 825

Value-Based Medicine and Integration of Tumor Biology
Gabriel A. Brooks, Linda D. Bosserman, Isa Mambetsariev, and Ravi Salgia 833

2017 ASCO Annual Meeting Disclosure

As the continuing education provider for the 2017 Annual Meeting, ASCO is committed to balance, objectivity, and scientific rigor in the management of financial interactions with for-profit health care companies that could create real or perceived conflicts of interest. Participants in the Meeting have disclosed their financial relationships in accordance with ASCO's Policy for Relationships with Companies; review the policy at asco.org/rwc.

ASCO offers a comprehensive disclosure management system, using one disclosure for all ASCO activities. Authors and participants are required to disclose all interactions with companies. Disclosures are kept on file and can be confirmed or updated with each new activity. Disclosures for the *ASCO Educational Book* are available to readers online, listed by author for each article.

Please email coi@asco.org with specific questions or concerns.

2016–2017 Cancer Education Committee

The Cancer Education Committee assesses the need for, plans, develops, and initiates the education programs for the Annual Meeting.

Michael A. Thompson, MD, PhD—*Chair*
David R. Spigel, MD—*Chair-Elect*
Apar Kishor Ganti, MD, MBBS—*Immediate Past Chair*

BREAST CANCER
Debra A. Patt, MD, MPH, MBA—*Track Leader*
Judy C. Boughey, MD
Jennifer A. Brown, MD
Rebecca A. Dent, MD
Alberto J. Montero, MD
Rinaa S. Punglia, MD, MPH
Hope S. Rugo, MD
Tallal Younis, MBBCh, FRCP

CANCER PREVENTION, HEREDITARY GENETICS, AND EPIDEMIOLOGY
Sofia Merajver, MD—*Track Leader*
Margreet Ausems, MD, PhD
Jeff Boyd, PhD
Monique A. De Bruin, MD
Joanne Jeter, MD
Prudence Lam, MD
Michael Mullane, MD
Surendra S. Shastri, MD, MBBS

CARE DELIVERY AND PRACTICE MANAGEMENT
Lee S. Schwartzberg, MD, FACP—*Track Leader*
Kelly Bugos, MS, RN, NP
Moshe C. Chasky, MD
Jeffery C. Ward, MD
Sue S. Yom, MD, PhD

CENTRAL NERVOUS SYSTEM TUMORS
Nicole A. Shonka, MD—*Track Leader*
Manmeet S. Ahluwalia, MD
Priscilla Brastianos, MD
Eric L. Chang, MD

DEVELOPMENTAL THERAPEUTICS AND TRANSLATIONAL RESEARCH
Francisco J. Esteva, MD, PhD—*Track Leader*
Julia A. Beaver, MD
Howard A. Burris, MD, FASCO
John C. Morris, MD
Naoko Takebe, MD, PhD

GASTROINTESTINAL (COLORECTAL) CANCER
Henry Q. Xiong, MD—*Track Leader*
Chi Lin, MD, PhD
Arden Morris, MD
Donald A. Richards, MD, PhD
Ashwin Reddy Sama, MD

GASTROINTESTINAL (NONCOLORECTAL) CANCER
Manish A. Shah, MD—*Track Leader*
Ramon De Mello, MD, PhD
Jimmy J. Hwang, MD
Vincent J. Picozzi, MD
Federico A. Sanchez, MD
William Small, MD

GENITOURINARY (NONPROSTATE) CANCER
Thomas E. Hutson, DO, PharmD, FACP—*Track Leader*
Jeanny Aragon-Ching, MD, FACP
Stephen Boyd Riggs, MD
Ulka N. Vaishampayan, MD

GENITOURINARY (PROSTATE) CANCER
Nicholas J. Vogelzang, MD, FASCO, FACP—*Track Leader*
Himisha Beltran, MD
Chris Parker, MD, BM Bchir, FRCR, FRCP
Edward M. Schaeffer, MD, PhD

GERIATRIC ONCOLOGY
Heidi Klepin, MD, MS—*Track Leader*
Gretchen Kimmick, MD
Stuart Lichtman, MD
Hyman Muss, MD, FASCO

GLOBAL HEALTH
Peter Paul Yu, MD, FASCO—*Track Leader*
Alex Mutombo Baleka, MD
Julie Gralow, MD, FASCO
Gilberto de Lima Lopes Jr., MD, MBA, FAMS

GYNECOLOGIC CANCER
Linda Van Le, MD—*Track Leader*
Ronald J. Buckanovich, MD
Elizabeth Dickson, MD
Elise C. Kohn, MD

HEAD AND NECK CANCER
Irina Veytsman, MD—*Track Leader*
John A. Ridge, MD, PhD, FACS
Joseph K. Salama, MD
John Truelson, MD

HEALTH SERVICES RESEARCH, CLINICAL INFORMATICS, AND QUALITY OF CARE
Ethan M. Basch, MD—*Track Leader*
Dawn L. Hershman, MD
Nicole M. Kuderer, MD
Ryan Nipp, MD
Jeremy Warner, MD, MS
Yousuf Zafar, MD, MHS

HEMATOLOGIC MALIGNANCIES—LEUKEMIA, MYELODYSPLASTIC SYNDROMES, AND ALLOTRANSPLANT
Steven Devine, MD—*Track Leader*
Jorge E. Cortes, MD
Jonathan M. Gerber, MD
Hanna Khoury, MD
David Leibowitz, MD

HEMATOLOGIC MALIGNANCIES—LYMPHOMA AND CHRONIC LYMPHOCYTIC LEUKEMIA
John M. Pagel, MD, PhD—*Track Leader*
Carla Casulo, MD
Ishmael Jaiyesimi, DO, MS, FACP
Matthew A. Lunning, DO
Barbara Pro, MD

HEMATOLOGIC MALIGNANCIES—PLASMA CELL DYSCRASIA
Parameswaran Hari, MD—*Track Leader*

Letter From the Editor in Chief

On behalf of my Associate Editor, Dr. Nathan Pennell, and Guest Editor, Dr. Hope S. Rugo, I welcome you to the 2017 ASCO Annual Meeting. It is an honor and privilege to present the 37th volume of the NLM-indexed *ASCO Educational Book*. The theme of this year's Meeting is "Making a Difference in Cancer Care ***WITH YOU***," and this theme celebrates the inclusiveness of those that work together to diagnose and care for people with cancer.

With his presidential theme, Dr. Daniel F. Hayes celebrates the inclusive nature of the oncology community. Only when the brightest minds in research, education, and care work together as a community are we able to deliver the highest quality of care to meet the needs of all of our patients. To celebrate the theme of the 2017 Annual Meeting, this volume contains articles coauthored not only by those who diagnose and care for patients with cancer, but also ancillary care specialists, such as nurses and advanced practice providers, and physicians in training. Coauthoring a manuscript takes immense planning and collaboration, and I would like to thank all of the authors for their contributions to the 2017 *ASCO Educational Book*.

We are honored to have Dr. Rugo join us as a Guest Editor for this year's Invited Articles. The Invited Articles allow us to explore critical topics in oncology that are closely related to this year's theme. I would like to thank Dr. Rugo for her dedication and her willingness to oversee this important section. Finally, I would also like to recognize the expert panel who selflessly dedicated their time to perform thorough and thoughtful reviews of the submitted articles. The tremendous work of Dr. Rugo, Dr. Pennell, the expert panel, and all of the authors is especially pertinent to this year's theme of inclusivity and support.

It is my honor to invite you to read the exceptional contributions that comprise this volume. For the first time in several years, the print edition contains the full collection of all of the 2017 articles and is available for purchase on the ASCO University Bookstore. All of the 2017 *ASCO Educational Book* articles, as well as articles from past volumes, are available to view online for free at www.asco.org/edbook.

We welcome your feedback and suggestions on how we can improve the content, so please contact us at edbook@asco.org with your comments.

Sincerely,

Don S. Dizon, MD
Editor in Chief

INVITED ARTICLES

This year's invited articles represent the 2017 ASCO Annual Meeting theme, "Making a Difference in Cancer Care ***WITH YOU***." These important contributions to the 37th volume of the *ASCO Educational Book* celebrate the inclusiveness of those that work together to diagnose and care for people with cancer. The authors represent a diverse, multidisciplinary set of expertise and backgrounds.

Authors were nominated by the *ASCO Educational Book* Editors and 2017 ASCO Annual Meeting leadership, and authors developed their topics under the guidance of Dr. Hope S. Rugo, Guest Editor of the Invited Articles.

Can Cancer Truths Be Told? Challenges for Medical Journalism

Elaine Schattner, MD

Journalism is a field undergoing rapid transformation. In 2016, nearly two-thirds of U.S. adults received news by social media. The Pew Research Center reported that the proportion and number of men and women seeking news on Reddit, Facebook, Twitter, Instagram, and YouTube has been climbing since 2013.[1] Meanwhile, traditional newspapers contend with falling print circulation, compete for online traffic, and drop staff. The number of U.S. newsroom employees fell steadily after 2006, from 55,000 to fewer than 33,000 jobs.[2]

Medical news presents a unique set of challenges, both for journalists and consumers. On the production side, reporters and editors aim to translate doctors' jargon-loaded updates into digestible, truthful, and appealing bits of information—stories—that resonate with a lay audience. The work is no small task, given the complexity and pace of science and clinical research. On the receiving end, patients or caregivers might read, watch, listen, or skim a feed, consciously or unconsciously taking notes. No matter what the source, an article might influence an individual's thinking about a personal medical decision. On a larger scale, medical journalism can sway policy makers.

The quality and accuracy of news has the potential to alter health outcomes. Put simply, the public depends on reliable news to support everyday medical choices and, occasionally, inform major decisions. When journalists get stories right, they help people to make reasoned choices and ask better questions of their physicians. Conversely, when reporters make errors or editors publish misleading headlines, people with medical conditions and other consumers of news, may be harmed.

This article will explore the capacity and limits of health journalism to inform the public about developments in oncology. We will focus on two issues: one is a perennial concern—balancing hype and reality, with appropriate skepticism—in what might be an era of true progress; second is the changing place of journalism amid a torrent of ungated medical information and stories channeled in blogs, social media posts, and celebrity statements. Finally, we will consider the emerging challenge of distilling valuable and relevant medical news amid a surplus.

BALANCING SKEPTICISM AND HYPE

A 2016 *CBS Evening News* story, "Promising Brain Cancer Trial Given Breakthrough Status by FDA," offers an instructive example[3] of how news can affect patients' thinking, hopefulness, and care. Scott Pelley, said by CBS on its website to be "one of the most experienced reporters in broadcast journalism," anchors the show. He stands upright, against a backdrop of laboratory research images; he speaks with a clear and authoritative voice: "We hope one day to lead the broadcast with a cure for cancer, but tonight, we might have the next best thing" (Fig. 1).

"The treatment is audacious, using poliovirus to kill glioblastoma, a vicious brain cancer that can kill in a matter of months," Pelley states. The program cuts to a young woman who, as told, was the first patient with brain cancer to volunteer in the clinical trial of an experimental treatment at Duke University. The newscaster reviews her case quickly, as a doctor might on rounds. In 2011, a 20-year-old nursing student experienced headaches; doctors found a brain tumor "the size of a tennis ball" and removed 98% of it in surgery; in 2012, the patient had recurrent glioblastoma. *60 Minutes* first reported on the experimental brain cancer treatment in March 2015.[4]

"Something unimaginable happened," Pelley says in the 2016 segment. Her tumor "shrank for 21 months, until it was gone." He shows the patient's MRI to television viewers and explains that it no longer reveals a brain tumor. She and at least two other participants in the phase I trial were doing well and in complete remission for over 3 years, Pelley reported.

Critiques of the *60 Minutes* and *CBS Evening News* coverage of the polio-derived brain cancer vaccine appeared at

From Weill Cornell Medicine, New York, NY.

Disclosures of potential conflicts of interest provided by the author are available with the online article at asco.org/edbook.

FIGURE 1. Scott Pelley, *CBS Evening News*, May 12, 2016

Related video available here: www.cbsnews.com/news/promising-duke-university-polio-brain-cancer-trial-given-breakthrough-status-60-minutes/. Accessed February 2017.

Forbes.com[5,6] (where I am a contributor) and HealthNewsReview.org, a health journalism watchdog site.[7] Criticisms included failure of Pelley's team to spell out alternative standard and experimental treatments for glioblastoma, no mention of costs, a heavy-weighting of views put forth by those involved with the trial at Duke, a lack of emphasis on the toxicity and deaths experienced by most of the research participants, and the use of the term breakthrough. The harshest piece[8] appeared in *MedPage Today*: "Brain Cancer: Did '60 Minutes' Report Raise False Hope?"

The original *60 Minutes* feature led to a slew of phone calls to the brain cancer team at Duke University, according to the *MedPage* story. A later piece[9] published by *The Hill*, "'60 Minutes': FDA Fast Tracks Cancer Treatment Using Polio Virus," reflects perception that television coverage accelerated the experimental trial and vaccine treatment. As told in the later *CBS Evening News* segment, the investigational agent is being developed by a company based at Duke and involves a scientist interviewed on the program.

The clip illustrates the challenges of discerning cancer progress from hype and news from advertisements. When I rewatched this episode on my personal computer in February 2017, an advertisement for a cancer treatment center kicked in. Yet I found the story compelling and valuable, overall; I wanted to know more about the brain cancer vaccine being tested at Duke University, a major academic medical center. Moreover, if I knew an otherwise healthy person with recurrent glioblastoma, I would want them to be aware of this promising treatment, in case they were seeking experimental options. A possible downside of this kind of story is that patients might have their hopes raised about entering the trial, only to find out that they are ineligible. On the plus side, for journalists to provide well-researched stories like this about the vaccine for glioblastoma, hearing of progress, however preliminary and carefully worded, might be comforting to people who have lost loved ones to the condition.

One reason the CBS story drew some flak may be that it begins with the term promising in the headline. That word—like breakthrough or miracle in a story having to do with cancer—causes journalists, and doctors, to bristle. Some teachers of health care journalism advise these hopeful words be avoided,[10] for similar reasons that oncologists instruct younger doctors not to tell a cancer patient they have been cured, but rather to say they are in remission. The problem with using such optimistic terms is they fail to prime the reader, or patient, for disappointment.

A research letter[11] published in *JAMA Oncology*, "The Use of Superlatives in Cancer Research," suggests that excessively positive language appears with undue frequency in journalism about cancer. The article, based on a Google search of terms in news published over 5 days in late June 2015, generated a blitz of coverage in late October 2015, when the paper appeared online. The story resonated, at least among journalists. "Half of the cancer drugs journalists called 'miracles' and 'cures' were not approved by the FDA," said Vox.com.[12] In a syndicated piece Reuters stated that "Glowing terms are often used for new cancer drugs in health news."[13] "If A New Cancer Drug Is Hailed As A Breakthrough, Odds Are It's Not," stated *NPR Health*.[14] "'Revolutionary.' 'Game changer.' 'Miracle.' How much are we hyping unproven cancer drugs?" asked *The Washington Post*.[15] A March 2017 *STAT News* opinion[16] by two oncology physicians, one of whom is the corresponding author of the original piece, reviews the *JAMA Oncology* report on superlative language. That column, titled "Few People Actually Benefit From 'Breakthrough' Cancer Immunotherapy," refers to "an ocean of hype" and links to another negative report.[17]

The message is clear: do not believe promising headlines about oncology drugs. But what if scientific and clinical advances have led to considerable gains for people with cancer? If progress against disease is real, as it may or may not be, a question for journalists is whether skepticism might be flipped: perhaps the current truth is not so bleak.

FAILING TO REPORT PROGRESS THAT IS SLOW, INCREMENTAL, AND IMPERFECT

Between 1991 and 2014, the death rate from cancer fell by 25% in the United States. This impressive figure headlined a report by the American Cancer Society (ACS), "Cancer Statistics, 2017," published on January 5, 2017.[18] In compiling this update, epidemiologists and statisticians drew on mortality data gathered by the National Center for Health Statistics. They also reviewed cancer incidence and survival data from the Surveillance, Epidemiology, and End Results (SEER) Program, the National Program of Cancer Registries, and the North American Association of Central Cancer Registries.

Yet a casual survey of my acquaintances who are not oncologists confirmed that some educated people, individuals who read print newspapers and listen to National Public Radio, for instance, remained completely unaware of this favorable trend. A recent search of the *New York Times* website using terms like "cancer deaths" and "American Cancer Society" finds no mention of the January 2017 ACS report on the 25% decline in U.S. cancer mortality. The *Wall Street Journal* also appears to have passed on covering this story.

Several national news outlets did pick up the ACS report. TIME.com published a short piece,[19] "Here's Why the Cancer Death Rate Has Plummeted." CNN.com ran a story,[20] "US Cancer Deaths Down 25% Since 1991, Report States," but did not produce searchable video or television coverage. Like CNN, NBC News posted an article[21] on its website, but does not appear to have supported it with video or television footage. *USA TODAY* did not cover the analysis directly, but posted a 47-second video,[22] "2017 Is Looking Healthier: Cancer Death Rate Drops a Fourth Since '91." A caption at USAToday.com attributes the video to Newsy NewsLook, a company[23] that provides a "premium video solution that increases views and revenue for Publishers and Creators." In other words, the *USA TODAY* story on the cancer decline was produced by a commercial video manufacturer.

SPINNING STATISTICS

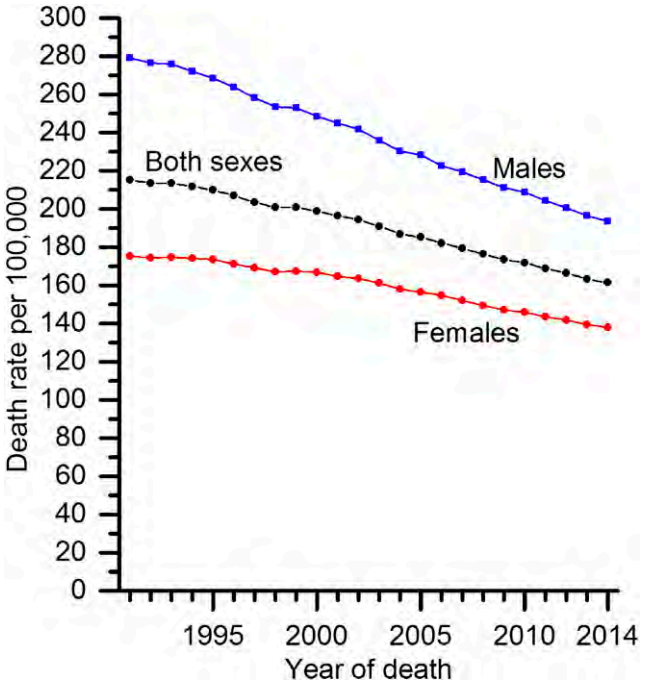
The 25% statistic raises questions (Fig. 2). A critical reader or journalist might ask if the reported reduction in deaths from cancer was observed only in people already known to have cancer (disease-specific mortality) or if the trend was observed in the larger U.S. population. For this ACS analysis, cancer deaths were tallied in the general population. Specifically, deaths from cancer peaked at 215.1 per 100,000 population in 1991 before falling to 161.2, also per 100,000 population, in 2014. That detail means that the lower reported death rate from cancer cannot be attributed to overdiagnosis. Overdiagnosis would affect the number of reported cancer cases (incidence) and might lower the apparent rate of cancer-specific deaths, but it would not affect mortality from cancer in the general population.

The figure persuades because the mortality curve falls steadily between 1991 and 2014; it is not a statistical fluke. U.S. cancer death rates fell for both men and women, although in the past decade, the decline was proportionately greater in men. The ACS authors attributed the trend to reduced smoking, which over time led to fewer lung cancers, and to early detection and treatment of several common cancer forms. The biggest declines were observed in mortality from lung, breast, prostate, and colorectal cancers.

Yet the drop is imperfect. Cancer remains the second-leading cause of death in U.S. men and women. Disparities in cancer incidence and deaths persist, based on race, insurance access, and geography. The ACS reported that death rates from cancer among U.S. blacks exceed those among whites by 15% overall.

A detail worth considering, because it confounds health statistics and public understanding of those, is the expanding and dynamic U.S. population. Although the cancer death rate fell, the Centers for Disease Control and Prevention reported a rising annual number of cancer deaths, from 514,657 deaths in 1991 to 591,699 deaths in 2014.[24] There is no discrepancy in these figures; the absolute increase in cancer deaths can be explained by growth of the population. Based on U.S. Census Bureau estimates,[25,26] the population expanded from 252,131 million in 1991 to approximately 318,700 million in 2014; these figures demonstrate

FIGURE 2. U.S. Cancer Mortality Trends (1991-2014)



over 26% growth in the U.S. population during the relevant 23-year interval.

This sort of apparent contradiction, based on two valid representations of U.S. cancer registry and death data, generates confusion and, sometimes, angry public debate. A relevant example comes from the surprisingly controversial subject of breast cancer statistics.[27] A contentious issue that crops up periodically in news, op-eds, on Twitter and advocacy group Facebook pages, is whether or not there has been meaningful progress in reducing breast cancer deaths.[28] The facts, based on SEER data, are these: in 1991, deaths from breast cancer numbered 32.69 per 100,000 women in the U.S. population; in 2013, those numbered 20.72, per 100,000 U.S. women.[29] These numbers demonstrate a 36% decline in the rate of deaths from breast cancer. Yet the absolute number of deaths declined only slightly during those 22 years, by a few thousand. The Centers for Disease Control and Prevention report that in 1991, deaths from breast cancer numbered 43,583; in 2013, 40,860 women and 464 men died of breast cancer.[30,31]

Although some might deem these statistical quibbles, these figures affect how and if journalists and others represent and perceive progress against breast cancer. These numbers influence the distribution of funding for research, screening, and care. The breast cancer death rate has declined by 36% in the U.S. population, but the annual U.S. toll of deaths from breast cancer still hovers over 40,000, causing consternation and frustration among patients, advocates, and others. Further clouding the picture is that invasive breast cancer is the most common cancer form not declining in the United States; the recent ACS report indicates

that among some groups, such as African Americans, the incidence has been rising.

FOCUS ON DISPARITIES (WHERE INFORMATION MIGHT HELP OUTCOMES)

The fact that cancer death rates have been declining, albeit unevenly, surfaced in a January 2017 *JAMA* analysis.[32] That paper confirms the drop in overall U.S. mortality from cancer after 1980 and highlights disparities. Cancer pockets—marked by a high incidence or death rate from malignancy—exist in broad U.S. geographical areas and small communities. Lung cancer disproportionately affects and kills people in Appalachia, for instance. A high death rate from breast cancer occurs along the lower Mississippi and southern belt states. Clusters, or hot spots, of kidney cancer appear in areas along the Mississippi and in North and South Dakota. Stage at diagnosis and cancer death rates vary among counties within states.

These regional differences in U.S. cancer outcomes support the need for improved education and journalism about health. In 2015, *Newsweek* dedicated an entire issue to cancer. In a long-form feature,[33] journalist Jessica Wapner reveals the outlook for patients with cancer in central Appalachia. She visited a region of eastern Kentucky where prevalent poverty and low education levels contribute to cancer's high toll. People in the area suffer health effects from heavy smoking and excess particulate matter in air. "A long history of poverty and disease in the region has led to a sense of resignation, a fatalistic belief about the inevitability of cancer and the death it brings," Wapner wrote. "Many people who are diagnosed refuse treatment because they don't see the point of going through the pain."

In the context of recent data about the declining U.S. cancer death rate, the *Newsweek* story points to the potential role of news to inform people about progress and nudge them toward better outcomes. Careful journalism might disrupt a fatalistic cycle of disbelief in cancer treatment's value that leads to late presentation of patients with cancer to physicians, lesser outcomes, and more deaths. Consider the plight of a woman or man living in rural Kentucky with a persistent cough and weight loss, symptoms of a possible lung cancer, today. Just knowing that cancer deaths in the U.S. population are down, by as much as 25% in recent years, might prompt some individuals to visit the doctor rather than ignore early signs of disease.

DESPITE PROGRESS, A DIM AND CONFUSING PICTURE

The recent 25% decline in U.S. cancer deaths—what might be deemed as evidence-based news about cancer that is not anecdotal—reflects progress. Yet it got little attention. Of course, with so much ongoing political changes in January 2017, including the possible repeal of the Affordable Care Act and the affect of the travel ban on doctors, the omission of cancer news from headlines might be understood. When newsrooms are strapped for reporters and editors need to choose stories that draw clicks, careful reporting about cancer research, drugs, and clinical developments might be put aside (Sidebar 1).

Yet reports about cancer appear constantly and often cast a negative slant. Many recent articles focus on the exorbitant costs of cancer medications. Some stories feed on anger over high drug prices, raise or address economic issues, and mix with political news. Although reports on treatment costs might be set apart from reports on effectiveness, the issues often get conflated, in part because economists and health policy experts discuss pricing models that depend on how well the drugs reportedly work.

Since January 2017, overlapping articles have emphasized the ineffectiveness of oncology treatments. One example, "Dozens of New Cancer Drugs Do Little to Improve Survival, Frustrating Patients,"[34] appeared in *Kaiser Health News* on February 9, 2017 (Fig. 3). The piece, also available in Spanish (*Nuevas drogas contra el cáncer, ¿ayudan a vivir más?*) draws on a lecture on "Unintended Consequences of Expensive Cancer Therapeutics" published in 2014 in *JAMA Otolaryngology–Head & Neck Surgery*[35] and a few recent papers finding marginal, if any, benefit of new oncology drugs. The story leads with the picture of a woman whose breast cancer progressed through multiple treatments, causing pain. It refers to high prices, averaging $171,000 per year, and relies heavily on negative quotes offered by critics of precision oncology. The same article ran in *USA TODAY* with an abbreviated headline,[36] "Dozens of New Cancer Drugs Do Little to Improve Survival," and on CNN.com,[37] "Amid Flurry of New Cancer Drugs, How Many Offer Real Benefits?"

SIDEBAR 1. Pressures on the Quality of Medical Journalism

1. Newsrooms reduce staff for reporting and editing.
2. Many outlets lack fact-checkers.
3. To keep their jobs, reporters need turn out stories quickly.
4. Journalists may lack the time or scientific background to critically evaluate reports of new technology and drug development.
5. Income is often incentivized by internet traffic (clicks).
6. Even for news outlets that do not acknowledge paying journalists based on traffic, a freelancer is more likely to get repeat assignments after stories "fly"; reporters and columnists lose jobs when clicks are insufficient.
7. Editors favor topics that drive traffic: stories with splashy headlines on financial toxicity, greedy pharmaceutical companies, and bad doctors gain disproportionate coverage.
8. Journalists hesitate before covering "breakthroughs," as they should, for not wanting to seem foolish.

In addition to dismissing the value of cancer drugs, recent health news casts doubt on the reliability of medical research. In January 2017, the BBC highlighted the reproducibility crisis with the headline "Most Scientists 'Can't Replicate Studies by Their Peers.'"[38] The journal *Nature* covers the Reproducibility Initiative, a project funded by the Laura and John Arnold Foundation that aims to replicate key findings in basic cancer research.[39] In early March 2017, *NPR Health* ran a related piece,[40] "Reports Of Medical Breakthroughs Often Don't Prove Out."

The triple takeaway might be that new cancer drugs rarely work, cost lots, and that reports of progress cannot be trusted. Yet the well-documented pattern of reduced U.S. cancer mortality supports that modern oncologists are doing something right overall. Perhaps the day-to-day medical news, with a focus on narrative and twists, and only occasional details about treatments, fails to capture the big picture about cancer and incremental progress.

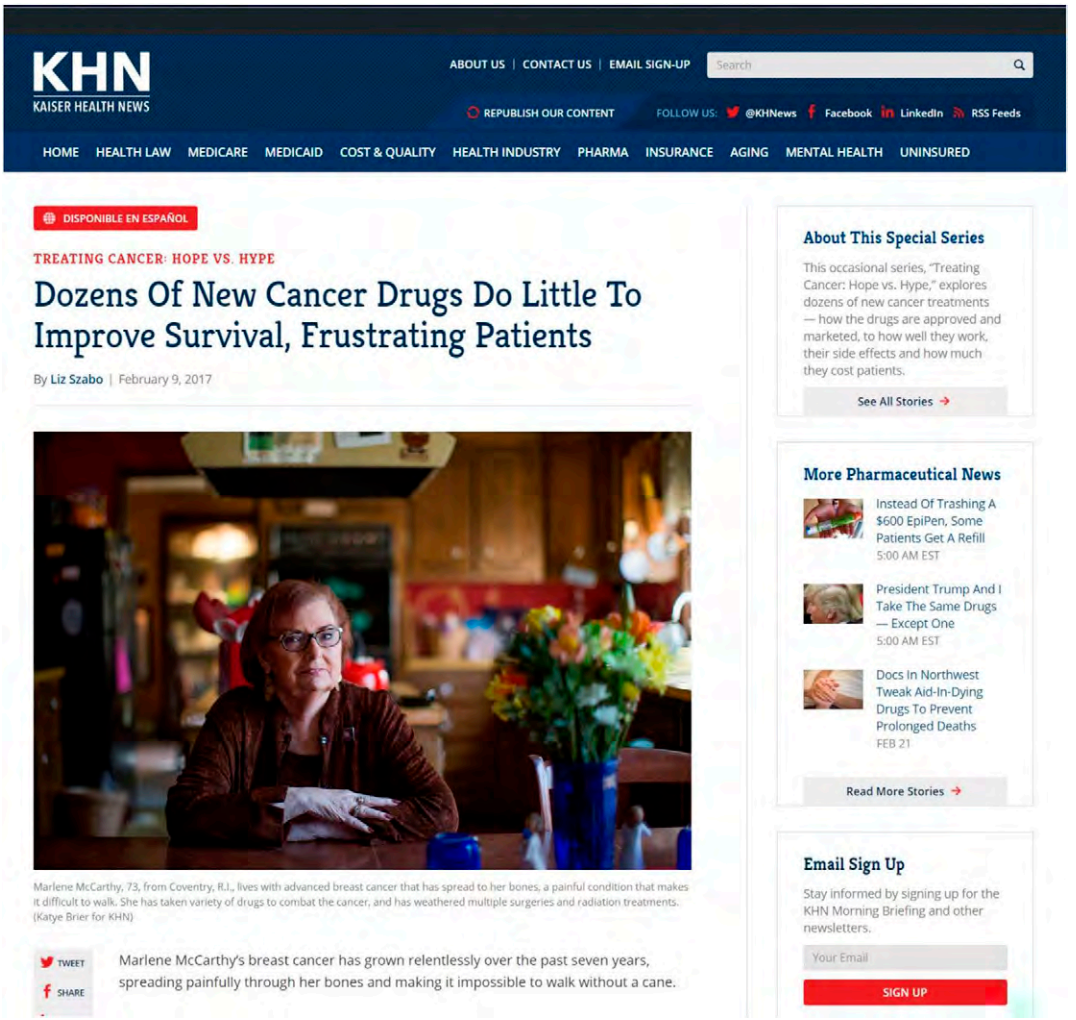
LOSS OF INFORMATION GATEKEEPERS

Thirty years ago, when I graduated from medical school, someone wanting to distribute a factual update, opinion, or analysis generally needed access to a publisher with printing equipment or a company with radio or TV broadcasting equipment. This is no longer the case. Today a doctor, high school student, refugee, patient with cancer, teacher, celebrity—anyone—can write a few lines, take a photo, or film something and post it to the web.

Social media posts, along with other sources of cancer-related information—ranging from direct-to-consumer advertisements sponsored by pharmaceutical companies, to articles put forth by cancer centers on fancy websites, to blog posts authored by individual clinicians—contribute to what might be described as an online free-for-all regarding cancer facts, treatments, and opinion. The expanding volume of stories and data about cancer offers patients and doctors an unprecedented amount of material to sort through. Distilling what is true, relevant, and helpful to an individual patient may be more difficult than ever before.

The disruptive and potentially helpful impact of Twitter, a social media platform, is hard to gauge in terms of clinical care and cancer outcomes. Although the numbers of oncologists, patients with cancer, advocates, researchers, and communications specialists representing pharmaceutical

FIGURE 3. Kaiser Health News: "Treating Cancer: Hope vs. Hype"



companies, hospitals, and pathology laboratories using social media are rising, the consequences of all this activity remain unclear. Preliminary reports about Twitter and health care cannot be generalized, because they draw on data from the platform's users.

Twitter does facilitate rapid transmission of health news. This could be most helpful during a public health emergency. How it might help patients with cancer and their caregivers is by directing those with a condition or interest, like sarcoma, to relevant news such as the U.S. Food and Drug Administration approval of a new drug, clinical trials, conferences, and websites providing vetted information.

POTENTIAL INFLUENCE OF CANCER NEWS ON PUBLIC HEALTH

Although the clinical and public health impact of most health journalism goes unchecked, some well-documented instances demonstrate the alerting function of high-profile stories. Some of the best-studied examples pertain to oncology and cancer screening and date over several decades.[41]

In September 1974, First Lady Betty Ford had a mastectomy for breast cancer. Ford's surgery took place a few weeks before Happy Rockefeller, wife of Vice President Nelson Rockefeller, underwent the same.[42] News surrounding the pair's procedures and their malignant diagnoses generated an uptick in mammography. A 1978 study[43] in *Public Health Reports* found a clear pattern, albeit transient, lasting months, of increased participation in the Health Insurance Plan screening program during that "period of high public attention to breast cancer."[43, p. 320] The authors referred to an "alerting function" of high-profile news; they attributed the term to Earl Ubell, the director of NBC TV News. The newscaster had penned a rare 1976 paper[44] on "Responsibility of the Mass Media in the Control of Sexually Transmitted Diseases."

A decade later, President Ronald Reagan underwent successful surgery to remove a small cancer from his colon in the early summer of 1985. The National Cancer Institute reported a spike in calls to its Cancer Information Service from people with questions about colon and rectal cancers; SmithKline Diagnostics, a large manufacturer of a screening kit to check for blood in stool, reported that its supply ran out.[45] Although Reagan's episode did not have any measured effect on public health, such as reduced deaths from colon cancer, his well-publicized case did influence attitudes about colon and rectal cancer. The *Los Angeles Times* discussed the impact of Reagan's surgery with Irving Rimer of the American Cancer Society: "The taboo against talking about colon and rectal cancer, about the elimination of wastes from the body, and about the bowels in general has been broken," Rimer said in July 1985.[46]

Over time, public cancer disclosures became increasingly frequent. In March 2000, *Today Show* host Katie Couric gained attention by undergoing a live-televised colonoscopy. After her husband's death at age 42 from colon cancer, Couric explicitly aimed to encourage screening. *Time* magazine called it "Katie's Crusade."[47] The strategy worked; in 2003, physicians documented a rise in colonoscopies, particularly among women. Doctors dubbed it "the Couric effect." Those reporting in the *Archives of Internal Medicine*[48] inserted a note of caution: "While celebrity spokespersons have remarkable potential to transmit important medical information, one notable concern is the possibility for well-meaning public figures to use their influence to promote unproven or even dangerous behaviors,"[48, p. 1604] they wrote. "For example, Ms. Couric has advocated colorectal screening at ages younger than recommended by most medical authorities, declaring, 'But all the doctors I know—and I know a lot of them—say they had or will get a colonoscopy by their 40th birthday. That ought to tell you something,'" the journal authors added. "Considering these results, celebrity spokespersons should be advised to deliver carefully targeted, evidence-based recommendations that will ultimately improve public health."

A more recent example comes from the double revelation of Angelina Jolie. In May 2013, the actress informed the world that she carries a *BRCA* mutation in a *New York Times* op-ed.[49] The article emphasized her personal decision to undergo prophylactic, bilateral mastectomy in light of her genetic disposition and strong maternal family history of breast cancer. Her story surely contributed to the increase in *BRCA* genetic evaluations that ensued. In 2015, Jolie followed up with a column about her oophorectomy.[50] Yet a 2016 report in the *British Medical Journal* found no rise in mastectomy after Jolie's revelation.[51] Her case, and the enormous publicity surrounding her decision, generated greater awareness about *BRCA* and, possibly, other hereditary cancer syndromes; it led to more DNA testing, but it appears not to have affected surgery rates.

Two prominent 2016 cases stand out by their possible consequences for men's health. The actor Ben Stiller disclosed that he was treated for prostate cancer found 2 years earlier, at age 48. He wrote a controversial blog post[52] on Medium: "The Prostate Cancer Test That Saved My Life." Stiller gave interviews on TV and radio about his prostate cancer evaluation, surgery, and treatment.[53] However, because the U.S. Preventive Services Task Force and physician groups advise against prostate cancer screening in men, Stiller got into some hot water over his post and remarks on prostate-specific antigen testing.[54,55] Also, in 2016, the Black Eyed Peas musician Jaime Gomez, known as Taboo, announced he had surgery and chemotherapy for testicular cancer.[56,57] The ACS named him a global ambassador. Gomez aims to increase awareness and lessen stigma about cancer in his Mexican and Native American communities.[58]

These cases reveal the potential of cancer news to influence public health. Celebrity health disclosures can help or harm, depending on how effectively, and if, their messages convey medical wisdom. However, most of what people hear about oncology has little to do with celebrities' experiences. The background effect of everyday stories likely has a greater effect on patients' decisions, but it may be impossible to measure.

A PRESCRIPTION FOR CANCER NEWS

One might consider if and why medical journalism matters. Although a physician or patient might enjoy reading a feature on immune therapy or listening to a podcast on ethical or technical aspects of genetic testing, few individuals would make treatment choices based on what they've read in the *Atlantic* or seen on CNN. Yet exposure to news—what journalists are writing in papers and magazines and saying on radio, TV, and social media—can influence a person's background view, so that when they enter a physician's office, they know what questions to ask; a patient might be more wary of an intervention or more willing to accept it. Health news affects whether a person enters a doctor's office in the first place.

I would suggest that good-quality health journalism might be more needed than ever before. As the number of competing online sources of information expands, and patients know their personal doctors less well, the potential consequences of news about oncology, and how that news is steered by editors and social media, will affect cancer patients' decisions, experiences, and outcomes.

Despite progress, negative stories constitute much of what people hear about cancer: patients suffer; many die after treatments fail; medications cost too much and can cause bankruptcy; survivors endure long-term side effects and chronic health problems; researchers fail to reproduce findings; bad oncologists carry out fraudulent billing, etc. News of treatment toxicity, such as recent reports about cardiac effects of oncology drugs,[59-61] might scare a patient, so that they decline treatment that is likely to help. Reports on chemobrain, recently substantiated,[62] could dissuade anyone from taking the medicines an oncologist recommends. Of course, it is every person's right to have this kind of information: the good, the bad, and the mixed results.

News, presented in a balanced way, could help guide patients and caregivers about the risks and benefits of treatment options. Journalism can inform patients' decisions about whether to try medicines, whether and when to accept consultation from a palliative care specialist, or choose hospice care. Although premature reports of groundbreaking findings in mice or breakthroughs in the laboratory can mislead, the public deserves to know about advances. The truth includes progress.

Producing balanced stories that convey information about progress against cancer, without hype, tasks journalists. Transparency will serve them and their audience: physicians and scientists need be upfront about conflicts of interest and funding; recognize and indicate the limits of conclusions from any study; and be open to correction. What journalists can do, although it is not easy, is to seek varied perspectives. Incorporating viewpoints of scientists, physicians, patients, and others, including some who are not directly involved in a story, should add depth and generally improve coverage (Sidebar 2).

As newsrooms shrink and reporters work at a quicker pace, the challenge of producing balanced stories that convey information about real progress against cancer, without hype, may push editors away from the subject. Unless the data for a treatment or experimental results are so extraordinary that they astonish seasoned oncologists, so much that they use terms like breakthrough or possible cure regarding previously hopeless tumors, journalists may think it wise to play it safe, skip coverage, and report on something else. The reality of incremental progress is unfortunately dull, except, of course, to the patients who experience these advances, their loved ones, and providers of care, including physicians who see them do well.

Some journalists might consider, as I have, that detailed information about cancer treatments belongs in doctors' offices and journals and not in the news. However, if people remain uninformed of trends, they may remain ignorant of the big picture. Even doctors who are not specialists may not be aware of some advances that have occurred in the past decade against metastatic lung cancer, melanoma, and a growing list of previously hopeless tumors. There is a need for good-quality news about cancer, especially in communities in which cancer mortality remains disproportionately high.

There is no easy prescription for distilling truth in oncology news. But I am hopeful, as journalists grapple with a changing pace of work and staff and as doctors contend with a changing pace of practice, that better education—of physicians and the public—about cancer, and in basic math, statistics, biology, and other fields relevant to oncology, will prove helpful. For journalists and for doctors, knowing how to interpret, convey, and interpret fluid information, is crucial for public health.

SIDEBAR 2. Possible Solutions for Health Journalism

1. Be transparent at all levels of reporting; reveal funding and other conflicts of interest that may influence physicians and scientists in academics and elsewhere, patients who may have organizational or industry ties, journalists, and publishers of news.
2. Reporters should seek input from varied sources.
3. Educate journalists about math, molecular biology, and statistics.
4. Independent health foundations might support in-depth coverage of advances.
5. Patient-driven "advocacy journalism" could help distribute critical information.
6. Increase public access to real-time and anonymized clinical data; this would enable constant re-evaluation of published work in context of new information.
7. Consider innovative systems of weighted commentary, culled from social media and other sources, to develop post-publication peer review of medical reports.

ACKNOWLEDGMENT

I would like to thank Carol DeSantis, of the American Cancer Society, for creating a figure for this article, and the ASCO Edbook staff, for their assistance in preparing this manuscript.

Future Genetic/Genomic Biomarker Testing in Non–Small Cell Lung Cancer

David Planchard, MD, PhD, Jordi Remon, MD, Frédérique Nowak, PhD, and Jean-Charles Soria, MD, PhD

The magnitude of the challenge that cancer poses is increasingly alarming, with a 60% projected increase in the annual incidence, from 12.7 million new cases in 2008 to 22.2 million new cases projected for 2030.[1] However, cancer prognosis has also changed significantly over the past few decades. In the United States, cancer mortality decreased by 32% and 22% in men and women, respectively, between 1990 and 2015,[2] reflecting dramatic improvements in cancer care in the last 25 years. Advances in genomic sequencing and molecular marker identification during the last decade have unequivocally demonstrated that cancer is a heterogeneous disease.[3] Globally, genotype-directed targeted therapies are revolutionizing cancer care, and genetic alterations in genes such as *EGFR, ALK, ROS1, HER2, KIT,* and *BRAF* have been validated as powerful predictive biomarkers in the management of non–small cell lung cancer (NSCLC),[4] along with gastric cancer,[5] gastrointestinal stromal tumors,[6] and melanoma.[7]

In France, eliminating inequalities in access to molecular profiling tests and consequent treatment is a priority.[8] To this end, the French National Cancer Institute (INCa) and the French Ministry of Health established a national network of 28 molecular genetics centers that perform molecular tests for all patients in their region, irrespective of the institution where they are being treated. This program was updated in 2013 introducing next-generation sequencing (NGS) for switching from a gene-by-gene approach to a multiplexed strategy. The economic impact of this strategy has also been evaluated.[9]

CURRENT TECHNOLOGIC APPROACHES

Implementation of personalized medicine requires widely accessible tumor molecular profiling in routine practice, along with molecular centers for performing high-quality tests. Various methods exist for molecular profiling, including conventional Sanger sequencing, amplification refractory mutations systems, restriction fragment length polymorphisms, and, more recently, targeted NGS panels.[10] As it is now standard to test for a high number of mutations to personalize treatment decisions, use of NGS panels that can evaluate tumor biopsies for a wide range of potentially targetable mutations is increasing. Rapid and low-cost sequencing is providing physicians with the necessary tools to translate genomic information into clinically actionable results.

Although the use of NGS is attractive as less DNA is required compared with multiple individual assays, these advancements are not without limitations, and there are substantial improvements to be made in sequencing technologies, data analysis bioinformatics pipelines, and computer resources. Reporting the limitations of an NGS assay along with the result is critical for clinical interpretation, especially in the context of the NGS detection of uncommon molecular alterations for which clinical significance assessment constitutes a real challenge.[10] These elements are increasingly being discussed in molecular tumor boards, which are becoming widespread within the clinical sector. For example, in NSCLC, molecular tumor boards are feasible in daily practice allowing treatment recommendations in a majority of these patients (up to 70%), enrichment of their inclusion in clinical trials (57%) or expanded access programs (23%), and limitation of off-label drug use (9%).[11]

More extensive analysis such as RNA sequencing (RNA-seq), whole-exome sequencing, and whole-genome sequencing are also starting to be used in routine practice (Table 1).[10,12] Compared with the targeted NGS approach, they have the ability to detect rare and novel mutations that occur outside of specific, predefined regions as well as other types of molecular abnormalities such as gene translocations. Whole-exome sequencing and whole-genome sequencing allow detection of germline events involved in cancer susceptibility.[12] However, robust bioinformatics algorithms are needed not only to analyze large volumes of high-throughput data being generated for each patient, but

TABLE 1. DNA/RNA Sequencing

Technique	Advantages	Disadvantages
Exome sequencing	Detection of genetics variations in all protein-coding regions of the genome	No detection of genetic variations in non–protein coding regions, including gene expression regulatory regions
	Detection of nucleotide variations and small insertions and deletions	Not feasible if limited material samples
	Discovered missense mutations, gene-disrupting mutations, and copy number variants	Slow turnaround time
	Exome size relatively small	
Genome sequencing	Detection of all genetic variations, including protein-coding and regulatory regions	High volume and complex data analysis because of the large size of the human genome
	Detection of nucleotide variations and genome reorganizations such as deletions, duplications, or translocations	High-level bioinformatics and computer resources required
		Greater amounts of DNA needed
		High cost for clinical use
RNA sequencing	Detection of genetic variations in protein-coding regions	Analysis restricted to genes expressed in the tissue or cell analyzed
	RNA expression levels	Genetic variations in untranscribed regions not detected
	Detections of RNA slicing variants and fusion transcripts	Adequate tumor tissue
	Size of the transcriptome smaller than the genome	

also to make predictions on the functional impact for each alteration, to classify drivers and passengers, and to prioritize different targets.

As much as the molecular analyses do themselves, the preanalytical steps of NGS tumor genotyping in routine practice also present practical challenges including sample quality, adequate biopsy specimens, and the need for repeat biopsies after development of drug resistance, emphasizing the importance of quality sample collection and proper processing techniques. It is thus incontestable that there is an unmet need for noninvasive assays that can broadly detect actionable genomic alterations.[13]

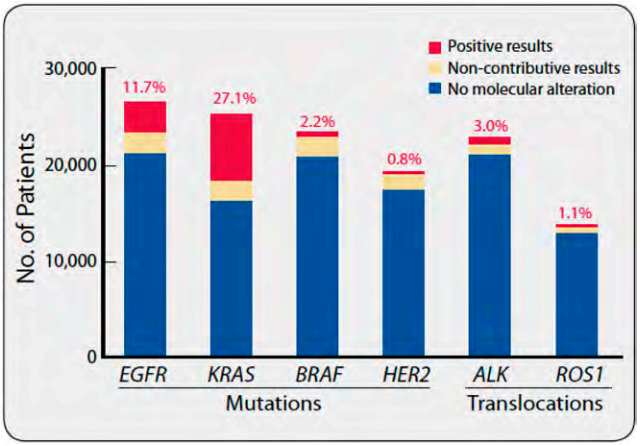
CLINICAL UTILITY OF MOLECULAR TESTING

Lung cancer remains the most common cancer at a global scale, both in terms of new cases (1.8 million cases, 12.9% of all total cancer cases) and deaths (1.6 million deaths, representing 19.4% of total cancer deaths).[14] It is also among the cancers with the highest mutation rates.[15] One of the most important therapeutic advances has been the identification of distinct molecular subsets amenable to targeted therapies, especially among adenocarcinomas, as well as the early success of immune checkpoint inhibitors.[16,17] In this indication, tumor genotyping is an essential routine diagnostic tool in clinical practice,[18] and this strategy correlates with survival improvement for those patients treated with personalized therapies.[4,19]

In lung cancer, the availability of several profiling platforms worldwide has seen impressive progress in molecular testing, breaking through the barrier of unselected treatment in NSCLC and pushing out survival limitations. In 2015, molecular screening (*EGFR, HER2, KRAS, BRAF,* and *PIK3CA* mutations, as well as *ALK* rearrangements) was performed in France at 28 certified centers for about 26,000 patients with NSCLC (Fig. 1). A clinical correlative work with the French Cooperative Thoracic Intergroup highlighted that a genetic driver alteration is recorded in about 50% of the analyses.[4] In addition to the organizational framework set up by the French INCa and the Ministry of Health, other examples of molecular profiling programs at a national level include initiatives from the Network Genomic Medicine in Germany,[20] the LC-SCRUM in Japan,[21] and the Lung Cancer Mutation Consortium in the United States.[19]

Druggable molecular alterations occur in 20% to 25% of adenocarcinomas.[4] The two most common are *EGFR* mutations, which occur in 12% of the Caucasian population (up to

FIGURE 1. Patients With Non–Small Cell Lung Cancer Screened for a Molecular Alteration in 2015



50% in Asian population),[22] and *ALK* rearrangements, which are seen in 5% of the population,[4] independently of the race. These alterations confer sensitivity to specific EGFR tyrosine kinase inhibitors (TKI) such as erlotinib, gefitinib, afatinib, and icotinib (only available in China), and to ALKs such as crizotinib or ceritinib. Up-front personalized treatment with a TKI confers statistically significant and clinically meaningful improvement in progression-free survival and response rate compared with platinum-based chemotherapy in patients with advanced *EGFR*-mutated[23] or *ALK*-rearranged NSCLC.[24,25] However, almost all patients acquire resistance to these therapies, and identifying the mechanisms of resistance becomes critical for the implementation of personalized treatment at progression, especially among *EGFR*-mutant tumors.

The most frequent pathway of resistance to EGFR TKI is the *Thr790Met* mutation in exon 20,[26] which confers sensitivity to third-generation EGFR TKIs such as osimertinib, improving the outcome at progression compared with standard chemotherapy.[27] Other mechanisms of resistance in *EGFR*-mutant tumors include *MET* amplification, *PIK3CA* mutations, *EGFR* amplification, and transformation to a small-cell phenotype.[26] The mechanisms of resistance seen following ALK inhibitor therapy again reflect tumor evolution with secondary *ALK* mutations, *ALK* copy number gain, secondary driver mutations in other genes, and bypass pathways.[28] A number of structurally distinct and more potent second- and third-generation ALK inhibitors are under evaluation for overcoming crizotinib resistance in the case of secondary *ALK* mutations. In this context, personalized treatment according to a molecular profile at progression is clearly the optimal strategy.

Putative oncogenic drivers in squamous cell carcinoma are rare, but several novel molecular abnormalities are being investigated as potentially actionable targets, specifically *FGFR1* amplification and *PIK3CA* and *DDR2* mutations.[29] Screening patients for solitary biomarker-driven studies requires both substantial time investment and adequate tumor tissue, resulting in low rates of enrollment. Because of this, new initiatives for lung treatment are in progress with trials integrating molecular screening and both targeted therapy and immunotherapy arms, such as the Lung Cancer Master Protocol (Lung-MAP; NCT02154490) for squamous cell carcinoma,[30] and the phase II umbrella trials National Lung Matrix Trial (NCT02664935)[31] and SAFIR02 Lung trial (NCT02117167) for squamous and nonsquamous NSCLC (Table 2). In SAFIR02, high throughput molecular analyses (e.g., CGH array, NGS) are used to evaluate the effect of treatment with targeted agents on progression-free survival compared with standard maintenance therapy in patients with metastatic NSCLC.

CHALLENGES AND SOLUTIONS

Beyond the more common nonsquamous NSCLC *EGFR* and *KRAS* mutations and *ALK* rearrangements, an important, albeit smaller, group of patients are found to harbor tumoral *HER2*, *BRAF*,[4] and *MET*[32] mutations or *ROS1*,[33] *NTRK1*,[34] and *RET*[21] gene fusions. The development of TKIs for other oncogene-driven NSCLCs may expand the portfolio of precision therapies as we enter a new paradigm of molecular therapies in oncology. As our understanding of tumor taxonomy and genotypes advances, it seems inevitable that some form of NGS platform will become the clinical standard for gene fusion detection instead of running multiple fluorescence in situ hybridization analyses. Both targeted and extensive RNAseq or whole-exome/whole-genome sequencing have the potential to detect *ALK* and other rearrangements.[10] To be widely used in clinical practice, RNAseq approaches have to be optimized for the clinical grade analysis of formalin-fixed, paraffin-embedded tumor samples. In addition to comprehensively identifying mutations in genes that encode members of RTK-induced signaling cascades, genomics efforts have uncovered mutations in genes involved in other important cellular processes (such as KEAP1-CUL3-NFE2L2, TP63, and SOX2, involved in the oxidative stress response and differentiation pathways).[29] Chromatin-modifying genes are recurrently mutated in lung adenocarcinoma and lung squamous cell carcinoma and also represent potential therapeutic targets in these diseases.[29,35]

The advent of immunotherapy presents additional challenges for molecular testing in NSCLC. To date, a number of potential biomarkers have been identified, but their relevance to clinical practice is still unclear and requires elucidation in prospective studies. Given that the marketing authorization of some checkpoint inhibitors has been restricted to patients with PD-L1–positive disease,[36] immunohistochemical evaluation of PD-L1 expression must be performed in routine practice. Nevertheless, some patients with PD-L1–low or PD-L1–negative tumors respond to these treatments. On a methodologic level, it is essential to harmonize the different detection and scoring methods before the routine use of PD-L1 expression as a predictive marker.[37] Recent whole-exome sequencing studies have shown a significant correlation between the total tumor mutational load and the predicted neoantigen load and clinical benefit with immune checkpoint inhibitors.[38,39] Characterization of neoantigens as a potential biomarker requires sufficient tumor DNA for whole-exome sequencing and carries major expense. But given the cost of these therapies, this initial outlay would be justified if the assay was sufficiently reliably predictive.[40]

Obtaining adequate tissue for diagnosis, tissue subtyping, molecular profiling, and treatment planning are critical for optimal patient management. Added to this, at the time of disease progression, a key challenge is also obtaining a recent sampling of the progressive tissue to determine the selection of second-line therapy. However, lack of tissue biopsy at progression is not uncommon, and furthermore, single site biopsies may not provide a representative profile of the overall predominant resistance mechanisms for a given patient.[41] Liquid biopsies based on circulating cell-free tumor DNA (ctDNA) analysis have been described as surrogate samples for molecular analysis, replacing solid tumor biopsies.[42] This approach offers the potential of real-time

TABLE 2. Molecularly Stratified Ongoing Umbrella Studies in Advanced Stage NSCLC

Study	Phase	No. of Patients	Primary Endpoint	Line	Screening Tests	Molecular Subgroups and Treatment
Lung-MAP[30] U.S.	Multisub-study, randomized phase II/III trial	10,000	PFS, ORR, OS	≥ second-line only SCC	NGS	GDC-0032 (PI3K inhibitor)
					IHC	MEDI4736 (anti-PD-L1)
						Palbociclib (CDK 4/6 inhibitor)
						AZD4547 (FGGFR 1-3 inhibitor)
						Docetaxel
National Lung Matrix Trial[31] U.K.	Multiarm, non-randomized, noncomparative phase II	620	ORR, PFS	≥ second line	NGS	AZD4547 (FGFR inhibitor)
						AZD2014 (MTORC1/2 inhibitor)
						Palbociclib (CDK4/6 inhibitor)
						Crizotinib (ALK/MET/ROS1 inhibitor)
						Selumetinib (MEK inhibitor)
						Docetaxel
						AZD5363 (AKT inhibitor)
						AZD9291 (EGFR and T790M inhibitor)
						MEDI4736 (anti-PDL1)
SAFIR02 Lung Study France	Open-label, multicentric, randomized phase II trial	650	PFS personalized vs. standard maintenance	First-line maintenance after four cycles of CT	NGS	AZD2014 (*m*-TOR inhibitor)
					CGH	AZD4547 (FGFR inhibitor)
						AZD5363 (AKT inhibitor)
						AZD8931 (HER2 and EGFR inhibitor)
						Selumetinib (MEK inhibitor)
						Vandetanib (VEGF, EGFR inhibitor)
						Pemetrexed
						MEDI4736 (anti PD-L1)

sampling of multifocal clonal evolution,[43] as well as potential dynamic markers for monitoring the efficacy of treatment[44,45] and early detection of resistance mutations.[46] Early detection has been reported in patients with EGFR TKIs often prior to radiographic progression[46] and allows therapy to be adapted accordingly.[47] Further studies confirming clinical implications of monitoring the emergence of resistance mutations in plasma are warranted to guide therapeutic strategies. The phase II APPLE trial (NCT02856893) is one example of a strategic trial that is expected to provide some answers in the near future (Fig. 2).

Discrepancies between the tumor biopsy and ctDNA genotyping may result from technologic differences or sampling of different tumor cell populations in a heterogeneous setting.[48] As sensitivity and specificity of ctDNA varies across different technology platforms,[49] the establishment of robust and standardized protocols for blood sampling, processing, storage, DNA extraction, and analysis will support the role of liquid biopsies as standard tests in the near future for tumor genotyping and predictive biomarkers.[49] These recent techniques will ensure that molecular genomic analysis and personalized treatments are soon available to more patients. Finally, circulating tumor cells isolated from the peripheral blood offer a complementary circulating biomarker to ctDNA. Circulating tumor cells permit further immunohistochemistry/fluorescence in situ hybridization characterization, while single-cell DNA sequencing or RNAseq is also possible, as well as the generation of tumor xenografts to assess drug response.[50] However, at present, the technologic complexity of circulating tumor cell isolation and the need to process samples quickly for functional/genomic studies results in greater expense compared with ctDNA analysis.

CONCLUSION

Molecular genotyping in NSCLC is common in the clinic. In the near future, noninvasive biopsies and standardization of NGS with detection of gene fusion alterations will become the new standard in daily clinical practice. With the development of NGS allowing for the detection of multiple genomic alterations, the need to prioritize these gene alterations to drug response is pressing. The immediate challenges in routine practice includes the cost of molecular profiling, limiting social inequalities that affect access to these tests, the widespread molecular tumor boards, and access to clinical trials for patients with uncommon mutations.

Molecular profiling for other thoracic malignancies is another important area currently being addressed. SPECTA-lung (NCT02214134) is a pan-European program aimed at screening patients with thoracic tumors (i.e., lung cancer,

FIGURE 2. APPLE Trial Design

malignant pleural mesothelioma, thymoma or thymic carcinoma at any stage) to identify the molecular characteristics of their disease to ensure efficient clinical trial access and personalized treatments in the case of specific mutations. Cross-analysis of mutational data with multiomics data, functional data, and clinicopathologic data in a larger number of samples is an integral part of this. Thus, international collaborative efforts as well as increased integration of technologic aspects of molecular characterization with clinical data are needed to further advance the treatment of patients with NSCLC.

Making the Case for Improving Oncology Workforce Diversity

Karen M. Winkfield, MD, PhD, Christopher R. Flowers, MD, MS, and Edith P. Mitchell, MD, FACP

Since its inception in 2008, ASCO's Diversity in Oncology Initiative has engaged in programming designed to support and promote diversity in the oncology workforce.[1] The programs, developed by the ASCO Health Disparities Committee and funded through the Conquer Cancer Foundation, include mentoring and award opportunities for medical students and residents from backgrounds that are traditionally underrepresented in medicine (URM). During a recent evaluation of the Initiative, it was recognized that a more comprehensive plan was needed to ensure it successfully met its intended goal. In response to the organization's goal of increasing diversity and inclusion in oncology professions, the Health Disparities Committee convened a task force in 2015 that ultimately formulated a strategic plan for racial/ethnic workforce diversity, consonant with ASCO's overall Workforce Strategic Plan.[2] In December 2016, the ASCO Board approved the strategic plan, affirming that diversity is central to its mission and strengthens the organization. Although some still question the rationale for efforts around diversity and inclusion, the current state of our nation and our nation's health care system clearly speak to the need for a concerted effort to diversify the oncology workforce.

CANCER DISPARITIES

Cancer is a major health care problem worldwide and the second cause of death in the United States. An estimated 600,920 individuals will succumb to cancer in 2017.[3] The most common cancer-specific causes of death are cancers of the lung and bronchus, colon and rectum, and prostate in men, and the lung and bronchus, colon and rectum, and breast in women. National attention has increasingly shifted to the issue of health disparities based on race/ethnicity and its impact on the health of the nation. African American, American Indian, and Alaskan Native populations have the poorest health status of all racial/ethnic groups in the United States.[4] These communities are plagued by increased incidence of obesity, HIV/AIDS, heart disease, and myriad other conditions. However, African Americans experience the worst cancer outcomes of all races/ethnicities (Fig. 1).[5]

Several metrics have been used to delineate disparate cancer outcomes experienced by medically underserved communities. Disparities in cancer screening, treatment, and outcomes are well documented by socioeconomic status, health care access, insurance status, and race.[4,6,7] For selected cancers, significant differences in incidence and mortality between racial/ethnic groups have been demonstrated. For example, African Americans are more likely to have more advanced-stage disease at the time of cancer diagnosis and to experience lower stage-specific survival rates compared with the white population. Presentation at late stage may be related to access to screening because of lower health insurance coverage rates in African Americans and other minorities compared with non-Hispanic whites. The impact of the Patient Protection and Affordable Care Act and the Health Care and Education Reconciliation Act of 2010 (Affordable Care Act or ACA) on rates of insured cannot be overstated. In 2015, the uninsured rates in the black population dropped to 11% from 21% in 2010. Similarly, for non-Hispanic whites, the uninsured rate declined from 12% in 2010 to 7% in 2015.[3] Although all racial/ethnic groups have seen a steady decline in cancer mortality, the overall cancer death rate in 2014 was 15% higher for African Americans than the white population. The persistent gap in mortality suggests that insurance alone is not enough to level the playing field; more is required to improve access to care along the cancer continuum.

Cancer disparities arise as a result of complex interactions between biologic, clinical, social, and environmental factors at the patient and the population levels (Fig. 2).[8,9] Establishing a comprehensive strategy to meet these needs of patients with cancer requires detailed population-level data on incidence rates and survival disparities that address these factors; an infrastructure to support clinical and basic research to understand how these factors that influence prognosis and survivorship can facilitate strategies and interventions that prevent cancer and improve outcomes; and a well-trained workforce that can use this infrastructure and other resources to examine and address the needs of underserved patient populations.

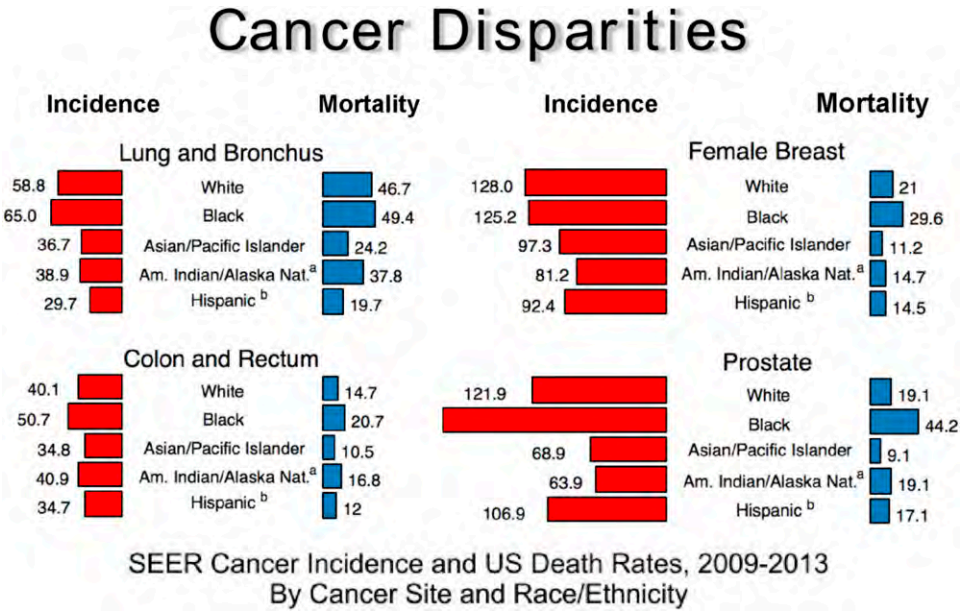
FIGURE 1. Incidence and Cause-Specific Mortality of the Top Four Cancer Sites in the United States by Race/Ethnicity



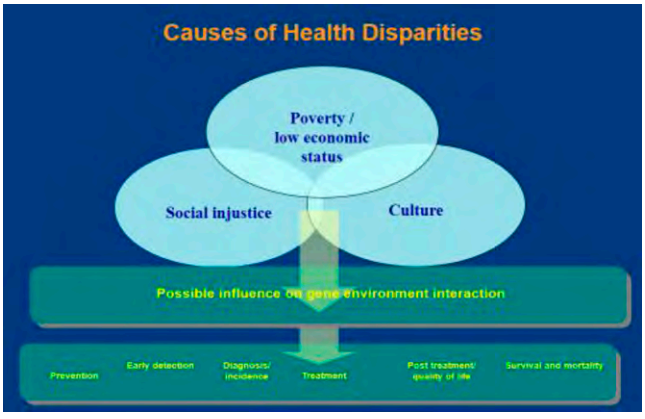
From the Surveillance, Epidemiology, and End Results data from 18 areas (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, Atlanta, San Jose-Monterey, Los Angeles, Alaska Native Registry, rural Georgia, California excluding San Francisco/San Jose-Monterey/Los Angeles, Kentucky, Louisiana, New Jersey, and Georgia excluding Atlanta/rural Georgia) and U.S. Mortality Files, National Center for Health Statistics, Centers for Disease Control and Prevention. Rates are per 100,000 and age-adjusted to the 2000 U.S. Standard Population (19 age groups; Census P25-1103).
(a) Rates for American Indian/Alaska Natives are based on the Contract Health Service Delivery Area counties. (b) Hispanic is not mutually exclusive from the white or black populations, Asian/Pacific Islanders, or American Indians/Alaska Natives. Incidence data for Hispanic numbers are based on North American Association of Central Cancer Registries Hispanic Identification Algorithm and exclude cases from the Alaska Native Registry.

Disparities in health care based on race/ethnicity represent a mutable factor that costs the U.S. government billions of dollars annually. A recent report estimates that from 2009 through 2018, the total cost of these disparities will be approximately $337 billion, with the annual cost estimated to more than double to $50 billion by 2050, attributed in part to the aging black and Hispanic populations.[10] Studies have consistently demonstrated the propensity of URM physicians to provide improved access to health care for underserved populations.[11-14]

ONCOLOGY WORKFORCE

Even the ACA recognized the importance of workforce diversity in stemming health inequities by establishing or renewing funding for several pipeline programs that may impact the racial composition of the workforce.[15,16] However, the U.S. Congress has yet to fund the National Health Care Workforce Commission,[17] an important component of the ACA that could make recommendations to compel institutions to consider workforce diversity in the design and implementation of their clinical practices. Therefore other strategies must be used to address the increasing challenges that will be faced as the diversity of patients with cancer and survivors continues to increase. According to the U.S. Census Bureau, by 2060, minorities (including African Americans, Hispanics, American Indians, and Alaska Natives) will make up 56% of the U.S. population,[18] a major increase from 38% in 2014. Although the lack of workforce diversity has been shown to negatively impact quality and health outcomes for minority patients, a diverse workforce can increase patients' comfort and trust with their providers, thereby improving patient access to and satisfaction with their health care.[12]

FIGURE 2. Causes of Health Disparities



The complex interplay between socioeconomic status, culture, and biology on cancer disparities. In addition to impacting access to care across the entire cancer continuum from prevention through survivorship, health disparities may influence the genetic environment as well.

Lack of diversity is compounded by the growing need for oncologists in general. According to the Association of American Medical Colleges (AAMC), in 1971, there were approximately 3 million cancer survivors in the United States. By 2001, the number of survivors increased to nearly 10 million.[19] Given that the number of cancer survivors likely will continue to increase, there will be a corresponding increase in demand for well-trained clinical oncologists. This is particularly relevant as the current oncology workforce continues to age without a corresponding increase in the number of fellowship positions. As noted above, ASCO had previously articulated a strategic plan focused on general workforce development and has now stepped up to address the need for increased racial/ethnic diversity.

BARRIERS TO ADDRESS

Unfortunately, the field of oncology and its subspecialties reflect and magnify the lack of racial and gender diversity present in the general medical field. In 2007, the AAMC reported that 59% of the oncology workforce from a sample of 4,000 physicians was white.[19] Black, Hispanic, and female physicians are statistically less represented in oncology than white males, perpetuated by a lack of minority and female clinicians entering the oncology workforce and reinforced by a lack of minority and women role models in leadership positions in academic medicine.[20] In 2015, only 3.7% of oncology fellows were black, and 5.3% of fellows were Hispanic.[21] These trends are even more worrisome with respect to the lack of diversity in cancer leadership positions. In 2013, minorities held only 4% of National Institutes of Health Research Project grants despite making up 29% of the U.S. population.[22] It has been long established that faculty diversity not only benefits medical students and trainees but also provides faculty from all backgrounds with an opportunity to enhance their ability to care for an increasingly diverse population.[14] If the oncology workforce continues to lack diversity, the health of the increasingly diverse patient pool will be at stake. Not only is there a need for in-depth training programs to address these disparities, but dissemination of the skills and courses taught to selected individuals who are focused on cultural humility also appears to aid in the dissemination of knowledge to cancer researchers at all levels, including those not in the training program.[23]

To combat these trends, inclusion and diversity have risen to the forefront as desired characteristics of successful organizations that are essential to competition.[24,25] For inclusion to be normalized, it must be integrated into multiple aspects of the entity, including hiring, promotion, and encouraging minority and women leaders to pave the way for those just starting their careers.[24] One evidence-based strategy for encouraging more minorities and women to pursue leadership roles in medicine is accessing programs that provide guidance and support for trainees to pursue clinical research. Dedicated mentorship from and collaboration with women and minorities who have already achieved success in the field is an important component of this strategy.[26] Supporting trainees at multiple levels within the pipeline can provide a career development pathway that is essential to ensuring a well-trained cohort of leaders and care providers in the future. Moreover, facilitating opportunities for minority mentor and minority mentee relationships among seasoned specialists/researchers and trainees has been demonstrated to be important for the career development of minority professionals.[19]

PROGRAMS TO IMPROVE PHYSICIAN WORKFORCE DIVERSITY

Increasing minority participation in science, technology, engineering, and mathematics education at all levels has been recommended as a national priority.[27] Although black and Hispanic individuals make up 11.7% and 14.6% of the U.S. population, respectively, they account for 7.2% and 7.7% of college degree holders and 4.8% and 6.1% of individuals in science and engineering occupations.[27] Having an experienced professional as a mentor can inspire younger mentees to pursue careers in science and clinical care, can provide encouragement for mentees to seek out leadership roles,[19] and is associated with greater career satisfaction.[28] Studies have shown that fostering such relationships benefits the mentors, influencing academic productivity and career advancement.[29,30]

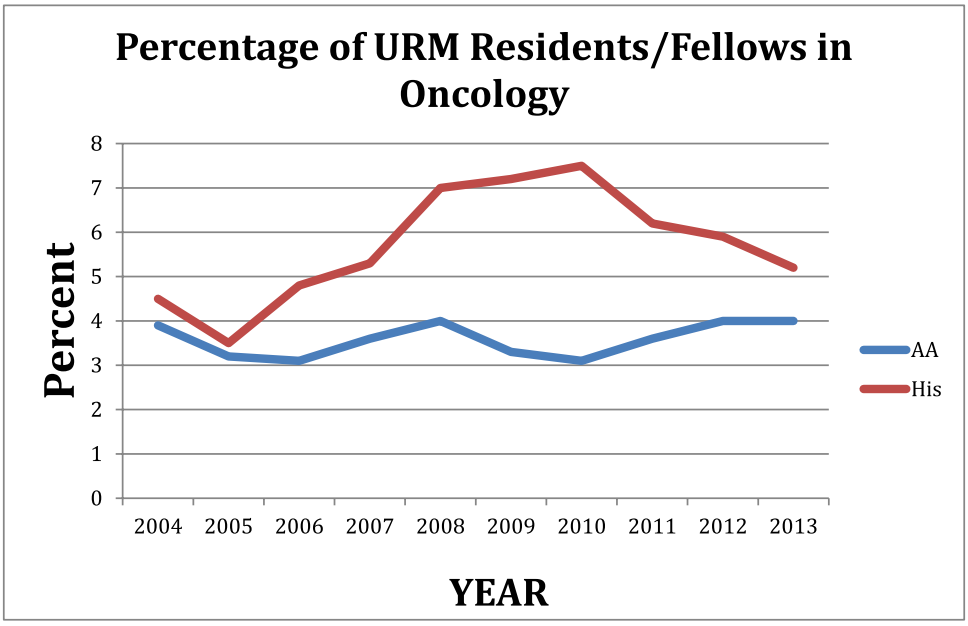
Even when underrepresented minorities enter medical school, several hurdles can restrict the successful recruitment and retention of minorities to careers in cancer clinical care and research. A key barrier is lack of exposure to programs that foster understanding and appreciation of the opportunities available in oncology practice and biomedical research. Prominent societies involved in cancer care, including the American Society of Hematology,[31] the American Society for Radiation Oncology,[32] and the American Association for Cancer Research,[33] among others, have established initiatives designed to provide exposure to research and clinical careers at varying stages of career development. Yet, the fact that some oncologists, even those at prominent academic centers with training programs, do not understand what the acronym "URM" stands for is a bit disconcerting. In 2003, the Association of American Medical Colleges shifted the expansion of "URM" from "underrepresented minority" (black population, Mexican Americans, Native Americans, which includes American Indians, Alaska Natives, and Native Hawaiians) to "underrepresented in medicine."[34] URM has grown to reflect the evolving demographics of the nation, but the sentiment of the acronym has remained consistent: "those racial and ethnic populations that are underrepresented in the medical profession relative to their numbers in the general population." It is imperative that all oncologists—but particularly those who are in a position to influence the character and makeup of training/fellowship programs—acknowledge the lack of diversity in the workforce and understand the importance of reaching out to URM medical students early in their curriculum.

For the past 9 years, ASCO's Diversity in Oncology Initiative program has awarded opportunities for medical students and residents who self-identify as URM. The ASCO Medical Student Rotation Award supports clinical oncology or cancer clinical research rotations and pairs URM medical students with a clinical oncologist who provides ongoing academic and career development advice. The ASCO Resident Travel Award supports residents to attend the ASCO Annual Meeting. Since 2008, the ASCO Diversity in Oncology Initiative has provided over $1 million to fund 137 individuals, and 81 recipients have become ASCO members, providing an early indication of the success of this program amid increasing oncology workforce diversity. However, to ensure sustainability and support the changing needs of the diverse population we serve, ASCO's recently adopted strategic plan for increasing racial and ethnic diversity in the oncology workforce provides a blueprint for a comprehensive approach to diversity and inclusion.

PROGRAM PARTICIPATION IS KEY

Although ASCO plans to set an example by demonstrating what diversity and inclusion looks like within the organization

FIGURE 3. Percentage of URM Residents/Fellows in Oncology Training Programs



Abbreviations: URM, underrepresented in medicine; AA, African American; His, Hispanic.

Adapted from: "The State of Cancer Care in America, 2016: A Report by the American Society of Clinical Oncology."[38] Note: Data represent the total number of fellows (MDs and DOs) in hematology, hematology/oncology, and clinical oncology graduate medical education programs accredited by the Accreditation Council for Graduation Medical Education.

and by continuing to provide opportunities to URM trainees, their efforts alone are not sufficient. Training programs, academic institutions, and individual practices, whether private or hospital-based, must be willing not only to diversify but to create a truly inclusive environment. Medicine has trailed behind in the recognition that diversity breeds innovation and even improves the financial bottom line. Bringing in new talent fromdiverse backgrounds will require an investment of time, thought, and energy. Leadership must set goals and priorities and articulate a vision for inclusivity that others within the organization will value and accept.

Recent reports have demonstrated that while the percentage of Hispanic trainees in oncology is improving, the number of black students graduating from medical school and entering oncology specialties has remained stagnant over the past few decades (Fig. 3).[35,36] Even with the slow increase in the number of Hispanic trainees, a workforce that sufficiently reflects the diversity of the United States will not happen over night. Until the number of URM oncologists increases to adequately address our nation's growing needs, thoughtful strategies related to employment of advanced practice providers from diverse backgrounds, such as nurse practitioners, physician assistants, and clinical nurse specialists, among others,[37] may provide a critical bridge. However, it is just as important for non-URM oncologists and staff to understand their cultural biases and learn the importance of cultural sensitivity and cultural humility. This is particularly important for minority-serving institutions that provide cancer care to a greater percentage of patients from diverse backgrounds. ASCO has thoughtfully created several programs related to cultural competency that can be accessed through ASCO University. There is even a membership category for advanced practice providers to help provide the support needed for these valued members of the oncology care team to develop the knowledge and skills required to fully engage in a diverse oncology practice.

The effective creation of a workforce that is reflective of the patients it serves first requires an institution to embrace diversity and inclusion as its core values. Change will not come quickly or easily, and therefore, the only way to succeed is for organizational leadership to be intentional in the design and implementation of programming.[25] By approving the strategic plan for improving racial/ethnic workforce diversity and sharing it with the world,[39] ASCO has raised the bar by openly setting specific goals and inviting others to hold them accountable. Hopefully, oncology training programs and practices around the country will soon follow the example and work toward creating a more diverse and inclusive environment that will enable us to provide better care for all of our patients.

Minimizing Minimally Invasive Surgery for Endometrial Carcinoma

Melissa K. Frey, MD, Stephanie V. Blank, MD, and John P. Curtin, MD

Endometrial cancer is the most common gynecologic malignancy, and, in contrast to many other cancer types, the incidence and mortality of endometrial cancer continue to grow. In the United States, there were approximately 40,000 cases of endometrial cancer in 2006; however, in 2017, there will be an estimated 61,380 new cases and 10,920 deaths.[1] The growing obesity epidemic is a considerable contributor to this trend, as more than half of endometrial cancers are attributable to obesity.[2,3] Furthermore, as obesity rates continue to rise, the incidence of endometrial cancer is expected to increase. Models predict an incidence of 42.13 cases per 100,000 women by the year 2030, representing a 55% increase over 2010.[4,5]

Given the substantial increase in the incidence of endometrial cancer, close association with obesity, and the increased prevalence among premenopausal women, management approaches that limit extensive surgical staging will become increasingly important. The Gynecologic Oncology Group LAP2 trial established the oncologic safety of minimally invasive surgery for the treatment of endometrial cancer. This study also demonstrated a reduction in postoperative adverse events and improved quality of life with a minimally invasive approach.[6] The LAP2 results culminated in the American College of Obstetricians and Gynecologists (ACOG) and Society of Gynecologic Oncology (SGO) practice bulletin stating that minimally invasive surgery should be embraced as the standard surgical approach for comprehensive surgical staging in women with endometrial cancer.[7] Minimally invasive surgery is especially important for obese patients, as obesity has been independently associated with increased surgical complications, and surgical morbidity is most profound in open surgery.[8,9] In the LAP2 study, there was a direct relationship between patient body mass index and conversion from laparoscopic approach to laparotomy. In part, this was due to the protocol mandate that all patients have pelvic and para-aortic lymph node sampling performed.

In this review article, we will review two methods that can further minimize minimally invasive surgery for endometrial cancer: (1) assessment of lymph nodes with sentinel lymph node (SLN) mapping, and (2) ovarian preservation at the time of endometrial cancer surgery. We purport that surgical approaches that reduce minimally invasive surgery are essential to the development of safe and cost-effective treatments for patients with endometrial cancer. Additionally, because the majority of women will survive and surpass their endometrial cancer, it is increasingly important to consider the long-term health implications of their treatments and optimize survivorship.

SLN MAPPING

Pelvic and para-aortic lymphadenectomy has been included in the surgical staging criteria for endometrial cancer since 1988.[10] Lymph node status is the most important predictor of survival and provides risk assessment that guides postoperative treatment planning.[11] The SEPAL study suggested a therapeutic effect of lymphadenectomy, with significantly longer overall survival among patients who had pelvic and para-aortic lymphadenectomy in this retrospective analysis.[12] However, two randomized controlled trials have failed to show a survival benefit with pelvic and selective para-aortic lymphadenectomy.[13,14] Lymphadenectomy has been associated with prolonged operating time, additional cost, and increased morbidity including lymphedema, lymphocysts, and neuralgia.[15] Although the therapeutic benefit of lymphadenectomy remains controversial, most agree that lymph node status can help determine which patients should undergo adjuvant therapy and which patients can avoid additional cancer-directed treatment and the associated morbidity. A Surveillance, Epidemiology, and End Results (SEER) database study demonstrated that patients who undergo lymphadenectomy are less likely to receive pelvic radiation.[11]

The SLN is the first node to receive drainage from a primary tumor. This lymph node, therefore, is most likely to

harbor cancer cells for those cancers that spread via the lymphatic system. SLN mapping and ultrastaging of SLNs have been proposed as a surgical method to reduce the morbidity of surgical staging while maintaining the prognostic information of lymph node status assessment. SLN mapping and ultrastaging are currently considered standard of care for the surgical staging of breast cancer, melanoma, and vulvar cancer.[16,17]

SLN Mapping Technique

Most of the early studies of endometrial cancer SLN mapping used a combination of radioactive tracer with lymphoscintigraphy or single-photon emission CT (SPECT-CT) and colored dye (patent blue, isosulfan blue, and methylene blue) to visualize nodes.[18] Drawbacks of radioactive tracers include difficulty detecting SLN close to the cervix as the gamma-probe detects high activity from the cervical injection site, patient inconvenience of having to undergo preoperative injection and imaging, and costly resources and equipment that are not available to all surgeons.[19] With the current widespread availability of the robotic platform and near-infrared imaging, many surgeons have replaced the dual injections with indocyanine green (ICG) and immunofluorescence detection (Fig. 1). ICG injection seems to negate the higher rates of failed SLN mapping observed in obese patients, possibly because of differences in the molecular weight of the isosulfan blue versus ICG and that ICG is more prominently visualized in the setting of visceral and retroperitoneal fat.[20] Of note, although widely used for endometrial cancer SLN mapping, ICG is not approved by the U.S. Food and Drug Administration for this indication.

In other cancers in which SLN mapping is the standard of care, like breast cancer and melanoma, direct peritumoral injection is straightforward; however, this is not the case for endometrial cancer. Several injection locations have been evaluated, including intracervical, uterine subserosal, fundal, and even peritumoral.[21-23] The SGO Clinical Practice Statement supports cervical injection, stating that it is a reproducible technique that adequately maps the pelvic lymph nodes and occasionally lower aortic nodes; however, they also have noted that there are insufficient data to suggest that the upper aortic lymph nodes (above the inferior mesenteric artery) can be reliably mapped using current cervical injection techniques.[16] López-De la Manzanara Cano et al[24] found that a deeper injection (3 cm) had improved detection of para-aortic SLNs. Many propose restricting the cervical injection to low/intermediate-risk tumors that have a low likelihood of para-aortic involvement,[25] a restriction that would include the majority of endometrial cancers. The SGO Clinical Practice Statement additionally suggests that decisions regarding para-aortic lymphadenectomy should be determined by tumor histology, intraoperative findings, and status of pelvic lymph nodes at surgery.[16]

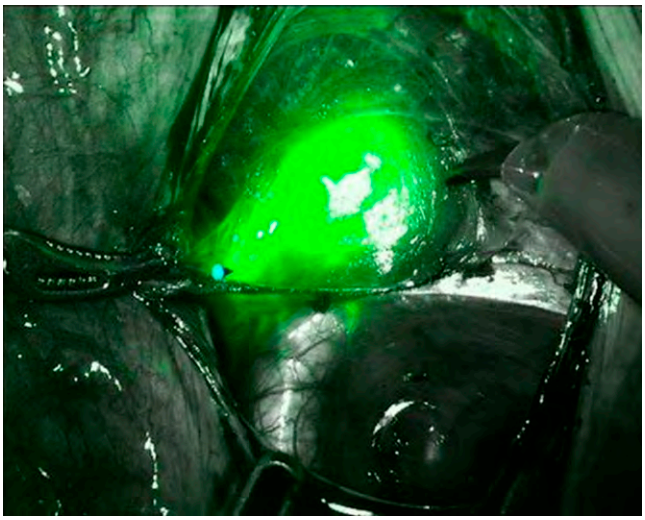
The Memorial Sloan Kettering SLN algorithm mandates that failure to map a SLN results in complete lymphadenectomy on the respective hemipelvis, as well as removal of any suspicious nodes and peritoneal lesions, and meticulous ultrastaging of SLNs. Barlin et al[26] found that applying this mapping algorithm significantly reduced the false-negative rate from 14.9% to 1.9%. A recently published modeling analysis proposed an approach termed SLN-restrictive frozen section strategy, in which patients who did not map SLNs would have intraoperative frozen-section evaluation, and the decision to perform a lymph node dissection would be determined by the identification of high-risk uterine features on frozen-section diagnosis.[27] Whether the ideal management of failed SLN mapping involves either of these approaches remains unknown, but both present reasonable options.

Pathologic ultrastaging of SLN varies among institutions, and clear guidelines have not been established for gynecologic pathologists. The process generally involves examination of multiple deeper level sections of the lymph node using routine staining and keratin immunohistochemical staining. Lymph node metastases are classified according to their size in accordance with the nomenclature used for breast cancer metastases.[28]

1. Macrometastasis: tumor clusters larger than 2 mm.
2. Micrometastasis: tumor clusters between 0.2 to 2 mm in size.
3. Isolated tumor cells: single tumor cells or tumor clusters that are 0.2 mm or smaller in size.
4. Isolated cytokeratin-positive cells.

Kim et al[29] found that SLN mapping detected additional low-volume metastases in 4.5% of patients relative to routine lymph node evaluation. Although most groups consider macrometastasis and micrometastasis to be positive SLN, the prognostic value of isolated tumor cells and isolated cytokeratin-positive cells remains uncertain. Furthermore, appropriate treatment of patients with low-volume metastatic disease is not yet known and varies by institution.

FIGURE 1. SLN Visualized With ICG and Immunofluorescence Detection



Abbreviations: SLN, sentinel lymph node; ICG, indocyanine green.

SLN Mapping Efficacy

Despite more than a decade of studies of SLNs in endometrial cancer, it has yet to be established as a standard of care for patients with this disease, and results in the literature vary. This is likely because of a myriad of currently used SLN mapping techniques combined with the complexity and bilaterality of the nodal basins that drain the uterus.[30-33] The initial results for SLN mapping were promising, including the SENTI-ENDO trial, which found 100% negative predictive value and 100% sensitivity of SLN when considering the hemipelvis as the unit of analysis and 97% negative predictive value and 84% sensitivity when considering the patient as the unit of analysis.[18] However, a meta-analysis of 26 studies found a detection rate of 78% and sensitivity of 93% and cautioned that the demonstrated good diagnostic performance of SLN mapping in endometrial cancer should be interpreted with caution because of the notable small-study effect.[34] A more recent meta-analysis identified a higher pooled detection rate (81%) and sensitivity of 96% for detecting lymphatic metastases, rates that approach those observed in breast cancer and melanoma.[32] The authors suggest that these improvements may reflect gynecologic surgeons' growing experience with SLN mapping and increased use of more innovative dye and detection techniques. To account for the learning curve, the SGO Clinical Practice Statement suggests that surgeons should train by performing SLN dissection and then lymphadenectomy on 20 patients prior to adopting SLN as their standard surgical method.

Benefits of SLN Mapping

The most important advantages of SLN mapping include improved detection of metastatic disease through ultrastaging of lymph nodes and reduction in morbidity by eliminating the complete lymph node dissection. Although finding metastases that would have otherwise been missed seems valuable, some might argue that altering therapy based on this information results in overtreatment, and the use of SLN in endometrial cancer has not been shown to improve oncologic outcomes. The inclusion of lymph node dissection in endometrial cancer staging procedures has been shown to increase operative room time, surgical blood loss, length of hospital stay, and morbidity, including permanent lymphedema. Dowdy et al[15] found that complications in the first 30 days following surgery occurred in 19.3% versus 37.5% of patients in the non–lymph node dissection versus lymph node dissection group. The 30-day cost-of-care was also found to be significantly higher in the lymph node dissection group, correlating directly with increasing severity of adverse events among these patients. There are yet to be prospective evaluations of the morbidity of SLN mapping in endometrial cancer; however, most would agree that these patients should have an experience that more closely emulates the patients without complete lymphadenectomy.

OVARIAN PRESERVATION

Whereas many debate the necessity of nodal assessment as part of the treatment of patients with endometrial cancer, hysterectomy and bilateral salpingo-oophorectomy are standard. The rationale for ovarian removal includes detection and removal of occult metastatic disease as well as synchronous ovarian cancers and diminishment of estrogen production. With an amplified incidence of endometrial cancer along with an increasing proportion of diagnoses occurring in younger women, the number of premenopausal women losing their ovaries to endometrial cancer will grow. Almost one-fourth of U.S. women with endometrial cancer are premenopausal at diagnosis,[35] and other reported incidences are even higher, such as in Korea, with 45% of cases occurring in premenopausal women, 10% in women under 40.[36,37] Removing the ovaries in premenopausal women subjects them to surgical menopause and its attendant symptoms of estrogen deprivation, along with increased risk of cardiovascular disease, osteoporotic fractures, cognitive impairment, and possibly diminished survival, although the most quoted study demonstrating survival benefit to ovarian retention did not include women with cancer.[35,38,39]

Citing these concerns, several groups have considered the safety of ovarian preservation among young women with endometrial cancer. A query of SEER data found that ovarian preservation in women under 45 with low-grade early-stage endometrial cancer had no effect on either cancer-specific or overall survival.[40] A population-based analysis using the National Cancer Database compared the 7% of women with stage I endometrial cancer under the age of 50 with retained ovaries to those who underwent bilateral oophorectomy and also found that ovarian conservation did not adversely affect oncologic outcomes.[41] A nationwide study from tumor registries in Korea evaluated 175 women with endometrial cancer who retained their ovaries. With median follow-up of 55 months, 4% recurrence risk was noted and none in patients with stage I endometrioid tumors. All patients who recurred had risk factors including a nonendometrioid histology, contralateral adnexal involvement, or deep myometrial or cervical stromal invasion. The authors concluded that in selected patients (Table 1), oophorectomy need not be a mandatory component of standard surgical therapy for endometrial cancer.[42] More recently, a follow-up SEER study of ovarian conservation in young women with early-stage low-grade endometrial cancer found the same cause-specific survival for retaining and removing ovaries but improved overall survival with ovarian retention as well as a lower cumulative risk of death from cardiovascular disease.[43]

This finding is not necessarily surprising. Several SEER studies have shown that among women with favorable endometrial cancers, cardiovascular disease is a more probable cause of death than is cancer,[44,45] in part because of the high likelihood of curative cancer treatment[46-52] and the prevalence of cardiovascular disease, especially among patients with endometrial cancer whose risk factors for endometrial cancer are also risk factors for cardiovascular disease. Additionally, when the indication for hysterectomy is not cancer, the case for ovarian retention is compelling. The Nurses' Health Study showed that all-cause mortality, coronary heart disease mortality, and deaths from all cancers

TABLE 1. Proposed Indications for Ovarian Preservation in Patients With Endometrial Cancer[42]

Proposed Indicators
Patients who want to retain ovarian function.
No gross intraoperative extra-uterine tumor spread.
No gross abnormality in bilateral ovaries.
Negative results of frozen biopsy for lymph nodes suspicious for metastasis.
Endometrioid-type histology in preoperative biopsy.
Patients who have no inherited predisposition to breast or ovarian cancer.

were diminished when ovaries were retained at the time of hysterectomy for benign disease versus when ovaries were removed.[39] Several smaller cohort studies similarly confirm this association.[53-56] More recently, a nationwide study in the United Kingdom compared ovarian removal to conservation and found conservation to be associated with lower all-cause mortality as well as lower death rates from heart disease and cancer, causing the authors to conclude that removing ovaries to prevent ovarian cancer comes at the cost of an increased risk of cardiovascular disease and other more prevalent cancers and higher overall mortality.[57]

CONCLUSION

We have explored two methods to additionally minimize minimally invasive surgery for endometrial cancer—SLN mapping and ovarian preservation. The greatest obstacle in adopting SLN mapping as standard of care for endometrial cancer is the lack of large prospective studies that perform complete systematic pelvic and para-aortic lymph node dissection as a true control arm. However, according to a survey of SGO members, 28.6% of respondents performed SLN mapping, 16.7% with the exclusion of pelvic lymphadenectomy, and 54% of institutions performed pathologic ultrastaging of SLN.[16] Furthermore, the National Comprehensive Cancer Network guidelines for endometrial carcinoma now include a SLN algorithm as an option for surgical management of endometrial cancer. The uncertainty surrounding the value of lymph node assessment in endometrial cancer is not likely to be resolved in the near future. However, SLN mapping is emerging as an effective surgical technique to allow tailored adjuvant therapy for high-risk patients while minimizing the risk of harm that occurs with a complete lymphadenectomy. A compelling case also can be made for ovarian retention in women with early-stage, early-grade endometrioid endometrial cancer, particularly in premenopausal women, but potentially in older women as well. Ovarian preservation has been associated with improved overall survival and lower risk of cardiovascular disease in many studies. This is not to say that ovarian preservation should be standard of care in these cases but that ovarian extirpation should not be automatic for all women with endometrial cancer, as a select group may benefit from keeping their ovaries.

The Road to Addressing Noncommunicable Diseases and Cancer in Global Health Policy

Heath Catoe, MD, PhD, Jordan Jarvis, MSc, Sudeep Gupta, MD, MBBS, Ophira Ginsburg, MD, FRCPC, and Gilberto de Lima Lopes Jr., MD, MBA, FAMS

Premature death and disability from cancer and other noncommunicable diseases (NCDs)—such as diabetes, heart disease, chronic respiratory disease, and others—are on a rapid rise in low- and middle-income countries. Whereas in 1990, 57% of global deaths were attributed to NCDs, they accounted for 70% (38.3 million) in 2013, with 80% of premature deaths reported in low- and middle-income countries.[1,2] Historically viewed as conditions largely affecting rich countries and elderly populations, global NCDs were long neglected as a development and even health priority in resource-limited settings. Now, these countries are experiencing an epidemiologic transition in which more patients are afflicted by NCDs, with longer suffering and death at younger ages than in high-income countries.[3]

Rising global rates of NCDs have enormous economic implications, estimated at a cumulative loss of 47 trillion between 2011 and 2030.[4] Premature NCD death and disability, defined by the World Health Organization (WHO) as those younger than age 70, result in people working fewer years, with lower productivity, and result in higher costs to both the health system and individuals.[5,6] As NCDs are both a cause and a consequence of poverty, they are a threat to sustainable human development on a global scale. Social, economic, and environmental factors, such as globalization, international trade, urbanization, education, labor practices, household income, and food production, all serve as risk factors for NCDs.

This previously under-recognized crisis underlies the importance of global coordinated action to increasingly recognize NCDs as a political issue. In many cases, we have solutions in the form of scientific and technical progress, but these are insufficiently implemented due to a lack of political will. Thus, a movement of stakeholders from across nongovernmental organizations, patient groups, academia, intergovernmental organizations, private sector, and governments have been working to advance global, regional, and national policy and time-bound measurable commitments to reduce the global burden of NCDs.

The inception of global policy to address the growing NCD crisis effectively dates back to the June 1992 United Nations (UN) Conference on Environment and Development in Rio de Janeiro, Brazil. Several key meetings under the auspices of the UN ensued, with a growing consensus and emerging multisector partnerships that would support the path to a set of NCD goals. The 2002 Johannesburg Declaration on Sustainable Development formally addressed the issue of NCDs, and the 2009 Economic and Social Council Ministerial Declaration recognized the burden NCDs placed on countries. These meetings helped lay out frameworks and goals that would eventually lead to the UN High-level Meeting in 2011, a high mark in the global effort to address NCDs.[6]

THE ROLE OF CIVIL SOCIETY

Whereas the HIV/AIDS movement had strong grassroots advocacy with the voices of patients featuring prominently, technical and policy discussions have been more dominant in driving the early stages of the NCD movement. However, an early catalyst for the NCD movement was a group of patients with diabetes in the Caribbean who drew attention to their preventable foot amputations and lack of prioritization of chronic diseases as a human rights concern.[7] They advocated to their governments, leading to the first-ever summit on NCDs involving heads of state in Trinidad and Tobago in September 2007 in which the Port-of-Spain Declaration "Uniting to Stop the Epidemic of Chronic Non-Communicable Diseases" was issued.[8] Leaders of CARICOM, a group of 20 countries within the UN system, raised their concerns about diabetes and other NCDs at the UN, setting the stage for the UN High-level Meeting to take place in 2011.

Strong global-level civil society mobilization on NCDs began in 2009, with the formation of the NCD Alliance

(https://ncdalliance.org) and other civil society groups, such as the Young Professionals Chronic Disease Network (www.ncdaction.org). As a coalition of disease federations, including the International Diabetes Federation, the World Heart Federation, the Union for International Cancer Control, and the International Union Against Tuberculosis and Lung Disease, the NCD Alliance was established to consolidate funding and influence for policy changes on NCDs as a group and avoid disease silos in global policy for health. Civil society, including academics, pushed for international support and clarification of goals in the form of a political declaration to address NCDs, leading up to the UN High-level Meeting on the Prevention and Control of Non-communicable Diseases in 2011,[9,10] at which international heads of state assembled for the second-ever UN High-level Meeting on a health issue.

UNITED NATIONS HIGH-LEVEL MEETING 2011

As part of its wide-ranging mandate, the UN General Assembly convenes high-level meetings to increase awareness while pressing for common ground and policies on issues of global importance.[11] Participation in the September 2011 meeting included 82 member states, including representation from 35 heads of state, civil society, private sector, and UN agencies. The political declaration on NCDs emerged after controversial negotiations, largely between groups of developed versus developing nations, on access to medicines, food and beverage policies, tobacco control, and financing commitments.[12] Most notably, tensions arose with the addition of intellectual property provisions for the World Trade Organization's Trade-Related Aspects of Intellectual Property Rights (TRIPS) agreement. These TRIPS "flexibilities" give countries the right, if criteria are met,[13] to circumvent patents to issue a compulsory license for medicines considered essential for the public health good at an affordable price.[14] Although the HIV/AIDS movement emphasized the right to treatment, this discourse was largely muted at the NCD High-level Meeting. To frame NCDs as a social justice issue and call for action and commitments, students, AIDS activists, and people living with NCDs held the first rally on NCDs outside the UN in New York.[7]

The UN political declaration on the Prevention and Control of Non-communicable Diseases passed, outlining policies to address the four major NCDs defined by WHO, which are cancer, cardiovascular disease, chronic respiratory diseases, and diabetes. Policies responding to current disease treatment revolved around improving health care infrastructure and systems including increased technical resources.[9] The impetus for such shift in policies relates to the goals of sustainable global development based on three pillars defined by economic growth, social equity, and environmental protection.[6] Some of the specific policies implemented soon after the 2011 meeting include those from Gabon with free screening for cancers, Niger aiming to ensure access and affordability of medicines, Spain rethinking health strategies on cancer, Mexico funding evidence-based clinical interventions and new technologies, Trinidad and Tobago starting a Chronic Disease Assistance Program to provide all people with medications, UNASUR (Union of South American Nations) aimed to ensure universal access to medicines, using TRIPS, and India further developing its National Program for Prevention and Control of Cancer to screen for disease.[15]

To provide member states with a clear road map to address NCDs, WHO was tasked to develop a set of targets, which now guide the global NCD response in the form of the NCD global monitoring framework and the NCD Global Action Plan 2013–2020.[16] The targets included advocating and raising awareness, disseminating knowledge and information, encouraging innovation and identifying barriers, advancing multisector action, and advocating for the mobilization of resources. An initial set of nine voluntary targets and 25 indicators for 2025 goals that provided an assessment of NCD mortality and morbidity, risk factors, and national systems response was developed. These targets include: 25% reduction in premature mortality from NCDs, 10% reduction in harmful use of alcohol, 10% reduction in physical inactivity, 30% reduction in tobacco use, 80% coverage of essential NCD medicines and technologies, and 50% coverage of drug therapy and counseling.[17]

ASSESSMENT THUS FAR

The formal process for monitoring progress on the goals is conducted under WHO auspices via country surveys to assess national capacity for the prevention and control of NCD from the 194 member states. These surveys had been ongoing for several years prior, but the questions varied significantly from prior versions, making comparisons problematic, and validation of the data proved challenging.[18] The first survey following the meeting was in 2013 and showed overall progress and improvements, specifically operational national NCD policy with a budget for implementation increased from 32% of countries in 2010 to 50% of countries in 2013, while highlighting the challenges faced by nearly all member states.

The WHO Global Survey was comparable in 2010, 2013, and 2015. Questions include public health infrastructure, partnerships and multisector collaboration for NCDs, the existence of NCD-relevant policies, strategies and action plans, capacity for surveillance to address NCDs and their risk factors at the national level, and capacity for NCD prevention, early detection, treatment, and care within the health system. Comparison of 2010 to 2013 showed increases in designating a unit, branch, or department with responsibility for NCDs from 89% to 94%, with a slight decline to 93% by 2015. Increased funding for NCD prevention and health promotions was shown from 81% to 88% from 2010 to 2015. During this period, 11% versus 6% reported absence of funding for NCDs with the variety in funding sources increasing, the most prevalent being general government revenues. In 2015, the first assessed prevalence of palliative care funding was found in 64% of countries.[18] Although policies were prevalent, operational policies took time to increase from 33% in 2010 to 63% in 2015. Operational plans addressing cancer specifically increased from 50% in 2010 to 71% in

2015. Cancer registries slightly increased from 80% to 81% to 84%, whereas national, population-based cancer registries changed from 39% to 59%.[18]

Monitoring risk factors with surveys increased with each assessment, especially tobacco use surveys. Primary prevention and health promotion increased as well as risk factor detection during this period. Although some form of guidelines for cancer management existed for 73% in 2013, only about half of those had fully implemented them. However, in 2015, evidence-based guidelines were assessed, revealing 60% of countries had them, with approximately 55% having some form of implementation of those guidelines. Prevalence of tests and procedures available increased, such as breast cancer mammogram from 81% to 84% as well as cervical cancer from 65% to 74% from 2010 to 2013. Availability of many essential medicines increased, but, for example, oral morphine went from 48% to 56% to 43% from 2010 to 2015. In 2015, 67% of countries had cancer centers or cancer departments at the tertiary level. However, availability of cancer surgery (69%) and subsidized chemotherapy (63%) were distinctly influenced by country income group.[18,19] One important point to draw from the WHO global surveys is cancer treatment availability is correlated with income of country.

With the 2011 high-level meeting, there may have been hopes to replicate the effect of the high-level meeting for HIV/AIDS in 2001 on funding and donations, which surged afterward, alleviating the treatment-access crisis at that time.[9] However, there remains a dearth of domestic funding information on NCD programs.[10] As was seen in the 2013 survey, there was policy in place for NCD work but less actually working plans in place, suggesting the difficulty of implementation. Funding is an important consideration with enacting domestic policies for prevention and treatment; however, there is a complex network of factors affecting individual countries in implementing domestic policies. A total of 77% to 87% of low- and middle-income countries in 2015 had a major source of funding for NCD programs come from international donors.[19] However, analysis of this funding by the WHO Working Group indicated that donor assistance for health goes mainly to other areas besides NCDs, even though NCDs are more of a health burden.[20] Current funding for NCD policies in low- and middle-income countries could be improved by better allocation of international assistance.

FACTORS IN TREATMENT IMPLEMENTATION

Although policy and goals can be set for prevention and treatment of cancer, implementation of such policies is complex, with barriers that will require creative solutions. The high costs of cancer medications can often be an insurmountable barrier to treatment in poor countries. This is in part due to new medications covered under patent laws that are priced for high-income countries.[14] International patent law is guided by different conventions, partnerships, and agreements, including obligations under the World Trade Organization and TRIPS agreement.[13,21,22] To obtain access to cancer medications, countries can use compulsory licensing to lower the cost of medication through lower domestic production costs and patent fees. Although this is an ongoing point of contention in international patent law, compulsory licensing has had success before with HIV/AIDS medications.[23] Creation of biosimilars, tiered price schemes, public-private partnerships, patent pools, and tax incentives are additional ways in which costs of cancer treatment can be curbed.[24]

Many governments are now considering how to prioritize medicines for cancer care with limited budgets. Guidance on which medications countries can consider as essential while adapting to their needs and public health priorities exists via the WHO Model List of Essential Medicines. In 2015, 16 cancer drugs were added to the existing WHO Model List of Essential Medicines, providing a suite of medications covering basic oncologic diseases, essentially prioritizing access to basic cancer treatments for 26 cancer types.[25] In 2011, the WHO published its Core Medical Equipment guide to further information on essential equipment. Currently the WHO is working on its list of priority medical devices specifically for cancer to guide cost-effective procurement. These guides, expected to be published in summer 2017, will help the lower income, poor resource, and poor infrastructure countries purchase priority medical products with a cost-effective logic in mind.

A COUNTRY EXAMPLE: INDIA IN THE SPOTLIGHT

To more thoroughly understand the whole of challenges faced by countries implementing strategies for cancer prevention and treatment, we will look at India's current state of affairs. India's National Cancer Control Program is a federally coordinated program that was launched in 1975 with the main aims of creating infrastructure for primary prevention, early detection, and treatment of cancers. The main lynchpin of strategy for providing therapeutic care was the creation of so-called Regional Cancer Centres that are so located as to bridge geographic gaps in the availability of public-sector cancer treatment facilities. There are 27 Regional Cancer Centres in India at present. However, infrastructure and human resource for cancer treatment remain inadequate for a country of India's physical size and population. For example, there are less than 1,000 trained medical oncologists and only about 340 radiation therapy centers in India.[26] A considerable fraction of health care capacity, including cancer care, in India is provided by private-sector industry for which services are beyond the reach of a majority of patients. The added complexity is with grossly uneven distribution of health care services in India in which the majority of infrastructure and human resources are located in urban regions, but the majority of the population resides in rural areas. There have been recent proposals to initiate basic cancer care services, including surgery and chemotherapy for common cancers, at the level of district hospitals, of which there are about 600 in India.[26] Several Indian states have initiated programs to deliver cancer care in rural and semi-urban regions along these lines.[27] Recently,

there has been improvement in human resource availability in underserved areas. Several strategies, some incentivized, have been initiated by the federal government to improve rural medical service.[28] There has also been a substantial increase in number of postgraduate training positions in oncology in the past few years. An important recent initiative to link more than 80 public- and private-sector cancer centers in India, called the National Cancer Grid, is also noteworthy in this context.[29] Its main aim is to provide uniform, evidence-based cancer care across different geographic areas in India.

One important aspect of India's cancer-control scenario is a relatively good quality national cancer registration program that has existed under the aegis of the Indian Council of Medical Research since 1981 and currently comprises 23 population-based cancer registries that collect data on cancer incidence from defined geographic regions. Most of these registries are located in urban areas, and very few collect data on mortality. It is estimated that there are about 1.0 to 1.1 million new cancer cases every year with about 0.5 million deaths for a mortality-to-incidence ratio of about 50%, which is much higher than that seen in developed countries.[30] The main contributors to high cancer mortality are advanced stage at diagnosis and inadequate health care infrastructure, especially in rural and semi-urban areas. For example, with a much lower cancer incidence in rural compared with urban areas, the mortality of cancers in males and females is almost equal in rural (95.6–96.6/100,000) and urban (91.2–102.4/100,000) regions of India.[31]

The main strength of Indian cancer-control scenario is widespread availability of inexpensive medications, including anticancer drug generics, biosimilars, and copies,[32] except for a few newer targeted and immunotherapy drugs. The main reason for this has been the development of a robust Indian pharmaceutical industry that has developed considerable expertise in past few decades in making generic versions of most drugs. The generic industry has been helped by legal interpretation of intellectual property rights in India that have generally been against the practice of evergreening of patents.[33] India has also used, somewhat sparingly, the route of compulsory licenses for on-patent drugs in recent years, with mixed results.[14,34] The only case of compulsory licensing by India in the domain of oncology was for sorafenib. This generated strong opposition from the patent holder, Bayer. The Government of India also exercises control over pricing of drugs through periodic Drug Price Control Orders under the Essential Commodities Act enacted in 1955. Again, the use of this legislation has had mixed results, for although it has kept essential drug prices under check, scarcity has been created for some medications that have become unviable to manufacture.[35]

Finally, provision of palliative care for advanced-stage patients has been inadequate, with India faring poorly on the Quality of Death index among various nations.[36] There needs to be urgent multisectoral action to improve availability of opioid analgesics, training of health care professionals, creation and adoption of locally relevant palliative care standards, and development of community models for providing home-based palliative care in India.

CONCLUSION

The ideals for treating NCD as a global health problem have a rich historical route that led to the high-level UN meeting in which the world's countries united around policies enacted to address prevention and treatment. The complexity of implementing those policies, specifically related to cancer, has hindered quickly achieving the WHO global NCD targets. Information on the prevalence and type of cancer in the region, income, and infrastructure is important in making judicious allocations of resources in medication and medical equipment procurement. While considering domestic policies and implementation of cancer prevention and control, one must acknowledge international limitations placed on individual countries through policies and country income. India is a prime example of the interplay between domestic and international factors that must be considered to have an effective system for prevention and treatment of cancer, especially in a low- to middle-income nation.

How Should We Intervene on the Financial Toxicity of Cancer Care? One Shot, Four Perspectives

S. Yousuf Zafar, MD, MHS, Lee N. Newcomer, MD, Justin McCarthy, JD, Shelley Fuld Nasso, and Leonard B. Saltz, MD

OVERVIEW

The median price of a month of chemotherapy has increased by an order of magnitude during the past 20 years, far exceeding inflation over the same period. Along with rising prices, increases in cost sharing have forced patients to directly shoulder a greater portion of those costs, resulting in undue financial burden and, in some cases, cost-related nonadherence to treatment. What can we do to intervene on treatment-related financial toxicity of patients? No one party can single-handedly solve the problem, and the solution must be multifaceted and creative. A productive discussion of the problem must avoid casting blame and, instead, must look inward for concrete starting points toward improvement in the affordability and value of cancer care. With these points in mind, the authors—representatives from the pharmaceutical industry, insurance providers, oncologists, and patient advocacy—have each been asked to respond with a practical answer to the provocative hypothetical question, "If you could propose one thing, and one thing only, in terms of an action or change by the constituency you represent in this discussion, what would that be?"

Cancer is one of the most expensive diseases to treat in the United States. The median price of a month of chemotherapy has increased by an order of magnitude during the past 20 years, far exceeding inflation over the same period. Some would maintain that prescribing patterns further contribute to higher costs. In the most common models of cancer care delivery, oncologists have little incentive to contain treatment costs when they prescribe chemotherapy, and only recently have considerations of cost and affordability begun to be openly incorporated into guideline development.

Because of increasing deductibles, increasing premiums, cost sharing, coinsurance, and frequent copayments, patients are directly shouldering a greater portion of those costs.[1] One in three American families face health care bills they cannot afford, and 50% of elderly Americans with cancer pay at least 10% of their income toward out-of-pocket treatment-related expenses.[2,3] A growing body of literature has described the treatment-related financial strain experienced by patients with cancer, often called the financial toxicity of cancer treatment. These studies have described how an increasing portion of patients with cancer are at risk for cutting back on groceries, selling their homes, being nonadherent to their prescribed treatment, or—in the most extreme cases—declaring personal bankruptcy to pay for their cancer treatments.[4,5]

What can we do to intervene on treatment-related financial toxicity of patients? Without question, any meaningful steps toward lower costs will involve collaboration among the pharmaceutical industry, insurance providers (government and otherwise), oncologists, and patients; no one party can single-handedly solve the problem. The solution must be multifaceted and creative; prosaic appeals to simply lower drug prices surely will fail. A productive discussion of the problem must avoid casting blame and, instead, must look for common ground, and must look inward for concrete starting points toward improvement in the affordability and value of cancer care.

With these points in mind, the authors of this article—representatives from the pharmaceutical industry, insurance providers, oncologists, and patient advocates—have each been asked to respond with a practical answer to the provocative hypothetical question, "If you could propose one thing, and one thing only, in terms of an action or change by the constituency you represent in this discussion, what would that be?" Note that this exercise is focused on the question of what changes we would make as opposed to the more comfortable and more often answered question of what changes others should make. We undertake this exercise with the full realization of the artificial nature of a limit to one simple answer of what is necessarily a complex, nuanced, and multifaceted problem and the

awareness that that there is no singular answer that any of us could offer that will be fully inclusive and satisfactory to all voices within each of our stakeholder groups. Rather, we aim here to provide ideas to serve as starting points, both for introspection and to promote discussion.

THE PHARMACEUTICAL INDUSTRY PERSPECTIVE (J. MCCARTHY)

Invest Additional Resources to Identify Patient Populations Most Likely to Benefit From Therapy

The idea of paying for value when it comes to pharmaceuticals is a widely accepted goal. However, there is still no consensus on what this means. Although this concept is still evolving, it relies at its core on biopharmaceutical companies to demonstrate that the products we develop provide meaningful benefits to patient populations, coupled with a reimbursement system that lowers barriers to high-value products. Biopharmaceutical companies should do their part to invest more resources to ensure that the right product is available to the right patient at the right time.

Cancer care is in the midst of an incredible transformation. Many cancers, previously intractable, now can be treated with targeted therapies that greatly boost the chances of better outcomes for patients. Some patients experience long-term benefits from immunotherapies. However, we still know too little about which types of patients are likely to respond best to a particular therapy. The pharmaceutical industry should invest additional resources in studies of a new drug after it has been approved to better understand its utility, whether to identify use at earlier stage of the disease, in a different tumor type, or for an even narrower patient population to avoid patient exposure when the risks are more likely to outweigh the benefits.

For our health care system to truly pay for value, stakeholders also must be willing to develop creative reimbursement mechanisms that incentivize high-value care. Payment reform demonstrations are underway across the health care sector to explore better ways to pay for inpatient and outpatient care. To date, however, little has been done in the prescription drug space. Biopharmaceutical companies and payers—public and private—should collaborate to explore new, high-value reimbursement methods. These methods could include the following:

- Outcomes-based contracts. Biopharmaceutical companies and private payers have experimented recently with contracts in which payment for products is tied to achievement of certain therapeutic goals (e.g., avoiding increased hospitalizations or increasing progression-free survival). These two sectors should work together to advocate removal of regulatory and legal barriers. Doing so would allow robust use of these promising tools to expressly tie payment to value.
- Value-based insurance design. Another nascent concept is value-based insurance design. Although this idea has been used in the context of outpatient and inpatient services, it has not been applied broadly to drugs. For example, an insurer could dramatically reduce cost sharing for high-value drugs or lower cost sharing after a patient experiences disease failure with a lower-cost medication.[6] These types of arrangements are still in their infancy but could help incentivize patients and providers to use and prescribe high-value products.

Transformation of our health care system to one that pays on the basis of value, not volume, will require coordination and cooperation across the sector. Biopharmaceutical companies should do their part to help demonstrate the value of our products to patients, payers, and providers.

KEY POINTS

- **Not only are drug prices rising, but patients also face high cost sharing forcing patients to shoulder a greater portion of costs.**
- **Current reimbursement models provide little incentive to contain costs.**
- **A solution to the problem of financial toxicity must be collaborative and multifaceted.**
- **As a starting point to the discussion, the authors have provided four ideas from each of their stakeholder perspectives as options available to reduce cancer treatment–related financial toxicity, including: high-value reimbursement models; removing coverage mandates for all FDA-approved cancer therapy; ensuring oncologists consider price in treatment decision making; and encouraging patient engagement in decision making to assure treatment truly matches patients' values and preferences.**

THE PAYER'S PERSPECTIVE (L. NEWCOMER)

Remove Coverage Mandates From State and Federal Insurance Law

Insurance regulation forces payers to pay for any U.S. Food and Drug Administration (FDA)–approved cancer therapy in 42 states; Medicare has a similar provision. Such mandatory coverage eliminates any consideration of value. A therapy with mandatory coverage could be curative or could simply add one additional day of life, but the price cannot be negotiated if that therapy has an FDA-approved indication. The laws were well intended originally. As expensive therapies emerged, legislators were concerned that insurers would simply refuse to pay. The unintended consequence of coverage mandates becomes apparent when multiple therapies are available; payers cannot make decisions on the basis of the value of therapy and substitute one therapy for another when it is clinically appropriate. Removal of this legislated requirement would open the marketplace, and pharmaceutical manufacturers would compete on price and outcomes. Payers would compete in the marketplace by offering the best values for therapy within a competitive premium. This competition requires that a transparent and understandable set of criteria for determination of value, partial value, or no value is presented. The market could function normally.

The lung cancer therapy necitumumab is an excellent example of why mandates force prices beyond reason.[7] This

drug was added to cisplatin and gemcitabine and compared with cisplatin and gemcitabine alone in patients with stage IV squamous cell lung cancer. Three percent of the patients who received necitumumab suffered a cardiac arrest. The difference in median progression-free survival was 0.2 months (5.7 vs. 5.5 months), but the overall survival favored the necitumumab group by 1.6 months (11.5 vs. 9.9 months). These results are so meager that the National Comprehensive Cancer Network assigned a category-3 recommendation to the drug—an endorsement that most insurers, including Medicare, do not cover. However, the mandates require coverage at any price, because the drug has an FDA approval. The manufacturer priced this drug at $11,430 per month. The competing regimen, cisplatin and gemcitabine, cost less than $1,000 per month. It is difficult to believe that anyone except the manufacturer would consider this to be a value, but it does not matter. The law mandates coverage; therefore, price is not negotiable.

Necitumumab is not an isolated example. Salas-Vega et al[8] reviewed 62 new cancer molecules approved between 2003 and 2013 in the United States and Europe. The review showed no evidence to suggest that 16 of those drugs (30%) increased overall survival compared with best alternative treatments. If manufacturers knew that these products would not be reimbursed in the market, they would focus their attention on different molecules that offer better results.

Other mandates are emerging. Several states are now considering laws to prohibit step therapy for cancer. Step therapy requires treatment with a preferred regimen before the patient is eligible for a second therapy. This strategy is useful for drugs that have similar clinical response rates, because a payer can obtain competitive bids and then give preference to the lowest-cost regimen. There have been so many drug discoveries in the past decade that many cancer types now have multiple effective agents. Step therapy allows patients to obtain treatment at a lower cost. Prohibition of step therapy eliminates competition, raises costs, and hurts everyone except the pharmaceutical manufacturer.

A free market determines prices on the basis of merit, and mandates prevent free market actions. Removal of mandates presents a win-win proposition for patients and payers.

THE ONCOLOGIST'S PERSPECTIVE (L. SALTZ)

Know the Price

Any one change that doctors could make would only be a first step toward the ultimate goal of provision of lower-cost, higher-value medicines for our patients. To me, that first step would be physician acceptance, practice, and promotion of transparency in price. In simple terms, that means knowing the prices of the drugs prescribed, considering those prices as one of the many factors in decision making, and discussing the prices of the prescribed drugs as openly as we discuss other risks, toxicities, and benefits.

I make a sharp distinction here between the words price and value. A true, constructive consideration of the value of a particular medicine cannot realistically occur unless we know the amount of money that we are being asked to pay for it. That is the definition of price, or cost, that I refer to for this discussion: the amount of money that will be paid for the drug. I am not, for this exercise, getting into who is paying for it, what other costs are or are not involved, what alternatives are available, or any other of a number of important, arguably relevant considerations, and I am not making a judgment about whether the price is too high, too low, or just right. I am simply saying that we must stop putting our heads in the sand and pretending that we do not need to know, think about, or talk freely about, what the price is.

Consider for a moment the inherent ambiguity in the word value. Value can be used as a noun or a verb. The way to define it in a constructive discussion aimed at definitions of high- and low-value care is as a noun; in that respect, the value of a drug would be defined by a ratio of objective positives and negatives of that drug, with price as one of the negatives. Note that price and value move in opposite directions. For any drug with a fixed degree of benefits and adverse effects, the higher the price, the lower the value, and the lower the price, the higher the value. So, we cannot begin to meaningfully determine the value until we know the price, just as we could not meaningfully determine value without knowing the other positive and negative aspects of the drug. Price is not the defining factor in value, but it is one of the components without which the value cannot be defined.

Too often, our consideration of price can be distracted by the shift of the discussion to value and its definition as a verb; we value a response, a defined amount of extended life, or relief from a symptom. The verb definition of value necessarily takes us into subjective, as opposed to objective, criteria, and the very nature of these resist correlation with a price. In fact, such a focus prevents delineation of value and distracts us from a meaningful and constructive discussion of what is high-value care and, just as important, what is not.

Doctors do not have the ability to unilaterally lower the prices of drugs. Doctors do have the ability to be aware of the prices of the drugs, tests, treatments, and recommendations we offer, both directly in terms of out-of-pocket expenses to our patients and more indirectly to society as a whole. Some have argued that it is only the immediate out-of-pocket expense of the individual that should be considered by doctors and that societal costs are not relevant to a patient-physician relationship. I respectfully disagree. Societal costs ultimately are distributed across the population, and all insured patients eventually bear these costs in terms of increased insurance premiums. The price of insurance and the percentage of paychecks that go toward health care costs have been increasing at a substantially more rapid rate than the increases in average worker wages or inflation. The term financial toxicity has gained increasing traction in our understanding of what these costs are doing to our patients on a regular basis. Even when the initial out-of-pocket

expense may appear small, one can realistically expect that these costs will appear in the insurance premiums for all in the years to come.

Even if one were to take the position that the physician focus should be on immediate out-of-pocket expenses of an individual patient (a short-sighted view, as I outlined in the previous paragraph), this would imply a responsibility to understand the coverage and actual out-of-pocket exposure of each patient, as well as, arguably, the ability of each patient to manage those expenses. This often may be beyond provider abilities. It is quite reasonable, however, to assume that vulnerability a patient may have toward the potential cost of even a small part of that therapy increases with more expensive therapy. Physicians see a decrease in simple copayments with fixed nominal costs and an increase in coinsurance charges, whereby the patient will pay a fixed percentage of the price of the drug. In this context, the more expensive drugs create greater out-of-pocket expenses at the same time that they contribute to the aggregate cost of health care and the necessarily compensatory increases in insurance premiums going forward.

Physicians frequently talk to patients about intimate and personal details of their lives. Physicians routinely ask about bowel function, bladder function, sexual function, anxiety, depression, alcohol and illicit drug use, and other intimate and personal details that would be far outside normal social discourse. Within this context, there is a startling inconsistency with any conversational taboo regarding costs. Yet, discussion of the prices of treatments has been a taboo in our doctor-patient relationships, and that requires re-evaluation. Bringing the realistic costs to bear in discussions would make the most involved members of society appropriately informed of the magnitude of the challenges faced in paying for drugs at the current prices. It would also facilitate rational discussions of efforts to use more cost-efficient regimens, use less expensive alternatives, or perhaps forego extremely expensive and toxic options that have little chance to provide meaningful benefit. There are very few things in life that people buy without an awareness of the purchase price. Such an awareness helps people make informed decisions about what goods or services they do or do not wish to purchase and can encourage people to make informed decisions about the consideration of alternatives.

From an academic perspective, discussion of price is warranted both in clinical trial design and in publications. When a trial is designed that increases the length of treatment or increases the dose of a drug to higher than the standard dose, physicians must know and consider what the costs of those changes will be. When a report is published about a regimen for which the prices of the drugs are known, those prices constitute a nontrivial toxicity to which patients will be exposed.

The purpose of academic paper about therapeutic options, and the purpose of open and complete discussions between patients and providers, is to maximize the awareness of the true risks, benefits, and alternatives of the treatment strategy under consideration. It would be wrong to exclude consideration of physical toxicities. It is equally counterproductive to exclude consideration of price, or financial toxicity. The inability to provide full awareness of either of these likely will increase, rather than decrease, the prevalence of and the harm done by these toxicities.

THE PATIENT ADVOCATE'S PERSPECTIVE (S. FULD NASSO)

Engage in Treatment Planning to Better Reflect Patient Values

Patient engagement in treatment decision making can reduce financial toxicity for patients by ensuring that treatments truly match the needs, values, and preferences of patients. A consideration of all clinically meaningful treatment options and their benefits, risks, and out-of-pocket costs should frame the patient decision-making process.

At an individual level, patients can play a role by being active participants in decisions about their care, researching their insurance coverage, initiating discussions about the cost of care with their care team, advocating for coverage of the care that they need, and seeking financial assistance from foundations and company-sponsored assistance programs. Empowered patients and family members know that they must advocate on their own behalf, or on behalf of their loved ones, in all aspects of their care, including financial considerations. Of course, not all patients are prepared and knowledgeable about health insurance, and many patients feel overwhelmed by the amount of information they must process about their diagnosis and treatment options, not to mention the question of how they will pay for their care. Patients need assistance with health insurance literacy; there is evidence that patients do not have a thorough understanding of key insurance constructs, like deductibles, copayments, and coinsurance.[9]

Ideally, patients and caregivers will raise the topic, ask the questions, and seek assistance from their care team and/or a financial counselor. However, a huge barrier for patients is embarrassment about discussions of financial considerations with their care team. It is essential that providers create a welcoming and open environment for patients to express their concerns. Providers should recognize how difficult it is for patients to raise the topic and should open the door to the conversation by asking a question as simple as "Do you have concerns about the cost of your treatment?"

At a practice and policy level, the comprehensive treatment planning process that has been defined by the Institute of Medicine[10]—a definition arrived at with substantial input from oncologists and patients—should be the standard for doctor-patient communication about cancer care. It is important to note that this planning is not about checking a box that a piece of paper was handed to a patient; it is about truly engaging patients in decision making about their care. This plan should include information related to diagnosis, prognosis, treatment goals, expected response to treatment, treatment benefits and harms, out-of-pocket cost of care, and a plan for meeting psychosocial needs. The care planning process also should include consideration of

advance care planning and advance directives and should lead to the development of a survivorship plan after treatment. This cancer care planning process should produce a patient-specific care plan that will guide treatment decisions and facilitate care coordination, including effective symptom management to reduce the burden and cost of adverse effects.

An important component of the planning process is a discussion of the out-of-pocket costs to a patient. We know that some patients do not wish to discuss costs; they might worry about the perception that the oncologist has of them, they might want the best treatment regardless of cost, or they might fear that a discussion of cost will result in inferior treatments.[11] Yet, most patients do want to have this conversation, even if they are reluctant to bring it up. Research shows that having the discussion, even without a change in treatment, can reduce costs for patients.[11]

Patients are concerned about their total financial responsibility across the life of their treatment, not just the cost of one aspect of treatment. Obviously, that is difficult for one provider to share, given the multidimensional aspects of treatment. To the degree that it is possible, knowledge about the total costs will help patients plan and understand the entire picture, not just the cost of a specific drug. Although some of the value frameworks, including those by ASCO, have considered the price of a drug, the out-of-pocket cost is what is most important to an individual to make decisions. In most cases, that distinction will require an understanding of the out-of-pocket maximum. It also is important for patients to understand whether any out-of-network services, which do not contribute to the out-of-pocket maximum, will be required.

CONCLUSION

As a starting point to answer the question (How can we reduce patients' financial toxicity?), we propose four potential solutions from the perspectives of the pharmaceutical industry, payers, physicians, and patients, which we feel are helpful. Of course, we are not the first to propose solutions to the growing financial burden of cancer treatment. The intent of this exercise was to consider solutions from within our own stakeholder groups rather than to pass the responsibility down the road.

As interventions to reduce financial toxicity and improve value are considered, all participants should consider and discuss many long- and short-term interventions. Policy interventions, such as facilitation of value-based contracting or removal of the coverage mandate, all warrant consideration and may be helpful to the long-term process but are unlikely to be realized overnight. In the meantime, short-term interventions, like price awareness and inclusion of cost in treatment and goals of care discussions, are necessary. The discussion cannot stop here. If anything, this exercise demonstrates that all stakeholders—the pharmaceutical industry, payers, providers, and patients—must continue the discussion to ensure the delivery of high-value care.

Practice Model for Advanced Practice Providers in Oncology

Jamie Cairo, DNP, APRN-BC, Mary Ann Muzi, APRN-BC, APCNP, Deanna Ficke, PA-C, Shaunta Ford-Pierce, MSN, NP, FNP-BC, Katrina Goetzke, PA-C, Diane Stumvoll, APGCNP-BC, MSN, Laurie Williams, APNP, MSN, and Federico A. Sanchez, MD

OVERVIEW

According to ASCO, the number of practicing oncologists has remained stable despite growth demands, leading to an overall shortage in many areas of the country. Nurse practitioners and physician assistants are advanced practice providers (APPs) who can assist in the provision of support and care to patients with cancer, but the role of the APP in the oncology setting has not been well defined. There exists a variety of different practice patterns for APPs who work in oncology, and the lack of role definition and absence of an established practice model are considered leading causes of APP attrition. According to the American Academy of Nurse Practitioners, it has been well demonstrated that, when nurse practitioners are allowed to work to the full scope of their education and preparation, there are notable cost reductions and quality improvements in patient care. The focus of APP education and training is on health promotion, disease prevention, and primary care medical management, but most APPs have limited exposure to management of cancer in patients. With this in mind, Aurora Cancer Care developed a practice model for APPs who work in oncology. The goal of the model is to enhance the quality of care delivered to patients and provide a stimulating work environment that fosters excellent collaborative relationships with oncologist colleagues, supports professional growth, and allows APPs to practice to the full extent of their licensure.

Aurora Health Care is a not-for-profit, large, integrated health care system that provides cancer services in 10 counties, 16 hospitals, and 22 clinics throughout eastern Wisconsin and northern Illinois. A subcommittee of seven APPs who practice in medical oncology was formed with the goals of defining current practice and identifying areas considered problematic or not well defined. The group used the NP Model of Care, designed by Kutzleb et al,[1] to identify five major areas of practice and then developed an action plan and rationale for each of these areas with supporting evidence found in the literature.

Cancer care is becoming increasingly complex, and health care systems are looking for ways to meet patient needs and address issues of cost, quality, and access including shortages of practicing oncologists in many areas of the country.[1,2] APPs can provide high-quality care to patients that not only is cost effective but also can improve outcomes for patients.[3] According to the American Academy of Nurse Practitioners, the best and safest outcomes for patients are produced when health care is provided in coordinated networks that recognize and encourage the unique knowledge base and skills of all practitioners.[4]

Emergency visits and hospital admissions have negative implications for health care systems, payers, and patients. Patients with cancer frequently experience urgent problems related to their cancer and/or its treatment. The majority of hospital admissions are due to uncontrolled symptoms, such as shortness of breath, pain, fever, and nausea, and vomiting, and these admissions tend to correlate with longer hospital stays and result in a higher rate of mortality.[5,6] Patients with cancer who present to the emergency department often experience long wait times and receive costly and fragmented care that does not always meet their needs. APPs can decrease readmission rates and increase the quality of patient care by meeting regularly with patients to manage their treatment plan and treatment-related issues. A model that can lead to improved and more cost-efficient care uses APPs to see patients in urgent care settings. In this model, the APP would perform assessment, triage, and treatment. This approach benefits not only the patient but also the physician, because it allows the physician to keep on track with scheduled appointments without interruptions.[7] There are many documented examples of the successful implementation of this model. For patients with oropharyngeal cancer, a weekly nurse practitioner–led symptom management clinic reduced the rates of both acute care hospitalization and chemotherapy dose deviations in patients receiving intensive chemotherapy and radiation.[8]

The American Cancer Society reports that more than 15.5 million cancer survivors are alive in the United States today, and that number will grow to more than 20 million

by 2026. Cancer survivors have unique physical and psychosocial needs that require specialized care, and APPs have the expertise to provide that care.[9,10] Given appropriate training, APPs also are able to perform select procedures, including bone marrow biopsies and intrathecal chemotherapy administration, independently.[11] Nationally, there is a demand for clinicians with palliative care knowledge. APPs are well suited to integration of palliative care into practice during care of chronically and terminally ill patients.[12]

Use of a collaborative practice model to integrate APPs into oncology practice has been proposed as an ideal solution to the challenge of complex cancer care across multiple settings.[4,13] When APPs work to the full extent of their training and licensure, there are improvements in patient and provider satisfaction as well as an overall positive impact on productivity and revenue.[14] As health care reform continues to be a topic of national conversation, APPs must be at the table and willing to take an active role in designing innovative models of care as members and leaders of interprofessional teams.[14,15] APPs also must take ownership of teaching and mentoring new nurse practitioners and physician assistants. A mentoring program for APPs that is supported and led by APPs can help those new to the field assimilate to their roles. This relationship can provide benefits for the mentee, the mentor, and the organization.[16] A meta-analysis found that job satisfaction and commitment, as well as career outcomes of compensation and promotions, were higher among those who had been mentored.[17]

ROLE OF THE APP IN ONCOLOGY PRACTICE MODEL

Deliver Direct Care and Coordinate the Interdisciplinary Plan of Care for Patients

It is important to introduce the role of the APP to patients as a vital part of the cancer care team. Best practice involves alternating visits between the APP and physician, which allows the APP to have set appointment schedules and an established role in the active care of patients who receive treatment. The following are among the many actions the APP will perform:

- Formulation of diagnosis and treatment plan in collaboration with the oncologist
- Management of chemotherapy in collaboration with the oncologist
- Management of symptoms
- Survivorship care
- Palliative care
- Psychosocial intervention
- Procedures (e.g., bone marrow biopsies, intrathecal chemotherapy)
- Patient education

KEY POINTS

- **APPs enrich the delivery of a comprehensive continuum of care for patients with cancer.**
- **Optimal use of APPs increases opportunities for the physician to focus on appropriately complex and more highly reimbursed patient scenarios, increases appointment opportunities for physicians to see new patients, and decreases wait times for patients. APP visits increase billable services and lead to shorter wait times for patients, which leads to improved clinic workflow.**
- **Optimal APP practice leads to a higher levels of job satisfaction, allows for professional growth and development, and decreases APP attrition.**
- **A collaborative practice of APPs with physician colleagues leads to best practice value-based care.**

Serve As a Consultant to Improve Care According to Expertise in Area of Specialization

Examples of the areas in oncology in which APPs can develop an area of expertise that would help an established oncology practice include the following:

- Establish a survivorship clinic: Survivorship visits allow for dedicated time to thoroughly discuss post-treatment concerns and guidelines for wellness promotion. Follow-up visits with the APP also offer opportunities to monitor chronic post-treatment side effects/signs of recurrence.
- Coordinated hospital consults and daily inpatient rounds: Consultations and rounds by APPs are convenient for physicians and also improves coordination and communication, especially with discharge planning.
- Management of oral chemotherapy: Oral chemotherapy use is increasing. Patients need the same level of monitoring, adherence tracking, and symptom management as those who receive other forms of chemotherapy.
- Specialized visits to focus on palliative and end-of-life care: APPs can provide palliative care visits that focus on goals of care, symptom management, patient and family education and counseling, coordination, and continuity of care.

Identify Learning Needs of Various Populations and Contribute to the Development of Educational Programs and Resources

APPs can provide and coordinate educational resources as outlined below:

- Staff education: APPs can be used as key advisors when educational opportunities are developed for caregivers. APPs hold graduate degrees; on the basis of their experiences and areas of expertise, they are in key positions to provide support and education to other providers within the organization and to serve as role models and provide the leadership needed to implement and expand evidence-based practice.
- Mentoring and training of APPs new to practice and/or oncology: APPs can lead the mentoring and training of new colleagues.
- Leading research: Nurse practitioners and physician assistants have graduate degrees and are well prepared to not only participate in clinical research but also design and lead such activities.

- Community speaking: APPs amass a wealth of knowledge and clinical expertise and are an excellent resource for educating the community at public events. They also spread knowledge by participating in professional associations and speaking/presenting at nursing or other advanced practice conferences and meetings.
- Working with APP colleagues in primary care and other service lines: Serve as a resource to the organization, providing expertise and support to the existing and emerging practices of other service line advance practice providers.

Evaluate the Impact of Changes in Clinical Practice and Formulate Recommendations About Appropriateness and Cost Effectiveness

As a crucial part of an oncology team, APPs can play an important role in the creation and maintenance of workflow processes that make any oncology practice successful. Examples of roles are the following:

- Serve as participant and leader on quality improvement committees
- Serve as consultant in design and implementation of new clinical programs
- Become involved in leadership on the national level with professional organizations and accreditation programs
- Publish articles and make presentations at regional, national, and international conferences

Identify and Build Collaborative Relationships With Physician Care Teams

To guarantee success in the process, it was felt that the APPs and the physicians needed to create outlined relationships. Examples of some relationships are as follows:

- The physician serves as a resource for the APP as part of collaborative relationship. A collaborative practice implies an effective working relationship, in which the APP and physician colleague(s) communicate with one another to provide best practice patient care.
- Physicians support orientation and training. The oncologist functions as an expert resource and support for the APP. Physician-supported orientation can nurture the collaborative relationship and affect the confidence and autonomy of the APP.
- Physicians market collaborative efforts. Physicians can introduce APPs to referring physicians. The networking effect can help facilitate awareness of the APP as a member of the health care team.
- APPs attend local tumor board/multidisciplinary conferences to represent their practice and meet referring surgeons and primary care providers. Attending multidisciplinary conferences and, when possible participating in clinics, can affect APP training and highlight APP knowledge and skills. Participation also offers opportunities for recognition of the APP as a member of the oncology health care team to other health care specialty providers.

FUTURE IMPLEMENTATION PLANS

After the model was formalized by the subcommittee, it was presented to the larger group of APPs who work in medical oncology for discussion and revision. The seasoned and established APPs were encouraged to take the model back to their individual practice sites and evaluate how their current practices fit within the model. There were practice-related issues in some locations, and the new practice model has served as a guide to redefine the scope of APP practice in those areas. In addition, the model has been used successfully as an orientation resource and as a guide for APPs who are new to a practice. Before development of the model, new caregivers often had questions about their defined roles in the clinics. The practice model has helped answer many of those questions and has led to smoother transitions to new practices. It also has guided both new and established APPs to enact performance goals and clarify the scope of professional development.

The model also has benefited physician colleagues. Although many physicians in medical oncology had long worked with APPs and understood the APP scope and practice, others had not and had questions and concerns when a new APP was introduced to their practice areas. This practice model has served as a guide for them and for nursing and clinic supervisors, and it has opened the door for meaningful discussions about collaboration. The model was presented and accepted by the cancer care executive team and now serves as a document to define the role of the APP and the scope of APP practice in the care of patients at the medical oncology practice at Aurora Health Care.

BREAST CANCER

Breast Cancer in the Central Nervous System: Multidisciplinary Considerations and Management

Nancy U. Lin, MD, Laurie E. Gaspar, MD, FASTRO, FACR, MBA, and Riccardo Soffietti, MD

OVERVIEW

Breast cancer is the second most common primary tumor associated with central nervous system (CNS) metastases. Patients with metastatic HER2-positive or triple-negative (estrogen receptor (ER)–negative, progesterone receptor (PR)–negative, HER2-negative) breast cancer are at the highest risk of developing parenchymal brain metastases. Leptomeningeal disease is less frequent but is distributed across breast cancer subtypes, including lobular breast cancer. Initial treatment strategies can include surgery, radiation, intravenous or intrathecal chemotherapy, and/or targeted approaches. In this article, we review the epidemiology of breast cancer brain metastases, differences in clinical behavior and natural history by tumor subtype, and important considerations in the multidisciplinary treatment of these patients. We will highlight new findings that impact current standards of care, clinical controversies, and notable investigational approaches in clinical testing.

Spread of cancer to the CNS, either in the form of parenchymal brain metastases or leptomeningeal disease continues to confer a poor prognosis and high symptom burden in many patients, though survival does appear to be improving over time in some patient subsets. Although the area of breast cancer brain metastases has historically been a relatively understudied area, several seminal clinical trials have altered the standard of care over the past few years, and other smaller studies have provided a variety of new treatment options for patients. Furthermore, multiple innovative investigational strategies are being tested in the clinic. For these reasons, more than ever, the management of brain metastases requires a thoughtful, multidisciplinary approach that integrates the anatomic and symptomatic burden of disease, the status of a patient's extracranial disease and systemic therapy needs, prior therapies, and life expectancy.

RISK FACTORS FOR THE DEVELOPMENT OF CNS METASTASES

Breast cancer is the second most common cancer associated with brain metastases in the United States following lung cancer.[1] As patients with advanced breast cancer live longer, the incidence of brain metastases appears to be increasing. In a subset of women, progression in the CNS has become a major life-limiting problem.

The incidence of brain metastases in patients presenting with stage I/II invasive breast cancer, according to subtype, is as follows[2]: luminal A, 0.1%; luminal B, 3.3%; luminal-HER2, 3.2%; HER2, 3.7%; and triple-negative, 7.4%.

Although these numbers are somewhat low, of those patients with distant metastases, approximately 30% to 50% will eventually develop brain metastases.[2-5] Factors associated with an increased likelihood of brain metastases include young age, lymph node positivity, higher grade, hormone receptor negativity and HER2 positivity, and time from diagnosis to first metastasis.[6] The time from the initial diagnosis of primary breast cancer to the development of brain metastases is also influenced by subtype, with the shortest interval observed for patients with triple-negative disease (27 months), and the longest interval observed for those with ER-positive, HER2-positive disease (54 months).[7]

PROGNOSTIC AND PREDICTIVE FACTORS OF SURVIVAL

The predictive factors and the prognosis of patients with brain metastases are now considered to be disease specific (Table 1). One tool that can be used is the Disease-Specific Graded Prognostic Assessment (DS-GPA).[8] The prognostic factors within the breast-specific GPA are presented in Table 2. Note that the time from primary diagnosis to brain metastases was not an independent significant prognostic factor in the breast GPA and is therefore not a part of the index.[7]

The DS-GPA was based on the observed outcome of patients referred for a radiation therapy opinion, and

patients underwent whole-brain radiotherapy (WBRT), stereotactic radiosurgery (SRS), surgery, or a combination of these treatments. Only 6% of patients had a GPA score of 1, with the remaining patients fairly equally distributed between GPA scores of 2, 3, and 4. This retrospective analysis cannot be used to predict the outcomes according to different treatments. Its utility lies in its use as a stratification tool for clinical trials and the comparison of results between clinical trials. It can also aid the oncologist in determining whether the patient might be best served by hospice.

National Comprehensive Cancer Network guidelines as of January 2017 state that CNS imaging of patients with asymptomatic breast cancer is not indicated, based on lack of available evidence of benefit. However, prospective studies to evaluate the risks and benefits of CNS imaging are scant. Given the incidence and relatively short interval to presentation of brain metastases in patients with triple-negative disease, and the high incidence of CNS metastases in patients with HER2-positive breast cancer, further investigation of this issue is highly warranted.

KEY POINTS

- **Risk factors for the development of brain metastases in breast cancer include tumor subtype (HER2-positive, triple-negative, estrogen receptor–negative), young age, higher disease grade, and shorter disease-free interval.**
- **Level I evidence, generated in mixed populations of patients with a variety of solid tumors, supports the role of surgical resection in patients with a single brain metastasis who have good performance status and controlled extracranial disease.**
- **For patients presenting with a limited number of brain metastases, the addition of WBRT to SRS improves intracranial control but does not improve survival and can be associated with neurocognitive deficits. Thus, SRS only is a reasonable approach in such patients. A caveat to these data is that they were generated in all-comers with solid tumors, and patients with breast cancer made up only a minority of patients enrolled.**
- **The use of memantine during and after WBRT is associated with delayed time to cognitive decline, reductions in the rates of decline in memory, executive function, and processing speed.**
- **To date, no systemic therapies have gained regulatory approval for the treatment of breast cancer brain metastases; however, several regimens have demonstrated activity in prospective studies, and multiple new approaches are being tested in ongoing clinical trials.**

LOCAL THERAPY

The Role of Surgery in Patients With Brain Metastases

Among local treatment options, surgery has a clear role in some subgroups of patients. Three phase III trials have compared surgical resection followed by WBRT with WBRT alone for a single brain metastasis (Fig. 1).[9-11] The first two studies have shown a survival benefit for patients receiving the combined treatment (median survival 10 vs. 4–6 months). In the Patchell study, patients who received surgery displayed a lower rate of local relapse (20% vs. 52%) and longer period of functional independence. The third study, which included more patients with active systemic disease (80% vs. 30%–40%) and a low Karnofsky performance status, did not show any benefit with the addition of surgery to WBRT. Therefore, class I evidence shows that the survival benefit of surgical resection in addition to WBRT is limited to the subgroup of patients with controlled systemic disease and good performance status.[12] In properly selected patients with two or three brain metastases, who are in good neurologic condition and have controlled systemic disease, complete surgical resection yields results that are comparable to those obtained in single lesions.[13] One caveat to these and much of the local therapy literature is that patients of multiple primary histologies were included in the trials, with a relatively small fraction of patients with breast cancer (typically 10%–20%), and thus, the recommendations are to some extent extrapolations based on a study population with primarily non–small cell lung cancer.

For the majority of patients, surgical resection allows an immediate relief of symptoms of intracranial hypertension, a reduction of focal neurologic deficits and seizures, and a rapid steroid taper. Gross total resection of a brain metastasis can be achieved with lower morbidity using contemporary image-guided systems, such as preoperative functional MRI, intraoperative neuronavigation, and cortical mapping.[14] An early postoperative MRI can detect residual tumor in up to 20% of patients, and this is associated with an increased risk of local recurrence.[15]

The impact of surgical methodology on the complication rate and functional outcome, as well as on local relapse in

TABLE 2. Prognostic Factors and Assigned Score in Breast Cancer GPA[8]

Prognostic Factor	0	0.5	1	1.5	2.0
KPS	≤ 50	60	70–80	90–100	n/a
Subtype	Basal	n/a	LumA	HER2	LumB
Age, years	≥ 60	< 60	n/a	n/a	n/a

Abbreviations: GPA, Graded Prognostic Assessment; KPS, Karnofksy Performance Status; LumA, luminal A; LumB, luminal B.

patients with a single brain metastasis, has been recently analyzed. Overall, the study suggests that postoperative complication rates are not increased by en bloc resection, as compared with piecemeal resection, for lesions in eloquent brain regions or large tumors.[16] Leptomeningeal dissemination can be a complication, especially for patients with posterior fossa metastases undergoing a piecemeal resection (13.8%) compared with en bloc resection (5%–6%).[17]

Last but not least, surgery is important in providing tissue for molecular analysis to define the molecular profile of the brain metastasis, which can be different from that of the primary cancer. This is critical in the near future for tailoring targeted therapies to the molecular profile of the brain metastases.

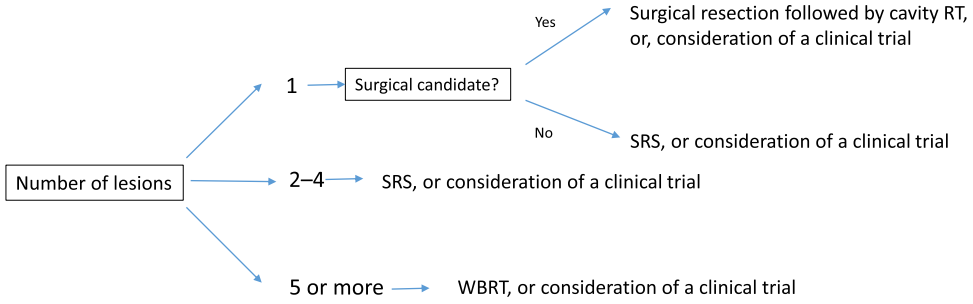
WBRT Compared With SRS Following Surgical Resection

Despite the randomized study by Patchell et al,[18] in which it was found that patients with a single brain metastases who underwent surgical resection and postoperative WBRT had fewer recurrences of cancer in the brain and were less likely to die of neurologic causes as compared with patients treated with surgical resection alone, there has been controversy regarding the role of WBRT in this setting. This led to the N107C/CEC.3 cooperative group study randomly assigning patients with a resected brain metastasis to receive either WBRT or SRS to the cavity. SRS to unresected brain metastases was allowed in both groups. Patients were stratified between primary lung cancer, radio-resistant histologies, or other histologies. This study was presented at the Plenary Session during the 2016 American Society for Radiation Oncology Annual Meeting but is not yet published.[19] Approximately 30% of enrolled patients fell into the other category, although breast cancer is not separated out otherwise. There was no reported difference in overall survival between the two treatment groups (11–12 months), with no difference seen according to age, extracranial disease status, number of brain metastases, histology, or size of resection cavity. However, there was a small but statistically significant difference in the cognitive deterioration–free survival favoring the SRS arm (2.8 months WBRT arm vs. 3.3 months SRS arm; $p < .0001$). Only 5.4% of patients in the WBRT arm were free of cognitive deterioration at 6 months as opposed to 22.9% in the SRS arm.

SRS With or Without WBRT

Several randomized studies have examined the outcome of SRS with or without WBRT.[20-23] One of these was a randomized controlled trial published in 2006 by Aoyama et al[20] (JROSG 99-1), which randomly assigned 132 patients with up to four brain metastases amenable to SRS. The primary endpoint was overall survival, but secondary outcomes included local recurrence, rate of salvage brain treatment, functional preservation, toxic effects, and cause of death. The study was closed earlier than the planned accrual when an interim analysis determined that more than 800 patients would be required to detect a significant difference in the primary endpoint. Breast cancer made up only 7% of enrolled patients, the majority being non–small cell lung cancer. In the SRS-only group, the median survival time and the 1-year actuarial survival rate were not significantly different between the two groups. However, the group receiving SRS and WBRT had a lower intracranial recurrence rate at 1 year (47% vs. 77%; $p < .001$), and required less frequent salvage treatment as opposed to the SRS-only group.

FIGURE 1. Management Algorithm for the Initial Treatment of Patients With Breast Cancer Brain Metastases



This figure provides a broad overview. For details and discussion of nuances of the recommendations, please refer to the text. Treatment recommendations will also depend on performance status, prior therapies, status of extracranial disease, comorbidities, and life expectancy. In most cases, outside of a clinical trial, surgery and/or radiation therapy will be given as initial therapy, and the systemic therapy will be determined by the status of a patient's extracranial disease (i.e., continue prior systemic therapy if systemic disease is stable, and switch if systemic disease is progressive).

Another larger study of 359 patients, of which 12% had breast cancer, randomly assigned patients with up to four brain metastases to receive local therapy (surgery or SRS) with or without WBRT.[23] Overall survival was similar between the two treatment arms (p = .89), although the local control (surgery vs. surgery WBRT: 59% to 27%, p < .001; SRS vs. SRS + WBRT: 31% vs. 19%, p = .04) and need for further salvage therapy (51% vs. 16%, p value not reported) were improved in the WBRT arm.

Lastly, a 2015 meta-analysis by Sahgal et al[24] of these randomized studies found that patients age 50 or younger had a significant survival benefit (p = .04) when SRS alone was used. This analysis found that these results were similar between patients with lung cancer and those with breast cancer, although the authors acknowledged the problems with small sample sizes. The authors concluded that SRS alone is the recommended initial therapy of patients age 50 or younger with one to four brain metastases.

The above findings showing that WBRT is not associated with improved survival, when combined with the data regarding the neurocognitive effects of WBRT, have led to many guidelines recommending SRS only for patients with one to four brain metastases (American Association of Neurological Surgeons, unpublished data, 2017).[22,25]

Quality of Life and Cognitive Dysfunction Following WBRT

Cognitive dysfunction following WBRT represents a topic of increasing importance. Historically, radiation-induced dementia with ataxia and urinary incontinence was described in up to 30% of patients by year 1 who were receiving unconventional, large-size fractions of WBRT (6–8.5 Gy), which are no longer used.[26] The picture on CT/MRI was that of a leukoencephalopathy (diffuse hyperintensity of the periventricular white matter on T2-weighted and fluid attenuation inversion recovery images) with associated hydrocephalus, for which placement of a ventriculoperitoneal shunt could be of some clinical value. When using more conventional size fractions (up to 3 or 4 Gy per fraction), the risk is that of mild cognitive dysfunction, consisting mainly in learning and memory impairment with a variable degree of damage of the white matter and cortical atrophy on MRI.

In recent years, several randomized trials have shed light on the short- and long-term effects of WBRT on neurocognitive function and quality of life. Aoyama et al compared the neurocognitive function of patients who underwent SRS alone or SRS plus WBRT.[27] Similar proportions of patients in both arms (p = .85) achieved a three point or more improvement in their Mini Mental State Examination score shortly after therapy (2–3 months). However, subsequent deterioration of neurocognitive function in long-term survivors (up to 36 months) after WBRT was observed. In a small randomized trial, Chang et al have shown that patients treated with SRS plus WBRT were at greater risk of a decline in learning and memory function at 4 months after treatment compared with those receiving SRS alone.[21] A randomized phase III trial (Alliance trial) has compared SRS alone with SRS plus WBRT in patients with one to three brain metastases using a primary neurocognitive endpoint, defined as decline from baseline in any seven cognitive tests at three months.[28] Neurocognitive decline was significantly more frequent after SRS plus WBRT compared with SRS alone (91.7% vs. 63.5%, p < .001). On individual tests, there was more cognitive deterioration in immediate memory (30.4% vs. 8.8.2%, p = .004), delayed memory (51.1% vs. 19.7%, p < .001), and verbal fluency (18.6% vs. 1.9%, p = .01) in the SRS plusWBRT arm. Finally, a quality-of-life analysis of the EORTC 22952-26001 trial has shown over 1 year of follow-up no significant differences in the global health-related quality of life, but patients undergoing adjuvant WBRT instead of observation had lower transient cognitive functioning, physical functioning, and more fatigue.[22]

Patients with arterial hypertension, diabetes, or other vascular diseases are at a higher risk of developing cognitive dysfunction. The pathogenesis of this radiation damage could consist of an injury of the endothelium of small vessels that leads to an accelerated atherosclerosis and ultimately to a chronic ischemia, resulting in a picture similar to that of the small vessel disease of vascular dementia. For this reason, there is interest in investigating vascular dementia treatments to prevent or reduce radiation-induced cognitive decline. One of these approaches is using memantine in combination with WBRT. Memantine is a noncompetitive, low affinity antagonist of the N-methyl-D-aspartate (NMDA) receptor, which is one of the receptors activated by glutamate, the principal excitatory neurotransmitter. Memantine has the potential to block the excessive NMDA stimulation following ischemia, which ordinarily could lead to excitotoxic damage of the normal brain. In a recently published randomized, double-blind, placebo-controlled phase II trial (RTOG 0614), the use of memantine during and after WBRT resulted in a mild improvement of cognitive function over time, specifically delaying time to cognitive decline and reducing the rates of decline in memory, executive function, and processing speed.[29] The use of another neurotransmitter regulator, such as donepezil, has shown only modest improvements in cognitive function in a controlled trial, especially among patients with greater pretreatment impairment.[30]

Radiation-induced cognitive deficits may result, at least in part, from a radiation injury to the neuronal stem cells in the subgranular zone of the hippocampus.[31] These stem cells are responsible for maintaining neurogenesis, which is critical for preserving memory function, especially in terms of encoding new episodic memories. Low-dose irradiation in rodents results in a blockade of hippocampal neurogenesis and damage of the neurogenic microenvironment, leading to significant short-term memory impairment. Thereby, it has been hypothesized that sparing the hippocampus during WBRT (hippocampal-avoidance WBRT, HA-WBRT) could prevent the damage of the neuronal progenitor cells and better preserve memory functions.[32] The recent single-arm, phase II RTOG 0933 trial has suggested that the conformal avoidance of the hippocampus during WBRT is

associated with some sparing of memory and quality of life; specifically, performance on standardized memory tests declined 7% from baseline to 4 months in patients treated with hippocampal-avoidance WBRT, as compared with 30% in an historical control group.[33] Importantly, 4.5% of patients developing intracranial progression had involvement of the hippocampal-avoidance area by metastatic disease. In this regard, building on results of RTOG 0933 and RTOG 0614, NRG-CC001 is a phase III trial evaluating the potential combined neuroprotective effects of hippocampal avoidance in addition to memantine during WBRT for brain metastases.[34]

Clinical Challenges: Tumor Progression, Radionecrosis, and Pseudoprogression

A critical issue is the distinction between post-treatment effects and true tumor progression in some particular scenarios. Following SRS, changes such as an increase in contrast enhancement, necrosis, edema, and mass effect on MRI are difficult to interpret: in this regard, PET with ^{18}F-fluorodeoxyglucose, amino acids or ^{18}F-fluorodeoxythymidine, MRI perfusion, and magnetic resonance spectroscopy may provide additional information, though are rarely diagnostic.[35-38] In general, careful monitoring with MRI, sometimes for many months, is needed. Radiation necrosis is commonly treated with steroids. Hyperbaric oxygen and/or the anti-VEGF agent bevacizumab, which may allow stabilization/normalization of the vascular permeability, can be useful in patients not responding to steroids,[39] while surgical resection is needed in some patients.

In patients receiving immunotherapy-based treatments, an initial increase in the number and size of metastases can be followed by radiographic stabilization or regression. This pattern might be related to the mechanism of action of immunotherapy, including immune infiltrates and the time to mount an effective immune response. If immune response–related radiographic changes are suspected, the advice is to not interrupt immunotherapy treatment until a short interval scan is obtained.[40,41]

SYSTEMIC THERAPY

Evidence for Efficacy of Available Endocrine Therapies and Cytotoxic Chemotherapies

To date, no systemic agents have gained regulatory approval for the treatment of breast cancer brain metastases. Nevertheless, as summarized in Table 3, CNS activity in case series or in small, prospective studies has been reported across a range of cytotoxic drugs. For example, Rivera and colleagues reported their experience in a phase I trial testing the combination of capecitabine and temozolomide in 24 patients with breast cancer brain metastases (14 newly diagnosed; 10 with progressive brain metastases after prior local therapy). The observed CNS objective response rate was 18%, with median time to progression of 12 weeks.[42] Given the general lack of activity of temozolomide in breast cancer, it would be reasonable to assume that the majority of the activity in this trial can be attributed to the capecitabine. Data from a small series of seven patients treated at Memorial Sloan Kettering Cancer Center corroborate the observation of capecitabine activity in the CNS.[43]

Anthracyclines are also associated with CNS responses in breast cancer, with response rates ranging widely from 17% to 62%, in small experiences. Single-agent temozolomide

TABLE 3. Summary of Case Reports, Case Series, and Prospective Studies Testing Cytotoxic Chemotherapy in Patients With Breast Cancer Brain Metastases

Agent	Details of Regimen	Type of Study	No. of Patients With Breast Cancer Treated With Specified Regimen	CNS ORR in Breast Cancer Subset	Reference
Capecitabine	Capecitabine + temozolomide	Phase I	24	18%	Rivera et al[42]
	Capecitabine	Case series	7	43%	Ekenel at al[43]
Anthracycline	Doxorubicin, cyclophosphamide	Case series	6	17%	Rosner et al[44]
	Pegylated liposomal doxorubicin	Phase II	8	62%	Caraglia et al[45]
	Liposomal doxorubicin + cyclophosphamide	Retrospective	29	41%	Linot et al[46]
Platinum	Cisplatin + etoposide	Prospective	56	38%	Franciosi et al[47]
	Cisplatin + etoposide	Case series	22	55%	Cocconi et al[48]
	Cisplatin + temozolomide	Phase II	15	40%	Christodoulou et al[49]
Irinotecan	Irinotecan + iniparib	Phase II	37	12%	Anders et al[50]
Temozolomide	Temozolomide	Phase II	19	0%	Trudeau et al[51]
	Temozolomide	Phase II	4	0%	Christodoulou et al[52]
	Temozolomide	Phase II	10	0%	Abrey et al[53]
	Temozolomide	Phase II	51	4%	Siena et al[54]
	Temozolomide + vinorelbine	Phase II	11	0%	Iwamoto et al[55]

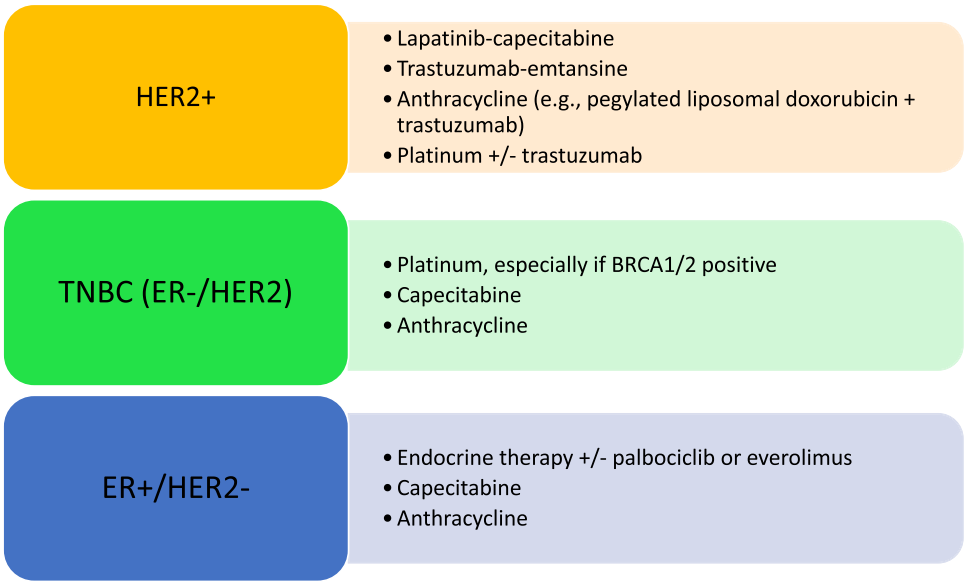
FIGURE 2. Options for Systemic Treatment of Breast Cancer Brain Metastases



This figure provides a broad overview. For details and discussion of nuances of the recommendations, please refer to the text. Note that very few prospective trials have been conducted to evaluate the role of systemic therapy for breast cancer brain metastases, and, in many cases, the recommendations above are therefore based on case reports or case series, or extrapolation from systemic therapy trials. See text for details. Of note, there have not been randomized trials directly comparing a local (i.e., surgery, radiation therapy) versus systemic approach for the treatment of breast cancer brain metastases. Treatment recommendations will depend on performance status, prior therapies, status of extracranial disease, comorbidities, and life expectancy.

appears to have minimal activity in breast cancer and does not clearly add to other agents when given in combination.[51,53]

CNS activity for platinum salts has been reported in older case series, including response rates of 38% to 55%, albeit in a patient population less heavily pretreated than a typical patient seen today.[47,48] In this context, recent efforts (not limited to the brain metastasis space) to identify predictive markers of platinum benefit are relevant. The TNT trial evaluated the efficacy of taxanes versus platinums in the first-line treatment of metastatic triple-negative breast cancer. Of note, patients with active brain metastases were excluded. The study demonstrated differential activity according to *BRCA1/2* germline status, with a substantially higher rate of response in extracranial sites to carboplatin compared with docetaxel in *BRCA1/2* carriers.[56] This hypothesis has not been formally tested in the CNS; however, anecdotally, Jennifer Ligibel, MD, and Judy Garber, MD, MPH, have observed durable CNS responses (including one in excess of three years) in some *BRCA1/2* carriers treated with platinum salts (personal communication, January 2017).

Case reports of CNS responses to a variety of endocrine agents, including tamoxifen and aromatase inhibitors, are also present in the literature; however, patients with estrogen receptor–positive tumors typically present with brain metastases late in their disease course, when their disease has become hormone refractory.[57-60]

In general, if considering off-label use of systemic therapy for the treatment of breast cancer brain metastases, the choice of therapy should be in accordance with a patient's tumor subtype, prior therapies, performance status, and comorbidities, in keeping with national and international guidelines for management of metastatic breast cancer (Fig. 2). As with the practice guidelines for use of cytotoxic chemotherapy in patients with extracranial metastases, sequential single-agent chemotherapy is generally preferable to combination chemotherapy.

Investigational Cytotoxic Approaches

In terms of cytotoxic chemotherapy, the trend for the development of compounds focused on the treatment of brain metastases has been to engineer compounds that more effectively penetrate the blood-brain barrier (Table 4). Two of the compounds furthest in development are etirinotecan pegol (NKTR-102) and ANG1005. NKTR-102 is a long-acting topoisomerase-I inhibitor that prolongs exposure to SN38, the active metabolite of irinotecan. CNS activity in breast cancer has been previously observed in the clinic with the parent compound irinotecan.[50] In a mouse model of breast cancer brain metastases (MDA-MB-231Br), NKTR-102 prolonged survival compared with conventional irinotecan.[61] A phase III trial for patients with heavily pretreated breast cancer (either without brain metastases or with stable brain metastases on study entry) was recently reported.[62] Though a negative study overall, a potential signal was observed in the stable brain metastasis subset and a confirmatory study is currently under way. ANG1005 is a novel taxane derivative that is able to penetrate the blood-brain barrier via the low-density lipoprotein receptor–related protein.[63] CNS responses have been observed in early-phase studies, and additional studies are ongoing.[64,65]

HER2-Targeted Therapies

The development of HER2-targeted therapies has dramatically improved overall outcomes for patients with

HER2-positive breast cancer, both in the early and advanced stages. Despite these improvements, up to half of patients with advanced HER2-positive breast cancer will relapse in the CNS.

The small molecule tyrosine kinase inhibitor (TKI) lapatinib has been studied as a single agent and in combination with chemotherapy in multiple prospective clinical trials. As a single agent in pretreated patients, its activity is modest at best, with CNS responses observed in only 6% of patients.[66] Greater activity has been observed in combination with capecitabine, with CNS response rates ranging from 18% to 38% in pretreated patients, and a CNS response rate of 66% in the newly diagnosed setting.[66-70] Responses have been durable in many cases, and overall, the results support the concept of evaluating HER2-targeted TKIs for the treatment of brain metastases.

HER2-targeted TKIs in clinical development include neratinib, afatinib, and tucatinib, among others (Table 4). Neratinib is an irreversible inhibitor of EGFR and HER2 currently in late-stage clinical testing (NALA, neratinib plus capecitabine versus lapatinib plus capecitabine in patients with HER2+ metastatic breast cancer who have received two or more prior HER2-directed regimens in the metastatic setting, NCT01808573). However, the ongoing phase III study excludes patients with active brain metastases. The Translational Breast Cancer Research Consortium is conducting a phase II study evaluating neratinib in patients with progressive brain metastases. Results of the monotherapy neratinib cohort have been published, with an observed CNS objective response rate of 8%.[71] Results of the neratinib/capecitabine combination cohort are anticipated in mid- to late 2017. Like neratinib, afatinib inhibits both EGFR and HER. Although it has gained regulatory approval in lung cancer, clinical development in breast cancer has been terminated based on negative results of the LUX-Breast 1 and LUX-Breast 3 randomized trials.[72,73] In particular, in the LUX-Breast 3 trial, the combination of vinorelbine and afatinib did not afford any additional benefits to patients with HER2-positive breast cancer brain metastases compared with treatment of provider choice.[72]

In contrast to either neratinib or afatinib, tucatinib (ONT-380; ARRY-380) selectively targets HER2 and has minimal activity against EGFR, leading to a more favorable toxicity profile, with less diarrhea and rash. The active metabolite appears to cross the blood-brain barrier, and improvements in survival have been reported in preclinical models of breast cancer brain metastases. In a phase I study of tucatinib with trastuzumab, CNS responses were observed in 7% of patients; approximately one-third of patients achieved stable disease of 16 weeks or longer.[74] The triplet of trastuzumab-capecitabine-tucatinib has been studied in a phase IB study among patients with highly refractory, HER2-positive metastatic breast cancer. Objective responses were observed in 61% of patients, including in 42% of patients who had measurable CNS disease at baseline.[75] The approach is now being tested in an ongoing randomized trial that includes patients with and without brain metastases.

Historically, monoclonal antibodies such as trastuzumab, pertuzumab, or trastuzumab-emtansine were thought to be too large and bulky to penetrate the blood-brain barrier.

TABLE 4. Ongoing Trials of Systemic Therapy for Breast Cancer Brain Metastases

Regimen	Phase	Patients With LMD Included?	Breast Cancer Subtypes	ClinicalTrials.gov ID
Neratinib + capecitabine	II	Yes, if also measurable parenchymal metastasis	HER2+	NCT01494662
Trastuzumab/capecitabine +/− tucatinib (ONT-380)	II	No	HER2+	NCT02614794
“High-dose” trastuzumab + pertuzumab	II	No	HER2+	NCT02536339
Intrathecal trastuzumab + pertuzumab	I	Not specified	HER2+	NCT02598427
“High-dose” lapatinib + capecitabine	I	Yes	HER2+	NCT02650752
Trastuzumab + vinorelbine + everolimus	II	Diffuse LMD excluded	HER2+	NCT01305941
Abemaciclib	II	Yes, separate cohort	ER+	NCT02308020
Palbociclib	II	No	HER2+ or TNBC	NCT02774681
Palbociclib	II	No	Any, but requires evidence of specific pathway alterations in brain metastasis tissue	NCT02896335
Cabozantinib	II	Yes, if also measurable parenchymal metastasis	ER+ or HER2+	NCT02260531
Pembrolizumab	II	Yes, separate cohort	Any	NCT02886585
Durvalumab	II	No	Any	NCT02669914
Etirinotecan pegol	II	No	Any	NCT02312622
Etirinotecan pegol	III	No	Any	NCT02915744
Cabazitaxel	II	No	Any	NCT02166658

Abbreviations: LMD, leptomeningeal disease; ER, estrogen receptor; TNBC, triple-negative breast cancer.

However, studies utilizing ^{89}Zr-labeled trastuzumab as a PET tracer have suggested there is some penetration through a disrupted blood-tumor barrier.[76] Penetration across the blood-tumor barrier is supported by emerging case reports and case series of the CNS activity of trastuzumab-emtansine (TDM1), with response rates qualitatively similar to that reported against extracranial disease.[77-79] A prospective U.S. study is being planned. Another approach under active investigation in the ongoing PATRICIA study is the use of high-dose trastuzumab (6 mg/kg IV weekly) in combination with standard pertuzumab every 3 weeks to drive up concentrations of trastuzumab in brain metastases. Accrual to the study is ongoing.

Clinical Challenges: Is There a Role for Chemoprevention of Brain Metastases?

There is great interest in preventing the emergence of brain metastases (primary prevention) and prolonging the time to subsequent CNS progression in patients who receive initial local therapy (secondary prevention). A common clinical question is whether systemic therapy should be modified following SRS to include a "CNS-active" regimen. At present, there is no direct evidence to support this approach, though the existing data have been sparse and do not perfectly address this question.

In the EMILIA trial, a subset analysis was performed among patients who entered the study with stable brain metastases to determine whether the benefit of trastuzumab-emtansine seen in the overall study (compared with lapatinib-capecitabine) held up in the brain metastasis subset.[80] Patients in the brain metastasis subset appeared to derive similar relative benefits in terms of overall survival prolongation with trastuzumab-emtansine, and there was no obvious signal in favor of lapatinib-capecitabine with respect to CNS progression. In addition, there were no obvious differences in the incidence of new CNS metastases among patients who entered the study without brain metastases at baseline (2% with trastuzumab-emtansine; 0.7% with lapatinib-capecitabine; p = not significant). The analysis had several limitations including that CNS scans were not mandated per protocol and emerging reports supporting CNS activity of trastuzumab-emtansine, making this potentially a comparison between two "CNS-active" regimens.

In general, the consensus approach for treatment of such patients is to continue the prior systemic therapy after SRS, if the systemic disease remains well controlled, but this is an area ripe for clinical trials.[81]

Other Targeted Approaches Under Clinical Investigation

A number of other targets are being explored in the treatment of breast cancer brain metastases, including CDK4/6 inhibitors, PARP inhibitors, and immunomodulatory therapies (Table 4).

When combined with endocrine therapy, the CDK4/6 inhibitors palbociclib and ribociclib prolong progression-free survival compared with endocrine therapy alone.[82-84] Among the CDK4/6 inhibitors, abemaciclib appears to have the best CNS penetration in preclinical models and has been demonstrated to reach therapeutic levels in human "window of opportunity" studies when given prior to planned resection.[85,86] Phase II studies of both palbociclib and abemaciclib for brain metastases are ongoing.

Given the frequency of brain metastases in patients with triple-negative breast cancer, there is interest in developing novel targeted approaches in this patient population. PARP inhibitors have clear activity against extracranial metastases in *BRCA1/2* carriers; however, single-agent activity in sporadic triple-negative breast cancer has been disappointing.[87] Three large randomized phase III trials comparing PARP inhibitors with standard chemotherapy in *BRCA1/2* carriers with metastatic breast cancer are ongoing, but all three studies exclude patients with active brain metastases. There is also ongoing interest in combination approaches to sensitize *BRCA1/2* wild-type breast cancer to PARP inhibitors, including combinations with platinum salts. The U.S. cooperative groups are collaborating on a planned randomized study (S1416) that will examine cisplatin with or without the PARP inhibitor veliparib (ABT-888). Given that veliparib crosses the blood-brain barrier in preclinical models, a CNS-specific cohort will be concurrently enrolled, with a primary endpoint of progression-free survival.[88]

There are accumulating preclinical and clinical evidence suggesting that the immune system is critical for disease outcome in breast cancer, particularly in the triple-negative and HER2-positive subtypes.[89,90] Moreover, PD-L1 expression appears to be common in breast cancer brain metastases.[91] Data in patients with melanoma and lung cancer support potential efficacy of immune checkpoint inhibitors in the CNS.[92] Beyond CTLA-4 and PD-1/PD-L1 inhibitors, there is a wealth of novel immunomodulatory compounds, including STING and GITR agonists, and inhibitors of IDO, TIM3, and LAG3. Unfortunately, the vast majority of ongoing trials of immunotherapy in breast cancer specifically exclude patients with active brain metastases, though there are some studies in this population that have recently opened or are in development (Table 4).

MANAGEMENT OF LEPTOMENINGEAL DISEASE

Estimates of the incidence of leptomeningeal metastases vary widely, ranging from 2% to 40%, either alone or associated with parenchymal brain metastases. In a case series of patients with leptomeningeal disease (1998 to 2013) from Memorial Sloan Kettering Cancer Center, both HER2-positive (26% of cases) and triple-negative (25% of cases) breast cancer subtypes were overrepresented, suggesting they are associated with a propensity toward dissemination in the leptomeninges.[93] Invasive lobular histology also appears to be associated with leptomeningeal spread.[94] The prognosis is poor with median survival of 3.5 to 6 months and 20% survival rate at 1 year.[93,95] Since patients can experience very poor survival, it is critical to consider prognostic factors early in weighing management options, including consideration

of a more palliative/hospice-oriented course, as appropriate. Favorable prognostic factors include HER2-positive subtype, preserved performance status, and CNS-only involvement. Unfavorable prognostic factors include poor performance status, progressive/treatment-refractory extracranial disease, and major neurological deficits.

The most typical management approach is radiation to sites of bulk disease followed by consideration of intra–cerebrospinal fluid (CSF) and/or systemic therapy. Radiation-based approaches, including WBRT, have the potential to provide rapid relief of symptoms, and should be strongly considered, particularly for patients presenting with neurological deficits. Intra-CSF chemotherapy has a role for palliation of neurologic symptoms and should be considered for patients with a large tumor cell load in the CSF.[96] Methotrexate, liposomal cytarabine, and thiotepa are the drugs of choice. At the time of the placement of an Ommaya catheter, and prior to injecting drugs into the CSF, flow studies are recommended to rule out the existence of subarachnoid blocks, as these could preclude optimal distribution of drug and increase the risk of leukoencephalopathy.[97-100] Systemic chemotherapy has been used off-label to treat patients with leptomeningeal disease based on observed efficacy in case reports and small case series. Regimens with reported efficacy (with caveats given the very limited data) include tamoxifen, aromatase inhibitors, high-dose intravenous methotrexate, capecitabine, lapatinib/capecitabine, and platinum salts.

From an investigational standpoint, leptomeningeal disease has frequently been excluded from clinical trials. However, a number of ongoing trials are exploring new therapeutic options (Table 4). Of note, a phase I/II study of intrathecal trastuzumab has recently completed accrual. In this study, trastuzumab was reconstituted in preservative-free sterile water, USP or preservative-free 0.9% sodium chloride, with an induction phase of more frequent administration, followed by tapering of the frequency of administration. The recommended phase II dose has been identified, and efficacy results from the phase II portion are expected later this year.[101] In general, we have not incorporated use of intrathecal trastuzumab into routine clinical practice, pending efficacy results of this study.

CONCLUSION

Increasingly, the management of breast cancer with brain metastases (parenchymal or leptomeningeal disease) requires close multidisciplinary collaboration, balancing the patient's disease burden in the CNS and extracranially, prior therapies, performance status, comorbidities, life expectancy, and preferences, with available treatment options. Surgical resection should be strongly considered in patients presenting with a single brain metastasis, or a large, symptomatic mass, particularly if they have good performance status and controlled extracranial disease. For patients with expected longer survival, the use of up-front SRS and avoidance of WBRT in the setting of a limited number of brain metastases is preferred. Although there are still no systemic therapies approved for the treatment of breast cancer brain metastases, a number of regimens have demonstrated clear activity in prospective experiences and can be considered in the clinic. At present, systemic therapy is an option for patients whose CNS disease has progressed through standard local therapy, and it can even be considered in patients with newly diagnosed disease in lieu of local approaches in some circumstances (e.g., asymptomatic or minimally symptomatic patients). Moving forward, many novel, promising approaches are being tested in the clinic, and results are eagerly awaited.

Lifestyle Interventions to Improve Cardiorespiratory Fitness and Reduce Breast Cancer Recurrence

Mark J. Haykowsky, PhD, Jessica M. Scott, PhD, Kathryn Hudson, MD, and Neelima Denduluri, MD

OVERVIEW

As patients are living longer after a cancer diagnosis, survivorship is becoming increasingly important in cancer care. The sequelae of multimodality therapies include weight gain and decreased cardiorespiratory fitness, which increase cardiovascular risk. Evidence suggests that physical activity reduces the risk of breast cancer recurrence and death. Avoidance of weight gain after therapy also improves outcomes after a diagnosis of breast cancer. Prospective randomized trials must be performed to determine the benefits of specific physical activity and dietary habits for survivors of breast cancer. This review outlines the important physiologic changes that occur with antineoplastic therapy and the important role of exercise and diet.

Breast cancer is the most frequently diagnosed cancer among women and the second leading cause of cancer death in the United States.[1] Breast cancer mortality has decreased by nearly 40% during the last 3 decades as a result of advances in prevention, early detection, and treatment.[2] As a result of improved survival and population aging, breast cancer is evolving into a disease of older survivors who face an important new set of health care challenges. Nearly one-third of breast cancer survivors have a peak oxygen uptake (peak VO2)—the gold standard measure of cardiorespiratory fitness—that is below the threshold level required for full and independent living.[3] A consequence of reduced fitness is decreased survival in healthy populations.[4]

In accordance with the multiple-hit hypothesis, unfavorable lifestyle factors (e.g., sedentary lifestyle, sarcopenic obesity) coupled with the adverse effects of anticancer therapy result in reduced physiologic and functional reserve capacity. Interventions that improve cardiovascular health and body composition outcomes (e.g., increased muscle mass, decreased visceral adiposity) may play an important role in improving cardiorespiratory fitness, reduce breast cancer recurrence, and improve mortality.

The aim of this chapter is to briefly review the mechanisms responsible for reduced peak VO2 in survivors of breast cancer and the role of exercise training to improve peak VO2 and the role of diet, weight reduction, and exercise in the moderation of cardiovascular disease sequelae, reduction of breast cancer recurrence, and improvement in mortality.

CARDIORESPIRATORY FITNESS AMONG BREAST CANCER SURVIVORS

Breast cancer survivors with normal resting left ventricular (LV) systolic function have a peak VO2 that is 19% (5.5 mL/kg/min) lower than healthy age-matched noncancer controls.[5-10] The magnitude of the decline in peak VO2 is greatest during the short-term period after completing adjuvant therapy.[3,11] Lower levels of cardiorespiratory fitness, as measured by peak VO2, may also have important prognostic implications and result in shorter survival in women with metastatic disease.[3] Thus, an important goal is to maintain an optimal level of cardiorespiratory fitness across the breast cancer survivorship continuum.

DETERMINANTS OF PEAK VO2: ROLE OF IMPAIRED CARDIOVASCULAR FUNCTION

Given that VO2 is equal to the product of cardiac output and arterial-venous oxygen content difference, the reduced peak VO2 among breast cancer survivors may be due to central (cardiac) or peripheral (skeletal muscle and its microvasculature) factors that result in decreased oxygen delivery to and/or extraction by the active muscles.[5,12]

To date, only one study has examined the acute hemodynamic cardiopulmonary response to maximal aerobic exercise in 47 survivors of breast cancer with normal resting LV systolic function (mean age, 59; mean LV ejection fraction, 64%) and 11 age-matched healthy controls.[6] As shown in Fig. 1, the decreased peak VO2 in survivors of breast cancer was primarily due to a lower stroke volume and cardiac output, as heart rate and arterial-venous oxygen difference

during maximal cycle exercise were not significantly different between groups.[6] The mechanism responsible for the reduced maximal exercise stroke volume was not examined; however, it may be the result of increased LV afterload as maximal systemic vascular resistance was 11% higher in breast cancer survivors compared with controls.[6]

Oxygen extraction is directly related to muscle oxygen diffusive conductance (e.g., transport of O2 from hemoglobin to muscle mitochondria) and inversely related to muscle blood flow.[12] Accordingly, our finding that maximal arterial-venous oxygen difference was not different between survivors of breast cancer and healthy controls despite a lower maximal cardiac output[6] (muscle blood flow) suggests that abnormalities in skeletal muscle microvascular and/or mitochondrial function may play an important role in limiting breast cancer survivors exercise performance.[5] To attenuate the decline (during adjuvant therapy) or increase peak VO2 (post-adjuvant therapy), therapies should focus on improving cardiovascular and skeletal muscle function.

KEY POINTS

- **Breast cancer survivors have reduced cardiorespiratory fitness secondary to impaired cardiovascular reserve.**
- **Exercise training is an effective intervention to improve cardiorespiratory fitness; however, the physiologic mechanisms underpinning this favorable adaptation are unknown.**
- **Concomitant diet and exercise interventions may abrogate breast cancer therapy–induced accelerated CVD sequelae, particularly in overweight/obese women.**
- **Epidemiologic evidence supports the participation in exercise before and after breast cancer diagnosis because it is a contributing factor in decreasing breast cancer recurrence, breast cancer–related mortality, and overall mortality.**

IMPROVEMENT IN PEAK VO2 WITH EXERCISE TRAINING

Exercise training is an effective intervention to improve peak VO2, physical functioning, and quality of life, and reduces symptoms of fatigue in breast cancer survivors.[13] The magnitude of the change in peak VO2 with training appears to be related to the volume of exercise performed, and the threshold workload required to obtain a clinically significant large increase in peak VO2 (effect size > 1) was 600 intensity-minutes in a 10-week supervised exercise training program performed for 90 minutes per week at 70% peak VO2.[14] Although the mechanisms underpinning the exercise-training mediated improvement in peak VO2 have not been studied, they may be due to favorable changes in cardiac, peripheral vascular, or skeletal muscle function.[5]

EFFICACY OF DIET AND EXERCISE INTERVENTIONS TO MODULATE THERAPY-INDUCED CARDIOVASCULAR DISEASE

Breast cancer survivors who are obese have a significantly higher overall, and breast cancer–related, mortality compared with their counterparts who are at a baseline healthy weight within 12 months after diagnosis.[15] There is increasing evidence demonstrating that breast cancer survivors are at a higher risk of morbidity and mortality. Indeed, compared with sex- and age-matched counterparts, patients with breast cancer have an increased incidence of risk factors for cardiovascular disease (CVD; e.g., obesity, hypertension, diabetes, dyslipidemia, exercise intolerance)[16] and CVD-specific morbidity (e.g., coronary artery disease and heart failure). Moreover, in survivors older than age 65, CVD is the leading cause of mortality.[17,18] As prolonged administration of anticancer therapies becomes increasingly common[19] and novel targeted therapies with potentially adverse cardiovascular safety profiles are included in treatment strategies,[20] the incidence of CVD morbidity and mortality among breast cancer survivors will likely continue to rise.

Thus, defining the feasibility and efficacy of innovative interventions that can attenuate CVD sequelae are of primary research and clinical importance.

Exercise, a pleiotropic stimulus leading to physiologic adaptation across multiple organ systems,[21] improves insulin sensitivity, decreases lipids, and lowers blood pressure with concomitant improvements in peak VO2 in noncancer settings.[22-26] Although comparatively less information is available in oncology settings, recent observational data of patients with breast cancer indicate that adherence to national exercise guidelines for adult patients with cancer (i.e., ≥ 9 MET hours/week) was associated with an adjusted 23% reduction in the risk of CVD events compared with not meeting the guidelines (< 9 MET hours/week; p = .0002).[27] The association with exercise did not differ according to age, most CVD risk factors, menopausal status, or anticancer treatment,[27] suggesting that, for many patients with breast cancer, exercise is a potent intervention that can modulate CVD sequelae. However, the protective effects of exercise did not extend to women with a body mass index (BMI) of 35 kg/m^2 or greater.[27] As a result, additional interventions may be required for patients with excess CVD risk associated with obesity.

Based on promising data indicating that weight control, physical activity, and/or diet quality reduce cancer recurrence and improve cancer-specific overall survival, the American Cancer Society issued Guidelines on Nutrition and Physical Activity for Cancer Survivors, which call for maintenance of a healthy body weight, regular physical activity regardless of BMI, and modest weight loss for cancer survivors who are overweight or obese.[28] Importantly, concomitant diet and exercise interventions in nononcology overweight/obese settings have been shown to improve LV function, exercise capacity, glucose, lipid, and blood pressure control, inflammation markers, body composition, and skeletal muscle function.[29] Thus, the synergistic benefits of multicomponent interventions could represent an optimal approach to offset CVD in patients with breast cancer.

CVD SEQUELAE AMONG PATIENTS WITH BREAST CANCER

The incidence of common risk factors for both CVD and cancer such as hypertension (up to 55%),[30] diabetes (up to 10%),[31] hyperlipidemia (up to 20%),[32] obesity (up to 62%),[33] and low exercise tolerance (up to 37%)[3] likely increase the risk of CVD morbidity and mortality[34] For example, Hooning et al examined the long-term causes of mortality among 7,425 women treated for early-stage breast cancer and found that after a median of 13.8 years, survivors diagnosed with one CVD risk factor at any time during the study follow-up had a 1.4- to 3.1-fold higher risk of CVD-related mortality relative to age-matched women among the general population.[16,17] Moreover, Playdon et al reported that a weight gain of more than 5% from diagnosis to post-treatment was associated with a 12% increase in the risk of all-cause mortality compared with weight maintenance in a meta-analysis involving 23,832 patients with early-stage breast cancer.[33] Similarly, among 3,993 women with early-stage disease (5.8 years postdiagnosis), those with a BMI greater than 30 kg/m^2 (classified as obese) had a CVD mortality rate 1.65 times that of women with a normal BMI (18.5–24.9 kg/m^2), and each 5 kg weight gain was associated with a 19% increase in CVD mortality.[35] These findings highlight the importance of identifying women at the greatest risk of accelerated CVD sequalae so targeted interventions can be initiated.

EVIDENCE OF EFFICACY OF COMBINED DIET AND EXERCISE INTERVENTIONS TO MODULATE CVD SEQUELAE

Evidence from nononcology trials indicate that multicomponent interventions may be critical for improving outcomes such as body composition, peak VO2, and biomarkers linked to CVD outcomes. For example, in 107 obese adults (BMI > 30 mg/kg^2) were randomly assigned to one of four groups for 52 weeks: (1) 27 patients in the control group, (2) 26 patients in the diet group, (3) 26 patients in the exercise group, and (4) 28 patients in the diet and exercise group.[36] Peak VO2 improved more in the diet and exercise group than in the diet or exercise alone groups (increases of 17% vs. 10% vs. 8%, respectively; p < .001), whereas body weight decreased by 10% in the diet alone group and by 9% in the diet-exercise group, but did not decrease in the exercise group or the control group (p < .001). Similarly, in 439 postmenopausal women who were overweight/obese and randomly assigned to: (1) a reduced calorie, weight loss diet (diet; 118 patients); (2) moderate-to-vigorous intensity aerobic exercise (exercise; 117 patients); (3) a combination of a reduced calorie, weight loss diet and moderate-to-vigorous intensity aerobic exercise (diet and exercise; 117 patients); or (4) control (87 patients),[37] leptin concentrations, a key regulator of energy homeostasis, metabolism, and adiposity, decreased in all of the intervention groups, but the greatest reduction occurred with diet and exercise (-40%). Taken together, these findings suggest that a combination of weight loss and an exercise program could provide greater improvement in multiple outcomes compared with either intervention alone in overweight/obese populations.

To date, the potential cardioprotective properties of multimodal interventions in patients with breast cancer have received limited attention; however, preliminary observational data indicate that adherence to diet and exercise guidelines improves patient morbidity and mortality. For example, among 938 breast cancer survivors in the Iowa Women's Health Study (mean age, 79; 8.6 years postdiagnosis),[38] adherence to the World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR) prevention guidelines for weight control, physical activity, and diet was associated with lower all-cause mortality (hazard ratio [HR] 0.67; 95% CI, 0.50–0.94), and a 40% reduction in CVD-specific mortality. The majority of trials of patients with breast cancer have examined the efficacy of either exercise alone to improve functional outcomes (e.g., VO2peak) or diet alone to direct weight management or weight loss. As a result, only approximately six trials have investigated

the effect of a combined diet and exercise intervention among patients with breast cancer. For example, 90 postmenopausal patients with breast cancer receiving adjuvant chemotherapy were randomly assigned to (1) a calcium-rich diet intervention (attention control), (2) calcium-rich diet and exercise, or (3) calcium-rich diet with high fruit and vegetable, low-fat diet and exercise. Demark-Wahnefried et al[39] reported that the high fruit and vegetable arm substantially attenuated therapy-induced increases in appendicular body fat. Similarly, Morey et al[40] reported that among 641 older, overweight, long-term survivors of breast (289 patients), prostate (261 patients), and colorectal (91 patients) cancer randomly assigned to either a 12-month home-based program of telephone counseling promoting exercise and diet, or wait-list control, weight loss was significantly greater in counseling groups compared with the wait-list control group (2.06 vs. 0.92 kg, respectively; $p < .001$).

The Life After Cancer Epidemiology (LACE) study examined the impact of dietary adherence in 1,901 women diagnosed with early-stage breast cancer. A prudent dietary pattern was defined by a high intake of fruits, vegetables, whole grains, and poultry, whereas a Western diet was defined by high intake of red and processed meats and refined grains. The prudent diet was associated with a significant decrease in risk of overall death (trend $p = .02$; HR for highest quartile 0.57; 95% CI, 0.36–0.90) and death from non–breast cancer causes (trend $p = .003$; HR for highest quartile 0.35; 95% CI, 0.17–0.73) independent of physical activity, body habitus, or tobacco use. In contrast, a Western diet was related to an increasing risk of overall death (trend $p = .05$) and death from non–breast cancer causes ($p = .02$). Interestingly, both dietary patterns were not associated with reduced risk of breast cancer recurrence or breast cancer–specific mortality.[41]

The Women's Health Initiative Dietary Modification primary breast cancer prevention trial randomly assigned 48,835 postmenopausal women with no prior history of breast cancer and normal mammograms to undergo dietary intervention or to a control group. The dietary intervention reduced dietary fat intake to 20% of calories, increased fruit and vegetable intake (five servings a day), and increased grains to six servings a day. During year 1, intervention group members participated in 18 group sessions and then quarterly maintenance meetings. The control group participants received dietary guidelines. Although the incidence of breast cancer was not significantly decreased among women in the low-fat diet group, women in the intervention group had improved overall survival at 8.5 years (HR 0.65; 95% CI, 0.45–0.94; $p = .02$. At the 16-year mark, breast cancer-specific mortality was still lower than those in the control group (234 vs. 443 deaths, respectively; HR 0.82; 95% CI, 0.70–0.96; $p = .01$). Women with baseline waist circumference of 88 cm or greater and higher baseline levels of dietary fat intake had a stronger interaction in terms of deaths after breast cancer.[42]

The randomized phase III WINS trial evaluated whether dietary fat reduction affected relapse-free survival among 2,437 patients with early-stage breast cancer receiving standard-of-care treatment. Women with a dietary fat intake greater than 20% of calories were randomly assigned to a dietary intervention group or a control group. Women were given a fat-gram goal by centrally trained, registered dietitians implementing a low-fat eating plan. Women in the intervention arm underwent 8 biweekly individual counseling sessions, were subsequently contacted every 3 months, and self-monitored their fat-gram intake using a "keeping score" book. Fat intake was externally monitored by unannounced 24-hour telephone recalls performed annually for 5 years. Women enrolled in the intervention group consumed 9.2% calories from fat and lost nearly 6 pounds. Although there was no survival benefit at 19.4 years, an exploratory subgroup analysis of the group with estrogen negative tumors showed higher median survival of 13.6 years in the intervention group compared with 11.7 years in the control arm (HR 0.46; $p = .006$).[42]

Although these findings are promising for patients with breast cancer with, or at high risk of obesity, the long-term implications of acute multimodal interventions on CVD morbidity and mortality are unknown. To this end, the Look AHEAD (Action for Health in Diabetes) study examined the incidence of a composite cardiovascular outcome (cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, or hospitalized angina) over 9.6 years in 5,145 overweight or obese individuals with type 2 diabetes randomly assigned to a diet and exercise intervention or control.[43] Although improvements in weight loss, fitness, and CVD risk factors were greater in the intervention group, there was no significant difference between the intervention and control group in CVD morbidity and mortality (403 vs. 418 events, respectively; 1.83/100 person-years vs. 1.92/100 person-years, respectively; HR 0.95; 95% CI, 0.83–1.09; $p = .505$).[43] Thus, the effect of multimodal interventions in patients with breast cancer on outcomes other than weight loss, or in patients with concomitant comorbidities such as hypertension, dyslipidemia, diabetes, or exercise intolerance, are important areas for further research.

In summary, given that patients with breast cancer now live long enough to be at risk for therapy-induced CVD morbidity and mortality, a research agenda that addresses the nature and magnitude of therapy-related CVD could define important targets for interventions. To this end, observational data indicating that exercise-induced modification of CVD events is attenuated in obese breast cancer survivors[27] suggest that, for a subset of patients with breast cancer who are overweight or obese, multimodal interventions may be critical to abrogating accelerated CVD. Prospective trials are needed to define the role of diet and exercise in the management of CVD sequelae in overweight and obese breast cancer survivors.

ROLE OF EXERCISE IN RISK REDUCTION OF BREAST CANCER

The role of exercise in secondary prevention and breast cancer–related mortality is not well-defined. However, the

known physiologic effects of exercise suggest that it may have an important role. Exercise may reduce adverse outcomes associated with fat accumulation such as an altered hormonal environment and adipokine production, which may act to promote tumor development and growth.[44] Randomized, controlled trials of physical activity among postmenopausal women who are overweight demonstrated declines in serum levels of androgen, estrogen, and leptin—hormones important for tumorigenesis.[45-47] For these reasons, exercise may be a modifiable behavior that has the potential to change important breast cancer outcomes. In the next section, we review the salient data on the impact of exercise on breast cancer recurrence and mortality.

Exercise and Risk of Recurrence and Effect on Breast Cancer Mortality: Epidemiologic Data

The majority of studies examining this question have been observational cohort studies based on patient self-reporting, an important limitation. The landmark study is the Nurses' Health Study, a prospective observational study of 2,987 female registered nurses with stage I to III breast cancer between 1983 and 1998.[48] The women were followed every 2 years until 2002 or time of death, and answered questions about their physical activity over the prior year. After adjusting for factors predictive of survival after breast cancer, compared with women who engaged in less than 3 MET-hours/week of physical activity, the relative risk (RR) of death from breast cancer was 0.80 (95% CI, 0.60–1.06) for 3 to 8.9 MET-hours/week; 0.50 (95% CI, 0.31–0.82) for 9 to 14.9 MET-hours/week; 0.56 (95% CI, 0.38–0.84) for 15 to 23.9 MET-hours/week; and 0.60 (95% CI, 0.40–0.89) for 24 or more MET-hours/week (trend p = .004). After multivariable adjustment, the RR of breast cancer recurrence was 0.83 (95% CI, 0.64–1.08) for 3 to 8.9 MET-hours/week; 0.57 (95% CI, 0.38–0.85) 9 to 14.9 MET-hours/week; 0.66 (95% CI, 0.47–0.93) for 15-23.9 MET-hours/week; and 0.74 (95% CI, 0.53–1.04) for 24 or more MET-hours/week as compared with women who engaged in less than 3 MET-hours/week of physical activity (trend p = .05). Interestingly, the RR for each adverse outcome was lowest for the intermediate level of activity, equivalent to walking 3 to 5 hours per week at an average pace. The protective benefit was similar among nonobese and obese women, but the benefit was particularly apparent in women with hormone-responsive tumors. The RR of breast cancer death for women with hormone-responsive tumors who engaged in 9 or more MET-hours/week of activity compared with women with hormone-responsive tumors who engaged in less than 9 MET-hours/week was 0.50 (95% CI, 0.34–0.74). An important limitation of this study is that the participants were mostly non-Hispanic whites and occupationally homogenous.[48]

The Collaborative Women's Longevity Study (CWLS) and the Life After Cancer Epidemiology (LACE) study used the same measure of physical activity as the Nurse's Health Study, but found different results.[49,50] In CWLS, a total of 4,482 eligible women age 20 to 79 diagnosed with invasive breast cancer stages I to III between 1988 and 2001 completed the questionnaire of physical activity a median of 5.6 years after diagnosis. After adjusting for relevant factors, women who engaged in greater levels of activity had a significantly lower risk of dying from breast cancer (HR 0.65; 95% CI, 0.39–1.08 for 2.8 to 7.9 MET hours/week; HR 0.59; 95% CI, 0.35–1.01 for 8.0 to 20.9 MET hours/week; and HR 0.51, 95% CI, 0.29–0.89 for > 21 MET hours/week; trend p = .05). Results were similar for overall survival (HR 0.44; 95% CI, 0.32–0.60 for > 21.0 vs. < 2.8 MET hours/week; trend p < .001) and were similar regardless of a woman's age (although the majority of women were age > 50), stage of disease, and BMI. Similar to the Nurse's Health Study, no benefit was demonstrated for vigorous-intensity activity and most of the participants were Caucasian. [50]

In the LACE study, 1,970 women age 18 to 79 with stage I to III breast cancer from 1997 to 2000 completed the physical activity questionnaire the prior 6 months only. Age-adjusted results suggested that higher levels of physical activity were associated with reduced risk of recurrence and breast cancer mortality (trend p = .05 and .07, respectively, for highest versus lowest level of hours per week of moderate physical activity), but were not significant after adjusting for prognostic factors and other variables. Of note, in multivariable analyses, there remained a significant protective association between physical activity and all-cause mortality (HR 0.66; 95% CI, 0.42–1.03; trend p = .04). A strength and unique characteristic of this study is that it contained 20% minorities. It is hypothesized that the lack of power and healthier nature of the participants led to the null results of this study.[49]

Several studies have looked at exercise in breast cancer at several time points, an advantage over the studies that evaluate a single point in time. The Health, Eating, Activity, and Lifestyle (HEAL) study was a prospective, observational study of 933 women age 18 and older diagnosed with stage I to III cancer between 1995 and 1998 that measured activity levels the year prior to diagnosis and 2 years after diagnosis. Compared with women who were inactive both before and after diagnosis, women who increased physical activity after diagnosis had a 45% lower risk of death (HR 0.55; 95% CI, 0.22–1.38), and women who decreased physical activity after diagnosis had a fourfold greater risk of death (HR 3.95; 95% CI, 1.45–10.50). Although the risk reductions were observed for total deaths, the majority of deaths were from breast cancer.[51] Similarly, the Women's Health Initiative (WHI) study measured activity at diagnosis and 3 or 6 years post diagnosis in 4,643 postmenopausal women. Women participating in at least 9 MET hours/week (approximately 3 hours per week of brisk walking) of physical activity after diagnosis had lower breast cancer mortality (HR 0.61; 95% CI, 0.35–0.99; p = .049) and lower all-cause mortality (HR 0.54; 95% CI, 0.38–0.79); p < .01). Even in women who were inactive prior to diagnosis, those who increased or maintained physical activity of at least 9 MET hours/week after diagnosis had lower all-cause mortality (HR 0.67; 95% CI, 0.46–0.96).[52]

The Women's Healthy Eating and Living Study (WHEL) similarly measured activity at baseline and 1 year in 2,361

women age 18 and older with stage I to III breast cancer. Adherence to activity guidelines was associated with a 35% lower mortality risk (HR 0.65; 95% CI, 0.47–0.91; p < .01). There was no effect seen on breast cancer events, although deaths were mostly secondary to breast cancer. Unlike the WHI study, in WHEL the change in activity during 1 year was not associated with improved outcomes, potentially secondary to shorter interval between reports.[53] The Shanghai Breast Cancer Survival Study (SBCSS) assessed exercise at three time points (6, 18, and 36 months post-diagnosis) in 4,826 Chinese women age 20 to 70 between 2002 and 2006. After adjusting for several covariates, exercise during the first 36 months post-diagnosis was inversely associated with total mortality and recurrence/disease-specific mortality with HRs of 0.70 (95% CI, 0.56–0.88) and 0.60 (95% CI, 0.47–0.76), respectively, regardless of stage and BMI. They observed a dose-response relationship between mortality rates and exercise duration and MET scores, and the mortality association was only among estrogen- and progesterone receptor–negative patients.[54] The clear strength of this study is that it evaluated more than two time points; however it is uncertain if this study can be applied to a Western breast cancer population.

EFFECT OF EXERCISE ON BREAST CANCER RECURRENCE AND MORTALITY: CLINICAL TRIALS

Data from randomized controlled trials are limited. The Supervised Trial of Aerobic versus Resistance Training (START) trial randomly selected 242 patients with breast cancer between 2003 and 2005 to usual care, supervised aerobic, or resistance exercise during chemotherapy.[55] The trial was originally designed to examine the independent effects of aerobic and resistance exercise on quality of life, health-related fitness, and other patient-reported outcomes. As an exploratory analysis, overall survival and disease-free survival was estimated. Eight-year disease-free survival was 82.7% for the exercise groups compared with 75.6% for the control group (HR 0.68; 95% CI, 0.37–1.24; log-rank p = .21). In exploratory subgroup analyses, the strongest effects were among women who were overweight or obese, had stage II/III cancers, estrogen receptor–positive tumors, HER2-positive tumors, and received taxane-based chemotherapies and optimal chemotherapy dosing.[56] This study is limited by its exploratory nature but is certainly hypothesis-generating. Phase III studies comparing exercise to usual care in breast cancer survivors are warranted.

EXERCISE SUMMARY AND RECOMMENDATIONS

Supportive data from randomized controlled trials are lacking, but epidemiologic evidence supports the participation in exercise before and after breast cancer diagnosis to decrease breast cancer recurrence, breast cancer–related mortality, and overall mortality. The American Cancer Society encourages cancer survivors to engage in 150 minutes per week of moderate or 75 minutes per week of vigorous aerobic exercise.[28]

CONCLUSION

Decreased cardiorespiratory fitness, obesity, and a sedentary lifestyle negatively impact the outcomes of breast cancer survivors. Lifestyle interventions to improve survival are of much interest. However, there is a paucity of prospective, randomized clinical trial data to suggest specific exercise and dietary recommendations to improve cardiovascular fitness and reduce breast cancer–specific mortality in this population. Prospective, randomized studies that address interventions are necessary to guide breast cancer survivors.

Novel Targeted Agents and Immunotherapy in Breast Cancer

Ingrid A. Mayer, MD, MSCI, Rebecca Dent, MSc, MD, FRCP, Tira Tan, MBBS, MRCP, Peter Savas, MBBS, FRACP, and Sherene Loi, MBBS, FRACP, PhD

OVERVIEW

The treatment of breast cancer is generally determined according to breast cancer subtype: hormone receptor–positive (luminal), triple-negative (basal-like), and HER2-overexpressing breast cancer. Recent years have seen the development of exciting novel and potent therapeutics based on molecular pathways, immune modulation, and antibody conjugates. In this article, we cover new and emerging therapeutic areas and ongoing clinical trials that may result in further improvements in breast cancer outcomes.

Breast cancer clinicians have been fortunate in the past to have proven efficacious treatment options to offer their patients. Novel therapeutics continue to expand treatment options for patients with early-stage and advanced breast cancer. For estrogen receptor–positive (ER+), HER2-negative, and HER2-amplified disease, novel agents can combine with existing effective therapies to reverse or delay treatment resistance. Determining the optimal combination and best treatment sequence remains a difficult challenge, however. In contrast, triple-negative breast cancer (TNBC) is a heterogeneous disease that has devastating consequences on relapse with limited treatment options, and improvements in outcomes will rely on novel therapies and identifying the subgroups of patients most likely to benefit. We discuss potential further therapeutic directions for the three main breast cancer subtypes in this article.

MECHANISMS OF ENDOCRINE THERAPY RESISTANCE IN ER+ BREAST CANCER

Acquired resistance (defined as recurrence at least 6–12 months after completion of adjuvant therapy or disease progression more than 6 months after endocrine therapy initiated in the metastatic setting) and occasionally primary resistance (recurrence either within adjuvant therapy or within 6–12 months of completion of adjuvant therapy or disease progression more than 6 months after treatment in the metastatic setting) to antiestrogen therapy is inevitable in patients with ER+ metastatic breast cancer (MBC).[1] A variety of mechanisms have been implicated in primary and acquired resistance to endocrine agents (Sidebar 1). Below we review some of the strategies to overcome endocrine therapy resistance.

Cyclin-Dependent Kinases 4 and 6 Inhibitors

Inhibitors of the cyclin-dependent kinases 4 and 6 (CDK4/6) have demonstrated impressive activity in patients with ER+/HER2-negative MBC.[2] Palbociclib is an orally active pyridopyrimidine first-in-class compound that is a potent and highly selective reversible inhibitor of CDK4/6.[3] By inhibiting CDK4/6, palbociclib prevents tumor cell entry into S phase.[4] Consistent with its CDK4/6 specificity, treatment with palbociclib reduces expression of the proliferation marker Ki67 and is completely inactive in Rb-deficient tumor cells.[5] Preclinical data have shown that endocrine-resistant ER+ breast cancer cells are highly sensitive to palbociclib with and without antihormonal therapy.[6]

In previously untreated metastatic ER+/HER2-negative MBC, the phase I/II PALOMA-1 trial found an impressive improvement in progression-free survival (PFS) with palbociclib plus letrozole over letrozole alone.[7] The confirmatory phase III PALOMA-2 study randomized a total of 666 postmenopausal patients with ER+ MBC and no prior systemic therapy to receive letrozole with palbociclib or letrozole with placebo. Median PFS (the primary endpoint) was 24.8 months versus 14.5 months in favor of the palbociclib arm (hazard ratio [HR], 0.58; 95% CI, 0.46–0.72; $p < .000001$).[6] Response rate was also improved in the palbociclib arm (42.1% vs. 34.7%, $p = .031$), and clinical benefit rate was 84.9% versus 70.3% ($p < .0001$). Similar evidence of efficacy was seen in the phase III PALOMA-3 trial with the combination of fulvestrant plus palbociclib, in which the PFS was 9.2 months versus 3.8 months with fulvestrant plus placebo (HR, 0.42; $p < .000001$) in patients with disease progression after at least one line of hormonal therapy and at most one line of chemotherapy but naive to CDK4/6 inhibitors.[2,8] In both phase III trials, the most common grade 3 or 4 adverse

SIDEBAR 1. Mechanisms of Resistance to Endocrine Agents

Primary Resistance

- Receptor tyrosine kinase/growth factor signaling pathway
- *FGFR* amplification
- *EGFR*/*ERBB2* mutations
- Cell cycle control signaling pathway
- Cyclin D1 amplification or expression
- *MYC* amplification and overexpression
- Hormone signaling pathway
- Loss of ERα
- Post-translational modification of ERα
- Expression of ER coactivation/corepression factors

Acquired Resistance

- PI3K/AKT1/MTOR signaling pathway
- PI3K/AKT/mTOR pathway activation
- Mitogen-activated protein (MAP) kinase pathway
- MAPK/ERK pathway activation
- Hormone signaling pathway
- *ESR1* mutations
- Changes in the tumor microenvironment

event in the palbociclib arms was neutropenia (incidence 62%–65%), but treatment was otherwise well tolerated. Both palbociclib with letrozole for first-line treatment and palbociclib with fulvestrant for second line treatment of patients with ER+/HER2-negative MBC are approved by the U.S. Food and Drug Administration (FDA).

KEY POINTS

- **Breast cancer was the first solid tumor type leading the way with targeted therapy: tamoxifen and, subsequently, trastuzumab.**
- **ER+, HER2-negative disease has lately seen the emergence of highly effective CDK4/6 inhibitors, which likely will represent a major advance for this breast cancer subtype.**
- **HER2+ breast cancer represents the poster child for oncogene addiction and targeted therapy: the advent of trastuzumab has resulted in early-stage HER2+ disease becoming highly curable, and we now understand that these tumors remain addicted to HER2-signaling. Newer HER2-directed therapies, probably in combination with immunotherapies, will result in patients with advanced disease enjoying long periods of time with excellent quality of life.**
- **Triple negative breast cancer remains the major challenge for breast cancer clinicians. It is hoped that newer DNA damage repair inhibitors, immunotherapies, and antibody-drug conjugates will result in improved survival.**

mTOR Inhibitors

The addition of the mTOR inhibitor everolimus to endocrine therapy can reverse endocrine resistance in ER+ MBC, as shown in the BOLERO-2[9] and TAMRAD[10] randomized phase III trials. In both studies, all patients were previously exposed to aromatase inhibitors (AIs), and most of them developed progression after initial response (acquired resistance). This led to the approval of everolimus by the FDA and the European Medicines Agency in combination with endocrine therapy after failure of AIs in 2012. In contrast to these positive results, the phase III HORIZON trial found the addition of the mTOR inhibitor temsirolimus to letrozole did not improve PFS over letrozole alone.[11] This trial was conducted in the first-line setting, and most patients were AI naive, suggesting that mTOR signaling may have a specific role in acquired resistance to endocrine therapy. There are several ongoing trials that will better define the role of everolimus in advanced disease: BOLERO-6 (NCT01783444), a phase II trial comparing exemestane/everolimus to capecitabine in ER+/HER2-negative disease refractory to AI, and BOLERO-4 (NCT01698918), a phase II single-arm study evaluating the role of everolimus as first-line treatment. Everolimus is also being evaluated in the adjuvant setting with two different studies using two different approaches: (1) SWOG1207 (NCT01674140) will randomly assign high-risk premenopausal and postmenopausal patients to add everolimus or placebo to their standard adjuvant endocrine therapy, and (2) NCT01805271 will evaluate the addition of everolimus to adjuvant endocrine therapy in high-risk ER+/HER2-negative patients with breast cancer who remain disease free after at least 1 year of treatment.

PI3K Inhibitors

PI3K inhibitors consist of pan-PI3K targeting all class I isoforms, isoform-specific PI3K inhibitors, and dual PI3K/mTOR inhibitors. Compounds may also display differential activity for wild-type and mutant PI3K proteins. Response rates with single-agent PI3K inhibitors are far below those of other kinase inhibitors in other cancer types (such as EGFR, ALK, or BRAF inhibitors). Frequent coexisting genetic alterations, compensatory feedback loops, and toxicity that precludes maintaining adequate dose intensity are possible explanations for this diminished efficacy.

Buparlisib (BKM120) is a pan-PI3K inhibitor with potent activity against mutant PI3Kα.[12] Early phase trials of buparlisib plus endocrine therapy reported activity and a manageable safety profile characterized by transaminitis, hyperglycemia, diarrhea, and mood disorders (anxiety, depression, irritability).[12,13] The randomized phase III BELLE-2 trial studied fulvestrant 500 mg plus buparlisib 100 mg daily or placebo in postmenopausal MBC progressing on AIs.[14] Buparlisib increased the median PFS by 1.9 months (6.9 months vs. 5.0 months, $p < .001$). For patients with PI3K/AKT pathway activation (defined as PIK3CA mutation or PTEN loss, assayed for the majority in the archival primary tumor) there was no difference in the benefit of buparlisib. However, in the subset of patients in whom *PIK3CA* mutation

was assessed by circulating tumor DNA at trial entry, buparlisib plus fulvestrant increased PFS in PIK3CA mutant cases compared with fulvestrant alone (7 months vs. 3.2 months; HR, 0.56; p < .001).

Using the same treatment arms as BELLE-2, the phase III BELLE-3 trial enrolled AI-experienced patients with disease progression in the past 30 days on an mTOR inhibitor plus endocrine therapy.[15] Median PFS for patients in the buparlisib arm was 3.9 months versus 1.8 months for fulvestrant/placebo, and 6-month PFS rates were 30.6% and 20.1%, respectively. Of 349 patients for whom *PIK3CA* mutation status from circulating tumor DNA was available, 147 had mutations in the gene. Among those with *PIK3CA* mutations, PFS was 4.7 months in the buparlisib arm versus 1.6 months in the placebo arm. A similar result was seen with *PIK3CA* status in tumor tissue.

PI3Kα is the isoform predominantly mutated in cancer, and studies have shown that selective inactivation of this isoform is enough to block PI3K/AKT signaling in response to different growth factor stimuli.[16-18] Early results with pan-PI3K inhibition suffered from substantial toxicity and reduced efficacy,[19] and inhibiting PI3Kα selectively is designed to achieve a better therapeutic index by targeting the driving isoform in a specific cancer. Two PI3Kα inhibitors are in clinical development for breast cancer in combination with endocrine therapy: alpelisib (BYL719) and taselisib (GDC-0032). Single-agent alpelisib showed preferential activity in solid tumors harboring *PIK3CA* mutations.[20,21] Alpelisib plus fulvestrant is being studied in a phase III trial for metastatic ER+ breast cancer progressing on AIs (SOLAR1, NCT02437318) and in a neoadjuvant phase II trial in combination with letrozole (NEO-ORB, NCT01923168). Taselisib is a is a potent inhibitor of p110α, p110δ, and p110γ but with 30-fold less inhibition of p110β relative to p110α and greater selectivity against *PIK3CA* mutant isoforms than wild-type.[22] Taselisib and fulvestrant is being tested in a randomized phase III study in the metastatic setting for women with previous exposure to AIs and enrichment for *PIK3CA* mutation (SANDPIPER, NCT02340221) and a neoadjuvant phase II trial in combination with letrozole (LORELEI, NCT02273973).

ESR1 Mutations

Mutations in the ligand binding domain of the ER gene *ESR1* result in estrogen-independent ER signaling and resistance to antiestrogen therapy.[23-26] *ESR1* mutations are uncommon in primary breast cancers at the time of diagnosis, but they have been identified in up to 55% of ER+ MBC previously treated with antiestrogen therapy.[27] *ESR1* mutations may have a role in determining optimal endocrine therapy. In the SoFEA phase III trial,[28] *ESR1* mutations were found in 39% of patients (63 of 161) with rates of mutation detection unaffected by delays in processing of archival plasma. Patients with *ESR1* mutations had improved PFS after taking fulvestrant (45 patients) compared with exemestane (18 patients; HR 0.52; 95% CI, 0.30–0.92; p = .02), whereas patients with wild-type *ESR1* had similar PFS after receiving either treatment (HR 1.07; 95% CI, 0.68–1.67; p = .77).[29] In PALOMA3, *ESR1* mutations were found in the plasma of 25.3% of patients (91 of 360), with mutations associated with acquired resistance to prior AIs. Fulvestrant plus palbociclib improved PFS compared with fulvestrant plus placebo in both ESR1 mutant (HR 0.43; 95% CI, 0.25–0.74; p = .002) and *ESR1* wild-type patients (HR 0.49; 95% CI, 0.35–0.70; p < .001).[29] *ESR1* mutations are often "polyclonal," with multiple different mutations detectable in the same patient.[29] There is considerable interest in developing antiestrogen therapies that are effective in the presence of *ESR1* mutations.

NEW APPROACHES IN TNBC: PARP INHIBITORS AND BEYOND

TNBC, which lacks all three predictive and prognostic immunohistochemical biomarkers, ER, progesterone receptor, and HER2, has few therapeutic options beyond chemotherapy which to date remains the standard of care. Clinically, TNBC has an aggressive tumor biology with the worst disease-specific outcome compared with other subtypes, representing an important challenge and unmet clinical need.[30,31] Survival data from clinical trials indicate that the median overall survival for patients with metastatic TNBC (mTNBC) is approximately 11 to 14 months and is indeed much shorter than among patients with other MBC subtypes.[32,33]

Subtypes of TNBC have been described on the basis of histopathologic features and gene expression profiling, highlighting the heterogeneity and complexity of these tumors.[34-37] Four distinct breast cancer subtypes (luminal A, luminal B, HER2-enriched, and basal-like) of prognostic and predictive significance were first described by Perou et al[38] in 2000 using microarray analysis. Of the four subtypes, basal-like tumors are typically of triple-negative phenotype, and the vast majority (approximately 80%) of TNBCs are of the basal-like subtype.[36,39] In analyzing gene expression profiles of TNBC, Lehmann et al[35] identified six distinct molecular subtypes (basal-like 1, basal-like 2, immunomodulatory, mesenchymal, mesenchymal stem-like, and luminal androgen receptor). This was refined into four tumor-specific subtypes (basal-like 1, basal-like 2, mesenchymal, and luminal androgen receptor) following histopathology and laser-capture microdissection, which identified infiltrating lymphocytes and tumor-associated stromal cells contributing to the immunomodulatory and mesenchymal stem-like subtypes, respectively.[36] In addition to microarray-based studies, the genomic landscape of this disease has also been extensively interrogated, identifying alterations adding to our burgeoning knowledge of TNBC.[27,40] The features and alterations unique to these various subtypes have been incorporated into many ongoing, rationally designed trials to refine treatment strategies. In this article, we discuss notable novel approaches in the treatment of TNBC.

Cytotoxic Chemotherapy

The triple-negative paradox describes a higher responsiveness of TNBC to chemotherapy despite the overall unfavorable prognosis.[41] Currently, chemotherapy is the mainstay

to treating TNBC. Taxane and anthracycline-containing regimens remain the preferred chemotherapeutic options, and recent results have clarified the role of nab-paclitaxel and carboplatin. The Triple-Negative Albumin-Bound Paclitaxel Combination International Treatment Study (tnppAcity) is a phase II trial evaluating nab-paclitaxel in combination with either gemcitabine or carboplatin versus gemcitabine plus carboplatin in previously untreated mTNBC.[42] It found a significantly longer PFS (median PFS, 7.4 months vs. 5.4 months, p = .03, and 7.4 months vs. 6 months, p = .02) and overall response rate (ORR; 72% vs. 39% and 44%) in favor of nab-paclitaxel plus carboplatin compared with paclitaxel plus gemcitabine or gemcitabine plus carboplatin.[42] In the Triple Negative Breast Cancer Trial (TNT), 376 patients with previously untreated mTNBC were randomly assigned to receive either carboplatin or docetaxel monotherapy.[43] Although there was no difference in the ORR or PFS between the two arms in the overall population, the key finding was patients who harbored deleterious germline BRCA mutations fared better when treated with carboplatin, with greater ORR (68% vs. 33.3%, p = .03) and PFS (6.8 months vs. 3.1 months, p = .03) compared with docetaxel.[43] Thus, both platinum and nab-paclitaxel should be included in our armamentarium of treatment of TNBC as well as other standard chemotherapies used for other subtypes of breast cancer.

Targeting Defective DNA Repair

A significant proportion of BRCA-mutated breast cancers are TNBC[44] or have gene expression profiles similar to basal-like TNBC.[45] The BRCA gene complex plays an important role in maintenance of genomic stability via homologous recombination, one of the coordinated pathways that act to identify DNA aberrations and restore genomic stability. Loss of function of BRCA confers a defective homologous recombination phenotype. This affords an opportunity for achieving "synthetic lethality" by using PARP inhibitors.[46] Concurrent tumor intrinsic BRCA loss of function and pharmacologic inhibition of PARP results in tumor cell death with a high therapeutic index.[47]

As a proof of concept, clinical trials in the initial development of PARP inhibitors have focused largely on BRCA-mutated tumors.[48-50] In a phase II trial of olaparib monotherapy in two sequential cohorts of BRCA-mutated advanced breast cancer, an ORR of 11 of 27 (41%) was seen in the cohort treated at 400 mg twice daily and 6 of 27 (22%) in the cohort treated at 100 mg twice daily. A significant proportion of both cohorts had TNBC; 7 of 13 triple-negative cases (54%) responded to 400 mg twice daily, while 4 of 16 triple-negative cases (25%) responded to 100 mg twice daily.[49] Ongoing phase III trials evaluating PARP inhibition in BRCA-mutant MBC include olaparib in OlympiAD (NCT02000622), which will report at the 2017 ASCO Annual Meeting with a press release noting that the trial had reached its primary endpoint, niraparib in BRAVO (NCT01905592), and talazoparib in EMBRACA (NCT01945775). Ongoing efforts are focused on molecular diagnostics beyond BRCA testing to predict benefit from PARP inhibition as well as applying PARP inhibitors in a broader population through combination strategies.

Immunotherapy: Checkpoint Inhibition

Approximately 20% of TNBCs are classified as the immunomodulatory subtype and are characterized by genes involved in the immune system.[36] Early-stage TNBC has high levels of tumor-infiltrating lymphocytes, and increasing levels of tumor-infiltrating lymphocytes predict a better prognosis.[51] These tumor-infiltrating lymphocyte contribute significantly to the gene expression profiles and express immune checkpoint genes such as programmed cell death–1 (PD-1) and programmed cell death ligand–1 (PD-L1).[36,52] T-cell checkpoint inhibitors, which relieve the immunosuppressive tumor microenvironment and promote antitumor immune responses, have generated much excitement by demonstrating lasting efficacy in some patients across a broad array of tumor types, including TNBC.

In a multicohort phase IB study of monotherapy with the anti-PD1 monoclonal antibody pembrolizumab, the ORR was 18.5% in 28 evaluable patients with TNBC displaying PD-L1 expression (positive staining in stroma or on at least 1% of tumor cells by immunohistochemistry).[53] The median duration of response was not reached, and three responders remained on study for at least 1 year. These promising results led to the initiation of KEYNOTE-086 (NCT02447003), a larger single-arm phase II study to evaluate the role of pembrolizumab in advanced TNBC and identify biomarkers of efficacy. The preliminary results of this study will be reported at the 2017 ASCO Annual Meeting. In addition, KEYNOTE-119 (NCT02555657), a randomized phase III study of pembrolizumab versus physician's choice single-agent chemotherapy in pretreated advanced TNBC, is estimated to complete recruitment in late 2017. Finally, atezolizumab has also shown efficacy as a single agent in a phase IA trial in PD-L1–positive tumors where a cohort of 12 patients with mTNBC were treated, with an ORR of 33%.[54]

Combinations of immunotherapy and chemotherapy may be more efficacious in TNBC. It has been postulated that chemotherapy could promote an immune response to cancer and hence be synergistic with immune therapy.[55] Several trials are investigating combination strategies enhancing the efficacy of immunotherapy and expanding its reach to a broader population of patients. In a phase IB trial of atezolizumab in combination with nab-paclitaxel in mTNBC, the ORR (including unconfirmed responses) in all patients was an impressive 71%, with a range of 43% in those patients treated in the third line and beyond to 89% in those previously untreated.[56] Importantly, the regimen had a tolerable safety profile, and responses were seen in both PD-L1–expressing and PD-L1–nonexpressing tumors. IMpassion130 (NCT02425891), a phase III study of nab-paclitaxel with or without atezolizumab in previously untreated mTNBC, is ongoing and expected to enroll 900 patients across 270 sites globally. KEYNOTE-355 (NCT02819518) is a two-part phase III study evaluating the safety and efficacy of pembrolizumab in combination with three different chemotherapies, in the first-line setting.

Androgen Receptor Blockade

Gene expression microarray-based studies have identified the luminal androgen receptor subtype, which highly expresses androgen receptor (AR) messenger RNA in addition to downstream AR targets and coactivators.[7,35,57] Thus, it is postulated that AR inhibition would have antitumor activity in a well-defined subgroup of TNBC. A phase II trial of abiraterone acetate, an inhibitor of 17-α-hydroxylase/17,20-lyase (CYP17) in a cohort of heavily pretreated AR-positive (at least 10% by immunohistochemistry) TNBC demonstrated a 6-month clinical benefit rate of 20% (95% CI, 7.7%–38.6%) and PFS of 2.8 months.[58] Similarly, in a phase II trial of enzalutamide, a potent AR inhibitor, the 24-week clinical benefit rate was 29% (95% CI, 20%–41%), and median PFS of 14 weeks (95% CI, 8–19 weeks) was seen in the 57 evaluable patients.[59] In this study, an androgen-driven diagnostic gene signature was associated with greater clinical benefit, and the phase III ENDEAR trial of paclitaxel plus enzalutamide/placebo and enzalutamide monotherapy has been initiated in diagnostic signature positive TNBC (NCT02929576).[60]

Antibody-Drug Conjugates

Antibody-drug conjugates (ADCs) are a novel class of cancer therapeutics, which amalgamate the selectivity of a targeted treatment and cytotoxicity of chemotherapy, resulting in an improved therapeutic index. Sacituzumab govitecan (IMMU-132) is an anti-Trop-2 ADC consisting of humanized IgG antibody against Trop-2 linked to SN-38, an active metabolite of irinotecan. The Trop-2 protein is an epithelial cancer antigen found to be highly expressed in a majority of TNBC compared with normal tissues and is associated with a poor prognosis and aggressive disease.[61] In the first-in-human phase I trial, sacituzumab govitecan had an acceptable safety profile and evidence of efficacy including one confirmed response and two minor responses seen in three of four patients with TNBC.[62] In the ongoing multicenter phase II trial, promising PFS of 5.6 months (95% CI, 3.6–7.1 months), overall survival of 14.3 months (95% CI, 10.5–18.8 months), and a response rate of 29% were seen in a heavily pretreated (median of five prior therapies) population of TNBC.[63] Sacituzumab govitecan has been given breakthrough therapy and fast-track designation from the FDA, and a phase III international multicenter randomized trial versus treatment of physician's choice in refractory mTNBC is planned for initiation in 2017 (NCT02574455).

Glembatumumab vedotin (CDX-011) is a fully human IgG2 monoclonal antibody with high affinity for extracellular domain of glycoprotein nonmetastatic B linked to the microtubule inhibitor monomethyl auristatin E (MMAE). Glycoprotein nonmetastatic B is highly expressed in TNBC in relation to normal tissue, predicts breast cancer recurrence, and is associated with reduced overall survival.[64] Early activity was seen in mTNBC and high-gpNMB-expressing tumors in the phase II EMERGE study.[65] The METRIC trial, a randomized phase III study evaluating glembatumumab vedotin versus capecitabine, is ongoing in gpNMB overexpressing TNBC (NCT01997333).

Targeting the PI3K/AKT/mTOR Pathway

Numerous studies have shown that the PI3K/AKT/mTOR pathway is activated in TBNC either through loss of pTEN or INPP4B or mutations in PIK3CA or AKT.[66-68] A neoadjuvant study of weekly paclitaxel/doxorubicin/cyclophosphamide in combination with the AKT inhibitor MK-2206 versus chemotherapy alone showed a pathologic complete response rate of 40% in the combination arm compared with 22% in the chemotherapy alone arm.[69] In the metastatic setting, the LOTUS trial (NCT02162719), a phase III study of paclitaxel alone or in combination with the AKT inhibitor ipatasertib, has completed recruitment and results will be available in 2017. Finally, the luminal AR subtype is known to be enriched with *PIK3CA* mutations, and the combination of antiandrogens with PI3K inhibitors is currently being evaluated.[70]

NOVEL THERAPEUTIC DIRECTIONS FOR HER2-AMPLIFIED BREAST CANCER

HER2-overexpressing breast cancer exemplifies the concept of oncogene addiction as a highly rewarding treatment target. The success of trastuzumab and subsequent HER2 therapies (pertuzumab, T-DM1, lapatinib, neratinib) highlights that these breastcancers remain highly dependent on the HER2 pathway as treatment resistance develops. Hence the search for more potent agents against the HER2 pathway remains highly active. With the success of the trastuzumab and pertuzumab combination, de-escalation of chemotherapy in the early-stage setting will become a tractable goal. Most patients with advanced disease, however, present with de novo metastatic disease, and here are required therapies that can achieve long term disease control with a favorable toxicity profile and are effective in preventing and managing central nervous system (CNS) metastases. We speculate the treatment in advanced HER2+ disease will become focused on ER+ versus ER-negative status presence or absence and the stability of CNS disease as well as determining the presence of preexisting host immunity as major determinants for deciding ongoing therapy.

Novel HER2 Tyrosine Kinase Inhibitors

The role of HER2 tyrosine kinase inhibitors (TKIs) in the management of early- and late-stage HER2+ breast cancer is evolving. The toxicity of lapatinib and neratinib has hampered their widespread use, and it remains unclear how to best use these drugs in managing CNS disease, and in combination with trastuzumab, pertuzumab or T-DM1. Next-generation HER2 TKIs may ameliorate these issues. Tucatinib (formerly ONT-380, ARRY-380), is a highly selective HER2 tyrosine kinase small-molecule inhibitor.[71] This selectivity is expected to ameliorate the diarrhea and skin toxicity, which are the most troublesome side effects of existing HER2 TKIs such as lapatinib. Additionally, studies with an intracranial HER2 xenograft mouse model demonstrated superior survival with tucatinib treatment over lapatinib or neratinib.[72]

The preclinical rationale for reduced toxicity was confirmed in a phase I study of tucatinib in solid tumors with

HER2 overexpression.[73] The study included an expansion cohort of 17 patients with metastatic HER2+ breast cancer. The dose-limiting toxicity was elevated liver transaminases. At the maximum tolerated dose of 600 mg twice daily, grade 1 or 2 diarrhea occurred in 26% of patients, with no cases of grade 3 or 4 diarrhea. Grade 1 and 2 nausea occurred in 33% of patients. Among the patients with HER2+ breast cancer treated with the maximum tolerated dose or higher, three of 22 had a partial response (14%).

A phase IB trial tested tucatinib 300 mg twice daily in combination with capecitabine (100 mg/m^2) and/or trastuzumab (6 mg/kg thrice weekly) in patients with prior exposure to trastuzumab, taxane, and T-DM1 (NCT02025192).[74] The ORR was 83% for capecitabine plus tucatinib (6 patients), 40% for trastuzumab plus tucatinib (15 patients), and 61% for capecitabine plus trastuzumab plus tucatinib (23 patients). The median duration of response in the triplet arm was 10 months. In the capecitabine-containing arms, grade 1 or 2 diarrhea occurred in 68% of patients. The rate of grade 3 diarrhea was 9% (three of 34), similar to treatment with capecitabine alone. A follow-up phase IB trial tested tucatinib plus T-DM1 in a similar patient population that had not experienced T-DM1 (NCT01983501).[75] The recommended phase II dose of tucatinib 300 mg twice daily was used. The ORR was 47% in 34 patients with measurable disease, with similar benefit in those having received one or more prior HER2 agents. The most common grade 3 and 4 toxicities were thrombocytopenia (28%), increased alanine transaminase (16%), and fatigue (12%). Diarrhea incidence was 56% grade 1 or 2 and 4% grade 3.

CNS disease remains a challenging problem in the management of advanced HER2+ metastatic disease. Recently, neratinib and afatinib monotherapy have been tested in the setting of progressive CNS metastases, with relatively poor results. The LUX-Breast 3 trial found no benefit and increased toxicity with afatanib alone or afatinib and vinorelbine compared with physician's choice therapy.[76] The Translational Breast Cancer Research Consortium (TBCRC) 022 single-arm phase II trial tested neratinib monotherapy in patients with progressive CNS metastases after prior CNS-directed therapy. The partial response rate was 8%, and 21% of patients experienced grade 3 or worse diarrhea despite loperamide prophylaxis.[77] Encouraging results in the setting of CNS metastases have been seen with tucatinib in a combined analysis of patients with CNS metastases across the two phase IB trials described above. The partial response rate was 38% in asymptomatic untreated CNS metastases and 33% in progressive CNS metastases after prior radiotherapy or surgery.[78]

Considering these results, the phase III HER2CLIMB study is comparing tucatinib versus placebo in combination with capecitabine and trastuzumab (NCT02614794) in patients who have received prior taxane, trastuzumab, pertuzumab, and T-DM1. Asymptomatic CNS metastases and previously treated CNS metastases are permitted. The study enrollment has recently expanded to 480 patients.[79]

CDK4/6 Inhibitors

Preclinical data in mouse models of HER2+ breast cancer have shown that CDK4/6 inhibitors can restore sensitivity to anti-HER2 therapy in resistant tumors.[80] The randomized phase II monarcHER trial compares abemaciclib plus trastuzumab plus fulvestrant versus abemaciclib plus trastuzumab versus physician's choice, in ER+/HER2+ MBC with at least two prior anti-HER2 therapies (NCT02675231).[81] The phase II PATRICIA trial is delivering palbociclib and trastuzumab with or without letrozole in postmenopausal patients with advanced HER2+ breast cancer and includes ER+ and ER-negative groups (NCT02448420). A phase IB trial of palbociclib and T-DM1 (NCT01976169) and a phase I/II trial of ribociclib and trastuzumab or T-DM1 (NCT02657343) are also under way. A randomized phase III study of maintanence palbociclib with endocrine therapy, pertuzumab, and trastuzumab after chemotherapy in advanced ER+/HER2+ disease is also about to commence (PATINA: NCT02947685).

PI3K/mTOR Inhibitors

Activation of the PI3K pathway, including PIK3CA mutations and PTEN loss, has been noted preclinically to confer resistance to trastuzumab.[82] The BOLERO1 and BOLERO2 3 trials investigated the addition of the mTOR inhibitor everolimus to trastuzumab and paclitaxel in first-line therapy and trastuzumab and vinorelbine following trastuzumab resistance, respectively.[83,84] A combined analysis of these studies found that tumors lacking PIK3CA mutations, PTEN loss, and PI3K pathway activation did not benefit from everolimus.[85] A phase I study of buparlisib with trastuzumab in trastuzumab resistant advanced HER2+ breast cancer showed good tolerance and an ORR of 17% in 17 patients. Several early phase trials are in progress combining alpelisib (NCT02038010), taselisib (NCT02390427), or pictilisib (NCT00960960) with various combinations of trastuzumab, pertuzumab, and T-DM1.

Novel Antibody and Antibody Conjugates

Germline polymorphisms in CD16A, which encodes the activating Fc receptor FcγRIIIA, have been shown to affect clinical outcomes with trastuzumab.[86] Margetuximab is a novel antibody that targets the same epitope as trastuzumab but has a modified Fc portion designed for enhanced affinity for FcγRIIIA receptor and reduced engagement with the inhibitory FcγR receptor.[87] In a first-in-human phase I study of margetuximab monotherapy in HER2+ solid tumors, 19 evaluable patients with breast cancer who had received at least one prior anti-HER2 therapy showed an objective response rate of 26%.[88] PFS for this group was 5.5 months. Toxicity was favorable, with the most common grade 3 and 4 adverse events being lymphopenia (17%), elevated lipase (8%), and anemia (3%). The currently recruiting phase III SOPHIA trial is comparing margetuximab plus physician's choice chemotherapy to trastuzumab plus chemotherapy after previous treatment with pertuzumab, trastuzumab and T-DM1 (NCT02492711).[89]

Patritumab (U3-1287) is a fully human anti-HER3 monoclonal antibody. In a phase IB study of patritumab, trastuzumab,

and paclitaxel in patients with metastatic HER2+ breast cancer previously treated with trastuzumab, the objective response rate was 38.9% (18 patients), with median PFS of 274 days.[90] No dose-limiting toxicity was reached. The I-SPY-2 phase II neoadjuvant trial added a patritumab and trastuzumab arm in October 2016 (NCT01042379).

Following the efficacy and favorable toxicity of T-DM1, a number of ADCs entered early-phase trials. These next-generation ADCs incorporate novel linker chemistry and aim to have larger amounts of payload drug attached to each antibody. DS-8201a consists of trastuzumab conjugated with a novel topoisomerase I inhibitor. It has shown efficacy in a T-DM1 resistant PDX, as well as PDXs with low HER2 expression, and is capable of substantial bystander cytotoxicity.[91,92] In a phase I trial, no dose-limiting toxicities were seen, and the ORR in 12 patients with breast cancer previously treated with T-DM1 was 42%.[93]

The XMT-1522 ADC targets an HER2 epitope distinct from the trastuzumab epitope and is conjugated with the cytotoxic agent auristatin.[94] It has the possible benefit of avoiding interference with trastuzumab and pertuzumab activity. In preclinical studies, it displayed similar levels of HER2 inhibition as trastuzumab and was effective in T-DM1-resistant and low-HER2-expressing models. It also showed synergistic activity when combined with trastuzumab and pertuzumab.[94] A phase IB study is being conducted in both HER2 1–3+ and HER2-amplified advanced breast cancers, as well as other HER2-expressing tumor types (NCT02952729).

MM-302 is an ADC of liposomal doxorubicin and a HER2 targeted antibody. Despite an efficacy signal in a phase I trial, the phase II HERMIONE trial of MM-302 plus trastuzumab versus physician's choice chemotherapy plus trastuzumab was terminated early in December 2016 because of futility (NCT02213744).

Immunotherapy

Multiple lines of evidence support the importance of the immune microenvironment in HER2+ breast cancer and trastuzumab therapy.[95-97] The phase IB/II PANACEA trial is evaluating the combination of the anti–PD-1 antibody pembrolizumab with trastuzumab in patients with metastatic HER2+ breast cancer that has progressed after at least one line of therapy (NCT02129556). The trial is including patients with both PD-L1–negative and PD-L1–positive tumors by immunohistochemistry. The randomized phase II KATE2 study is comparing T-DM1 plus the anti–PD-L1 antibody atezolizumab to T-DM1 plus placebo in patients with prior trastuzumab and taxane treatment (NCT02924883).

A novel approach to skin metastases involves the application of the topical Toll-like receptor 7 agonist imiquimod directly to skin lesions. A single-arm phase II study of imiquimod and nab-paclitaxel in patients with treatment refractory breast cancer chest wall metastases showed an ORR of 72% in 14 patients, some of whom were HER2+.[98]

T-cell cellular therapies are a promising therapeutic intervention for refractory malignancies. In a phase I study, priming peripheral blood T-cells ex vivo with a HER2 vaccine before expansion in culture and reinfusion produced a response in 43% of patients (seven with HER2+ breast cancer, one with ovarian cancer).[99] Chimeric antigen receptor (CAR) T cells have had dramatic success in hematologic malignancies, where they target cell surface receptors such as CD19. This strategy is attractive for HER2+ advanced breast cancer, as HER2 overexpression represents an accessible target for the CAR. Early use of HER2-targeted CAR T cells was associated with substantial toxicity,[100] but more recently, improved CAR technology and optimized infusion protocols have been well tolerated and efficacious, as was seen in a phase I/II study of HER2 CAR T cells in HER2-expressing sarcomas.[101] CAR T-cell therapy could be an option in advanced refractory HER2+ breast cancers.

Vaccination with HER2-derived peptides has repeatedly shown that antigen-specific T-cell immunity can be induced. However, a strong efficacy signal has been lacking, and the benefit of vaccination against HER2 may be low in HER2 amplified tumors. The E75 HER2-derived peptide together with a GM-CSF as an adjuvant was tested in a phase I/II trial of 195 patients with early-stage breast cancer with a range of HER2+ expression. The nature of the vaccine requires that patients possess the HLA-A2 or A3 allele. In the optimally dosed group, 5-year disease-free survival was 94.6% compared with 80.2% in the control group ($p = .05$, log-rank test). With the E75 vaccine, the benefit of vaccination seems highest in tumors that are HER2 1+ or 2+.[102] A similar result was seen with the AE37 vaccine, consisting of a hybrid HER2 peptide designed to enable direct loading onto HLA class 2 molecules.[103] The E75 vaccine is being tested in the phase III PRESENT study, restricted to patients with HER2 1+ or 2+ expression. In the advanced disease setting, robust immune responses were noted with the combination of an anti-HER2 vaccine and trastuzumab.[104] The combination of T-cell checkpoint inhibitors and vaccines may also be a viable strategy in the advanced disease setting.[105]

CONCLUSION AND FUTURE DIRECTIONS

In the past year, ER+ disease has seen the debut of the highly active and well-tolerated CDK4/6 inhibitors. CDK4/6 inhibitors are now being evaluated in the adjuvant setting. In TNBC, immunotherapy holds much promise, particularly in combination with other therapies, and the subgroups that define patients most likely to benefit from specific therapies such as PARP inhibition or AR inhibition are becoming increasingly well defined. For HER2+ disease, next-generation HER2 TKIs with improved toxicity and better CNS activity will be a key development if preliminary data are confirmed, and the first results of the immunotherapy studies in combination with HER2-targeted agents are expected soon for advanced disease. As a platform, ADCs are expected to continue to bear fruit in HER2+ disease, and further evidence of efficacy in TNBC is eagerly awaited. The lengthening list of efficacious novel therapies is cause for cautious optimism about the future of breast cancer treatment, and results of ongoing clinical trials are eagerly awaited.

Optimal Management of Early and Advanced HER2 Breast Cancer

Sara A. Hurvitz, MD, FACP, Karen A. Gelmon, MD, FRCPC, and Sara M. Tolaney, MD, MPH

OVERVIEW

Approximately 15%–20% of breast cancer is HER2 positive, and patients with this subtype of disease historically had worse outcomes than patients with HER2-negative disease. However, the introduction of HER2-directed therapies has dramatically altered outcomes for these patients, especially for persons with early disease. However, despite these achievements, metastatic disease is still not curable. This review summarizes the current treatment approach for patients in the preoperative and adjuvant setting, including data regarding selecting the optimal chemotherapy partner as well as determining the duration and type of anti-HER–directed therapy. This article also reviews how to approach patients with advanced HER2-positive disease and discusses promising new therapies that are in development.

The initial studies of HER2-positive breast cancer focused on advanced disease, in which a novel monoclonal antibody directed against HER2 (which soon came to be known as trastuzumab) was shown to have single-agent activity in tumors that overexpressed HER2.[1,2] After the initial discovery of activity, the pivotal study by Slamon et al[3] showed benefit in terms of progression-free survival (PFS) and overall survival (OS) for both the combination of doxorubicin and cyclophosphamide with the antibody as well as the couplet of paclitaxel and trastuzumab. Although the anthracycline combination was more active, the cardiotoxicity that was reported led to the approval in 1998 of trastuzumab and paclitaxel as standard therapy for HER2-positive advanced breast cancer.[4]

WHERE ARE WE WITH THE TREATMENT OF ADVANCED HER2-POSITIVE BREAST CANCER?

The years after the 1998 approval of trastuzumab were dominated by studies examining the combination of trastuzumab with almost every known cytotoxic, exploring the prolonged administration of the antibody past progression and examining different dosing schedules (including the three-weekly scheduling that has become widely used).[5-7] In addition, many studies examined the optimal way to define HER2 in the laboratory, with the recognition that the best results were seen in those tumors that overexpressed HER2.[8] Although many individuals with true HER2-positive advanced disease respond to treatment, the majority of patients develop a resistance and disease progression, which has led to the pursuit of additional anti-HER2 agents or combinations to improve outcomes. Studies have tried to exploit other pathways in addition to HER2 to improve outcomes and to develop novel agents. This section briefly summarizes the work since trastuzumab became the standard of care, concentrating on those strategies that have influenced guidelines.

Targeting HER2 With Other Agents

Tyrosine kinase inhibitors. There were theoretical reasons to look at small molecules to target HER2, with the idea that they may have both mechanistic and practical advantages over a large antibody. Many of the small-molecule tyrosine kinase inhibitors (TKIs) had less specificity than trastuzumab, which was potentially of value in a tumor with heterogeneity. In addition, small molecules could potentially cross the blood-brain barrier, be given on a continuous schedule, be orally available, and possibly have less cardiac toxicity than the approved drug, trastuzumab. The first widely tested agent was lapatinib, which reversibly binds to and inhibits the intracellular domain of HER1 and HER2 and was shown to have both single-agent activity and be able to be combined with cytotoxics, including capecitabine and paclitaxel. The combination of capecitabine and lapatinib was compared with capecitabine alone, showing an improved time to progression with a hazard ratio (HR) of 0.49 (95% CI, 0.34–0.71; $p < .001$) but no OS benefit; this led to its approval in the second-line setting.[9,10] In addition, combined anti-HER2 therapy with trastuzumab and lapatinib showed activity in multiple pretreated patients with advanced breast cancer compared with lapatinib alone, with improved PFS

(from 8 weeks to 11 weeks with the combination; HR, 0.74; 95% CI, 0.58–0.94; p = .011) and OS (from 10 months to 14 months; HR, 0.74; 95% CI, 0.57–0.97; p = .026).[11] In a head-to-head comparison in the first-line setting in combination with taxanes (MA31), lapatinib was shown to be inferior to trastuzumab. This trial demonstrated that trastuzumab in combination with a taxane had significantly longer intention-to-treat PFS of 11.3 months compared with lapatinib combined with a taxane of 9.0 months (HR, 1.37; 95% CI, 1.13–1.65; p < .001) and more toxicity, in terms of diarrhea and rash, was observed with lapatinib compared with trastuzumab combined with taxane (p < .001).[12] Although initial data suggested a benefit in brain metastases, this has not been clearly shown with specific studies such as CEREBEL or compared with other agents as in the EMILIA trial.[13-15] The toxicity of the drug with diarrhea (up to 60% any grade) and rash (up to 27% any grade), as well as the efficacy of newer agents such as trastuzumab emtansine (T-DM1), led to the changing role of lapatinib from the second-line setting to later lines.

Other small TKIs may have additional activity. Initial studies of neratinib, an irreversible pan-HER TKI of HER1, HER2, and HER4, suggest that it may be more active than lapatinib with single-agent activity. Burstein et al[16] reported a median PFS of 22.3 and 39.6 weeks, respectively, among patients previously treated with trastuzumab (66 patients) and those that were treatment naive (70 patients), with objective response rates of 24% for patients who received prior trastuzumab treatment and 56% for the trastuzumab-naive cohort.

Diarrhea, which is the major toxicity with neratinib administration, must be controlled early to derive the benefit from this drug and maintain dosing. The NEfERT trial was an open-label randomized study in first-line metastatic disease comparing neratinib and paclitaxel to trastuzumab plus paclitaxel. Median PFS was 12.9 months with neratinib/paclitaxel and 12.9 months with trastuzumab/paclitaxel (HR, 1.02; 95% CI, 0.81–1.27; p = .89).[17] With neratinib/paclitaxel, the incidence of central nervous system recurrences was lower (relative risk, 0.48; 95% CI, 0.29–0.79; p = .002) and time to central nervous system metastases was delayed (HR, 0.45; 95% CI, 0.26–0.78; p = .004). Common grade 3/4 adverse events were diarrhea (30.4% with neratinib/paclitaxel, 3.8% with trastuzumab/paclitaxel), neutropenia (12.9% vs. 14.5%), and leukopenia (7.9% vs. 10.7%); no grade 4 diarrhea was observed. The NALA phase III study is comparing neratinib in combination with capecitabine to capecitabine plus lapatinib for patients with HER2-positive metastatic breast cancer who have received two or more prior HER2-directed regimens (NCT01808573).

ONT-380 is a reversible TKI with selective HER2 inhibition with antitumor activity, and it is suggested to improve activity in brain metastases.[18,19] This agent is being combined with trastuzumab T-DM1 as well as capecitabine or both; further data are pending to further delineate this agent's potential benefit.

Antibodies. Although the initial development was rather slow, pertuzumab has now established its role in the first-line advanced setting. Activity was seen in phase II studies after preclinical studies showed the impact of blocking HER2 and HER3, which led to the CLEOPATRA study. CLEOPATRA randomly assigned patients with newly diagnosed advanced HER2-positive breast cancer to docetaxel and trastuzumab with or without the addition of intravenous pertuzumab.[20-22] This international phase III study showed a very powerful PFS of 18.5 months compared with 12.4 months in the trastuzumab arm and an OS benefit of 56.5 months in the trastuzumab/pertuzumab arm compared with 40.8 months in the trastuzumab cohort. Although the majority of patients in this study had de novo metastatic disease, the small number with prior exposure to trastuzumab in the adjuvant setting also responded. Studies have also shown benefit for pertuzumab with paclitaxel and vinorelbine, providing additional options for combination treatment and leading to its widespread use. This drug is well tolerated, causing only minimal increases in diarrhea for many patients and no notable additional cardiotoxicity. To date, there are no data to suggest a continued benefit of pertuzumab past progression.

T-DM1 is an antibody-drug conjugate linking trastuzumab with the powerful agent emtansine, a derivative of maytansine, an older microtubule cytotoxic initially evaluated in the 1970s.[23,24] A large phase III study, EMILIA, was launched in the second-line metastatic setting comparing single-agent T-DM1 to capecitabine and lapatinib for patients with prior trastuzumab and taxane exposure.[15] This study showed a statistically and clinically relevant benefit in PFS, response, duration of response, and OS for T-DM1, with a median 3.2-month PFS benefit (HR, 0.65; 95% CI, 0.55–0.77; p < .001) and a median 5.8-month OS benefit (HR, 0.68; 95% CI, 0.55–0.85; p < .001) compared with capecitabine plus lapatinib. The drug is very well tolerated, with the major side effects being thrombocytopenia (seen for 12.9% of patients) and occasional increases in liver enzymes (occurring for 2.9% and 4.3% of patients, for aspartate aminotransferase

KEY POINTS

- **The advent of anti-HER2 therapies have transformed the prognosis of HER2-overexpressing breast cancer.**
- **Dual targeting of HER2 with the antibodies pertuzumab and trastuzumab has been a successful strategy in both early and metastatic breast cancer.**
- **In the the metastatic setting, TDM-1, a novel antibody-drug conjugate, has become standard second-line therapy.**
- **In low-risk, early-stage breast cancer, modified protocols with limited chemotherapy are effective, although 12 months of anti-HER2 treatment remains the standard.**
- **Current neoadjuvant therapy results in higher pCR rates but also highlights the differences between estrogen receptor–positive, HER2-positive breast cancers and those that are HER2-positive but estrogen receptor negative.**

and alanine aminotransferase, respectively). An analysis of the EMILIA study showed that dose decreases may be associated with decreased efficacy, suggesting a rather narrow therapeutic window.[25] Of interest is that despite being a large antibody complex, there is activity against brain metastases seen in the EMILIA study and a number of other reports.

The TH3RESA study reported efficacy of T-DM1 for a heavily pretreated population, confirming the role of T-DM1 in advanced HER2-positive cancers. This randomized phase III study compared T-DM1 to physician's choice therapy and demonstrated an improved PFS of 6.2 months for T-DM1 compared with 3.3 months for physician's choice therapy ($p < .001$).[26]

In the first-line setting, a phase II study comparing T-DM1 to trastuzumab and docetaxel showed improvements in PFS of 14.2 months for T-DM1 compared with 9.2 months for trastuzumab, with an HR of 0.59 (95% CI, 0.36–0.97; $p = .035$).[27] MARIANNE was a three-arm randomized phase III study comparing trastuzumab plus a taxane (either paclitaxel or docetaxel) to single-agent T-DM1 or to the doublet T-DM1 and pertuzumab; it was hoped that this would to lead to the first-line approval for this well-tolerated drug.[28] Although expectations favored the experimental arms, there was disappointment for many when the addition of pertuzumab to T-DM1 did not improve the PFS of the monotherapy T-DM1. In addition, there was a noninferior PFS outcome for the two T-DM1 arms compared with the trastuzumab plus taxane arm. Fewer notable adverse events and better quality-of-life outcomes were seen for the two experimental T-DM1–containing arms. There was not a trastuzumab/pertuzumab arm similar to the CLEOPATRA cohort in the MARIANNE study. This trastuzumab/pertuzumab triplet remains the standard first-line treatment, except for selected patients who may not tolerate a taxane.

MM-302 is a new experimental agent comprising a HER2-targeted nanoparticle containing doxorubicin, a cytotoxic with well-known anti-HER activity.[28] MM-302 has been studied alone, in combination with trastuzumab, and in combination with cyclophosphamide and has demonstrated safety and preliminary efficacy. A phase II trial (HERMIONE) in anthracycline-naive advanced disease with prior progression on pertuzumab and T-DM1 that randomly assigned patients to receive MM-302 plus trastuzumab compared with physician's choice chemotherapy plus trastuzumab was recently closed early because an unfavorable futility analysis (NCT02213744).[29]

Other new agents. Ertumaxomab, a bispecific antibody targeting HER2 and cluster of differentiation-3 with selective binding to activatory Fcγ-type I/III receptors, has been shown to elicit an immune response and antitumor activity and is now in an open-label dose-escalating study of patients with HER2-expressing advanced solid tumors (NCT01569412).[30,31]

In addition, there are a number of studies of trastuzumab biosimilars being reported. These agents may have the role of providing choice for patients if these drugs are truly more advantageous economically.

Targeting of two pathways. Laboratory studies suggested that angiogenic pathways were active in HER2-positive cancers, leading to the idea of targeting both VEGF and HER2.[32] Many studies were initiated; in the advanced setting, the phase III trial of bevacizumab and trastuzumab in addition to docetaxel (AVEREL) did not show a statistically notable benefit for dual targeting of 424 patients who were randomly assigned to treatment, leading to a general abandonment of this combination strategy.[33] Other early strategies included combining heat shock protein agents with trastuzumab.[34] Although responses were seen, these have not led to large phase III studies or changes in guidelines.

With approximately half of HER2-overexpressing cancers also being estrogen receptor (ER)–positive, endocrine and anti-HER2 agents are an obvious combination in the advanced setting. An initial phase II study was done with trastuzumab and letrozole, with a 3.3-month PFS for the endocrine therapy alone and a 14.1-month PFS for the anti-HER2 therapy and endocrine therapy.[35] The phase III randomized TANDEM study of anastrozole and trastuzumab showed improvements in PFS with the addition of anti-HER2 therapy (from 2.4 months for anastrozole vs. 4.8 months for the combined anastrozole and trastuzumab).[36] The combination of lapatinib plus letrozole was studied in another large phase III trial. In the confirmed HER2-positive population, the median PFS rose from 3 months for the letrozole arm compared with 8.2 months for the lapatinib and letrozole arm, which led to the regulatory approval of this combination.[37] However, the results of both of these studies were inferior to those of trastuzumab with chemotherapy for this patient population, leading to a limited uptake of this strategy as upfront treatment of most patients with ER-positive, HER2-positive advanced breast cancer. This is an option for patients with low-burden disease or comorbidities. More recently, the phase II PERTAIN trial (NCT01491737) enrolled 258 postmenopausal women with HER2-positive, hormone receptor–positive, metastatic, or locally advanced breast cancer to receive first-line pertuzumab plus trastuzumab and an aromatase inhibitor (anastrozole or letrozole), or trastuzumab plus an aromatase inhibitor. Preliminary results showed that adding pertuzumab to trastuzumab and an aromatase inhibitor significantly reduced the risk of progression or death by 35% versus treatment with trastuzumab and an aromatase inhibitor alone (HR, 0.65; 95% CI, 0.48–0.89; $p = .0070$). The median duration of response was 27.1 months and 15.1 months in the pertuzumab arm and the trastuzumab-only arm, respectively (HR, 0.57; 95% CI, 0.36–0.91; $p = .02$).

Knowing that the phosphoinositide 3 kinase/protein kinase B (AKT)/mechanistic target of rapamycin (mTOR) pathway has been implicated in resistance and that activating mutations in PI3KCA or PTEN (phosphatase and tensin homolog) are seen in a large number of HER2-positive metastatic tumors, initial phase II studies combined everolimus with trastuzumab and either vinorelbine or paclitaxel to target mTOR concurrently with HER2.[38,39] There are now reports from two phase III studies that randomly assigned

patients with advanced HER2-positive breast cancer to receive either paclitaxel plus trastuzumab (BOLERO I) or vinorelbine plus trastuzumab (BOLERO III), each with an experimental arm adding oral everolimus. In BOLERO I, which was in the first-line setting, there was no improvement in PFS, although an analysis of the HER2-positive/ER-negative cohort suggested an improved PFS from 13.1 months to 20.3 months.[40] In BOLERO III, which was done in the later setting for patients who had progressed with prior trastuzumab, there was a statistically significant improvement in PFS from 5.78 months to 7.0 months (HR, 0.78; 95% CI, 0.65–0.95; p = .0067).[41] There was considerable toxicity seen with the addition of everolimus and no improvement in OS was reported at this time. This lack of clinically relevant benefit coupled with toxicity has not led to changes in standard clinical practice although some individual patients may benefit. Correlative work suggested that patients with low PTEN concentrations may preferentially respond, but this needs further evaluation prior to being considered a predictive marker. Newer and more specific phosphoinositide 3 kinase inhibitors are in clinical trials in the advanced HER2-positive setting, including alpelisib, taselisib, and pictilisib. A phase II study of alpelisib, an alpha-specific inhibitor, has shown tolerability and responses among patients who had previously progressed during or following treatment with T-DM1.[42]

More recently, a number of studies have been initiated with checkpoint inhibitors and either trastuzumab or T-DM1 in advanced HER2-positive breast cancer. Preclinical laboratory work, as well as the demonstration of tumor-infiltrating lymphocytes (TILs) in HER2-positive breast cancer, has led to excitement in this area and a number of studies. These include the phase Ib/II PANACEA trial, which is combining the anti–PD-1 inhibitor pembrolizumab (MK-3475) with trastuzumab (NCT02129556). The Canadian Clinical Trials Group is combining durvalumab with trastuzumab in multiply pretreated patients with HER2-positive metastatic breast cancer to assess toxicity and biologic activity (NCT0264968). In addition, defining which cancers may respond to these costly therapies will be important. Vaccines are also being studied and initial reports have shown immune responses.

Finally, an area of new interest is the combination of CDK4/6 inhibitors and anti-HER2 agents, with the preclinical evidence of activity in this subtype suggesting in transgenic mouse models that resistance may be overcome by this strategy and the tumors become resensitized to EGFR/HER2 blockade.[43] Currently, studies of palbociclib and T-DM1 (NCT01976169) and abemaciclib plus trastuzumab are being done after preliminary activity has been reported (NCT02675231). The PATRICIA trial is comparing palbociclib plus trastuzumab with or without letrozole for patients with triple-positive advanced cancers who have had prior trastuzumab treatment (NCT0244840).

Ongoing Issues

Although there has been major progress in the treatment of HER2-positive advanced breast cancer, there are a number of ongoing issues that have not been resolved. First, as new agents are introduced into the neoadjuvant and adjuvant settings, including potentially pertuzumab, the selection of drugs and the optimal sequence in the advanced setting for previously treated patients may need to be revised. There are currently no data on how long to continue treatment for patients who appear to have a complete response, leading to a rather ad hoc approach to these rare cases. Most patients continue with anti-HER2 therapy indefinitely, because there is concern about tumor recurrence. We continue to struggle with tumor resistance, because this is the major cause of treatment failure. How much does tumor heterogeneity impact resistance and will this limit some of our more specific and HER2-directed treatments? What are the mechanisms of resistance? Although there have been clues, we are still a long way from defining them among most individual patients. Serial sampling and cell-free DNA studies may help our understanding. A notable number of patients still develop central nervous system disease, which continues to be difficult to treat despite studies of new agents and intrathecal drugs, including intrathecal trastuzumab. The development of new drugs is not easy with the small numbers of patients with advanced HER2-positive disease eligible for studies in some centers, generally requiring multicenter trials, which adds to the complexity and expense. This is a statement of our success but does extend the time to develop potentially active agents, particularly in later lines of therapy. Finally, will patients be able to afford new agents in the future or possibly continued treatment in the present?

OPTIMIZING NEOADJUVANT/ADJUVANT TREATMENT OPTIONS FOR THE PATIENT WITH HER2-AMPLIFIED BREAST CANCER

It has now been 12 years since trastuzumab was first reported to significantly improve disease-free survival (DFS) for HER2-positive breast cancer in the curative setting.[44] The positive impact of trastuzumab cannot be overstated, because its use has been shown to alter the natural course of this disease, transforming it from an aggressive subtype with poor outcomes to one that may be expected to have a prognosis as favorable as HER2-normal disease (Table 1).[45-48]

In the past decade, findings from multiple studies have become available to inform the optimal treatment of this form of breast cancer. These trials have addressed fundamental issues, including optimal duration of trastuzumab, timing with chemotherapy, chemotherapy backbone, and relative risks and benefits of adding other novel biologic therapies, including the use of dual HER2 targeting. Importantly, ongoing studies are now addressing the use of less toxic regimens with novel therapeutics and are evaluating prognostic or predictive biomarkers for long-term outcome. These data will no doubt be invaluable in maximizing the therapeutic index for patients diagnosed with early-stage HER2-driven disease. This section reviews how results from large adjuvant studies have significantly influenced management of this disease and describes major findings from neoadjuvant clinical trials that have provided essential clinical and molecular information in an efficient and cost-effective manner.

Four Trials, One Enormous Breakthrough

In February 2000, the first phase III clinical trial to evaluate the use of adjuvant trastuzumab (NSABP B-31) was launched; within less than 2 years, three additional large randomized adjuvant trials dedicated to evaluating trastuzumab in HER2-overexpressing or amplified breast cancer were activated, including the NCCTG N9831, BCIRG-006, and BIG 01-01 HERceptin Adjuvant (HERA) studies[44,51,52] (Table 2). Updated results for each of these trials, with 8 years[53] to 10 years[50,54] of median follow-up, demonstrated persistent substantial DFS and OS benefits associated with the addition of trastuzumab to standard chemotherapy. The designs of each of these clinical trials, as well as the design and results of subsequent studies, have provided important data to guide optimal treatment of early-stage disease. These will each be considered below.

Optimal Timing of Trastuzumab With Chemotherapy

Although several studies used concurrent chemotherapy and trastuzumab,[44,51,56] two were designed to give the trastuzumab after chemotherapy.[52,57] In HERA, 5,102 patients who had completed adjuvant chemotherapy were randomly assigned to either observation or 1- or 2-year treatment with trastuzumab.[52] With 10 years of follow-up, DFS (HR, 0.77; 95% CI, 0.68–0.86; p < .0001) and OS (HR, 0.74; 95% CI, 0.64–0.86; p < .0001) remained statistically significantly better with a year of trastuzumab compared with observation.[54] In a similarly designed study (FNCLCC-PACS-04),[57] 528 patients with HER2-positive breast cancer were randomly assigned after chemotherapy to receive trastuzumab for a year or to undergo observation, but they did not demonstrate a notable improvement in DFS with trastuzumab; the small size of the study, coupled with the fact that only 84% of the patients received at least 6 months of trastuzumab, may explain these discordant results.

To date, the N9831 trial is the only study that has prospectively compared the sequential or concurrent approaches.[58] With a median follow-up of 6 years, patients treated with concurrent paclitaxel chemotherapy and trastuzumab had a 5-year DFS of 84.4% compared with 80.1% for patients treated with paclitaxel followed by trastuzumab (HR, 0.77; 99.9% CI, 0.53–1.11; p = .0216). Although this did not cross the prespecified boundary for significance (p = .00116), this trend toward an increase in DFS with the concurrent administration led the authors to conclude that trastuzumab should be given concurrently with taxane chemotherapy.

Optimal Length of HER2-Targeted Therapy

Although the original decision to give trastuzumab for 1 year was relatively arbitrary, we now have the benefit of data from several studies that have addressed the ideal length of trastuzumab treatment. In addition, several other studies addressing the optimal length of trastuzumab treatment have enrolled patients but results are yet to be reported. The HERA trial was the first to address length of therapy by including not only an observation and 1-year trastuzumab arm but also a 2-year trastuzumab arm.[52] At a median 8 years of follow-up, there was no difference in DFS for patients treated for 1 or 2 years (HR, 0.99; 95% CI, 0.85–1.14; p = .86).[55] Importantly, the rates of grade 3/4 adverse events were higher for patients in the 2-year group (20.4%) compared with the 1-year group (16.3%). This included a higher rate of cardiac toxicity (4.1% and 7.2% for the 1-year and 2-year groups, respectively).

To date, two trials that evaluated whether a shorter course of trastuzumab yields similar outcomes to 1 year have been reported. FinHer was a 1,010-patient trial, in which patients were randomly assigned to receive three cycles of docetaxel or vinorelbine followed three cycles of 5′ fluorouracil/epirubicin/cyclophosphamide.[56] The 232 women with HER2-positive breast cancer were randomly assigned to receive a 9-week course of trastuzumab concurrently with the vinorelbine or docetaxel. Three-year recurrence-free survival was significantly improved for trastuzumab-treated patients (HR, 0.42; 95% CI, 0.21–0.83; p = .01) with a trend toward improved OS (HR, 0.41; 95% CI, 0.16–1.08; p = .07).[56] With longer follow-up, however,[48] the distant DFS benefit was no longer statistically significant but still tended to be in favor

TABLE 1. Overall Survival for HER2-Positive, Trastuzumab-Treated Early Disease Similar to or Better Than HER2-Normal Disease

Study	Reference	Median Follow-Up (Years)	No. of Patients With HER2-Positive Disease (%)		No. of Patients With HER2-Negative Disease (%)
			Yes Trastuzumab	No Trastuzumab	
BCIRG-005 and BCIRG-006	Mackey et al[49] and Slamon et al[50]	10	1,841/2,149 (86)*	870/1,073 (81)	2,647/3,298 (80)*

Italian Registry	Musolino et al[45]	4.1	52/53 (98)*	140/161 (87)	1,108/1,186 (93)*
GeparQuattro	von Minckwitz et al[47]	5.4	392/446 (88)*		889/1,049 (85)*
FinHer[6]	Joensuu et al[48]	5	12/115 (90)	21/116 (82)	61/778 (92)

*Data from these studies indicate that, in general, HER2-positive trastuzumab-treated disease has a similar or better outcome than HER2-negative disease.

Studies that included patients with both HER2-positive (trastuzumab treated and trastuzumab nontreated) and HER2-negative disease are included (NOAH, Italian Registry, GeparQuattro, FinHer). In addition, BCIRG-005 (HER2 negative) and BCIRG-006 (HER2 positive) are included, because these studies were conducted at many of the same sites during similar time periods. Patients with HER2-positive disease were referred to BCIRG-006 and those with HER2-negative disease were referred to BCIRG-005.

TABLE 2. Four Large Initial Adjuvant Trastuzumab Trials

Trial	Reference	Arms	No. of Patients	DFS	OS	Hazard Ratio*		Median Follow-Up (Years)	Crossover (%)
						OS	DFS		
NCCTG N9831 and NSABP B-31	Perez et al[53]	NCCTG N9831**: AC → wP (group A), AC → wP → wH (group B),† and AC → wPwH (group C)	3,351	10-year DFS for groups C/2 vs. A/1: 73%, AC/PH; and 62%, AC/P	10-year OS for groups C/2 vs. A/1: 84%, AC/PH; and 75%, AC/P	0.63	0.60	8	20

*Statistically significant.

**NCCTG N9831: AC → P, doxorubicin/cyclophosphamide for four cycles followed by weekly paclitaxel 12×; AC→ wP → wH, doxorubicin/cyclophosphamide for four cycles followed by weekly paclitaxel 12× followed by weekly trastuzumab for 1 year; AC → wPwH, doxorubicin/cyclophosphamide for four cycles followed by weekly paclitaxel plus weekly trastuzumab 12× followed by weekly trastuzumab to complete a year.

†Not included in the joint analysis.

‡NSABP B-31: AC → P, doxorubicin/cyclophosphamide for four cycles followed by paclitaxel (weekly 12× or every 3 weeks 4×); AC → PwH, doxorubicin/cyclophosphamide for four cycles followed by paclitaxel (weekly 12× or every 3 weeks 4×) plus weekly trastuzumab followed by weekly trastuzumab to complete a year.

HERA: trastuzumab every 3 weeks for 1 year or 2 years.

BCIRG-006: AC/TH, doxorubicin/cyclophosphamide for four cycles followed by docetaxel/trastuzumab for four cycles, followed by maintenance with trastuzumab every 3 weeks to complete a year; AC/T, doxorubicin/cyclophosphamide for four cycles followed by docetaxel for four cycles; TCH, docetaxel/carboplatin/trastuzumab for six cycles followed by maintenance with trastuzumab every 3 weeks to complete a year.

Abbreviations: AC, doxorubicin; DFS, disease-free survival; H, trastuzumab; OS, overall survival; P, pertuzumab; PH, pertuzumab and trastuzumab; T, docetaxel; TCH, docetaxel/carboplatin/trastuzumab; wH, weekly trastuzumab; wP, weekly paclitaxel; wPwH, weekly paclitaxel plus weekly trastuzumab.

of trastuzumab-based therapy (HR, 0.65; 95% CI, 0.38–1.12; p = .12). Thus, although the safety and financial aspects of 9 weeks of trastuzumab treatment are attractive, the long-term benefits are not certain.

The second study reported to date to evaluate a shorter duration of trastuzumab is PHARE, a phase III noninferiority study aimed to evaluate 6 versus 12 months of trastuzumab for patients who had completed chemotherapy, surgery, and up to 6 months of trastuzumab treatment.[59] The prespecified noninferiority HR margin was set at 1.15. With a median follow-up of 42.5 months, the HR was 1.28 (95% CI, 1.05–1.56; p = .29); thus, noninferiority of 6 months of trastuzumab compared with 12 months was not demonstrated. An ongoing phase III study with a noninferiority DFS endpoint (PERSEPHONE) is also addressing 6 versus 12 months of trastuzumab. This study completed accrual of more than 4,000 patients in 2015. Cardiac safety data from the first 2,500 patients enrolled were reported in 2016, demonstrating a substantial reduction in cardiac events associated with 6 months of therapy compared with 12 months.[60]

Several studies addressing the optimal length of trastuzumab therapy are ongoing (Table 3). On the basis of currently available data, the standard of care remains 1 year of trastuzumab treatment. It should be noted that one phase III randomized study, EXTENET (described below), is evaluating a year of HER2-targeted therapy with neratinib for patients who already completed a full year of trastuzumab for early-stage disease.[61] Thus, in addition to evaluating a novel HER2-targeted therapy in the adjuvant setting, this study is addressing whether 2 years of HER2-targeted therapy improves outcomes compared with 1 year. A prespecified early analysis at the 2-year mark demonstrated that invasive DFS was significantly improved for patients who received neratinib, especially those with hormone receptor–coexpressing cancer. These intriguing data are in contrast with the 8-year HERA results, in which 2 years of trastuzumab did not provide additional benefit compared with 1 year, regardless of hormone receptor expression.[55] One theory to explain this differential outcome is that in contrast with trastuzumab, neratinib may more effectively interfere with receptor crosstalk between human EGFRs and ERs, leading to particular benefit in hormone receptor–positive tumors. Pending longer follow-up of this trial as well as data to guide management of the gastrointestinal toxicity associated with neratinib, 1 year of trastuzumab in the adjuvant setting remains the standard of care.

Optimizing the Cardiac Risk

Although the DFS and OS benefits of trastuzumab clearly support its use in the curative setting, the risk of cardiac

TABLE 3. Ongoing Studies Evaluating Duration of Trastuzumab

Study	No. of Patients (Enrollment Status)	ClinicalTrials.gov Identifier	Treatment Arms	Endpoint

Hellenic Oncology Research Group	489 (closed)	NCT00615602	FEC 4× → TH 4× → H for 6 months FEC 4× → TH 4× → H for 12 months	DFS

Abbreviations: AC, doxorubicin/cyclophosphamide; DFS, disease-free survival; EC, epirubicin and cyclophosphamide; FEC, fluorouracil/epirubicin/cyclophosphamide; H, trastuzumab; iDFS, invasive disease–free survival; TH, trastuzumab; THP, trastuzumab/pertuzumab.

toxicity should be carefully considered, especially in the early-stage setting, in which a relatively substantial proportion of patients may be cured with local measures alone. A meta-analysis that included eight randomized controlled trials of trastuzumab (11,991 patients) reported a 5.11 times higher risk of congestive heart failure (2.5% vs. 0.4%) and a 1.83 times higher risk of left ventricular ejection fraction (LVEF) decline (11.2% vs. 5.6%) for trastuzumab-treated patients compared with control-treated patients.[62] Although these rates of cardiac dysfunction are relatively low compared with the improvements in DFS and OS, it is concerning to note that 7%–10% of patients who began anthracycline-based chemotherapy in the B-31[63] and N9831[64,65] trials were unable to ever receive trastuzumab-based therapy because of unacceptably low cardiac function.

This raises an important point relating to the chemotherapy backbone: the majority of adjuvant trastuzumab trials used an anthracycline, making it difficult to distinguish the relative impact on cardiac outcome contributed by trastuzumab and anthracycline. Seven-year follow-up of the B-31 trial reported cardiac events for 4.0% of patients treated with trastuzumab compared with 1.3% of patients in the control arm.[63] The prevalence of clinically occult cardiac damage is difficult to gauge, however, because this study was designed to measure LVEF data for asymptomatic patients for up to only 18 months. Of 947 trastuzumab-treated patients in the B-31 trial, 12% stopped taking trastuzumab because of an asymptomatic decline in LVEF; altogether, 15.5% stopped trastuzumab prematurely, owing to cardiac-related issues.[63]

The N9831 study also reported the rates of asymptomatic LVEF decline observed in the 18–21 months postrandomization. Of 1,944 patients who began post-AC (doxorubicin/cyclophosphamide) treatment, LVEF declined 10% or more for 26% of patients treated with AC/T (arm A), 35% of those treated with sequential paclitaxel and trastuzumab AC/T/H (arm B), and 40% of those treated with concurrent paclitaxel trastuzumab AC/trastuzumab (arm C).[65] A small proportion of patients (33%) consented to have another LVEF measurement at the 6-year time point. Data from these 651 patients showed that a substantial proportion in each treatment arm had a decrease in LVEF of at least 10% (arm A, 21%; arm B, 20%; and arm C, 23%), a decrease in LVEF of at least 15% (arm A, 9%; arm B, 7%; and arm C, 9%), and a decrease to below the lower limits of normal (arm A, 6%; arm B, 5%; and arm C, 5%). The percentage of patients with LVEF decline was similar among the treatment arms, and the median LVEF change from baseline to year 6 also appeared to be similar among the three treatment arms (−3.0%, −2.5%, and −3.0% in arms A, B, and C, respectively), leading the authors to speculate that one explanation for long-term LVEF dysfunction may be related to anthracycline exposure as opposed to trastuzumab exposure.[65]

To date, the only adjuvant study comparing a nonanthracycline regimen to an anthracycline regimen is BCIRG-006.[51] This study was prospectively designed to not only evaluate the relative efficacy of the two trastuzumab-containing arms (docetaxel/carboplatin/trastuzumab [TCH] and doxorubicin/cyclophosphamide followed by AC/trastuzumab) to the AC/T control arm but also aimed to prospectively follow cardiac function out to 5 years. Data from 48 months of follow-up demonstrated congestive heart failure for 2.0% of patients in the AC/trastuzumab arm, 0.7% in the AC/T arm, and 0.4% in the TCH arm. Moreover, a decline in mean LVEF of greater than 10 points was reported for 18.6% of patients in the AC/trastuzumab arm, 9.4% in the TCH arm (AC/trastuzumab vs. TCH: $p < .001$), and 11.2% in the AC/T arm.[51] With over 5 years of follow-up, the decline in mean LVEF did not appear to persist over time in the TCH arm.[50] However, persistence in this decline was observed among anthracycline-treated patients. In terms of efficacy, with a median follow-up of 10.3 years, both trastuzumab-containing arms demonstrated significant improvements in both DFS (AC/trastuzumab vs. AC/T: HR, 0.72; $p < .0001$; TCH vs. AC/T: HR, 0.77; $p = .0011$) and OS (AC/trastuzumab vs. AC/T: HR, 0.63; $p < .0001$; TCH vs. AC/T: HR, 0.76; $p < .0075$).[50] Although the study was not powered to test equivalence of the two trastuzumab-based arms, it is notable that 10-year DFS was quite similar in the two trastuzumab arms for higher-risk

patients with lymph node–positive (69.6%, AC/trastuzumab; 68.4%, TCH) or 4 or greater lymph node–positive disease (62.8%, AC/trastuzumab; 62.9%, TCH). To date, more than 5,000 patients have been treated with TCH-based therapy in clinical trials.[51,66-70]

Optimal Study Design to Evaluate Novel Therapies: Neoadjuvant Versus Adjuvant Settings

Around the same time that the large adjuvant trastuzumab studies were enrolling patients, two studies were started to evaluate the use of trastuzumab in primary breast tumors.[71-73] Both showed that trastuzumab more than doubled pathologic complete response (pCR) rates and also improved relapse-free/event-free survival.[46,71,73] Subsequently, several other trials were conducted to evaluate neoadjuvant trastuzumab.[74-76] Collectively, data from these studies support the routine clinical use of neoadjuvant trastuzumab, especially for larger tumors.

Traditionally, clinical trials of new agents have been conducted in the adjuvant setting. However, there are several potential advantages to the use of a neoadjuvant study design. First, the pCR rate appears to be a reliable surrogate marker of long-term outcome, especially for HER2-positive breast cancer.[77] This enables a relatively rapid readout of primary endpoints as well as smaller sample sizes. Neoadjuvant studies have been conducted to compare the activity and safety of trastuzumab to lapatinib[78-80]; to evaluate dual HER2 targeting with trastuzumab plus lapatinib,[68,81-85] trastuzumab plus pertuzumab,[67,86] and T-DM1 plus pertuzumab[87]; and to gauge activity of combining HER2- and hormonally targeted approaches (Table 4).[70,88,89] In addition, the neoadjuvant setting allows for serial biopsies to be performed, thus enabling in vivo molecular analyses to be conducted to assess for novel markers of response or resistance to therapy. This will be critical as we aim to personalize treatment regimens to provide an individual the highest therapeutic benefit with the least amount of toxicity. That said, although the design allows for more cost-effective trials to be done in an efficient manner, their small size makes it unlikely these studies will be powered to evaluate long-term outcomes. Thus, adjuvant studies are still needed to validate promising findings from the neoadjuvant setting. It is hoped that utilization of the neoadjuvant study design for the testing of novel targeted therapeutics will allow for weeding out of the less effective or more toxic agents, thus sparing the high expense, long follow-up, and large patient numbers required in the adjuvant setting.

Optimal HER2-Targeted Agents

Tyrosine kinase inhibitors. Evidence supporting activity of the oral TKI lapatinib in the preclinical and metastatic settings provided strong rationale for the evaluation of lapatinib alone and in combination with trastuzumab in the adjuvant setting.[9,11,90-92] In the TEACH trial, 3,147 patients with HER2-positive stage I–IIIC breast cancer who had completed adjuvant chemotherapy were randomly assigned to lapatinib (1,500 mg daily) for 12 months or placebo.[93] With a median follow-up of approximately 4 years, lapatinib-treated

TEAL	30 (open)	NCT02073487	T-DM1/lapatinib → nanoparticle albumin–bound paclitaxel vs. trastuzumab/pertuzumab/paclitaxel	pCR

Abbreviations: DFS, disease-free survival; ETC, epirubicin/paclitaxel/cyclophosphamide; FEC, fluorouracil/epirubicin/cyclophosphamide; iDFS, invasive disease–free survival; pCR, pathologic complete response; PMCb, paclitaxel/nonpegylated liposomal doxorubicin/carboplatin; sq, subcutaneous.

patients had an 87% DFS compared with 83% for placebo-treated patients (HR, 0.83; 95% CI, 0.70–1.00; p = .053). It now appears, based on results from other comparative trials (discussed above and below), that lapatinib is less clinically active than trastuzumab. However, it is possible that the sequential administration of lapatinib after chemotherapy lessened its benefit. In addition, it is notable that a large proportion of patients enrolled when they were more than a year from their diagnosis of cancer (29% of lapatinib-treated patients were more than 4 years from their diagnosis) and, importantly, on central review, 21% of patients were found to have HER2-normal cancer. DFS analysis of the patients with centrally confirmed HER2-positive disease did suggest a significant reduction in risk (HR, 0.82; p = .04). That said, the DFS benefits were borderline at best, leading most to envision this as a negative study.

Another large study that evaluated lapatinib in the curative setting was ALTTO.[66,94] This study was unique, in that it not only compared a year of trastuzumab treatment (T) to a year of lapatinib, but it also evaluated a sequential arm (12 weeks of trastuzumab followed by 34 weeks of lapatinib) and an arm that used dual HER2 targeting. In 2011, the lapatinib arm was closed after an interim analysis determined futility to show noninferiority compared with trastuzumab/lapatinib. With a median follow-up of 4.5 years and a prespecified level of significance of .025 for each of the comparisons, lapatinib/trastuzumab was not shown to significantly improve DFS compared with trastuzumab (HR, 0.84; 95% CI, 0.70–1.02; p = .048), nor was trastuzumab followed by lapatinib shown to be different from trastuzumab (HR, 0.96; 95% CI, 0.80–1.15; p = .61). Moreover, compared to trastuzumab, lapatinib was associated with lower rates of completion of HER2-targeted therapy, owing to its notable toxicity.[94]

Lapatinib has also been evaluated in combination with chemotherapy in at least seven neoadjuvant clinical trials.[68,79-81,83-85] pCR rates with lapatinib were significantly inferior to trastuzumab in two trials making the head-to-head comparison.[79,80] The effects of single-agent lapatinib, trastuzumab, or their combination have been assessed in several of these trials.[68,81,83-85] Although all of these studies demonstrated numeric improvements in pCR with dual HER2 blockade, only two of these studies demonstrated a statistically notable improvement in pCR.[81,85] The toxicity associated with lapatinib resulted in lower rates of completion of HER2-targeted therapy in several of these trials.[81,83,85] Moreover, the pCR benefits noted in one of the studies (NeoALTTO) was not shown to translate into event-free survival benefits.[82]

Given its unfavorable safety profile and lack of demonstrated notable benefit in two large adjuvant studies and multiple smaller neoadjuvant studies, lapatinib is not considered appropriate therapy in the early-stage setting. That said, another TKI, neratinib, is showing promise in the adjuvant setting. As mentioned above, EXTENET is a phase III placebo-controlled study in which 2,840 patients who had completed trastuzumab were randomly assigned to 1 year of neratinib or placebo.[61] At 2-year follow-up, invasive DFS was 93.9% for neratinib-treated patients compared with 91.6% for the control arm (stratified HR, 0.67; 95% CI, 0.50–0.91; p = .0091). This benefit came at the expense of relatively severe gastrointestinal toxicity, with 40% of patients reporting grade 3 diarrhea. An ongoing study is being conducted to evaluate whether diarrhea can be mitigated with primary prophylaxis with loperamide (NCT02400476). At this point, neratinib is not available outside of a clinical trial.

Pertuzumab. In September 2013, based on the results of two relatively small phase II trials,[67,86] the U.S. Food and Drug Administration approved three neoadjuvant regimens for HER2-positive tumors greater than 2 cm in size. The three approved regimens all used dual HER2 targeting with pertuzumab and trastuzumab given concurrently with chemotherapy. One of the regimens approved (trastuzumab/pertuzumab 4×, followed postoperatively by fluorouracil/epirubicin/cyclophosphamide 3×) was based on the results of NeoSphere,[86] a four-arm randomized phase II trial that compared docetaxel plus either trastuzumab (TH), pertuzumab (TP), or both trastuzumab and pertuzumab. A fourth arm that used a chemotherapy-free regimen comprised of pertuzumab and trastuzumab was also included (HP). The pCR rates were significantly higher in the trastuzumab/pertuzumab arm and, importantly, the combination was shown to be relatively safe. The study was not powered to demonstrate event-free survival benefit but an exploratory analysis at 5-year follow-up showed a numerical trend in favor of the trastuzumab/pertuzumab arm compared with TH.[95] The other two regimens approved in 2013, docetaxel, carboplatin, trastuzumab and pertuzumab (TCHP) and fluorouracil/epirubicin/cyclophosphamide 3× followed by trastuzumab/pertuzumab 3×) were based on TRYPHAENA, a 225-patient, three-arm study primarily aimed to evaluate the cardiac safety of three pertuzumab/trastuzumab-based regimens.[67] pCR rates (in breast and lymph nodes) were similarly high among the three treatment arms (notably, 64% for TCHP and 55% for fluorouracil/epirubicin/cyclophosphamide followed by trastuzumab/pertuzumab). No long-term data from this study are currently available, but the tested regimens appeared to be safe from a cardiac perspective.

The largest neoadjuvant study reported to use pertuzumab and trastuzumab in combination with chemotherapy is GeparSepto.[96] This phase III trial was aimed to test noninferiority of nanoparticle albumin–bound paclitaxel–based chemotherapy to solvent-based paclitaxel. All patients with HER2-positive disease in this study (n = 396) received both pertuzumab and trastuzumab; thus, relative benefits imparted by dual HER2-targeted therapy compared with trastuzumab could not be assessed. pCR rates for the HER2-positive subset were 62% with nanoparticle albumin–bound paclitaxel and 54% with solvent paclitaxel (p = 0.13), providing further evidence of the activity of pertuzumab/trastuzumab-based therapy.

Although these data and the regulatory approval support the clinical use of trastuzumab and pertuzumab in the neoadjuvant setting, long-term safety and efficacy data from larger confirmatory studies are awaited (Table 3) before routine use of dual HER2 targeting in the adjuvant setting.

Optimizing Therapy for Hormone Receptor–Coexpressing Disease

At least half of HER2-positive breast cancer coexpresses one or both hormone receptors, and this coexpression may serve as a pathway for resistance to HER2-targeted therapy. This does not mean that HER2-targeted therapy is inactive in hormone receptor–positive breast cancer. In fact, analyses from the AC/trastuzumab and AC/T arms of the BCIRG-006[51] and B-31[53] trials show that the HRs for DFS are very similar for hormone receptor–positive (HR, 0.65 and 0.61 for BCIRG-006 and B-31, respectively) and hormone receptor–negative (HR, 0.64 and 0.62 for BCIRG-006 and B-31, respectively) disease. This also holds true for OS. Similarly, subset analysis of the HERA study at 10 years of follow-up also demonstrates long-term trastuzumab benefit for all patients regardless of HR status.[54] Although trastuzumab imparts DFS and OS benefit regardless of hormone receptor status, the presence of ER may indicate more indolent, luminal-like tumor behavior. For example, Kaplan–Meier curves from HERA indicate that although the long-term risk of recurrence is similar in hormone receptor–positive and hormone receptor–negative subtypes, patients with hormone receptor–negative disease have earlier recurrences, in keeping with more aggressive disease biology. Further evidence supporting the notion that disease behavior differs based on hormone receptor expression comes from neoadjuvant clinical trials, which have consistently shown that pCR rates are lower for hormone receptor–positive, HER2-positive breast cancer than for hormone receptor–negative disease.[67,77,81,83] That said, the longer follow-up of the NeoSphere trial[95] indicates that patients with hormone receptor coexpression have numerically higher PFS compared with those with tumors lacking hormone receptors (5-year PFS for patients who achieved pCR: 90% if hormone receptor positive, 84% if hormone receptor negative; 5-year PFS for patients who did not achieve pCR: 80% if hormone receptor positive, 72% if hormone receptor negative). Thus, patients with hormone receptor–positive tumors may do better in the long run. Intriguing biomarker analyses from HERA suggest that although ER-positive tumors with a high level of HER2 amplification (by FISH ratio) derive clear benefit from trastuzumab, those with a low level of HER2 amplification may not receive benefit from trastuzumab-based therapy.[97]

Several clinical trials aimed to evaluate cotargeting hormone receptor and HER2 have been conducted. The first of these, TBCRC-006, evaluated 12 weeks of neoadjuvant lapatinib plus trastuzumab (with letrozole for ER-positive tumors).[88] pCR (breast) in HER2-positive/hormone receptor–positive tumors was 21% in this proof-of-concept study, indicating that a relatively well-tolerated chemotherapy-free regimen might be highly effective for patients if accurate biomarkers for selection could be identified.

Trastuzumab emtansine has also been evaluated in the neoadjuvant and adjuvant settings. The WGS-ADAPT study compared four cycles of T-DM1, either alone or in combination with endocrine therapy, to trastuzumab plus endocrine therapy for patients with hormone receptor–positive, HER2-positive disease.[89] This relatively short course of T-DM1 was associated with an impressive pCR rate (breast and lymph nodes) of 41%, which was considerably higher than that achieved with trastuzumab plus endocrine therapy.

Although neither of these relatively small studies has changed the standard of care, the intriguing results should encourage the investigation of whether less toxic regimens like these might be beneficial for selected patient populations.

In December 2016, the results of the NSABP B-52 trial were presented. This study was designed to evaluate whether the addition of an aromatase inhibitor to standard chemotherapy plus HER2-targeted therapy (TCHP) would improve pCR rates for hormone receptor–positive/HER2-positive breast cancer, and to also test whether endocrine therapy would be antagonistic in combination with chemotherapy.[70] Although the addition of endocrine therapy to TCHP did not lead to a statistically notable improvement in pCR (41% for TCHP vs. 46% for TCHP plus endocrine therapy), it did not appear to be antagonistic, leaving room for future studies to test less toxic chemotherapy regimens concurrently with hormone therapy approaches.

In summary, in just over a decade, the management of early-stage HER2-positive breast cancer has changed drastically because of the development of highly effective biologically targeted therapy. The therapeutic options available to the patient in both the neoadjuvant and adjuvant settings are now nearly countless, making the choice of optimal therapy somewhat difficult at times. Our pursuit to provide patients with the safest and most effective therapies for their particular disease requires us to design carefully selected clinical trials with attention toward the discovery of molecular drivers of disease biology and markers of response to therapy.

DE-ESCALATING TREATMENT IN THE ADJUVANT SETTING IN HER2-POSITIVE DISEASE

Although there has been much work done to improve outcomes for patients with HER2-positive breast cancer by adding additional HER2-targeted agents to a standard chemotherapy backbone, it is important to consider that there may be some patients for whom we may be able to de-escalate treatment. One way to achieve this would be to use biomarkers that predict which patients are likely to benefit from less therapy. Although there are several biomarkers being explored, there is not yet one identified that can help us preselect patients for less therapy. Another approach would be to consider using clinical features to help determine which patients may be able to achieve good outcomes with less toxic regimens. Three clinical features we could consider to help us select patients

include tumor size, patient age, and response to preoperative therapy.

Using Biomarkers to De-escalate Therapy

Much work has been done to try to identify biomarkers that may help us identify patients that are likely to benefit to anti-HER2 therapy. A meta-analysis performed by Loibl et al[98] suggests that the presence of a PIK3CA mutation is associated with a significantly lower rate of pCR to anti-HER2 therapy; however, this difference in pCR was not associated with a difference in DFS. These data suggest that although those patients without a PIK3CA mutation may achieve better pCR rates than those with a mutation, the mutation is not predictive of long-term outcomes and thus cannot help us select patients that may be able to receive less therapy.

In a recent meta-analysis presented by Denkert et al,[99] high levels of TILs correlated with pCR rates among patients receiving anti-HER2 therapy and were associated with improved PFS. These data are in contrast with data from the N9831 study, which suggested that the presence of stromal TILs was associated with an improvement in recurrence-free survival of patients treated with chemotherapy alone but not of patients treated with chemotherapy and trastuzumab. In addition, high levels of stromal TILs were associated with lack of trastuzumab benefit.[100] Further work must be done to assess whether those patients with high TILs may achieve similar outcomes with less chemotherapy, and whether replacing chemotherapy with immunotherapy may be beneficial for these patients.

De-escalating Therapy Based on Clinical Parameters: Tumor Size

Systemic therapy for small (stage I) HER2-positive breast cancers has been a challenge for clinicians. This is largely attributable to the fact that the pivotal adjuvant trastuzumab trials included very few patients with stage I disease and even fewer with tumors smaller than 1 cm. In addition, as mammographic screening has become more widespread, the number of women diagnosed with T1 tumors has increased significantly. For example, among middle-aged women in the U.S. Surveillance, Epidemiology, and End Results registry, the diagnosis of T1 tumors increased from 143.5 per 100,000 to 163.5 per 100,000 women between 1990 and 1998.[101] Thus, providers face management of small, node-negative HER2-positive tumors with increasing frequency. Moreover, data from several retrospective studies looking at outcomes for patients with untreated tumors suggest that even the smallest node-negative HER2-positive tumors may have a substantial risk of recurrence (Table 5). Some of the most informative prognostic data for stage I HER2-positive breast cancers comes from a population-based cohort from British Columbia; this study demonstrated 10-year relapse-free survival of 71.6% for patients with stage I HER2-positive disease.[102] Similarly, a Finnish cohort of patients with pT1N0 disease had 72% 9-year distant DFS.[103] No patients in either cohort received trastuzumab therapy.

Studies looking at outcomes for T1abN0 tumors also suggest that even these tumors have a notable risk of recurrence. An MD Anderson Cancer Center study demonstrated that 5-year recurrence-free survival was 77.1% among 98 patients with untreated HER2-positive tumors that were less than or equal to 1 cm.[108] In a study examining a slightly larger population of patients within the National Comprehensive Cancer Network with similar disease characteristics, Vaz-Luis et al[110] demonstrated 5-year distant recurrence-free survival of 94%–96%. In a Kaiser Permanente study in which a minority of patients received chemotherapy and/or trastuzumab, 5-year distant invasive recurrence-free interval was 96.5%.[107,110] Although definitions for recurrence vary across retrospective studies and some trials included patients who received systemic therapy, the rates of recurrence across trials range from approximately 5% to 30%, indicating that these patients are at more than just minimal risk of recurrence.

Because these patients were excluded from the large adjuvant trials, the Adjuvant Paclitaxel and Trastuzumab (APT) trial was designed to prospectively address treatment of patients with small, node-negative HER2-positive breast cancer.[111] Eligible patients in this single-arm trial had a primary tumor size of less than or equal to 3 cm and had node-negative or N1mic disease (nodal disease greater than 0.2 mm but not more than 2 mm). Patients were treated with weekly paclitaxel and trastuzumab for 12 weeks, followed by completion of 1 year of trastuzumab. The study enrolled 406 patients, of which 67% had hormone receptor–positive tumors and 49.5% of tumors were less than or equal to 1 cm; 8.9% of patients had tumors greater than 2 cm and 1.5% of patients had N1mic disease (the remainder had N0 disease). Survival free from invasive disease, the primary endpoint of the trial, was 98.7% (95% CI, 97.7%–99.8%) at 3 years. Toxicity in the APT trial was minimal; 3.2% of patients experienced an asymptomatic but notable decline in cardiac ejection fraction, 0.5% of patients (2 patients) developed symptomatic heart failure. The majority of cardiotoxicity events were reversible after trastuzumab was held.[111] In a substudy of chemotherapy-related amenorrhea following the adjuvant trastuzumab regimen, which included 64 APT trial participants who were premenopausal at the time of APT trial enrollment, 28% of women were amenorrheic at a median of 51 months from study enrollment.[112] This compares favorably to the approximately 50% rate of chemotherapy-associated amenorrhea seen for premenopausal recipients of the standard AC/trastuzumab adjuvant regimen[113] and suggests that the trastuzumab regimen may have the added benefit of decreased fertility concerns among young, appropriately selected women with HER2-positive cancers.

Another prospective, single-arm phase II trial that looked at treatment of patients with early-stage HER2-positive breast cancer administered four cycles of docetaxel with cyclophosphamide and trastuzumab, followed by every-3-week trastuzumab to complete a year of therapy.

Of those patients enrolled, 284 (57.6%) had stage I HER2-positive disease. Three-year DFS for patients with node-negative disease was 97.8% (95% CI, 95.6–98.9).[114] Because this DFS is very similar to outcomes in the APT trial, there is likely little role for the addition of cyclophosphamide in the management of the lowest-risk HER2-positive tumors. Work is ongoing to determine whether even less toxic regimens may be effective in this population. The ATEMPT trial (NCT01853748) recently completed accrual and randomly assigned patients in a 3:1 fashion to T-DM1 or to the paclitaxel plus trastuzumab regimen used in the APT trial. This study was designed to compare clinically relevant toxicities between the two arms and to also examine DFS among those patients receiving T-DM1.

De-escalating Therapy Based on Patient Age

Elderly individuals comprise another group of patients for whom we should consider de-escalation of therapy. Data from Freedman et al[115] looking at the incidence of early-stage HER2-positive disease by age within the National Comprehensive Cancer Network showed that 26% of cases arise for patients older than age 60. These data also demonstrate that older patients were less likely to receive adjuvant trastuzumab, and those with notable comorbidity appear to be less likely to complete adjuvant trastuzumab therapy. Given evidence that shorter-duration trastuzumab adversely affects outcomes,[59] adherence to trastuzumab may be an important factor to consider when selecting an initial regimen. Previously conducted clinical trials of adjuvant trastuzumab-based regimens included few older patients, with women older than age 60 comprising approximately 15% of all participants. In addition, patients older than age 70, as well as those with cardiac conditions, were either excluded or poorly represented. Because trial eligibility is selective with regard to comorbidities, the landmark trials of trastuzumab provide limited data regarding tolerability and effectiveness of therapy among older patients. Multiple studies do, however, suggest that older women with more cardiac comorbidity may be at higher risk of cardiac toxicity with anthracycline-based therapy.[105,116,117]

When making decisions about these patients, it is important to factor in the potential benefits and toxicities of therapy, particularly in disease settings like HER2-positive cancer, in which recurrences can occur earlier rather than later. Older patients without notable comorbidities should be considered for standard adjuvant regimens; however, individuals with multiple medical problems may be those

that should be considered for less toxic treatments. The ATOP trial (NCT02414646) is currently assessing a less toxic regimen for older patients; in this trial, patients older than age 60 with stage I–III HER2-positive breast cancer, for whom standard regimens are not felt to be appropriate, are treated with 1 year of adjuvant T-DM1. Another study looking at de-escalation of therapy for older patients is the RESPECT trial (NCT01104935) conducted in Japan, which is randomly assigning women age 69–81 with stage I–IIIA HER2-positive breast cancer to treatment with trastuzumab alone versus trastuzumab plus chemotherapy. This study will have the potential to address the question of whether trastuzumab monotherapy has a place in treated elderly patients with HER2-positive disease.

De-escalation of Therapy Based on Response to Preoperative Therapy

Consideration of de-escalation of therapy is also warranted for the group of patients who achieve a pCR to preoperative therapy. Data suggest that patients with HER2-positive breast cancer who achieve a pCR have better long-term outcomes, with improved DFS and OS.[77] In a pooled analysis of 12 international trials (11,955 patients), a notable association was found between pCR and event-free survival. There is, however, no association of treatment effects on long-term outcomes, suggesting that randomized trials with long-term follow-up are needed to understand outcomes for specific therapies. It is therefore critical that we begin designing clinical trials to assess outcomes for patients who achieve a pCR to a highly active regimen, rather than just administering further therapies with associated toxicities that may not be providing additional benefit. We should also consider using escalation of biologic therapy as a mechanism to de-escalate chemotherapy. If adding pertuzumab to trastuzumab-based chemotherapy is found to improve long-term outcomes in the APHINITY trial, perhaps patients may achieve similar outcomes with less chemotherapy and highly effective biologic therapy. One strategy would be to consider doing a prospective randomized trial of doxorubicin/cyclophosphamide/taxane with trastuzumab and pertuzumab compared with a taxane plus trastuzumab and pertuzumab regimen and see whether patients receiving less chemotherapy can do just as well.

Optimizing Breast Cancer Adjuvant Radiation and Integration of Breast and Reconstructive Surgery

Henry M. Kuerer, MD, PhD, Peter G. Cordeiro, MD, and Robert W. Mutter, MD

OVERVIEW

Postmastectomy radiotherapy (PMRT) reduces the risk of locoregional and distant recurrence and improves overall survival in women with lymph node–positive breast cancer. Because of stage migration and improvements in systemic therapy and other aspects of breast cancer care, the absolute benefit of PMRT and regional nodal irradiation may be small in some favorable subsets of patients with very low nodal burden, and newer consensus guidelines do not mandate PMRT in all node-positive cases. The use and need for PMRT may considerably complicate breast reconstruction after mastectomy and therefore mandates multidisciplinary input that takes into account patient choice given potential risk of acute and long-term toxicities, benefits, life expectancy, the biology of the tumor, plans for systemic therapy, and actual tumor burden. Management of axillary lymph node metastases is changing with selective use of axillary lymph node dissection for advanced disease, sentinel lymph node biopsy alone for clinically and pathologic node-negative cases receiving mastectomy, and targeted axillary dissection alone among patients with eradication of initial biopsy-proven nodal metastases with neoadjuvant systemic therapy use. In general, when the need for PMRT is anticipated, autologous reconstruction should be delayed. This comprehensive article reviews the current indications and implications regarding integration of breast cancer surgery and timing of reconstruction with optimum radiation delivery to achieve the best possible patient outcomes.

In contemporary practice, there is uniform consensus that PMRT is indicated for patients at high risk of local regional failure, such as those with stage III breast cancers. However, locoregional and distant recurrence rates are lower than in past decades when randomized controlled trials demonstrated overall survival benefits in all patients with lymph node–positive disease.[1-3] Therefore, there is much controversy on the role of PMRT in patients with earlier stage breast cancer, particularly among those with low-volume nodal metastases identified with sentinel lymph node (SLN) dissection. Added to this treatment conundrum, recent evidence suggests that regional nodal irradiation (RNI) in itself may provide a survival benefit in patients with early-stage breast cancer despite only modest reductions in locoregional recurrence.[4-6] These RNI studies highlight the importance of long-term follow-up of prospective studies to fully assess the impact of locoregional therapies on breast cancer–specific and all-cause mortality. At the same time, stage migration from increased screening and improved diagnostic imaging, in addition to advances in systemic therapy, surgical techniques, pathologic evaluation, and radiotherapy delivery, all must be taken into consideration when applying the results from past locoregional studies to patients assessed in the clinic today.[7] These advances add complexity to counseling regarding the absolute risks and benefits of PMRT for each individual patient. In this context, new consensus guidelines related to the use of PMRT were recently released by the ASCO, the American Society for Radiation Oncology (ASTRO), and the Society of Surgical Oncology (SSO) to provide additional guidance on some continued areas of controversy, including the role of PMRT in patients with one to three positive lymph nodes, the role of PMRT in the setting of preoperative chemotherapy, as well as technical aspects of PMRT such as indications for internal mammary node irradiation (IMNI).[2]

Coupled with great institutional variability in applying PMRT and RNI guidelines is the complexity of integrating breast and nodal surgery together with plastic reconstructive surgery. Breast cancer nodal metastases plays a considerable role in determining radiotherapy indications and treatment targeting, yet recently there have also been marked changes in axillary management, starting with SLN biopsy for clinically node–negative disease and newer techniques to stage the axilla after neoadjuvant systemic therapy in node-positive breast cancer and new trial results related to use of adjuvant radiotherapy without completion dissection for SLN-positive breast cancer. Finally, patient decisions regarding whether to pursue immediate reconstruction

may be impacted by a recommendation for PMRT, as PMRT may increase the risk of complications and adverse cosmetic outcome, and immediate reconstruction has been reported to pose challenges to PMRT delivery.[8-10] All of these factors underscore the imperative of close communication by multidisciplinary teams to best prospectively coordinate and deliver patient-centered breast cancer care. This special ASCO educational article will address the current indications and implications regarding integration of breast cancer surgery with optimum radiation delivery to achieve the best possible patient outcomes.

INDICATIONS AND IMPLICATIONS FOR OPTIMAL CONTEMPORARY ADJUVANT RADIATION THERAPY DELIVERY

The PMRT Randomized Controlled Trials

In the period from 1978 to 1990, three seminal randomized controlled trials (Table 1) were conducted (one in British Columbia, Canada, and two in Denmark) that evaluated the role of PMRT in patients receiving systemic therapy.[11-13] Eligibility criteria included one or more pathologically involved axillary lymph node. In addition, approximately 8% and 10% of patients in the premenopausal Danish Breast Cancer Cooperative Group (DBCG) 82b study and the postmenopausal DBCG 82c study, respectively, were node negative and enrolled on the basis of a primary tumor more than 5 cm or invasion of the skin or pectoral fascia. Each study reported similar findings, a 9% to 10% absolute improvement in 10-year overall survival with the addition of PMRT. However, there has remained heterogeneity in the uptake of PMRT, particularly in the subset of women with one to three positive nodes. Some physicians have favored offering PMRT in the majority of women meeting eligibility criteria (i.e., one or more positive lymph nodes) based on the high level of evidence provided by these prospective randomized controlled trials.[14] Others highlighted that inadequate axillary surgery and inadequate systemic therapy regimens without taxanes and anti-HER2 therapy have limited applicability to patients with low nodal burden in modern practice who have much lower recurrence rates.[15,16] In the DBCG 82b and 82c studies, a median of just seven lymph nodes were identified in pathologic specimens from axillary dissections. In the British Columbia study, the median number was 11. To address these concerns, the DBCG performed an analysis of patients with one to three positive lymph nodes from the DBCG 82b and 82c studies but in which they excluded patients with fewer than eight nodes removed. That analysis demonstrated a statistically significant overall survival benefit with the addition of PMRT (57% vs. 48%; p = .03).[14] In 2014, the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) published an individual patient data meta-analysis on the effects of PMRT. In it, they specifically assessed the role of PMRT in patients who underwent axillary lymph node dissection. For the 1,133 women with one to three positive nodes who underwent axillary lymph node dissection and received systemic therapy, PMRT reduced the 20-year breast cancer mortality rate from 49.4% to 41.5% (relative risk 0.78; p = .01).[17] These findings lead to unanimous agreement by an ASCO/ASTRO/SSO expert panel in 2016 that PMRT reduces recurrence and breast cancer mortality for patients with T1-T2 breast cancer with one to three positive axillary lymph nodes.[18] However, there was also recognition by the ASCO/ASTRO/SSO panel that patients with T1-T2 breast cancer and one to three positive nodes are a heterogeneous group with varying prognoses. They highlighted that subsets of patients in this population are likely to have such a low recurrence risk that the benefit of PMRT may be outweighed by the potential risks.[18]

Indeed, improvements in systemic therapy have significantly reduced both locoregional and distant recurrence risk because the three landmark randomized PMRT studies were conducted. It is noteworthy that patients included in the aforementioned EBCTCG analysis received cyclophosphamide, methotrexate, and fluorouracil (CMF), or tamoxifen, and the duration of tamoxifen for most patients was just 1 year.[17] These agents and schedules have since been replaced by more effective strategies, including anthracyclines, taxanes, HER2-targeted therapies, and prolonged endocrine therapy, frequently with aromatase inhibitors. In addition, the introduction of SLN dissection has resulted in the identification of smaller volume axillary macro- and micrometastases.[19] Therefore, improvements in both multidisciplinary management and stage migration have reduced

KEY POINTS

- **Prospective multidisciplinary review, communication, and coordination is necessary to optimize breast cancer local-regional control, survival, cosmetic outcome, and define a unified clear patient-centered path forward.**
- **PMRT reduces the risk of locoregional and distant recurrence and improves overall survival in women with lymph node–positive breast cancer. Because of stage migration and improvements in systemic therapy and other aspects of breast cancer care, the absolute benefit of PMRT may be small in some favorable subsets of patients with very low nodal burden.**
- **PMRT use may complicate breast reconstruction and requires multidisciplinary input that takes into account patient choice given potential risk of acute and long-term toxicities, benefits, life expectancy, the biology of the tumor, plans for systemic therapy, and actual tumor burden.**
- **Management of axillary lymph node metastases is changing with selective use of axillary lymph node dissection for advanced disease, sentinel lymph node biopsy alone, and targeted axillary dissection alone among patients with eradication of initial biopsy-proven nodal metastases with neoadjuvant systemic therapy.**
- **Immediate two-stage implant-based reconstruction is usually preferable in the majority of patients with breast cancer facing PMRT due to its preservation of autologous tissue and often acceptable outcomes, and PMRT can be administered either to the tissue expander or the final implant.**

TABLE 1. Select PMRT and RNI Randomized Controlled Trials

Study	Dates	No. of Patients	Inclusion Criteria	Systemic Therapy	Radiotherapy Target	Locoregional Recurrence	Distant Recurrence	Disease-Free Survival	Breast Cancer–Specific Survival	Overall Survival
British-Columbia	1979–1986	318	Premenopausal, pN+	CMF for 6–12 months	Chest wall, axillary, SC, and bilateral IMNs	20-yr ILRFS, 90 (RT) vs. 74% (no RT); p = .002. For 1–3 positive nodes, 91 vs. 79%	20-yr SBCFS, 48 (RT) vs. 31% (no RT), p = .004. For 1–3 positive nodes, 58 vs. 44%	20-yr BCFS, 48 (RT) vs. 30% (no RT); p = .001. For 1–3 positive nodes, 57 vs. 41%	20-yr BCSS, 53 (RT) vs. 38% (no RT); p = .008. For 1–3 positive nodes 64 vs. 53%	20-yr OS, 47 (RT) vs. 37% (no RT); p = .03. For 1–3 positive nodes, 57 vs. 50%
DBCG 82b	1982–1989	1,708	Premenopausal, pN+, or primary tumor > 5 cm, invasion of skin or pectoral fascia	CMF eight to nine cycles	Chest wall, axillary, SC and IMNs	Isolated LRR alone as first event 5 (RT) vs. 26% (no RT)	Distant metastases alone as first event 34 (RT) vs. 26% (no RT)	10-year DFS, 48 (RT) vs. 34% (no RT); p < .001. For 1–3 positive nodes, 54 vs. 39%	Not reported	10-yr OS, 54 (RT) vs. 45% (no RT); p < .001. For 1–3 positive nodes, 62 vs. 54%
DBCG 82c	1982–1990	1,375	Postmenopausal, age < 70, pN+, primary tumor > 5 cm, invasion of skin or pectoral fascia	Tamoxifen for 1 yr	Chest wall, axillary, SC and IMNs	Isolated LRR alone as first event 4 (RT) vs. 29% (no RT)	Distant metastases alone as first event 25 (RT) vs. 39% (no RT)	10-year DFS, 36 (RT) vs. 24% (no RT); p < .001. For 1 3 positive nodes 44% vs. 31%	Not reported	10-yr OS, 45 (RT) vs. 35% (no RT); p = .03. For 1–3 positive nodes, 55 vs. 44%
EORTC 22922/10925	1996–2004	4,004	Stage I, II, or III with a centrally or medially located primary tumor, irrespective of axillary involvement, or pN+ and externally located	According to institutional practice; of patients enrolled, 25% received chemotherapy, 30% received hormonal therapy, and 30% received both.	Breast or with/without chest wall vs. breast or with/without chest wall and RNI (axillary, SC, and IMNs)	Locoregional events 8 (RNI) vs. 10% (no RNI)	10-yr DDFS 78 (RNI) vs. 75% (no RNI); p = .02	10-yr DFS 72 (RNI) vs. 69% (no RNI); p = .004	10-yr breast cancer mortality 12 (RNI) vs. 14% (no RNI); p = .02	10-yr OS, 82 (RNI) vs. 81% (no RNI); p = .06

TABLE 1. Select PMRT and RNI Randomized Controlled Trials (Cont'd)

Study	Dates	No. of Patients	Inclusion Criteria	Systemic Therapy	Radiotherapy Target	Locoregional Recurrence	Distant Recurrence	Disease-Free Survival	Breast Cancer–Specific Survival	Overall Survival
NCIC MA.20	2000–2007	1,832	pN+ or primary tumor ±5 cm or primary tumor ±2 cm, < 10 axillary nodes removed, and one of grade 3, ER negativity, or lymphovascular invasion	According to institutional practice; of patients enrolled. 86% received an anthracycline; 25% received both an anthracycline and taxane; 57% received an aromatase inhibitor, and 19% received tamoxifen. After June 2005, trastuzumab was recommended for patients with HER2-positive disease.	Breast vs. breast plus RNI (axillary, SC, and IMNs)	10-yr ILRFS, 95 (RNI) vs. 92% (no RNI); p = .009	10-yr DDFS, 86 (RNI) vs. 82% (no RNI); p = .03	10-yr DFS. 82, (RNI) vs. 77% (no RNI); p = .01	10-yr breast cancer mortality, 10 (RNI) vs. 12% (no RNI); p = .11	10-yr OS, 83 (RNI) vs. 82% (no RNI); p = .38

Abbreviations: BCFS, breast cancer–free survival; BCSS, breast cancer–specific survival; CMF, cyclophosphamide, methotrexate, and fluorouracil; DDFS, distant disease-free survival; DFS, disease-free survival; ER, estrogen receptor; ILRFS, isolated local recurrence-free survival; IMNS, internal mammary node; LRR, locoregional recurrence; OS, overall survival; pN+, pathologically node positive; RNI, regional nodal irradiation; RT, radiotherapy; SBCFS, systemic breast cancer–free survival; SC, supraclavicular; yr, year.

the absolute risk of recurrence in patients with one to three positive lymph nodes considered for PMRT compared with years past and with it the absolute risk reduction that can likely be expected for some subsets with the addition of PMRT.[20-22] Yet more recently published prospective studies still demonstrated improvements in the therapeutic ratio with the addition of RNI (i.e., high axillary, supraclavicular, and internal mammary irradiation) in more contemporary treated populations with low axillary nodal burden.

IMNI, RNI, and the Relationship Between Locoregional and Distant Relapse

The National Cancer Institute of Canada MA.20 clinical trial assessed the role of the addition of RNI to whole breast irradiation (WBI) in women after breast-conserving surgery.[4] Fifty percent of the study population consisted of women with just one positive axillary lymph node, and 85% had one to three positive nodes. An additional 10% of women had high-risk node-negative disease. Eighty-six percent of patients received anthracycline-based chemotherapy, and 26% also received a taxane. Both tamoxifen and aromatase inhibitors were administered according to institutional practice, with 57% receiving an aromatase inhibitor alone or after a period of tamoxifen and 19% receiving tamoxifen alone. HER2-directed therapy was only recommended in the final 20 months that the study was open. MA.20 did not meet its primary endpoint of a 5% improvement in 5-year survival. Moreover, the 2% absolute improvement in 10-year rate of breast cancer mortality with the addition of RNI to WBI did not reach significance (hazard ratio 0.80; p = .11). However, RNI significantly improved the 10-year rate of disease-free survival from 77.0% to 82.0% (hazard ratio 0.76; p = .01). Interestingly, the absolute improvement in the rate of 10-year distant disease-free survival with the addition of RNI to WBI was 4.0%, greater than the 3.0% improvement in 10-year isolated locoregional disease-free survival. In the same journal issue, the European Organization for Research and Treatment of Cancer (EORTC) published results of EORTC 22922/10925, which also evaluated the role of RNI in patients with early-stage breast cancer.[5] The study population was slightly different than MA.20, with 44% of the population being node negative and 24% having undergone mastectomy. In this larger study, the 2% absolute improvement in breast cancer mortality with the addition of RNI reached statistical significance (hazard ratio 0.82; p = .02). Similar to MA.20, a provocative finding was that RNI prevented more distant events than locoregional events.

MA.20 and EORTC 22922/10925 evaluated the role of comprehensive RNI, including axillary, supraclavicular, and IMNI. Despite IMNI being a component of PMRT in 20 of the 22 trials in the EBCTCG analysis, the need for IMNI has been questioned, as the risk of isolated nodal failures in the IMNs has historically been reported to be 1% or less.[5,15] In addition, targeting the IMNs increases the dose to the heart and lungs, raising concern that IMNI could increase the late effects of treatment.[23] DBCG-IMN was a prospective population-based cohort study that specifically evaluated the effect of IMNI in patients with node-positive early-stage breast cancer.[6] All patients with right-sided disease were allocated to IMNI, whereas patients with left-sided disease received no IMNI to minimize cardiac exposure. The majority of patients enrolled had one to three positive nodes. With a median follow-up of 8.9 years, right-sided patients who received IMNI had an 8-year overall survival rate of 75.9% versus 72.2% for left-sided patients treated without IMNI (hazard ratio 0.82; p = .005). The results of these three studies evaluating nodal irradiation contradict a highly cited principle put forth in an earlier EBCTCG analysis of trials initiated between 1951 and 1991 that differences in radiotherapy and extent of surgery that result in a less than 10% difference in 5-year local recurrence risk are unlikely to impact breast cancer mortality.[24] Given the relatively high number of distant events prevented, the findings suggest that clinically substantial residual locoregional disease may go undetected or be only detected after a distant relapse has occurred. Therefore, caution should be exercised if de-escalating radiotherapy based on retrospective locoregional patterns of failure data alone.[16,25,26]

It is worth noting that most clinically detected locoregional recurrences after mastectomy occur on the chest wall, not in the regional lymphatics.[15,27] The data from MA.20 and EORTC 22922/10925 is not directly applicable to PMRT because the majority of patients in these studies underwent breast conservation therapy. However, because PMRT typically includes both chest wall and RNI, it is reasonable to infer that if patients with similar disease features were treated with mastectomy, the proportional and absolute reduction in recurrence with PMRT would have been at least as great. At the same time, favorable long-term breast cancer event rates have been reported in single-institution retrospective analyses of well-staged and carefully selected patients (a majority with T1, estrogen receptor–positive, and a single involved axillary micro- or macrometastases) treated with mastectomy and systemic therapy without PMRT.[1,28] In women with one to three positive lymph nodes being considered for PMRT, radiation oncologists must carefully consider individual patient and clinical features that not only influence the risk of locoregional relapse, but also distant relapse. Factors such as patient age, tumor size, number, size, and percentage of sampled nodes involved, grade, subtype, proximity of margins, and molecular profiling, if available, may all assist in estimating a patient's risk of recurrence and assist in identifying those with low nodal burden who are most likely to benefit from PMRT.[4,5,16,25,27,29-33]

PMRT in the Setting of Neoadjuvant Chemotherapy

Increasingly, patients are being treated with preoperative systemic therapy, and for most breast cancer subtypes, tumor response is the most important prognostic factor for recurrence in that setting.[34] Patients with residual disease in the lymph nodes after preoperative chemotherapy are at elevated risk of recurrence, and it is generally agreed that these patients should be treated with PMRT.[35,36] Patients who have a complete response in the breast but residual

disease in the axillary nodes after preoperative chemotherapy have a similar risk of recurrence as those with residual disease in both the breast and nodes and should also receive PMRT.[37] Whether such an approach is also appropriate for low-grade, slowly proliferating estrogen receptor–positive tumors (i.e., luminal A tumors) in whom preoperative endocrine therapy approaches are increasingly considered is uncertain and warrants further investigation.[38] Although retrospective analyses suggest locoregional recurrence risk is low, there is a dearth of prospective data on the benefits of administration or the safety of omitting PMRT in patients with lymph node–positive clinical stage II breast cancer who are converted to node negative after preoperative systemic therapy or who achieve a pathologic complete response in both the breast and axillary nodes.[39,40] The NRG Oncology Group 9353 trial randomizes patients with biopsy-proven axillary node involvement before preoperative chemotherapy who become pathologically node negative at the time of mastectomy to PMRT or no irradiation. In patients who undergo lumpectomy, the randomization is to WBI versus whole breast plus RNI (NCT01872975). Eligible patients are best treated as part of this clinical trial.

Toxicity of Radiotherapy in Modern Practice

Finally, the potential benefits in disease control with the administration of radiotherapy must be weighed with the risks of toxicity in each individual patient and take into consideration their values on minimizing treatment morbidity versus avoiding recurrence. For example, complications of PMRT are higher in women pursuing implant-based reconstruction (discussed below), as well as those who have previously undergone axillary lymph node dissection, relative to SLN biopsy.[41-43] Although toxicity outcomes of patients treated in past eras provide valuable lessons on the importance of optimizing radiotherapy delivery, the multidisciplinary team must be familiar with the expected acute and late toxicity of PMRT using the techniques and technology of today, not of decades past.[44,45] For example, a greater appreciation for the potential risks of low-dose cardiac irradiation and improved radiotherapy planning and delivery have led to much lower cardiac exposure in women undergoing radiotherapy today.[45] Proton therapy is being investigated for breast cancer and routinely enables heart, lung, and other nontarget normal tissue doses to be significantly lower than optimized photon and/or electron techniques and can further improve targeting of the IMNs in patients with challenging anatomy, such as those with bilateral reconstruction (Fig. 1).[46-50] Therefore, there is strong justification to support clinical trials and prospective registries investigating whether these newer techniques can further improve long-term outcomes.

PMRT Targeting and Techniques

PMRT should be delivered to both the chest wall and regional lymphatics, including the IMNs, provided that appropriate normal tissue constraints can be met.[18] At the Mayo Clinic in Rochester, MN, 50 Gy in 25 fractions is prescribed. We do not routinely boost the chest wall given concern about the potential additional risk to the reconstructed breast mound.[42] For photon PMRT, in cases of bilateral reconstruction, we routinely deflate the contralateral expander before CT simulation to avoid exposure from partially wide tangents that are generally used to target the IMNs. An added advantage of proton therapy is that contralateral tissue expander deflation is not necessary because protons are administered from anteriorly directed beams.[46] For both photon and proton PMRT, the ipsilateral expander is overinflated before simulation to facilitate the second stage of reconstruction and is maintained in the same state during treatment to ensure reproducibility of the radiotherapy plan. Evidence suggests that proton therapy further improves targeting in the setting of immediate reconstruction.[46,48,50] In patients undergoing WBI, hypofractionation resulted in less acute and late toxicity than conventional fraction.[51] Whether hypofractionated schedules can further improve the therapeutic ratio in patients undergoing PMRT, including those with reconstruction, is an important area of future investigation.

In summary, the absolute benefit of PMRT in some subsets of women with node-positive breast cancer is likely smaller in today's practice because of a lower baseline risk of recurrence. However, the relative benefit of PMRT may be greater because of improved systemic therapy, resulting in less risk of early systemic dissemination, better targeting of areas at risk with modern treatment planning, and reductions in dose to nontarget normal tissues. Thus, careful multidisciplinary consideration of individual risk factors for recurrence, toxicity, and patient values is crucial to optimize patient counseling. Investment by all stakeholders in locoregional therapy randomized studies will be required to address many of the controversies that persist.

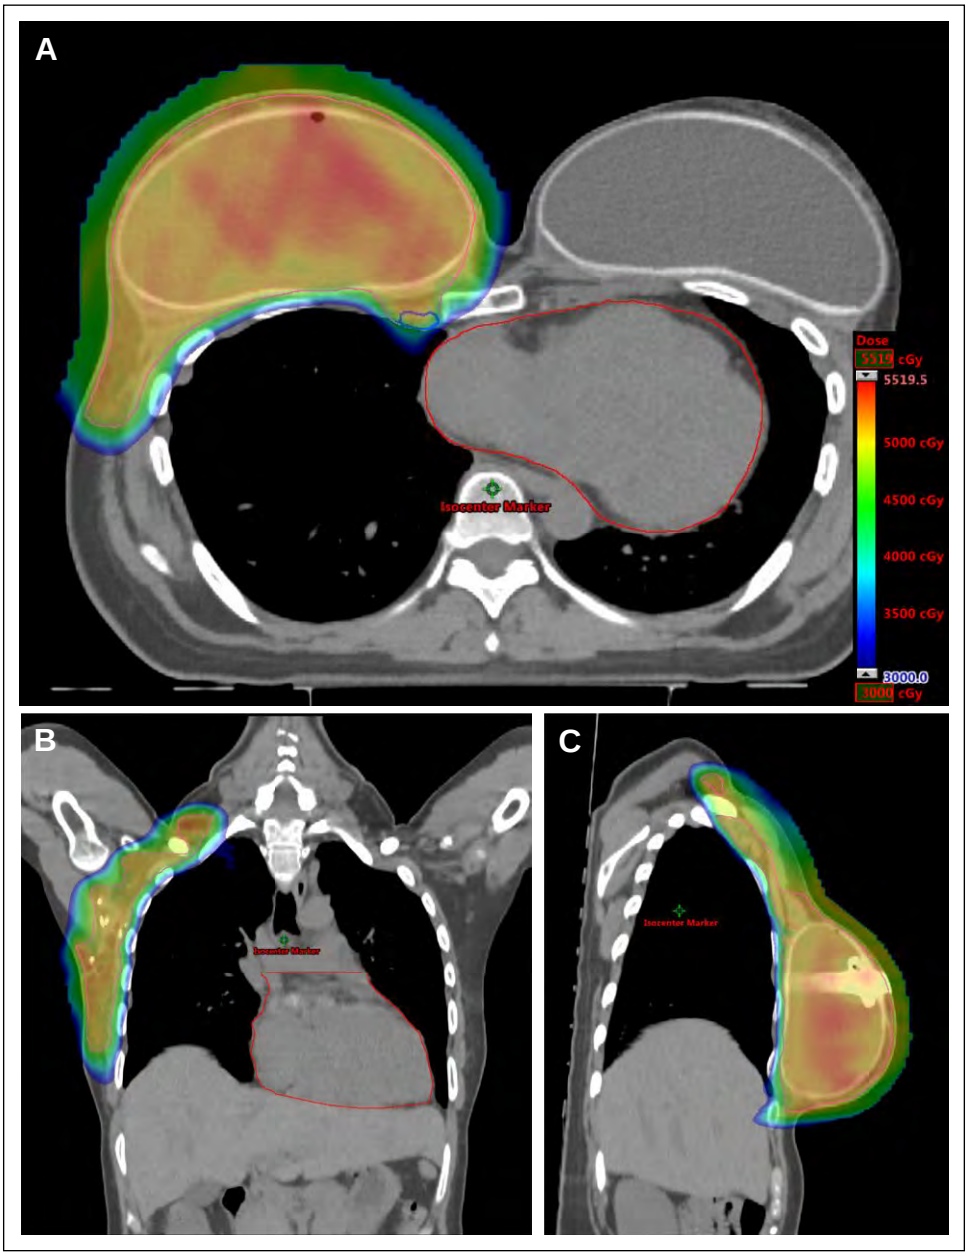
MANAGEMENT OF THE AXILLA IN PATIENTS WHO UNDERGO MASTECTOMY AND BREAST CONSERVATION

There have been many changes regarding the surgical management of node-positive breast cancer with respect to axillary surgery over the last 5 to 10 years. However, every day, all clinicians initially evaluating patients with breast cancer, and specifically the breast surgical oncologist, evaluate routine complexities that are discussed, including the need for or choice of mastectomy or choice of breast conservation. Further confounding these discussions is the potential for neoadjuvant systemic therapy in decisions regarding ultimate surgery and implications for PMRT. It becomes obvious and intuitive that these complex decisions are best made prospectively by a multidisciplinary team including the breast surgical oncologist, the radiation oncologist, the plastic surgeon, and the medical oncologists in conjunction, of course, with the patient.

SLN Biopsy for Clinically Node-Negative Patients

Simply stated, intraoperative lymphatic mapping and SLN biopsy for breast cancer is the accepted international standard for evaluating patients with a clinical node-negative axilla whether the patient receives breast-conserving therapy or mastectomy with or without immediate breast reconstruction.[52]

FIGURE 1. Axial (A), Coronal (B), and Sagittal (C) Colorwash Images of the Intensity-Modulated Proton Therapy Plan of a Patient With Bilateral Tissue Expander Reconstruction Undergoing PMRT



Chest wall (magenta) and internal mammary (blue) clinical target volume is well covered while sparing the heart (red) and contralateral reconstructed breast mound.

Before recently, it was more or less dogmatic that a patient with node-positive breast cancer and receiving mastectomy would be a candidate for PMRT. This concept is changing based on new consensus guidelines taking into account tumor biology as well as tumor burden such that any given patient with one or two positive SLNs may not be recommended PMRT.[2] However, despite these new guidelines, most patients who are younger with node-positive breast cancer and those patients with larger primary tumors and other risk factors will in fact be recommended for PMRT.[3] Currently, ultrasound with biopsy of suspicious axillary nodes is an excellent methodology to identify patients with axillary nodal metastases and can be quite valuable in making decisions regarding the use of neoadjuvant systemic therapy and planning for PMRT and reconstruction. Despite the utility of ultrasound, most imaging is neither sensitive nor specific for definitively identifying breast cancer nodal metastases.[53] A negative nodal ultrasound does not rule out metastatic carcinoma, and this has led some clinicians to perform a separate SLN procedure if the status of the lymph node would change systemic therapy sequencing and/or the type of reconstruction based on the potential need for PMRT. This has not been the MD Anderson approach—patients with a benign nodal ultrasound but with large primary tumors would either undergo preoperative systemic therapy if indicated or primary surgery and SLN biopsy,

usually with a tissue implant that could then easily be deflated for delivery of the PMRT if indicated and then be expanded for final reconstruction.[54]

Unsuspected Nodal Micrometastases Identified in SLNs

Patients receiving breast conservation and in whom unsuspected nodal metastases is identified in one or two lymph nodes do not have formal axillary lymph node dissection based on American College of Surgeons Oncology Group Z0011 randomized trial of axillary dissection versus observation for SLN-positive disease.[55] For those with more nodal metastases identified receiving breast conservation, a multidisciplinary decision is made for recommendation of axillary lymph node dissection as the current standard, although some patients decline dissection, and groups of clinicians do offer nodal radiotherapy for this group of patients if axillary dissection is not performed. For unsuspected nodal micrometastases in patients with mastectomy, the standard has been recommendation for completion axillary lymph node dissection, although many patients decline this surgery and opt for observation, particularly when systemic therapy is given with or without PMRT.[56] In this regard, although the National Comprehensive Cancer Network guidelines suggest that axillary radiotherapy could be used in this scenario instead of completion axillary dissection, the recent PMRT consensus guidelines specifically state that if completion axillary dissection is not performed after a positive sentinel node, patients should receive PMRT only if there is already sufficient information to justify its use.[2]

The International Breast Cancer Study Group (IBCSG) 23-01 noninferiority randomized clinically T1/2, N0 patients with micrometastases identified in SLNs to dissection versus observation.[57] Twenty-two percent of patients on that study who underwent breast-conserving surgery received no adjuvant radiotherapy or received intraoperative partial breast irradiation without any axillary treatment. An additional 9% underwent mastectomy without adjuvant radiotherapy. The 5-year local regional recurrence rates in both arms of the study were less than 3%, and no notable disease-free or overall survival difference was identified. Based on this additional study taken together with the Z0011 study, it has become standard practice to avoid axillary dissection among similar patients.

It is been well known for several decades that radiotherapy can be used to treat undissected breast cancer nodal disease. The EORTC 10981-22023 AMAROS (After Mapping of the Axilla, Radiotherapy or Surgery?) trial enrolled clinically node-negative patients with positive SLNs and a breast cancer less than 3 cm in diameter (approximately 17% of each group underwent mastectomy, and about 5% of cases in each arm had three or more positive SLNs).[41] The study reported a 5-year axillary recurrence rate of 0.43% after dissection and 1.19% in the axillary radiotherapy group with no overall or disease-free survival difference yet significantly lower rates of clinical lymphedema in the radiotherapy arm compared with dissection group (23% compared with 11%; $p < .0001$).[41] Thus, axillary radiotherapy seems to control regional residual microscopic disease among patients with positive SLNs, although, taken together with the results from the Z00011 and IBCSG study, may potentially overtreat some patients.

Management of Biopsy-Proven Axillary Nodal Metastases: SLN Biopsy and Targeted Axillary Dissection

Neoadjuvant systemic therapy can eradicate documented breast cancer axillary nodal metastases in 40%–74% of patients.[53,58] Therefore, it was of interest to see if the SLN procedure could accurately identify patients without residual disease to avoid axillary lymph node dissection and potential complications associated with that type of surgery. Retrospective and prospective clinical trials demonstrated that the false-negative rates of SLN biopsy alone were often higher among patients with documented nodal metastases treated with neoadjuvant systemic therapy compared with patients receiving surgery first.[59-62] The false-negative rates markedly decreased after placing a marker within the lymph node with documented carcinoma, such that it could be localized and tested after neoadjuvant systemic therapy as an accurate reflection of the remaining lymph nodes.[41,63] The concept intuitively makes sense, as the lymph node to test would be an actual lymph node that had carcinoma before the introduction of systemic therapy. The new technique, called targeted axillary dissection (TAD), in which a radioactive seed is placed within the previously biopsy-proven positive clipped node after preoperative chemotherapy and removed along with any other SLNs, reduced the false-negative rates to about 2% in The University of Texas MD Anderson Cancer Center clinical trial.[64] Ensuring removal of the clipped lymph node seems to improve the accuracy of sentinel lymphadenectomy after preoperative chemotherapy, because approximately 25% of the time, the clipped node with documented carcinoma is not retrieved as a standard SLN, probably because of fibrosis in the lymphatics and nodes secondary to treated carcinoma.[64] Patients at MD Anderson who do not have residual nodal metastases found on TAD do not go on to full completion axillary lymph node dissection. Patients with residual nodal metastases with TAD have an approximately 50% chance of harboring additional nodal disease and undergo completion dissection or are enrolled in the Alliance for Clinical Trials in Oncology 11202 (NCT01901094), a trial with the primary aim to determine whether axillary radiation alone is not inferior to axillary lymph node dissection with radiotherapy among patients with initial documented nodal disease both before and after receipt of neoadjuvant systemic therapy.

RECONSTRUCTION IMPLICATIONS OF PMRT

General Approach to Breast Reconstruction in the Patient Needing Radiation

PMRT is used with increasing frequency in the treatment of patients with advanced breast cancer. The plastic surgeon is faced with the challenge of reconstructing a breast before

radiotherapy or sometimes in a previously radiated field. In these patients, the timing and sequence of mastectomy, reconstruction, chemotherapy, and radiation has not been clearly established. A reasonable algorithm for management of these complex patients is outlined in Fig. 2. Generally, if radiation is anticipated, immediate two-stage implant-based reconstruction is recommended. This allows for reconstruction of a usually acceptable breast mound and leaves autologous tissue as a potential salvage in the case of failure of the implant-based reconstruction. This section will outline why it is generally preferable not to do immediate autologous reconstruction and the outcomes and timing for immediate two-stage reconstruction with implants in the setting of PMRT.

AUTOLOGOUS RECONSTRUCTION AND RADIOTHERAPY

Immediate Autologous Flap Reconstruction

Immediate breast reconstruction with a flap followed by PMRT remains controversial and is usually not recommended.[65,66] This is principally the result of multiple studies that have demonstrated higher complication rates, flap fibrosis, fat necrosis, and poor aesthetic outcomes in flap reconstructions that receive radiation.[65,67,68] Although free flap reconstruction can result in high flap-survival rates, these patients frequently require additional procedures and often a second flap for salvage of the reconstruction. Although there are some proponents of immediate autologous reconstruction followed by PMRT who believe that acceptable aesthetic results are feasible,[69] this approach remains controversial, and most guidelines do not routinely recommend autologous reconstruction in patients who will definitely need PMRT.[70]

DELAYED AND DELAYED-IMMEDIATE AUTOLOGOUS FLAP RECONSTRUCTION

The most acceptable approach for the patient choosing autologous reconstruction is to perform reconstruction after the completion of mastectomy, chemotherapy, and radiation. Alternatively, a two-stage reconstruction can be performed by first placing a tissue expander underneath the mastectomy flaps and then radiating the tissue expander after early, rapid expansion. Once radiated, a flap reconstruction can be performed after a delay. This approach has been described as "delayed-immediate reconstruction" and in concept preserves more native mastectomy skin for the delayed reconstruction, potentially to the benefit of the aesthetic outcome. However, this approach does involve an additional surgical procedure. Further, it is not clear whether performing the flap reconstruction within a very short period of time after radiation therapy may actually increase the chances of perioperative complications as compared with traditional delayed autologous breast reconstruction.

ALLOPLASTIC RECONSTRUCTION AND RADIOTHERAPY

Two-stage implant-based reconstruction is the most common approach to breast reconstruction, and it is well-established that the long-term reconstructive failure rate of prosthetic reconstruction is significantly lower in nonradiated versus radiated reconstruction. The largest prospective series of immediate two-stage breast reconstruction has demonstrated that patients who undergo PMRT after implant reconstruction will lose the implant reconstruction in 9.1% of cases as compared with only 0.5% in the nonirradiated group. In addition, the high-grade capsular contracture rate is greater

FIGURE 2. Breast Reconstruction Management Algorithm When Postmastectomy Radiation Is Anticipated

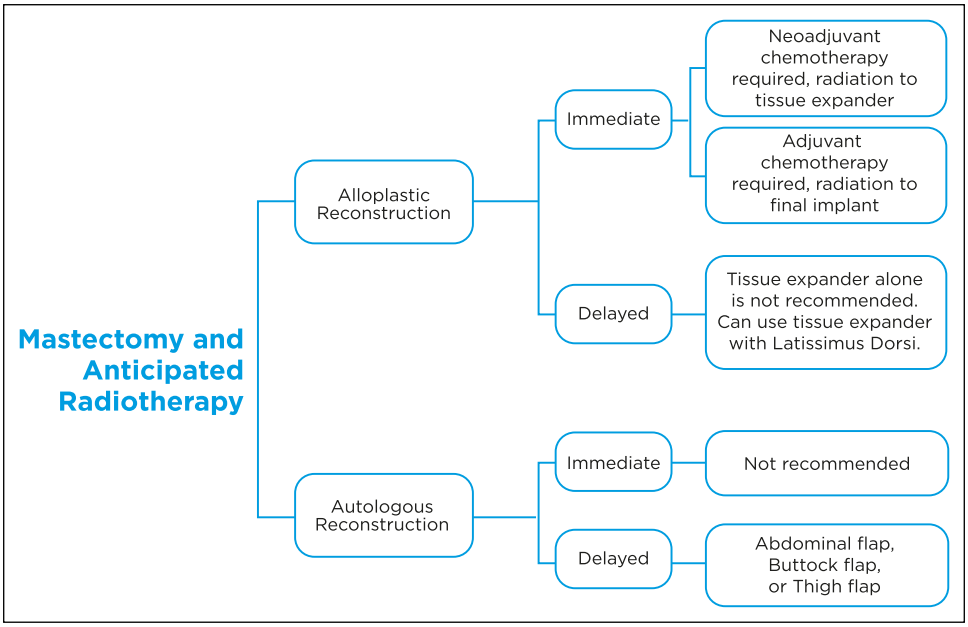


FIGURE 3. Timing and Sequence of Immediate Two-Stage Prosthetic Breast Reconstruction With Mastectomy, Chemotherapy, and Radiation

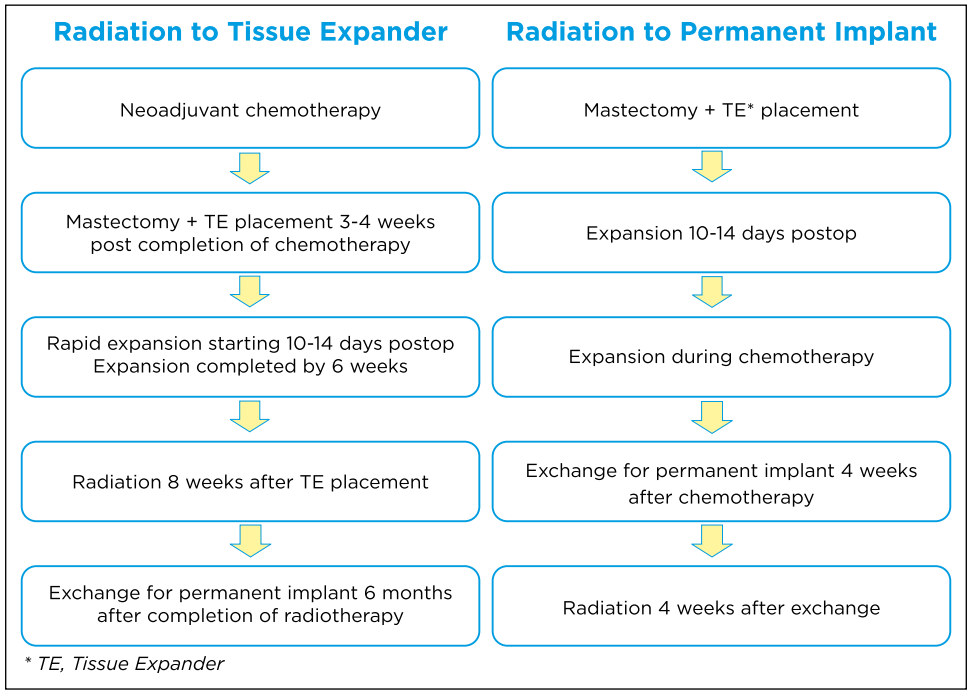

(6.9% in radiated versus 0.5% nonradiated), and the aesthetic outcomes are generally inferior in patients with radiated reconstruction.[71] It is an open question whether immediate alloplastic reconstruction is still acceptable given these inferior outcomes and more importantly whether this procedure can be timed and sequenced appropriately within the oncologic treatment scheme.

TIMING AND SEQUENCE OF IMMEDIATE RECONSTRUCTION WITH MASTECTOMY, CHEMOTHERAPY, AND RADIATION

How can the reconstructive surgeon best collaborate with the oncologic surgeon, oncologist, and radiation oncologist to provide the patient with a successfully reconstructed breast mound in the face of PMRT? Figure 3 outlines the two principal approaches with regard to the sequencing of surgery and PMRT in patients who undergo two-stage prosthetic breast reconstruction: either the expander can be exchanged for permanent implant before radiation or the tissue expander is first radiated and then exchanged for the permanent implant. There have been numerous proponents for both of these approaches, although the literature primarily consists of small, retrospective series, often without control subjects.[42]

The protocol at Memorial Sloan Kettering Cancer Center (Fig. 2) was derived primarily for patients who underwent mastectomy, adjuvant chemotherapy, and then PMRT. These patients underwent immediate reconstruction with a tissue expander at time of mastectomy, expansion during adjuvant chemotherapy, and exchange for permanent implant 4 weeks postchemotherapy. The final implant reconstruction was then radiated 4 weeks later. This timing and sequence of oncologic treatment and reconstruction is not possible in patients undergoing neoadjuvant chemotherapy followed by mastectomy followed by radiation. In patients for whom treatment follows the neoadjuvant chemotherapy to mastectomy to PMRT sequence, exchange before radiation is not feasible because of the resulting 4- to 5-month gap between chemotherapy and PMRT. Thus, the approach to these patients involves rapid expansion within 6 weeks and radiation to the tissue expander within 8 weeks postsurgery. The exchange to permanent implant is performed 6 months after completion of PMRT.

The largest prospective series that compares long-term outcomes of patients receiving prosthetic breast reconstructions with PMRT to the expander versus those receiving radiation to the permanent implant demonstrates that reconstructions undergoing radiation therapy to the tissue expander before exchange to the permanent implant have doubled the 6-year predicted failure rate (32%) of those receiving radiation after placement of the permanent implant (16%).[8] Therefore, in principle, the final implant should be radiated to minimize reconstructive failure. The data on long-term aesthetic outcomes of the two approaches are not entirely clear. Nava et al[72] found that subjective evaluations of shape and symmetry assessed by several surgeons and the patient's opinion of the final reconstruction favored radiation of the final implant. However, the data from Cordeiro et al[8] suggest that patients with radiation to the tissue expander might have slightly better aesthetic outcomes

and slightly lower capsular contracture grades than patients with radiation to the permanent implant. With either approach, one must keep in mind that it is still possible to have good-to-excellent outcomes in approximately 50% of patients.

What then is the ideal timing of reconstruction and PMRT? What is the timing of radiation to the tissue expander or to the permanent implant? For patients who have already undergone neoadjuvant chemotherapy, the decision is a priori dictated by the oncologic treatment because these patients cannot delay radiotherapy and should receive radiation to the tissue expander. In the case of patients who undergo mastectomy followed by adjuvant chemotherapy, the reconstructive surgeon is faced with the dilemma of choosing to recommend radiation therapy to the tissue expander, accepting that approach's higher rate of reconstructive failure as worthwhile given its potentially superior aesthetic result? Or should long-term viability of the reconstruction be more important than a lesser aesthetic result? The pros and cons of these options should be discussed with the patient. Perhaps the best approach is to provide the patient with the data, review her goals and expectations, and then let the patient make the final decision.

One could argue that because the overall implant survival rate, aesthetic outcomes, and capsular contracture rates are significantly worse in patients who undergo immediate prosthetic breast reconstruction in the face of PMRT, these patients should not be reconstructed and should instead undergo delayed breast reconstruction. However, patients who undergo mastectomy and PMRT alone would likely never undergo delayed two-stage prosthetic reconstruction because they cannot be expanded successfully. These patients would then be relegated to delayed reconstruction with autologous tissue. Many may not be candidates for autologous reconstruction because of age, comorbidity, or inadequate tissue at donor site; may not survive long enough to ever undergo delayed reconstruction; or may simply not be interested in further extensive, complicated operations given what they have already experienced in the course of cancer treatment. One could also argue that by providing a very simple reconstructive approach consisting of small operations and quick recoveries, most of these patients are still extremely happy to have some form of reconstructed breast and are accepting of the aesthetic tradeoff. Patient-reported outcomes data demonstrate lower satisfaction levels in those patients with radiated implant reconstructions as compared with those that are not radiated.[71] However, overall satisfaction in many patients remains high enough that it is certainly worthwhile. We therefore still strongly advocate immediate two-stage implant-based breast reconstruction in any patient who might be interested, despite the potential need for PMRT.

Standard and Genomic Tools for Decision Support in Breast Cancer Treatment

N. Lynn Henry, MD, PhD, Philippe L. Bedard, MD, and Angela DeMichele, MD, MSCE

OVERVIEW

Over the past few decades, comprehensive characterization of the cancer genome has elucidated pathways that drive cancer and mechanisms of resistance to therapy and provided important insights for development of new therapies. These advances have resulted in the development of prognostic and predictive tools for use in clinical settings, which can assist clinicians and patients in making informed decisions about the benefits of established therapies. In early-stage breast cancer, multiparameter genomic assays are now available for decision making about the duration of adjuvant endocrine therapy and the use of adjuvant chemotherapy. Similarly, in metastatic disease, there are multiple commercially available next-generation sequencing options for identifying genetic alterations in tumors that may be targeted with a drug. Although these tools hold great promise for providing precision medicine, it can be difficult for the treating physician to evaluate their clinical utility and appropriately select tools for individual clinical situations. This review summarizes the currently available genomic tools in breast cancer, the data underlying their clinical validity and utility, and how they can be used in conjunction with standard clinicopathologic data for making adjuvant and metastatic treatment decisions.

The knowledge generated by The Cancer Genome Atlas on the genetic profile of breast and other cancers along with the development and widespread availability of sophisticated technologies for commercial testing of the cancer genome in clinical settings has led to a desire to use these tools to improve patient care and outcomes. This has catalyzed the development of a variety of prognostic and predictive tools designed to assist clinicians and patients in making informed decisions about the benefits of established therapies, as well as potentially identifying new treatment options. Although these tools hold promise for personalized care and rational molecularly based treatments, it can be difficult for the treating physician to evaluate their quality and clinical utility and select tools that are appropriate for an individual patient and/or clinical situation. This review summarizes the framework for evaluating new genomic tools in breast cancer and the data underlying their utility for making adjuvant and metastatic treatment decisions.

QUALITY OF BIOMARKERS

All biomarkers, including genomic and molecular tools, require rigorous development and evaluation prior to incorporation into clinical care.[1] According to the Evaluation of Genomic Applications in Practice and Prevention framework, biomarkers must have analytic validity, clinical validity, and clinical utility.[2] The assay for the biomarker must be accurate and reproducible. Once an assay is analytically valid, it must be shown in multiple independent cohorts to have the ability to divide a population of interest into separate groups, and it must be demonstrated that use of the biomarker adds to current clinical care in a meaningful way without introducing substantial risk to the patient. Although it would be ideal to evaluate all biomarkers in prospective trials, similar to what is done for medications, this is not practical, so the Tumor Marker Utility Grading System was developed to assess the level of evidence supporting the clinical utility of individual biomarkers,[3] which allows all potential new biomarkers to be evaluated in a standardized way.

USING MOLECULAR TOOLS TO MAKE ADJUVANT ENDOCRINE THERAPY DECISIONS

Prognostication Without Treatment

Adjuvant endocrine therapy reduces the risk of breast cancer recurrence and improves survival[4] for hormone receptor–positive (HR^+) breast cancer irrespective of age, menopausal status, involvement of axillary lymph nodes, or tumor size.[5] A variety of molecular tools, including the 21-gene recurrence score assay (Oncotype DX),[6-8] the 70-gene signature (MammaPrint),[9-11] the PAM50 risk-of-recurrence assay (Prosigna),[12] the Breast Cancer Index,[13,14] and EndoPredict,[15,16] can identify subsets of patients who are HR^+/

TABLE 1. Summary of Available Multiparameter Genomic Assays for Decision Making in Early Breast Cancer

Name	Description	Results	References
Breast Cancer Index	HoxB13/IL17BR plus molecular-grade index	Low vs. high risk for both prognosis and prediction	13,14,17
EndoPredict	11-gene signature	Low vs. high risk	15,18,19
uPA/PAI-1 (Femtelle)	Urokinase plasminogen activator plus plasminogen activator inhibitor type 1	Low vs. high risk	20
70-gene breast cancer recurrence assay (MammaPrint)	70-gene signature	Low vs. high risk	
Mammostrat	5-gene signature	Low vs. moderate vs. high risk	
21-gene recurrence score assay (Oncotype DX)	21-gene signature	Low vs. intermediate vs. high risk	6,7,21
PAM50 risk of recurrence score (Prosigna)	46-gene signature plus 18-gene proliferation score plus tumor size	Low vs. intermediate vs. high risk	12,22,23

HER2$^-$ and have a low risk of distant recurrence (< 5% at 5 years and/or < 10% at 10 years; Table 1). However, the vast majority of patients included in these series were treated with adjuvant endocrine therapy (and some also received chemotherapy). There are less data regarding prognostic performance for patients who were untreated.

MammaPrint (70-gene signature) was initially developed from a cohort of 78 patients with lymph node–negative breast cancer who were younger than age 55 by using distant metastasis-free survival at 5 years from diagnosis to derive the "good prognosis" from "poor prognosis" 70-gene signature.[9] All patients who were distant metastasis-free at 5 years, as well as 29 of 34 patients who developed metastases, had not received adjuvant endocrine therapy or chemotherapy. A subsequent independent validation by the TRANSBIG consortium included 302 patients from six European institutions with node-negative breast cancer diagnosed between 1980 and 1998 who had not received adjuvant endocrine therapy or chemotherapy.[24] The 10-year distant metastasis-free survival in the "low-risk" 70-gene profile group approached 90%. Similarly, a subset of 198 patients with available RNA from this cohort were analyzed for a 76-gene prognostic profile,[25] independently developed by investigators at the Erasmus Cancer Center in Rotterdam, the Netherlands, with minimal gene overlap with the 70-gene profile.[26] The 10-year distant metastasis-free survival in the "good risk" 76-gene profile group was 94% in the absence of systemic therapy.[25]

The Oncotype DX assay, a 21-gene signature, was initially validated in a cohort of 668 patients with HR$^+$, node-negative breast cancer treated with adjuvant tamoxifen and no chemotherapy in NSABP B-14.[6] This trial randomly selected patients to receive 5 years of tamoxifen versus placebo. For patients in the placebo group, a low-risk recurrence score lower than 18 was associated with a 10-year distant disease-free survival of 85.9% compared with 93.1% in patients who received tamoxifen.[27]

Recent data from prospective clinical trials demonstrate excellent outcomes for patients with HR$^+$ breast cancer with "low-risk" gene-expression profiles treated with endocrine therapy alone. In the TAILORx trial, patients with HR$^+$, HER2$^-$, node-negative breast cancer with an Oncotype DX recurrence score of 10 or lower were treated with tamoxifen or an aromatase inhibitor, and their rate of 5-year freedom-from-distant recurrence was 99.3%.[7] Similarly, in the West German Study Group Plan B, trial patients with HR$^+$, HER2$^-$, breast cancer with recurrence scores of 11 or lower (including patients with 1–3 involved lymph nodes) were treated with endocrine therapy alone without chemotherapy, and their 3-year disease-free survival was 98%.[28] In the MINDACT trial, patients with HR$^+$, HER2$^-$ breast cancer with up to three positive lymph nodes who were low risk based on clinical (based upon Adjuvant! Online) and genomic (based upon MammaPrint) criteria had a 5-year distant disease-free survival of 97%.[11]

KEY POINTS

- **Numerous multiparameter genomic assays have been developed that provide prognostic information for HR$^+$, HER2$^-$, node-negative breast cancer, and a subset are also predictive of the benefit from adjuvant chemotherapy and endocrine therapy.**
- **Studies are underway examining the clinical utility of multiparameter genomic assays for determining benefit from extended adjuvant endocrine therapy.**
- **Comprehensive next-generation sequencing approaches are being developed to identify targetable lesions, and clinical tests focused on actionable mutations are currently available.**
- **Liquid biopsies, which can be used to identify circulating tumor cells and circulating tumor DNA, are less invasive, may better reflect tumor heterogeneity, and can be used to identify tumor mutations that are complementary to those found in tumor biopsies.**
- **Prospective trials using genomic tumor testing for treatment selection in the metastatic setting have not demonstrated clinical utility in improving patient outcomes. Thus, this testing is not recommended by ASCO for this purpose, although it may be useful for eligibility in investigational trials.**

These excellent outcomes raise the question of whether these patients might also fare well without endocrine treatment. Outside of well-controlled clinical trials, up to 40% of patients with early-stage HR+ breast cancer are nonadherent with tamoxifen or aromatase inhibitor therapy.[29,30] Persistence with endocrine treatment decreases over time, due in part to side effects, including vasomotor and mood symptoms, arthralgias, weight gain, and sexual dysfunction. Intriguingly, a retrospective analysis of the randomized Stockholm Tamoxifen trial (STO-3) reported a 20-year disease-specific survival rate of 94% in node-negative women who received no adjuvant systemic therapy and who had a predefined "ultra-low-risk" MammaPrint score; in the tamoxifen-treated group, the 20-year disease-specific survival was 97%.[31] Although only 15% of patients in this analysis had an ultra-low-risk MammaPrint score, molecular tools may identify a higher proportion of patients with indolent biology in the modern era of mammographic breast cancer screening.[32] However, considering the long natural history of recurrence risk for HR+ breast cancer, the generally favorable safety profile of tamoxifen and aromatase inhibitors, and the continued reduction in recurrence risk beyond the duration of endocrine treatment,[4] the current evidence is insufficient to withhold endocrine therapy based upon the results of molecular testing.

Prediction of Benefit From Endocrine Treatment

Data for prediction of endocrine treatment benefit with molecular tools are even more limited. In the NSABP B-14 trial, the greatest benefit with adjuvant tamoxifen versus placebo was observed in patients with low (< 18) and intermediate (18–30) Oncotype Dx scores compared with high (≥ 31) scores (for low scores: 10-year distant relapse-free survival [DRFS], 93.1% vs. 85.9%; p = .039; for intermediate: 10-year DRFS, 79.5% vs. 62.2%; p = .02; for high: 10-year DRFS, 70.3% vs. 68.7%; p = .82).[27] The National Cancer Institute of Canada Clinical Trials Group MA.12 trial randomly selected premenopausal women with stage I–III breast cancer of any hormonal status to receive tamoxifen versus placebo following adjuvant chemotherapy.[33] A retrospective analysis using the PAM50 assay showed a benefit in disease-free survival for tamoxifen (hazard ratio 0.52; 95% CI, 0.32–0.86) in the luminal (A + B) subtypes compared with nonluminal subtypes (hazard ratio 0.80; 95% CI, 0.50–1.29), although the interaction test was not statistically significant (p = .24).[34] There are no randomized data available for prediction of endocrine treatment benefit with other molecular tools. These data are insufficient to inform endocrine treatment decisions for patients with HR+ breast cancer identified using standardized immunohistochemistry testing methods.[35]

Data to evaluate the differential predictive benefit of one endocrine treatment approach versus another are also limited. In the TransATAC study, the prognostic value of recurrence score was compared for postmenopausal patients who were HR+ and randomly selected to receive 5 years of anastrozole versus tamoxifen using a multivariate model adjusted for tumor size, tumor grade, nodal status, and age.[8] The hazard ratios for distant recurrence per 50-point change in recurrece scores were similar in each treatment group, and tests for recurrence score × treatment interactions were not noteworthy. The TEAM trial compared 5 years of upfront exemestane versus a switch regimen of tamoxifen (2 years to 3 years) followed by exemestane (3 years to 2 years). No differential effect in DRFS prognostication was observed in patients treated with 5-year exemestane or the switch regimen according to Mammostrat score, which stratifies patients based on five immunohistochemical markers.[36]

Prognostication of Late Relapse

HR+ breast cancer has a unique natural history, with a relatively constant ongoing annual hazard of distant relapse following an initial peak within the first 5 years of diagnosis.[37,38] Recent studies demonstrate a reduction in recurrence risk with extended adjuvant endocrine therapy with tamoxifen[39,40] or an aromatase inhibitor[41-43] following 5 years of upfront tamoxifen. Data regarding the benefit of extended adjuvant endocrine therapy after 5 years of upfront aromatase inhibitor or a switch regimen of 2 year to 3 years of tamoxifen followed by 2 year to 3 years of aromatase inhibitor are conflicting.[44-47] Extended adjuvant endocrine treatment is associated with bothersome side effects and potentially serious risks, such as endometrial cancer and venous thromboembolism with tamoxifen and bone fracture and cardiovascular events with aromatase inhibitors.

A variety of molecular tools may identify patients at very low risk of late relapse more than 5 years from diagnosis who might be spared extended adjuvant endocrine treatment. In NSABP B-14, node-negative patients treated with 5 years of tamoxifen who had high *ESR1* mRNA expression and recurrence scores lower than 18 had a low risk of distant recurrence in years 5–15 (6.8%) compared with scores of 18–30 (11.2%) and scores 31 or higher (16.4%; p = .01).[48] The risk-of-recurrence score model integrates the expression profile of a subset of 46 genes from the PAM50 intrinsic subtype classifier with an 18-gene proliferation score and tumor size. In TransATAC, recurrence score and risk of recurrence were associated with relapse risk during years 5–10 from diagnosis in multivariate analysis,[49] although risk-of-recurrence scoring was a stronger prognosticator of late recurrence than recurrence scoring. A combined analysis of TransATAC and the ABCSG-8 trial found that the risks of distant relapse in years 5–10 for women with low, intermediate, and high risk-of-recurrence scores were 2.4%, 8.3%, and 16.8%, respectively.[50] For women with node-positive disease, the 5–10-year distant recurrence risk with a low risk-of-recurrence score was only 3.3%.

Likewise, a combined analysis of the ABCSG-6 and ABCSG-8 trials found that EPclin, which combines the EndoPredict score with tumor size and nodal status, was prognostic for late distant recurrence (> 5 years) in patients with HR+, HER2− breast cancer.[51] At 10 years of follow-up, the rate of distant metastasis was 1.8% for EPclin-low patients compared with 17.1% for EPclin-high patients. BCI combines the two-gene HOXB13/IL17BR ratio with the five proliferation

gene Molecular Grade Index. A cubic risk model was developed using the tamoxifen arm of the STO-3 and was found to be prognostic of late recurrence in an independent validation cohort of HR$^+$, node-negative patients.[17] Risks of distant recurrence in years 5–10 were 2.5%, 16.9%, and 15.0% for the low-, intermediate-, and high-risk cohorts, respectively. A linear risk model was also shown to prognosticate for late recurrence in TransATAC[13] and restratify low and intermediate reucrrence score groups into distant recurrence risk subsets.[52]

A recently published ASCO guideline using data available through August 2014 did not recommend any molecular tools to inform extended adjuvant endocrine therapy.[53] The review panel concluded that clinical validity for late recurrence was not shown for any individual assay in more than one study, and clinical utility had not been demonstrated. Although there are limitations of the available evidence, the consistency of highly favorable outcomes for late recurrence risk reported for “low-risk” patients across studies suggests that these molecular tools that are driven by quantification of proliferation may play an increasingly prevalent role in extended adjuvant treatment decisions.

Tools for Chemotherapy Decision Making

Clinicopathologic tools. Breast cancer is heterogeneous. At diagnosis, patients can present with breast tumors that differ by stage, histology, and pathologic characteristics. When deciding whom to treat with cytotoxic chemotherapy, providers synthesize the data for individual patients to develop a personalized treatment recommendation. In particular, treatment decisions are driven by clinical factors such as patient age and comorbidities, as well as pathologic factors such as disease stage, tumor grade, and receptor status, including estrogen receptor and progesterone receptor overexpression as well as overexpression or amplification of HER2. A number of organizations have developed guidelines for chemotherapy use in patients with stage I–III breast cancer based on these standard clinicopathologic characteristics, including the National Comprehensive Cancer Network, ASCO, and the St. Gallen International Expert Consensus Panel.[54-57]

Quantitative decision aids have been developed for use by providers making treatment recommendations. One of the first to be widely used was Adjuvant! Online (www.adjuvantonline.com), in which providers input details including age, tumor size, nodal involvement, grade, and estrogen and progesterone receptor status and receive estimates of likelihood of recurrence or mortality within 10 years based on different treatment options. The data used to develop the tool were derived from Surveillance, Epidemiology, and End Results data for estimates of prognosis as well as data from the Early Breast Cancer Trialists’ Collaborative Group meta-analysis for estimates of response to endocrine and cytotoxic chemotherapy.[58] Although useful, the tool has limitations, including lack of incorporation of HER2 status into the estimates. In addition, the site is currently offline for updating.

A second decision aide has been developed that addresses some of the limitations of Adjuvant! Online. This model, called PREDICT (www.predict.nhs.uk), is derived from a database of patients treated in the United Kingdom between 1999 and 2003 and provides survival estimates for patients based on clinicopathologic factors, including HER2, Ki67, and mode of detection of breast cancer.[59] It has been validated using a number of independent data sets.[60,61] In addition to providing 5- and 10-year survival data, the site also provides information about likelihood of benefit from second- and third-generation chemotherapy regimens as well as endocrine therapy.

Although these decision aides can be used for treatment decision making for patients with estrogen receptor–negative, progesterone receptor–negative, and HER2$^-$ breast cancer (termed "triple-negative" breast cancer), decisions regarding use of chemotherapy are primarily driven by tumor size and lymph node involvement.[54,55,57,62] Similarly for patients with HER2$^+$ disease, use of chemotherapy plus anti-HER2 therapy is recommended for most patients with tumor size greater than 5 mm and/or lymph node involvement because of the reduction in risk of recurrence with chemotherapy and the additional 40% improvement in disease-free survival from the addition of trastuzumab.[54,55] Therefore, although these decision aids can estimate prognosis for an individual patient, they are often less useful for making decisions about treatment. In contrast, for patients with HR$^+$ disease, the Adjuvant! Online and PREDICT decision aids may be more useful for informing decision making regarding treatment with chemotherapy in addition to endocrine therapy.

Multiparameter genomic assays. More recently, multiparameter genomic assays have been developed that complement standard clinicopathologic data for treatment selection (Table 1). A subset of these has been recommended for use in the most recent ASCO biomarker guidelines[53] because of demonstrated clinical utility, including Oncotype DX,[6,7,63] EndoPredict,[15,18,21] PAM50/Prosigna,[12,19,22] Breast Cancer Index,[13,14,17] and the combination of urokinase plasminogen activator and plasminogen activator inhibitor type 1.[23] Importantly, current ASCO guidelines recommend these assays for use in patients with HR$^+$, HER2$^-$, node-negative breast cancer.[53] The guidelines do not recommend use of these assays for guiding adjuvant systemic therapy decisions in patients with HR$^-$, HER2$^+$, or node-positive disease.[53] Selected assays will be discussed in more detail below; details about the other assays can be found in the provided references.

The first assay to be incorporated into routine clinical use in the United States was Oncotype DX.[6] The assay was originally developed using samples from patients with HR$^+$, node-negative breast cancer treated with tamoxifen on a randomized clinical trial. The assay analyzes the expression of 16 tumor-related genes and five housekeeping genes from formalin-fixed, paraffin-embedded tumor specimens to generate a recurrence score that corresponds with the 10-year risk of distant disease recurrence assuming 5 years of treatment with tamoxifen.

Subsequent studies using samples derived from a separate trial demonstrated that the recurrence score is also predictive of response to chemotherapy. Patients with low scores (0–17) were shown to have no benefit from adjuvant chemotherapy in addition to endocrine therapy, whereas those with high scores (31–100) were shown to benefit from chemotherapy followed by endocrine therapy.[63] For those with intermediate scores (18–30), the optimal treatment approach remains uncertain and is currently being investigated in the TailoRX clinical trial (NCT00310180). Observational studies have demonstrated that incorporation of the assay into routine clinical care has resulted in decreased use of chemotherapy for women with node-negative breast cancer.[20] In addition, data from prospective-retrospective trials have demonstrated there is similar benefit from use of Oncotype DX in patients with node-positive disease[8,64]; the prospective SWOG 1007 RxPONDER clinical trial (NCT01272037) is ongoing to provide more definitive results.

The use of a different multiparameter genomic assay, MammaPrint, for chemotherapy decision making has also been studied in a large prospective randomized trial, MINDACT.[11] MammaPrint separates patients into two categories, either good or poor prognosis. In MINDACT, the investigators evaluated patient prognosis based on both standard clinicopathologic factors using Adjuvant! Online and genomic factors using MammaPrint. Those patients who were discordant, with high clinical risk but low genomic risk, were randomly selected to receive chemotherapy or not, in additional to endocrine therapy. The 5-year rate of survival without distant metastases in those patients who did not receive chemotherapy was 94.7% (CI, 92.5% to 96.2%), which met the criteria for success in this trial. They concluded that those patients at low genomic risk of recurrence might not require chemotherapy, despite being at high risk based on standard clinicopathologic factors. Of note, the results of this trial were published after the development of the most recent ASCO biomarker guidelines.[53,65]

In summary, multiparameter gene expression assays complement standard pathologic factors and provide additional information to support treatment decision making. The primary use of multiparameter assays, therefore, is to inform the decision about adjuvant systemic therapy in situations in which chemotherapy in being considered. For patients who definitely will or will not be receiving chemotherapy based on standard clinicopathologic factors, including comorbidities and patient preferences, testing is unnecessary because it will not alter the planned treatment. Additional high levels of evidence data are forthcoming regarding use of these assays in other patient populations, including those with node-positive disease.

THE ROLE OF GENOMIC TESTING IN THE METASTATIC SETTING

Breast cancer is the second leading cause of cancer death in women.[66] Approximately 30% of women diagnosed with the disease will ultimately recur, and over 40,000 women die annually of metastatic breast cancer.[66] Standard treatment is guided by expression of HR or HER2, with sequential endocrine therapies initially in most HR^+ disease, chronic anti-HER2 therapy (with or without chemotherapy) in $HER2^+$ disease, and sequential chemotherapy in triple-negative and endocrine-resistant disease.[67] Development of resistance is universal, and patients are in a continual state of alternating disease control and progression.

Receptor expression and genetic changes can differ between a breast primary and metastases,[68] as tumors continue to evolve both stochastically and in response to treatment. Several meta-analyses[69] have documented that pooled estimates for the absolute frequency in changes from positive to negative ranged from 5.7% to 9.5% for estrogen receptor status and 17% to 24% for progesterone receptor status, whereas ranges for changes from negative to positive ranged from 3% to 8.8% and 6.9% to 7.3% for estrogen receptor and progesterone receptor, respectively. The overall rate of absolute change in HER2 status (in either direction) was approximately 6%, and some studies have demonstrated that discordance is associated with shorter survival.[70-72] Next-generation sequencing (NGS) technologies have led to the development of numerous commercial assays that can detect genomic variability both within tumors and in the circulation through the identification of intact circulating tumor cells (CTCs) and shed tumor DNA (patient tumor DNA [ptDNA]). A number of studies have reported on the spectrum of mutations identified by massively parallel sequencing in primary and metastatic breast cancer,[73-76] and similar recurrent genomic alterations have been identified both in tumor and blood.[77-81] Although these data have the potential to improve prognostication, expand therapeutic targets,[82-85] or enable tracking of therapeutic response,[86] evidence supporting the clinical utility of either tumor- or blood-based genomic assays for these purposes is scant.

Available Tools for Genomic Testing of Metastatic Disease

Approaches to evaluating the spectrum of genetic mutations or other alterations, such as copy number changes, generally use NGS approaches to enable simultaneous evaluation of many genes, with commercial and proprietary panels in widespread use. This requires tumor biopsy, which can be difficult or risky depending on the location of disease, limits the amount of tissue that can be obtained, and may not be representative of the entire tumor because of tumor heterogeneity. Technologies underlying these panels use whole-exome sequencing on paraffin-embedded tumor specimens and bioinformatics approaches to identify driver mutations, mutational hot spots, and those that are actionable—that is, for which there are potentially effective targeted therapies. Those approved for use in making treatment decisions must be done in a Clinical Laboratory Improvement Amendments–certified laboratory, meeting requirements for clinical and analytic validity. Platforms can vary substantially in sensitivity, specificity, and the spectrum of mutations that can be detected, and there are biologic

challenges to identifying true drivers in this context of tremendous biologic heterogeneity.[87] In addition to identifying mutations, amplifications in many genes are also biologically important, and thus, copy-number changes are typically included in these tests.

Concurrently, technologies have developed to measure circulating markers of tumor burden, including CTCs and tumor-derived DNA. These technologies are appealing as a way to provide a liquid biopsy from the blood, obviating the difficulties in procuring surgical tumor specimens. However, these technologies also differ in sensitivity and specificity, require specific blood processing and storage protocols, and, in the case of CTCs, require immediate processing. CTCs can measure tumor burden and be profiles for surface receptors, including estrogen receptor, progesterone receptor, and HER2. ptDNA can detect specific mutations but with the same limitations as tumor NGS. Prior studies of concordance between tumor and ptDNA in breast cancer have been mainly restricted to analysis of pathogenic mutations, demonstrating concordance rates above 70%[88-90] when the same platform is used. In addition, as shown in a prospective study of 32 patients comparing NGS data sets from three distinct patient-matched samples types (formalin-fixed, paraffin-embedded and CTC-DNA ptDNA) using common amplicon-based resequencing panels, CTC-DNA and ptDNA evaluation yielded complementary molecular information from the same blood sample.[85,91] However, in clinical practice, the need for rapid turnaround times for clinical decision making and differences in commercial platforms can lead to lack of concordance between tumor and blood due to purely technical reasons, such as differences in test coverage of genes, laboratory variant reporting practices, variant classification, and allele frequency thresholds for detection based on total sequencing depth. Consideration of these limitations is are extremely important for practicing oncologists when ordering and interpreting the results of such tests to avoid erroneous conclusions about potential therapeutic targets or the gain or loss of specific mutations or overall changes in mutational burden under the pressure of therapy.

Current Knowledge of the Unique Biology of Metastatic Disease

The development of massively parallel sequencing technologies such as NGS has led to a proliferation of studies that have characterized primary tumors and enable comparison of metastatic breast tumors to matched primaries. The Cancer Genome Atlas characterized the genomic landscape of early breast cancer, demonstrating that approximately one-third of tumors have *TP53* or *PIK3CA* mutations, and up to 20% have amplifications in *ERBB2*, *FGFR1*, and *CCND1*.[73] Studies taking a broad approach with NGS have demonstrated that whole-exome or whole-genome sequencing uncovers discordant, novel mutations in both primaries and matched metastases.[79,92-94] Studies using comparative genomic hybridization to detect copy number changes between matched primary and distant metastases have been contradictory, with some but not all studies finding increased copy number changes in metastases compared with primaries.[95-97] The largest metastatic profiling study to date, examining 216 metastatic breast tumors/blood pairs compared with 712 TCGA primary tumors as reference, found that 12 genes (*TP53*, *PIK3CA*, *GATA3*, *ESR1*, *MAP3K1*, *CDH1*, *AKT1*, *MAP2K4*, *RB1*, *PTEN*, *CBFB*, and *CDKN2A*) were identified as significantly mutated in metastatic breast cancer (false discovery rate < 0.1). Eight genes (*ESR1*, *FSIP2*, *FRAS1, OSBPL3*, *EDC4*, *PALB2*, *IGFN1*, and *AGRN*) were more frequently mutated in metastatic breast cancer as compared with early-stage breast cancer (false discovery rate < 0.01). *ESR1* was identified both as a driver and as a metastatic gene (n = 22; odds ratio 29; 95% CI, 9–155; p = 1.2e-12) and also presented with focal amplification (n = 9) for a total of 31 metastatic breast cancers with either *ESR1* mutation or amplification, including 27 HR^+ and $HER2^-$ metastatic breast cancers (19%). $HR^+/HER2^-$ metastatic breast cancers presented a high prevalence of mutations in genes located in the mTOR pathway (*TSC1* and *TSC2*) as compared with $HR^+/HER2^-$ early-stage breast cancer (6% and 0.7%, respectively; p = .0004). Other actionable genes were more frequently mutated in HR^+ metastatic breast cancer, including *ERBB4* (n = 8), *NOTCH3* (n = 7), and *ALK* (n = 7). Analysis of mutational signatures revealed a notable increase in APOBEC-mediated mutagenesis in $HR^+/HER2^-$ metastatic tumors as compared with primary TCGA samples (p < 2e-16). These data and others that are emerging paint a picture of the enormous genetic heterogeneity of metastatic breast cancer.

Clinical Utility of Genomic Testing for Patient and Treatment Selection in Metastatic Trials and Practice

Despite advances in technology and our understanding of metastatic tumor biology as well as the proliferation of clinical and commercial tools to perform genomic assessment of tumor genomics and ptDNA, the clinical utility of these tests has not yet been established in metastatic breast cancer. Clinical utility of a genomic test in this context is defined as the identification of targetable alterations (those causing perturbations in proteins, pathways, or both that can be specifically intercepted pharmacologically[98]) with the use of such agents leading to a favorable outcome over standard of care. As stated earlier, high-level evidence supporting the use of such tools in clinical practice relies on prospective studies designed and powered for clinically meaningful outcomes.

Only one trial to date, the SAFIR trial,[77] has prospectively profiled metastatic breast tumors and assessed treatment responses based upon genomically guided decision making. This trial, conducted in 18 centers in France, enrolled 423 patients with biopsy-accessible tumors. Biopsy samples from 407 patients underwent comparative genomic hybridization, genome-wide single nucleotide polymorphism array, and Sanger sequencing of *PIK3CA* (exons 10 and 21) and *AKT1* (exon 4). The primary outcome was the proportion of patients for whom genomic analysis identified a targeted therapy, with a goal of achieving a 30% or higher success

rate. Overall, 46% of patients were found to have actionable mutations, and therapy could be personalized in 13%. Of the 43 assessable patients, 9% had partial response to therapy, and 21% had stable disease for at least 16 weeks. Although these results are promising and demonstrate feasibility, they do not provide evidence that using this approach is superior to use of estrogen receptor, progesterone receptor, or HER2 overexpression for clinical decision making.

Similar multidisease trials are either completed or underway. To date, results are mixed, and it is too early to define a role for testing specifically in breast cancer. However, there are hints that such an approach could have traction. In the MOSCATO trial,[99] patients were used as their own control subjects. The progression-free survival (PFS) from the most recent therapy on which the patient had just experienced progression before enrollment in MOSCATO was compared with the PFS observed under the targeted therapy selected within the MOSCATO trial based upon molecular genomic testing of the patient's tumor, which was selected from over 60 phase I trials at the study center. A total of 33% of patients treated within the MOSCATO trial had an improved outcome, defined as at least a 30% increase in their PFS with the targeted therapy as compared with their baseline reference PFS. Moreover, 62% of the patients had an objective response or stable disease. The SHIVA trial[100] took a slightly different approach. This was an open-label, randomized, controlled phase II trial that included adult patients with any metastatic solid tumor refractory to standard of care, provided they had good performance status, disease that was accessible for a biopsy or resection of a metastatic site, and at least one measurable lesion. The molecular profile of each patient's tumor was established with large-scale genomic testing, and the trial enrolled only patients for whom a molecular alteration was identified within one of three molecular pathways (HR, phosphoinositide 3-kinase/AKT/mTOR, and RAF/mitogen-activated protein kinase kinase), which could be matched to 1 of 10 regimens, including 11 available molecularly targeted agents. Patients were randomly assigned (1:1) to receive a matched molecularly targeted agent (experimental group) or treatment of the physician's choice (control group). This trial was not limited to breast cancer, although patients with breast cancer constituted 20% of the study population, and patients with tumor alterations that matched a standard-of-care therapy (such as tamoxifen for HR^+ disease) were not included in the analytical group. With 11.3 months of follow-up, there was no considerable difference in PFS between those who received a matched therapy and those who received physician's choice (hazard ratio 0.88; 95% CI, 0.65–1.19; p = .41) nor were the findings noteworthy within each of the specific types of alterations. The small size of the subset of patients with breast cancer precluded analysis for that group specifically. Similar trials, including MATCH,[101] SAFIR02, and TAPUR, are ongoing and enrolling patients with breast cancer.

Given the current state of evidence on the biology of breast cancer metastases and the lack of definitive utility of genomic testing tools for treatment selection, ASCO guidelines[102] currently recommend using ER, PR, and HER2 status of the metastatic tumor for treatment selection and support biopsy of metastatic sites for this purpose. The panel considered any use of NGS testing to be investigational and does not recommend the use of this testing to initiate systemic therapy or direct selection of new therapy outside a research setting.

FUTURE DIRECTIONS

In the past decade, there have been considerable advances in the development of genomic assays and incorporation of these tools into routine clinical care, primarily for chemotherapy decision-making. Increasingly, there are also data evaluating use of these same assays for making decisions about extended adjuvant endocrine therapy, although use of these tools has not yet been incorporated into treatment guidelines. In the arena of metastatic breast cancer, comprehensive genomic analysis of metastatic lesions is being intensively studied to determine if the identified changes have sufficient clinical utility to guide treatment. Continued technological advances will lead to more comprehensive findings from both tumors and liquid biopsies, at lower cost. Results of studies examining the impact of this knowledge on disease outcomes, and the clinical utility of these results for guiding patient care, are eagerly awaited.

Therapeutic Bone-Modifying Agents in the Nonmetastatic Breast Cancer Setting: The Controversy and a Value Assessment

Michael Gnant, MD, FACS, Catherine Van Poznak, MD, and Lowell Schnipper, MD

OVERVIEW

Clinical trials and meta-analyses investigating bisphosphonates as an adjuvant breast cancer therapy have shown a consistent trend, with postmenopausal women and women receiving ovarian suppression with gonadotropin-releasing hormone therapy gaining improved breast cancer outcomes with the use of adjuvant bisphosphonate therapy. The interpretation of these data is controversial, because the primary endpoints of the majority of adjuvant bisphosphonate studies have been negative. Pros and cons as well as the value of adjuvant bisphosphonate therapy are discussed here.

Despite notable recent advances in therapy, breast cancer remains one of the leading causes of cancer deaths among women worldwide. Adjuvant endocrine therapy is the state-of-the-art adjuvant treatment for all patients with estrogen receptor–positive early-stage breast cancer. For postmenopausal patients, aromatase inhibitors have been identified as one standard of care for this endocrine treatment, owing to their superior efficacy compared with tamoxifen, as demonstrated in several large clinical trials.[1-8] The main side effect of aromatase inhibitors is their ability to compromise bone health,[9-11] based on the (oncologically intended) reduction of estradiol levels.[12] Thus, the concomitant use of bone-targeted agents has been extensively investigated to protect patients from these side effects and to prevent treatment-induced bone loss and fractures.[13]

Several trials using antiresorptive agents such as bisphosphonates have demonstrated that treatment-induced bone loss can be successfully prevented.[13-21] It remains controversial whether these successful interventions actually lead to a notable reduction in the incidence of fractures. More recently, the anti–receptor activator of nuclear factor kappa-B ligand denosumab was shown to dramatically reduce fractures in a pivotal phase III trial. As a result, most clinical practice guidelines recommend monitoring of bone mineral density, as well as treatment with bisphosphonates or denosumab.[22]

In addition to their ability to protect and restore bone health for patients with early breast cancer, antiresorptive drugs have also been investigated for their oncologic benefits as adjuvant therapy. This was based on their antineoplastic potential, which was well described in preclinical in vitro and in vivo studies, as well as on putative indirect effects of antiresorptive therapies on the bone microenvironment.[23]

Clinical trials and meta-analyses investigating bisphosphonates as an adjuvant breast cancer therapy have shown a consistent trend, with postmenopausal women and women receiving ovarian suppression with gonadotropin-releasing hormone therapy gaining improved breast cancer outcomes with the use of adjuvant bisphosphonate therapy. The interpretation of these data is controversial, because the primary endpoints of adjuvant bisphosphonate studies have been negative. Pros and cons as well as the value of adjuvant bisphosphonate therapy are discussed here.

THE CASE FOR USING BONE-MODIFYING AGENTS AS ROUTINE ADJUVANT THERAPY

Early Studies

More than 2 decades ago, several trials investigated the adjuvant effects of the first-generation bisphosphonate clodronate. In a pivotal German trial,[24] 302 patients were selected because of the presence of disseminated tumor cells (DTCs) in their bone marrow and they were randomly assigned to receive oral clodronate or not. Early results from this trial demonstrated significant improvements in disease-free survival (DFS; 87% vs. 71% at 3 years; $p < .0001$) and even overall survival (96% vs. 85%; $p = .0001$); however, later updates did not confirm these findings. In addition, the Royal Marsden trial examining 2 years of clodronate treatment versus placebo yielded notable outcome improvements (HR at 5

years, 0.69).[25] A third adjuvant clodronate trial not only failed to confirm these promising results, but it even reported a detrimental effect of adjuvant clodronate on outcomes (i.e., increasing nonbone metastases).[26] As a result of these controversial trial results, oral bisphosphonates never became accepted as a standard of care.

More Recent Studies With Oral Bisphosphonates

Oral bisphosphonates were also studied in more recent larger trials. NSABP B-34 is a randomized, double-blind, placebo-controlled study among more than 3,300 patients with breast cancer. Patients were stratified by age, axillary nodal status, and hormone receptor status and were randomly assigned to either 1,600 mg of oral clodronate per day for 3 years or placebo. After a median follow-up of almost 8 years, overall DFS did not differ between the groups (hazard ratio [HR], 0.91); however, a beneficial effect was observed for postmenopausal patients (see below).[27] This was also seen in the GAIN study, a multicenter, open-label, randomized controlled phase III trial that recruited more than 3,000 patients to investigate the adjuvant effect of ibandronate in node-positive early breast cancer. Patients were randomized in a 2:1 ratio to either 50 mg of ibandronate per day or placebo for 2 years. Again, the overall results of this trial were negative: oral ibandronate did not improve outcomes of patients but there was a positive trend for DFS in the postmenopausal subgroup,[28] fueling the discussion about differential effects of adjuvant bisphosphonates according to menopausal status.

Adjuvant Studies With Intravenous Aminobisphosphonates

Most adjuvant bisphosphonate studies have used zoledronic acid, the most potent bisphosphonate. With respect to DTCs, smaller studies among women with high-risk early breast cancer have reported that monthly zoledronic acid in addition to treatment with cytotoxic anticancer therapy can effectively increase DTC clearance and can reduce DTC numbers and persistence in bone marrow compared with standard therapy alone.[29-31] These bisphosphonate-mediated decreases in DTC have been suggested as a potential mechanism underlying the observed clinical benefits in the large adjuvant studies.

In the ABCSG-12 trial, anticancer effects with zoledronic acid were seen both in and outside bone. When patients who received zoledronic acid were compared with those who did not, improved DFS and fewer locoregional, visceral, and nonvisceral recurrences were observed.[32] After longer-term follow-up (median 76 months), a persistent benefit in DFS more than 3 years after completion of treatment suggests a sustained "carryover" benefit from adding zoledronic acid to endocrine therapy.[33] In addition, zoledronic acid also produced a significantly improved overall survival (HR, 0.59; p = .042). Further analyses on the mature dataset from ABCSG-12 revealed a significant difference in zoledronic acid treatment effects based on patient age at enrollment[33]: although no significant decrease was observed in women age 40 or younger, zoledronic acid produced a 42% reduction in the risk of DFS events among premenopausal women older than age 40 at study entry (HR, 0.58; p = .003). In addition, zoledronic acid was associated with a strong trend toward a 43% reduction in the risk of death for this older subset of patients (HR, 0.57; p = .057).

These results were supported by two adjuvant zoledronic acid trials (ZO-FAST and Z-FAST) among postmenopausal women, in which DFS was a secondary end point. In ZO-FAST,[34] the zoledronic acid group showed a significant DFS improvement of 41% (HR, 0.588; log-rank p = .0314) after a median follow-up of 3 years. The sibling study, Z-FAST,[35] showed similar results, in which zoledronic acid yielded reduced disease recurrence at 61 months of follow-up.

In the AZURE trial, however, the addition of zoledronic acid to standard adjuvant breast cancer therapy did not significantly increase DFS compared with the overall population.[36] Notably, a differential effect of the bisphosphonate was observed with respect to menopausal status of trial patients. There was no difference in DFS with zoledronic acid among pre- or perimenopausal patients; however, among patients who were postmenopausal for at least 5 years before study entry, zoledronic acid significantly reduced the risk of DFS events by 24% (p = .02) and the risk of death by 29% (p = .017).[37]

Thus, the indirect metastasis-preventing effect of bisphosphonates is confined to postmenopausal women and to premenopausal women who receive ovarian function suppression, but not younger patients without ovarian function suppression. This suggests that estrogen effects on the bone microenvironment play a substantial role in determining who may benefit most from adjuvant bisphosphonate therapy.[38]

Eventually, the large Early Breast Cancer Trialists Collaborative Group meta-analysis confirmed this by assembling patient-level data on the majority of patients included in any

KEY POINTS

- **Adjuvant breast cancer systemic therapy is given with curative intent.**
- **Data are evolving to suggest that the adjuvant use of a bone-modifying agent (bisphosphonate or denosumab) may have anti–breast cancer effects for postmenopausal women (or women receiving ovarian-suppressing therapy).**
- **The primary endpoints of the majority of adjuvant bisphosphonate studies to date have been negative, with the positive anticancer findings identified through subset analyses.**
- **Controversy exists over whether the existing data are sufficient to influence adjuvant breast cancer treatment recommendations.**
- **The value of adjuvant bone-modifying agents for adjuvant breast cancer care will be discussed, taking into account the clinical benefit and toxicity of these agents and their cost.**

adjuvant clinical bisphosphonate trial. Based on data from almost 19,000 patients, the results of this meta-analysis were clearly positive: bisphosphonates were demonstrated to have a positive effect on the recurrence of bone metastasis and overall survival for postmenopausal patients with breast cancer.[39] It is important to note that outcome benefits appear to be confined to patients who are postmenopausal (either naturally or therapy induced) at diagnosis; clinically important benefits were seen for these women, with improvements in overall breast cancer recurrence, distant recurrence at any site, bone recurrence, and breast cancer-specific mortality (relative risk of 0.86, 0.82, 0.72, and 0.82, respectively).

DFS Results of Adjuvant Denosumab

In an early and premature analysis of the ABCSG-18 data,[40] adjuvant denosumab appears to yield DFS benefits that are similar to what was observed in the bisphosphonate meta-analysis. Further follow-up of this trial as well as the results of the large D-CARE trial are expected for 2018 and will clarify the outcome effects of adjuvant denosumab.

RESERVATIONS ON THE USE OF BONE-MODIFYING AGENTS AS ANTICANCER THERAPY IN THE NONMETASTATIC SETTING

Adjuvant breast cancer studies investigating bone-modifying agents with a bisphosphonate or denosumab have been reported, and additional studies are ongoing.[41] The majority of reported studies have identified a positive effect of the bone-modifying agent in secondary or exploratory analyses. The anticancer benefits are particular to postmenopausal women. For the purposes of this discussion, the term "postmenopausal" applies to women who are clinically not pre- or perimenopausal and includes women receiving ovarian suppression with gonadotropin-releasing hormone therapy.

The fundamentals of bisphosphonate pharmacology are known, including absorption, distribution, elimination, pharmacokinetics, and pharmacodynamics and the impact that structural alterations to the bisphosphonate chemical structure have on potency.[42] Bisphosphonates enter the osteoclast by endocytosis. Nitrogen-containing bisphosphonates, such as zoledronic acid and ibandronate, inhibit farnesyl pyrophosphate synthase and prevent the prenylation of small guanosine 5′-triphosphatase proteins essential for the function and survival of osteoclasts. The non–nitrogen-containing bisphosphonates, such as clodronate, are incorporated into adenosine 5′-triphosphate analogs in the osteoclast and promote apoptosis.[42]

Bisphosphonates may have direct or indirect antitumor effects within the bone and may impact tissues outside of the skeleton. There are data suggesting that bisphosphonates alter tumor behavior; affect host or tumor vasculature, the tumor microenvironment, and its associated immune cells, fibroblasts, stromal cells, and macrophages; and effect circulating factors.[43,44] It is not known whether any, or which, of these properties are related to the potential anticancer effects seen with adjuvant bisphosphonate therapy for postmenopausal women with breast cancer.

Incorporating an adjuvant bone-modifying agent into the care plan of postmenopausal women may reduce the risk of osteoporosis, osteoporotic fractures, and possibly the risk of breast cancer outcomes. The risk of serious toxicities affecting the gastrointestinal tract, renal system, osteonecrosis of the jaw, and atypical fractures appears to be lower than the potential benefits in anticancer outcomes. Yet the use of adjuvant bisphosphonates for postmenopausal women with early-stage breast cancer does not appear to be uniformly embraced by clinicians, patients, or health care payers. Indeed, the Canadian Bone and the Oncologist New Updates meeting debated "are adjuvant bisphosphonates now standard of care in early stage breast cancer" and the majority of the meeting attendees voted "no."[45]

Ten potential reasons to hesitate before adopting adjuvant bisphosphonates in the care of postmenopausal women with breast cancer are outlined here.

1. The adjuvant bisphosphonate clinical trials were not designed to test the hypothesis that there would be an effect in postmenopausal women that differs from pre- and perimenopausal women.
2. Meta-analyses do not substitute for well-designed, randomized clinical trials testing an a priori hypothesis.
3. Confidence in the data and the durability of the anticancer findings may be questioned. First, ZO-FAST and Z-FAST are "twin" studies in which zoledronic acid was used up front or in a delayed manner for postmenopausal women receiving an adjuvant aromatase inhibitor.[46] These parallel studies do not report the same cancer outcomes at 5 years. ZO-FAST reports improved DFS with the use of immediate use of zoledronic acid (HR, 0.66; 95% CI, 0.44–0.97; p = .0375), and Z-FAST does not have statistical significance for disease recurrence or death between the arms.[34,47] Second, the long-term follow-up of ABCSG-12 does not show retained statistical improvement in DFS.[48] The long-term follow-up of AZURE does not show maintained statistical significance for improved overall survival with use of zoledronic acid for participants who were more than 5 years since menopause.[37]
4. No proven mechanism to explain the different cancer outcomes among pre-, peri-, and postmenopausal women has been identified.
5. For postmenopausal women, adjuvant bisphosphonates appear to affect the risk of bone metastases. Estrogen receptor–positive breast cancers are more likely to metastasize to bone than estrogen receptor–negative, progesterone receptor–negative, and HER2-negative (triple-negative) breast cancers.[49] Yet tumor characteristics (i.e., estrogen receptor status) did not correlate with benefit from adjuvant bisphosphonate use.
6. Patient selection factors that may be used in the decision to treat with adjuvant bone-modifying therapy are not refined. The use of adjuvant bisphosphonate

therapy for all postmenopausal women with a risk of breast cancer recurrence seems indiscriminate.

7. If the decision is made to use an adjuvant bone-modifying agent, the data do not provide clarity on the optimal time to start an adjuvant bone-modifying agent or on the drug selection, dose, dosing interval, or duration of therapy.
8. If there are challenges in tolerating adjuvant therapy, it is not known whether the bone-modifying agent should be discontinued or perhaps changed to an alternative drug and/or dosing schedule.
9. Polypharmacy can negatively influence compliance with, adherence to, and persistence of medication use. These factors must be investigated as related to adjuvant bone-modifying therapy.
10. The value of using an adjuvant bone-modifying agent and the financial toxicities to the patient and the health care system have not been prospectively defined.

In summary, confidence in the data is undermined by the limited hypothesis testing and the absence of a proven biologic mechanism to account for the reported anticancer outcomes among postmenopausal women treated with adjuvant bisphosphonate therapy. This is complicated by challenges in identifying which postmenopausal women to treat and an optimal treatment regimen. Guiding principles in medical care address having an understanding of the drug to be used, its mode of action, the risk-benefit profile for the patient to be treated, the dosage to be prescribed, the dosing interval to be used, the duration of therapy, and the toxicity profile (which may include financial toxicities) prior to prescribing a medication. Today, there remains uncertainty on many of these key factors. Additional data are needed to optimally understand the utility of adjuvant bone-modifying agents and to identify those patients most likely to benefit from therapy.

BISPHOSPHONATES AS ADJUVANT THERAPY FOR EARLY BREAST CANCER: A VALUE ASSESSMENT

The value associated with the use of bisphosphonates as adjunctive therapy for early breast cancer is controversial. Administration of bisphosphonates has two plausible goals: one is to abrogate bone loss (particularly when using aromatase inhibitors) and the other relates to potential beneficial effects on disease recurrence, as well as mortality, for postmenopausal women. Multiple studies have addressed this question, yet controversy remains. The following remarks attempt to view the question of the utility of these agents in the context of the value framework developed by ASCO.

ASCO's Value in Cancer Care Task Force has been committed to identifying approaches that support the highest quality of cancer care, while bending the cost curve downward. The basic assumption is that provision of high-quality cancer prevention and treatment practices at the lowest reasonable cost is the embodiment of high-value care. Examples of the initiatives the ASCO task force has undertaken thus far include participation in the "Choosing Wisely" campaign of the American Board of Internal Medicine Foundation and *Consumer Reports*.[50,51] Ten commonly used practices in medical oncology were identified on the basis of there being no evidence that they add clinical value but do have high associated costs. These included unnecessary imaging, unnecessary staging in early cases of breast and prostate cancer, proper use of cytokines and high-quality end-of-life care that shifts from cancer-directed to symptom-directed treatment,[50,51] and the development of a model system with which to assess the value of antineoplastic therapies.[52,53] ASCO's model framework enables assessment of the incremental benefit associated with a new drug or regimen when compared in a prospective randomized clinical trial. The original intent of the framework was to provide physicians and patients with a rapidly accessible, easily comprehensible way of viewing comparative options for management of a specific cancer, as well as to demonstrate the cost associated with administering the therapies both from the perspective of societal and out-of-pocket costs to the patient. The latter have been a steadily growing burden, frequently resulting in emotional stress, physical symptoms, personal bankruptcy, and possibly earlier mortality.[52,53] The use of tools such as this and other frameworks is another area that is receiving substantial attention from the payer community.

The ASCO Value Assessment Framework[54,55] measures the incremental clinical impact (termed the net health benefit [NHB]) of a new therapy compared with a control treatment when these have been evaluated in a prospective randomized trial. The framework includes several parameters, each of which is assigned a maximum point score that reflects the difference between the arms in a trial. Two distinct frameworks have been developed, one for advanced disease and the other for the potentially curative setting. The elements within the framework are as follows:

1. Clinical benefit: the maximum score is 100 when comparing magnitude of difference of the test regimen and its control.
2. Toxicity: a maximum of 20 points can be added or subtracted from the clinical benefit score depending on the relative toxicity or lack thereof of the new therapy compared with the comparator.
3. Bonus points: these are awarded for specific milestones reached such as improved symptom control in advanced disease.
4. NHB: the NHB represents the sum of clinical benefit and bonus scores from which is subtracted (or added) the toxicity score.
5. Cost for adjuvant regimens or the total cost (based on average sale price of the control and test regimens): the cost of the new regimen is not factored into a final value assessment but is represented in parallel with the clinical benefit. The goal is to promote discussion between physician and patient about the clinical impact of a therapy and whether the extent of benefit is justified by the financial cost to the patient and family unit.

The Early Breast Cancer Trialists Collaborative Group performed a meta-analysis of all prospective randomized trials and concluded that "some years of adjuvant bisphosphonate treatment can reduce breast cancer recurrence rates in bone and improve breast cancer survival, but have provided clear evidence of benefit only in women who are postmenopausal (natural or induced) at the time bisphosphonates are started."[39] The European Society of Medical Oncology has evaluated the aggregated data from a large number of clinical trials and has published guidelines that support the use of adjuvant bisphosphonates as part of the systemic treatment of early-stage breast cancer for postmenopausal women, whether they are postmenopausal through a natural menopause or as a result of ovarian suppression.[41]

The value assessment of adjuvant bisphosphonate is based on a subset of 11,767 postmenopausal women included in the meta-analysis of trials comparing bisphosphonate use versus no bisphosphonate use in early breast cancer. The included studies used durations of bisphosphonate treatment varying between 2 and 5 years, with no conclusion as to the optimal period of treatment.

The meta-analysis demonstrated an 18% reduction in the risk of breast cancer mortality at 10 years among postmenopausal women who took a bisphosphonate compared with those treated with placebo. In absolute terms, the advantage is quite small (3.3%). When using the ASCO value framework, this difference in outcome yields a clinical benefit score of 18 points (of a possible 100). Most studies of bisphosphonates registered small increases in toxicity. Were there no toxicity, the ASCO framework would yield no added or subtracted points. Because the toxicities were generally few and mild, for the purposes of this analysis, the clinical benefit will be reduced by 5%, thereby subtracting 1 from the clinical benefit score to yield an NHB of 17. To place this in perspective, in the study comparing ibrutinib to chlorambucil as first-line therapy for chronic lymphocytic leukemia, the NHB score was 77 based upon a reduction in risk of death of 84%. In a comparison between chemotherapy (doxorubicin, cyclophosphamide, and paclitaxel vs. the same agents plus trastuzumab), the NHB score in favor of the trastuzumab-containing regimen was 47. The cost of the adjuvant endocrine therapy plus bisphosphonate will be presented in parallel with the NHB calculations. Comparisons with clinical trials in which the lest agent yielded a larger NHB will be shared to demonstrate the range of possible outcomes in the value analysis.

CANCER PREVENTION, HEREDITARY GENETICS, AND EPIDEMIOLOGY

European/U.S. Comparison and Contrasts in Ovarian Cancer Screening and Prevention in a High-Risk Population

Marian J. Mourits, MD, PhD, and G. H. de Bock, PhD

OVERVIEW

The history of screening and prevention of ovarian cancer among high-risk women in the United States and Europe is one of mutual inspiration, with researchers learning from each others' findings and insights and collaborating with investigators from both sides of the Atlantic ocean. Examples of simultaneous and joint development of knowledge and scientific points of view include the paradigm shift from ovarian to fallopian tube high-grade serous cancer and the cessation of simultaneous adoption of ovarian cancer screening by clinicians in both the United States and Europe. Examples of joint efforts with fruitful results include international collaboration in large population-based, genome-wide association studies and in epidemiologic database studies. Research in the field of hereditary ovarian cancer is a great example of mutual inspiration and joint efforts for the purpose of improving knowledge and health care for women with hereditary ovarian cancer.

Ovarian cancer is the most lethal of all gynecologic cancers. The poor prognosis of ovarian cancer is largely attributable to the fact that patients with the disease present late. Although the symptom index for ovarian cancer may help to identify women with the disease, symptoms are not early signs, and most women are diagnosed at an advanced stage.[1,2]

Once the malignancy is detected, usually when classified at International Federation of Gynecology and Obstetrics stages III to IV, standard treatment consists of a combination of debulking surgery and chemotherapy, and survival rates have shown little improvement.[3] Over the last decade, it became clear that ovarian cancer is not a single disease; different histologic subtypes of epithelial ovarian cancer with different molecular pathogeneses and prognoses can be identified.[4] This knowledge will guide future research initiatives to improve early detection of and prognosis for epithelial ovarian cancer.[5]

OVARIAN CANCER SCREENING

Although ovarian cancer screening cannot prevent cancer, it was long hoped that screening might permit detection at an early stage when a cure is possible. Data from general population screening were disappointing; therefore, a large, more sophisticated screening study began in the 1990s in the United Kingdom.[6] Postmenopausal women age 45 or older were randomly assigned to a screening or control group. Women randomly assigned to screening were offered three annual screens that included: cancer antigen 125 (CA125) measurements; pelvic ultrasonographies if the CA125 measurement was greater than 30 U/mL; and referrals for gynecologic counseling if the ovarian volume reached 8.8 mL or greater. The development of epithelial ovarian cancer was the study endpoint. The median survival of women with index cancers was longer for the screened group than for the control group (72.9 vs. 41.8 months; p = .01), however, the number of deaths attributable to ovarian cancer did not differ.[6] To further improve screening results, a new ovarian cancer risk algorithm was designed using pelvic ultrasonography and trends in serum CA125. This algorithm was developed by the U.K. Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) group, another large screening study.[7] Outcomes of the UKCTOCS study showed a favorable stage distribution using the risk of ovarian cancer algorithm, however, there was no notable survival benefit in the screened group compared with the control group.[8] In the United States, the Prostate, Lung, Colorectal, and Ovarian (PLCO) cancer screening trial investigators randomly assigned women between age 55–74 to an annual screening group and a control group. The screened group underwent an annual pelvic ultrasound and serum CA125 measurement. Increased morbidity was reported owing to high false-positive results (8%) in the screening group, which resulted in women undergoing surgery, however, no reduction in ovarian cancer mortality by screening was found.[9]

Because the positive and negative predictive value of screening depends on the incidence of the disease, screening was

expected to be more effective for a high-risk population. The U.K. Familial Ovarian Screening Study (UKFOCSS) was developed as a prospective cohort study to assess the value of screening in a high-risk population specifically. The UKFOCSS recruited more than 5,000 high-risk women between 2002 and 2009, and screening was performed with four monthly CA125 measurements analyzed by the risk of ovarian cancer algorithm. Although the final UKFOCSS results are not yet available, screening is not expected to improve ovarian cancer–specific survival nor to be cost-effective.

HEREDITARY OVARIAN CANCER

Since the *BRCA* genes were discovered in 1994 and 1995,[10,11] clinicians worldwide have begun developing guidelines for a systematic ovarian cancer screening program for women with *BRCA1/2* mutations, consisting mostly of an annual pelvic ultrasound and serum CA125 measurement.[12-16]

Lynch syndrome (LS) is another hereditary syndrome with an increased ovarian cancer risk. LS is an autosomal dominant predisposition characterized by germline mutations in one of four DNA mismatch repair genes: *MLH1*, *MSH2*, *MSH6*, and *PMS2*.[17] For female carriers with LS, endometrial cancer is, after colon cancer, the most common tumor type with a cumulative lifetime risk of 21%–71%; the risk of ovarian cancer is between 6% and 12%.[18] Because of these high cancer risks, women with LS are regularly surveyed. Endometrial cancer surveillance seems to be effective in early detection of endometrial cancer[19-21]; however, the value of surveillance for ovarian cancer has not yet been proven.[19,22]

In a recent review on ovarian cancer in LS, the mean age of women with LS and ovarian cancer was 45.3 years and patients had a wide age range of onset (between age 19–82).[23] For these patients, ovarian cancer was mostly diagnosed at an early stage (International Federation of Gynecology and Obstetrics stage I–II), exhibited a variety of histopathological subtypes (frequently endometrioid or clear cell), and had a survival rate of 86%.[23] Data on the role of surveillance in the detection of ovarian cancer in women with LS were scarce, and the early stage could not be attributed to screening.[23]

KEY POINTS

- **Ovarian cancer screening is not effective in early detection of the disease.**
- **Most, if not all, high-grade serous ovarian cancers arise in the fallopian tube.**
- **All women with epithelial ovarian cancer should be offered genetic counseling and testing to reduce morbidity and mortality for patients and their relatives.**
- **The only effective strategy to prevent high-risk women from dying of the disease is to remove the ovaries and fallopian tubes before the cancer incidence rises.**
- **Research in the field of hereditary ovarian cancer is an example of a joint effort and fruitful collaboration between researchers on both sides of the Atlantic ocean.**

TIME TO STOP OVARIAN CANCER SCREENING

After 2 decades of ovarian cancer screening, and despite major efforts in large prospective trials, no evidence of a survival benefit of screening has been reported. Clinicians, almost simultaneously in the United States and European Union, began to omit gynecologic screening and instead adopted risk-reducing salpingo-oophorectomy (RRSO) and reported on their results.[24-30] In 2009, a meta-analysis on risk-reduction estimates showed that RRSO, performed at ages 35–40 for BRCA1 and 40–45 for BRCA2 mutation carriers (i.e., before the cancer incidence rises[31]), is effective in the detection of more than 96% of BRCA-associated ovarian cancers (hazard ratio, 0.21; 95% CI, 0.12–0.39).[32]

NEW PARADIGM OF OVARIAN CANCER IN BRCA1/2 MUTATION CARRIERS

Since the adoption of RRSO for BRCA1/2 mutation carriers, increasing percentages of fallopian tube (pre)malignancies have been found. In 1998, Dubeau[33] was the first to propose that the various ovarian cancers (serous, endometrioid, mucinous, and clear cell) resemble the epithelium of the fallopian tube, endometrium, endocervix, and gastrointestinal tract, respectively. In 2001, a group of Dutch researchers published a small series on the fallopian tubes of high-risk women and found preneoplastic lesions in benign fallopian tube tissue, not in controls.[34] One patient, a BRCA1 mutation carrier, showed loss of the wild-type BRCA1 allele in a severely dysplastic lesion of the distal fallopian tube.[34] The publication by Piek et al[34] opened the eyes of many pathologists around the world, including Crum and colleagues[35] in Boston, Massachusetts, who were the most successful in further elaborating the new paradigm. They were the first to describe the phenomenon of tubal intraepithelial carcinomas, later designated serous tubal intraepithelial carcinomas. From that point, fallopian tubes were more carefully examined, which resulted in an increasing incidence of premalignant and early stages of high-grade serous cancer in prophylactically removed fallopian tubes.[36-39] Many research projects have since been initiated and are still ongoing to find definitive evidence that the fallopian tube is the tissue of origin of pelvic high-grade serous cancer.[40,41]

IDENTIFICATION OF MUTATION CARRIERS

Since the isolation of *BRCA1/2*, the National Comprehensive Cancer Network, which is an alliance of leading U.S. cancer centers, and various family cancer clinics in Europe have developed guidelines for surveillance and prophylactic surgery.[12,14,16] More recently, with the introduction of next-generation sequencing and the availability of gene panels, genetic testing for patients with ovarian cancer and family members of mutation carriers is within reach of many women. Year by year, the costs for genetic testing have dropped dramatically, and genetic counseling and testing was recently incorporated in practice guidelines in the United States and Europe.[42,43] However, referral for genetic counseling and testing is not implemented among all patients with ovarian cancer in the United States and Europe, and

accessibility differs among patient groups. A recent study on adherence to National Comprehensive Cancer Network guidelines showed differences in genetic testing for patients with ovarian cancer in the United States: women were more frequently tested if they were younger at diagnosis, had a lower stage of ovarian cancer, were white, had private/managed care insurance, and had a family history of cancer.[44] Adherence and access to genetic counseling guidelines in different European countries has not yet been studied. Because genetic counseling and testing of all patients with ovarian cancer can reduce morbidity and mortality from ovarian (and breast) cancer among their relatives, and because prophylactic surgery is cost-effective, referral of all women with epithelial ovarian cancer should be encouraged, regardless of age, histologic type, and family history.[42,43]

COMPARISON AND CONTRASTS BETWEEN THE UNITED STATES AND EUROPEAN UNION

The knowledge and understanding of inherited ovarian cancer has expanded greatly since the discovery of *BRCA1/2*. Scientific expertise has developed on both sides of the Atlantic ocean, and researchers all over the world are sharing new findings and insights on the implications of the hereditary cancer syndrome and the ovarian cancer paradigm shift. Collaboration between geneticists and epidemiologists from Western countries resulted in large cohorts of BRCA1/2 mutation carriers (e.g., CIMBA, IBCCS, kConFab, BCFR, GEO-HEBON, EMBRACE, GENEPSO), resulting in numerous important studies on risk estimates, genetic modifiers and correlation of cancer incidence, and lifestyle and reproductive factors.

There are no scientific controversies on the pathogenesis and extraovarian origin of high-grade serous ovarian cancer, and the paradigm shift concerning the cell of origin arising from the fallopian tube is an excellent example of mutual inspiration and collaboration.[34,45] Regarding clinical implications, no controversies exist regarding the cessation of ovarian cancer screening, which was adopted almost simultaneously on both sides of the ocean.[42,43] If there are contrasts between countries and continents, they exist mostly in the field of access to genetic counseling and testing for all patients with ovarian cancer and in models of care for women at increased risk.[46,47]

One contrast across the ocean seems to be the extent of risk-reducing surgery, with or without hysterectomy. Although the overall risk of uterine cancer after RRSO is not increased, more clinicians in the United States than in Europe are inclined to offer a hysterectomy with RRSO.[47]

In conclusion, research and guidelines on hereditary ovarian cancer is a great example of mutual inspiration and joint efforts of researchers from all over the world, for the purpose of improving knowledge and health care for women with hereditary ovarian cancer.

Social Media and Mobile Technology for Cancer Prevention and Treatment

Judith J. Prochaska, PhD, MPH, Steven S. Coughlin, PhD, and Elizabeth J. Lyons, PhD, MPH

OVERVIEW

Given the number of lives affected by cancer and the great potential for optimizing well-being via lifestyle changes, patients, providers, health care systems, advocacy groups, and entrepreneurs are looking to digital solutions to enhance patient care and broaden prevention efforts. Thousands of health-oriented mobile websites and apps have been developed, with a majority focused upon lifestyle behaviors (e.g., exercise, diet, smoking). In this review, we consider the use and potential of social media and mHealth technologies for cancer prevention, cancer treatment, and survivorship. We identify key principles in research and practice, summarize prior reviews, and highlight notable case studies and patient resources. Further, with the potential for scaled delivery and broad reach, we consider application of social media and mHealth technologies in low-resource settings. With clear advantages for reach, social media and mHealth technologies offer the ability to scale and engage entire populations at low cost, develop supportive social networks, connect patients and providers, encourage adherence with cancer care, and collect vast quantities of data for advancing cancer research. Development efforts have been rapid and numerous, yet evaluation of intervention effects on behavior change and health outcomes are sorely needed, and regulation around data security issues is notably lacking. Attention to broader audiences is also needed, with targeted development for culturally diverse groups and non-English speakers. Further investment in research to build the evidence base and identify best practices will help delineate and actualize the potential of social media and mHealth technologies for cancer prevention and treatment.

New cancer cases in the United States number nearly 1.7 million annually. With earlier detection and improved treatments, the 5-year cancer survival rate increased from 49% during 1975 to 1977 to 69% during 2005 to 2011. Yet, cancer remains the second leading cause of death in the United States, with a substantial proportion of cancers preventable. Tobacco use alone is estimated to cause 29% of all cancer deaths,[1] and more than one in five cancer diagnoses are related to lifestyle factors of obesity, physical inactivity, alcohol consumption, dietary factors, sexual health, and sun exposure.[2] Vaccinations and regular cancer screening also are important for cancer prevention and early intervention. Among cancer survivors, quitting smoking and maintaining a healthy body weight through physical activity and healthy nutrition reduces the risk of disease recurrence or progression.

Given the number of lives affected by cancer and the great potential for optimizing well-being via lifestyle changes, patients, providers, health care systems, advocacy groups, and entrepreneurs are looking to digital solutions to enhance patient care and broaden prevention efforts. In this review, we consider the use and potential of social media and mHealth technologies for cancer prevention and cancer care. Social media are websites and applications (apps) that allow users to create, share, and participate via virtual communities and networks. Social media can provide fellowship with others, because of sharing common attitudes, interests, goals, or experiences, person-to-person, in real time, at low or no cost. mHealth, more broadly, refers to the delivery, facilitation, and communication of health-related information via mobile telecommunication and multimedia technologies (e.g., handheld devices, smartphones, tablets). The boom in mHealth has been made possible by the high penetration of internet access and increased use of smartphones. An estimated 89% of United States adults are now online, with smartphone ownership at 72%.[3] As such, social media and mHealth technologies offer the ability to scale and engage entire populations, develop supportive social networks, connect patients and providers, encourage adherence with cancer care, and collect vast quantities of data for advancing cancer research.

Our review attends to the use of social media and mHealth technologies in cancer prevention, cancer treatment, and survivorship. The field is broad and emerging rapidly with

the need for determination of evidence base and identification of best practices for patient care and data security. Given the breadth of our interest, a comprehensive review is not feasible. Instead, we identify key principles in research and practice, summarize prior reviews, and highlight notable case studies and patient resources. Further, with the potential for scaled delivery and broad reach, we consider application of social media and mHealth technologies in low-resource settings and best practices for dissemination.

SOCIAL MEDIA APPLICATIONS TO CANCER PREVENTION AND CANCER CARE

Social media come in several forms with differing audiences and emphases (Table 1). Among United States adults online, 79% use Facebook, 32% Instagram, 31% Pinterest, 29% LinkedIn, and 24% Twitter.[4] Further, social media use in the United States has become routine, with daily use reported by 76% of Facebook users, 51% of Instagram users, and 42% of Twitter users.

Most health-oriented research has been performed on general social media outlets such as Facebook and Twitter, with relatively little information available on smaller or specialized networks such as Snapchat. Yet, the emphases of specialized networks may make some platforms more optimally suited for specific intervention components. For example, video on YouTube or photos on Instagram may be effective for instruction and role modeling. Smaller and more private social networks may be preferred when discussing sensitive topics such as weight, tobacco, heavy alcohol use, or sexual activity. If using a larger and more general social medium, it may be prudent to consider private invitation-only groups, such as the example presented on use of Twitter to deliver private, peer-to-peer, quit-smoking groups (Sidebar 1). Closed quit-smoking groups targeting young adults also have been tested on Facebook[5,6] and WhatsApp[7] with encouraging short-term effects.

KEY POINTS

- **Innovations in mHealth and social media applications are occurring across the cancer spectrum, from primary prevention to screening, early diagnosis, treatment, survivorship, and end-of-life care.**
- **Thousands of health-oriented mobile websites and apps have been developed, with most focused upon lifestyle behaviors (e.g., exercise, diet, stress, smoking).**
- **Advantages of social media and mHealth technologies include low- or no-cost, high scalability, self-tracking and tailored feedback functionalities, use of images and video for enhanced health literacy, broad reach, and data sharing for large-scale analytics.**
- **Although development efforts have been rapid and numerous, evaluation of intervention effects on behavior change and health outcomes are sorely needed, and regulation around data security issues is notably lacking.**
- **Targeted development is also needed for culturally diverse groups and non-English speakers.**

TABLE 1. Categories of Existing Social Media and Popular Examples

Category	Examples
Major general-purpose social media outlets	Facebook; Twitter
Social media with a chronic illness focus	Smartpatients; CaringBridge; PatientsLikeMe
Photo-emphasizing social media	Instagram; Snapchat
Video-emphasizing social media	YouTube; Periscope
Blogs and message board–style networks	Tumblr; Reddit; Medium
Social video game or simulation networks	Xbox Live; Apple GameCenter; Second Life

Social media can provide varying degrees of anonymity, which may be attractive for stigmatized behaviors or medical conditions. When faced with the unknowns of a new diagnosis and a menu of treatment options, each with particular risks and benefits, social media can provide a unique connection with others who have direct personal experience. For example, with a focus on empowering patients, *PatientsLikeMe* is a free website, organized by medical conditions, where people can share health data, track their progress, connect with others, and contribute to big data analytics. *PatientsLikeMe* reports nearly 450,000 registered users and offers communities on nine cancer types.

With a specific focus on cancer survivors, *Springboard Beyond Cancer* addresses more than 20 symptoms and health behaviors. The site promotes skills training and use of strategies for active self-management among cancer survivors with the aim of lessening the impact of disease and treatment side effects and improving quality of life.[9] The mobile-optimized website draws existing information from Cancer.org, Cancer.gov, and literature related to survivorship and health behavior interventions.

With social media sites that are largely uncurated or expert moderated, patients should be forewarned that negative or inaccurate health information might be posted. For example, user communities may encourage excessive dieting, vaccine avoidance, or use of nonevidence-based treatments (e.g., laser or herbs for quitting smoking). Harassment also can be a problem on more open networks such as Twitter and Reddit. Review of online content on breast cancer identified difficulty finding accurate information because of the lack of regulated sites.[10] Although social media has become an important channel for disseminating findings from medical studies, the problem of fake news, including fake health news, is real, with growing recognition of the need for countermeasures.[11,12]

KEY PRINCIPLES OF SOCIAL MEDIA TO ENHANCE CANCER PREVENTION AND TREATMENT

At the foundation of social media applications for cancer prevention and control are techniques related to social support, health communication, self-regulation, and motivation enhancement.

SIDEBAR 1. *Tweet2Quit* Smoking-Cessation Intervention

Description

In private and by invitation-only 20-person groups, *Tweet2Quit* fostered peer-to-peer support and accountability for maintaining commitment to quit smoking. The Twitter-based intervention encouraged engagement via two scheduled automessages a day: (1) discussion questions based on tobacco treatment clinical practice guidelines and (2) individualized autofeedback based on past-day participation. A customized computer program automatically downloaded the group's tweets daily, analyzed those who tweeted versus not, and sent prewritten and varied messages that praised tweeters for participating and encouraged nontweeters to do so. The groups lasted 100 days.

Study Design

In a two-group randomized controlled trial with 160 tobacco smokers, *Tweet2Quit* was combined with a web guide (smokefree.gov) and nicotine patch. The comparison group received the web guide and nicotine patches without the Twitter support group. Tobacco abstinence was reported at 60 days follow-up.

Examples of Group Tweeting

M1: I've smoked.:-(but I hide when I do bc I'm ashamed.:-p
M2: Who you hiding from? YOU are the one that wants to quit…start over and try again!
M3: Its ok to trip u just need to get back on track it sounds like u want to quit maybe u need more patches
M1: I am going to get more and start fresh. Ty!!!
M4: It's ok to stumble. just keep getting back up. you can do it!
M1: When I saw myself failing I stopped tweeting so much. Didnt want to bring the rest of you down.:-/
M2: You need to keep tweeting! Maybe WE can bring you back UP!
M3: Know we r all here to help anytime day or night u want to smoke txt us we r here for u

Study Findings

Tweet2Quit participants reported significantly greater sustained tobacco abstinence compared with control subjects: 40% vs. 20%; p = .012. Engagement was high, with participants averaging 57 tweets over an average of 47 days. More tweeting was associated with quitting (p = .003).[8]

Study Limitations

The sample was largely non-Hispanic white (88%), and outcomes were self-reported and short term (60 days). A larger randomized controlled trial is underway with an ethnically diverse sample and 6-month bioconfirmed outcomes of tobacco abstinence.

Future Applications

Social media may be leveraged to create support groups to attend to other cancer-related behaviors such as diet, physical inactivity, and excessive alcohol use.

Social Support, Influence, and Norms

Online social networking for fostering social support has a long research history, from online mailing lists and message boards to more modern iterations such as Instagram. Social support is important for behavior change broadly,[13-15] and ample evidence indicates that existing social media groups can provide informational and emotional support to cancer survivors and caregivers.[16-18] Online communities have been linked to increased empowerment[19] and retention[20]; engagement with the communities has been linked to behavior change success for weight loss, smoking cessation, and other cancer-related behaviors,[8,21,22] although some effects are small.[23-25] Additionally, structured short message service and text messages to generate forum discussions, provide reminders, or offer tips and strategies have been effective build-ins.[26] Ideally, social support is bidirectional, and attention should be paid to facilitate receipt as well as provision of social support. A recent intervention study found that expressing social support was associated with perceived bonding within the social media group and positive coping strategies, whereas receipt alone of supportive messages was not.[27]

With a focus on influencing perceived social norms, social media interventions have demonstrated preliminary efficacy for reducing problematic alcohol consumption.[28,29] Yet, of concern, the literature also finds social networking associated with negative outcomes related to social comparison, such as poor body image and depression.[13,30] When designing interventions for cancer prevention and survivorship, it is important to consider potential unintended negative consequences and attempt to avoid or ameliorate them. For example, implementing weight-related programming

in photo-sharing media may require private groups, stricter rules, or additional intervention to reduce negative social comparisons to participants with lower weights, "thinspiration" accounts, or slim celebrities.

Health Communication

Communication campaigns using social media such as Twitter and Facebook are increasingly popular. Both large-scale national and international campaigns as well as smaller campaigns by local organizations and clinics have demonstrated engagement with their target audiences using social media.[14,15] Role model narratives are effective methods of persuasion with demonstrated positive impacts on cancer prevention behaviors[19-21] and can easily be delivered using video and photo tools in most popular social media systems. Evaluation of a breast cancer awareness campaign launched on Facebook by the Centers for Disease Control and Prevention found greatest engagement for posts with photos rather than status/links or videos; posts released in the early morning and afternoon (2:00 PM to 6:00 PM) versus other time periods; and posts shared earlier (2014) than later (2016) in the campaign.[31] Social media also can provide opportunities for truly interactive intervention methods. For example, a study found that participation in cocreating antismoking campaign content on Facebook produced greater information searching and intention to quit than simply viewing the content online.[22]

Self-Regulation

Self-regulation techniques, such as goal setting and feedback, are the foundation of many interventions that seek to change health behaviors, both for cancer prevention and adherence with cancer treatment regimens. Social networks are incorporated into some health-related apps and websites to promote self-regulatory skill-building,[26] and many general social networks include large subcommunities related to these topics. Some forms of these media may be particularly well suited to promoting self-regulation. For example, video-sharing services can provide highly detailed instruction and rich feedback from peers as well as experts.[32]

Motivation Enhancement

Social media shows promise for delivery of general and social rewards. In fact, several scholars have suggested that virtual rewards such as badges may be more effective when implemented within some form of social network, to emphasize personal status, group affiliation, and reputation.[33,34] Recommendations for gamification emphasize the importance of social engagement, personal reflection, and nurturing game elements for producing long-term motivation,[35,36] all of which can be facilitated via social media.

Engagement

Inadequate engagement can be a major limitation to cancer-related social media interventions.[37] Research consistently has found that posting photos results in a greater amount of engagement than other post types.[31,38,39] A study of scientific communication with the public across social media platforms by the European Organization for Nuclear Research found that "wow" photographs (i.e., awe-inspiring photographs) produced the most engagement, especially when posted on the photo-emphasizing platform Instagram.[40] Another recurring finding is that users may prefer different social media platforms, making formative research and/or use of multiple channels an important consideration.[7,41]

MHEALTH APPS AND WEARABLE DEVICES FOR CANCER PREVENTION AND CANCER CARE

A full range of mHealth apps are available for download from digital marketplaces (e.g., iTunes, Google Play) for use on smartphones, tablets, and other handheld devices. Thousands of health-oriented apps have been developed, with most focused upon lifestyle behaviors (e.g., exercise, diet, stress, smoking).[42] Yet, a mere 36 comprise half of the downloads. The focused use is attributed to the very limited functionality of most mHealth apps: just 10% can connect to a device or sensor, only 2% sync with providers' systems, and few incorporate social networking functions.[43] Table 2 presents categories and examples of mHealth apps relevant to cancer prevention and cancer care.

Several reviews have been published on mHealth apps. With attention to the prevention, detection, and management of cancer, one review identified 295 mHealth apps available in 2012.[44] Most common were apps on breast cancer (47%) or cancer in general (29%), apps aimed at raising cancer awareness (32%), providing cancer education (26%), supporting fundraising (13%), assisting in early detection (12%), or promoting a charitable organization (10%). Far fewer were apps designed to support disease management (4%), cancer prevention (2%), or social support (1%). The authors conducted a companion systematic review of the

TABLE 2. Categories of mHealth Apps With a Cancer Focus and Examples

Category	Examples
General health apps	Find a Health Center; Medscape
Health risk assessment apps	BRisk; BCSC; Rotterdam Prostate Cancer Risk Calculator
Quit-smoking apps for patients/providers	ASPIRE; QuitStart; QuitGuide; QuitMedKit
Diet and fitness apps	SuperTracker; SWORKIT; Endomondo
Self-regulation apps with social networking	Fitbit; Lose It!; My Fitness Pal; QuitNet
Symptom navigator apps	My PearlPoint Cancer Side Effects Helper
Patient portals	OhMD
Health condition trackers	My Breast Cancer Journey
Screening exam apps	ePrognosis Cancer Screening
Environmental exposure apps	Detox Me, Healthy Living Mobile App
Cancer treatment and survivorship apps	Cancer.Net (ASCO), iCancerHealth; National Comprehensive Cancer Network

health literature (1990–2012) and could not identify a single empirical evaluation of a cancer-focused mHealth app.

With a focus on breast health, a search of breast symptoms and diseases in major app stores identified 185 mHealth apps, of which 139 (75%) focused on breast cancer. Most of the apps (51%) were educational, 16% were self-assessment tools, only 14% were deemed evidence-based, and a mere 13% involved medical professionals in their development. Potential patient safety concerns were identified in 29 (16%) of the apps. Needed are mHealth cancer prevention apps informed by behavior change theory that attend to multiple risk factors and are appropriate for patients with low health and e-health literacy. As an illustrative example, the purposeful design of a breast cancer prevention app is summarized in Sidebar 2.[45]

A recent study conducted with 54 women at elevated risk for breast cancer evaluated, in a randomized controlled design, the combination of a wearable technology to monitor physical activity (Fitbit One) with a smartphone app to monitor diet (My Fitness Pal), and coaching calls from trained counselors. The goal was weight loss. Women randomized to the wearable plus mHealth app plus coaching achieved significantly greater weight loss (4.4 vs. 0.08 kg; p = .004) than women randomized to usual care.[46]

With a focus on managing symptoms following breast cancer treatment, The-Optimal-Lymph-Flow health IT system is an mHealth site with an electronic assessment and education on self-care strategies for lymphedema symptom management.[47] Evaluated over 12 weeks with 355 survivors of breast cancer, 97% reported high satisfaction with ease of use, and participants reported less pain, less soreness, less aching, less tenderness, fewer lymphedema symptoms, and improved symptom distress (all p values < .05).

In the area of tobacco control for cancer prevention, a number of apps have been developed with good interest. A 2014 search identified 546 smoking-cessation apps in the Apple Store and Google Play, which were downloaded an estimated 3.2 million times in the United States and 20 million times worldwide.[48] A review specifically of Android apps for quitting smoking identified 225 apps available between 2013 and 2014.[49] Most provided simplistic tools (e.g., calculators, trackers). Use of tailoring was limited, though positively related to app popularity and user ratings of quality.

The numbers are anticipated to rise as interest in mHealth apps and wearable health devices continues to grow. The past 2 years (2014–2016) saw a doubling in consumer use. One in three adults now report using an mHealth app and

SIDEBAR 2. Development of the Physical Activity and Your Nutrition for Cancer (PYNC) Prevention App

Objective
To promote healthy diet, nutrition, physical activity, and weight loss among women at risk of breast cancer who have varying levels of health literacy and e-health literacy.

Methods
An eight-step process is being followed to ensure that the intervention materials are appropriate for the intended audience. Development to date has included literature reviews, conceptual design, drafting informational and motivational content, acceptability review with community members, and scientific review by the research team. Remaining steps include prototyping materials, assessment of health literacy level, usability testing with community members, and final modifications.

Framework
The app uses Leventhal's Common Sense Model of Health Behavior, which describes how thoughts and beliefs about health and disease risk influence behavior.

Components
The app draws upon commercially available technology for monitoring physical activity, caloric intake, diet, and nutrition (Fitbit, LoseIt!, and USDA's ChooseMyPlate) while providing evidence-based information about breast cancer and ways that women can reduce their risk of the disease.

Prototype Feedback
Recommendations included use of "more relaxed language" and presentation of information "in a more visual way." Other suggestions included ideas for easy-to-prepare healthy foods, instruction on how to read food labels, and information on environmental contaminants and chemicals that may influence cancer risk, such as cleaning and beauty products.

Future Directions
Next steps are testing the efficacy of the mHealth intervention in increasing physical activity, improving diet and nutrition, and managing weight through a randomized controlled trial.

21% a wearable device, with use greatest among adults age 18–34. The most popular mHealth app segments are fitness (59%) and diet/nutrition (52%), followed by symptom navigators (36%), patient portals (28%), health condition trackers (25%), medication trackers (12%), and disease-management apps (10%). Most consumers (77%) and doctors (85%) view health wearables as helping to engage patients in their health, and over a third of physicians have recommended mHealth apps to their patients.[43,50] In the area of cancer care, novel wearable technology concepts include balance sensors for patients with chemotherapy-induced peripheral neuropathy[51] and Google glasses with a fluorescence imaging system for complete resection of tumors in surgical oncology.[52]

The demonstrated evidence, however, for mHealth apps in promoting and sustaining behavior change is still limited. A 2016 review of 38 articles of mobile phone applications for behavior change, four specific to cancer, was unable to identify a single best practice approach to evaluate mHealth apps, which the authors noted was further complicated by a general lack of regulation.[53] Similarly, a systematic review of randomized controlled trials testing the efficacy of mHealth apps for cancer prevention identified only four trials for smoking cessation and two for sun safety and concluded a meta-analysis was premature in this area.[54]

Health apps also have been developed to help consumers reduce exposures to known or suspected carcinogens and other toxicants in work or home environments. App functions include education, scanning of product bar codes at point-of-purchase, and self-tracking. With the same limitations acknowledged above, to date, the environmental health apps have not been tested for acceptability, feasibility, or effectiveness in randomized controlled trials.[55]

PRIVACY AND CONFIDENTIALITY CONCERNS WITH SOCIAL MEDIA AND MHEALTH TECHNOLOGIES

Although technologies such as smartphone mHealth apps and other remote monitoring devices have the potential to transform oncology care,[56] they also raise new considerations with regard to patient privacy and confidentiality. Apps may support a patient's self-report of symptoms or passively record location and other information using global positioning systems, accelerometers, and physiologic sensors. The ability to collect large amounts of personal data over long periods of time provides clinicians and researchers with insights into disease treatment and progression and also raises unique ethical issues.[57,58] We consider in this study the privacy and confidentiality concerns of social media and consumer-oriented mHealth technologies; patient safety, data security, and confidentiality of mHealth technologies; and regulatory developments. With direct application to practice, we also consider clinician-patient discussion points regarding the risks and benefits of using mHealth technologies.

Patients who purchase consumer-facing smartphone apps and other mHealth technologies (e.g., apps for weight loss and wearable devices for monitoring steps, heart rate, and sleep) may not be well informed of privacy practices. Systematic reviews of health and wellness apps available from generic app stores have identified deficiencies in the extent to which data uses are documented and appropriate security measures are implemented.[59,60] Among the most commonly used apps available for iOS and Android, only 183 of 600 (31%) had privacy policies, and 66% of the privacy policies did not specifically address the app.[59]

Consumers may be unaware that smartphone apps may share sensitive information such as sensor data on location with third parties such as advertisers. Many apps sold direct to consumers send unencrypted data to third party sites for advertising or analytics.[61] The main security risk is unauthorized access to data during collection, transmission, or storage. Unencrypted data (e.g., global positioning system coordinates, telephone numbers, email addresses, health information) transmitted over the internet can be intercepted. Efforts have been made to create secure devices and apps, but many contain serious flaws.[62]

Security threats also exist for provider-facing mHealth technologies. Ethical and regulatory issues related to mHealth technologies used by providers for patient care relate to patient safety and the security and confidentiality of patient data transmitted and stored in mobile medical apps.[63] Hackers and malware pose an increasing threat to the security of mobile medical apps.

REGULATION AND CERTIFICATION OF MEDICAL APPS AND MHEALTH TECHNOLOGIES

In some countries, government agencies have begun to regulate or curate medical apps.[63-65] In 2013, the U.S. Food and Drug Administration (FDA) released guidance for mobile medical apps that draws a distinction between unregulated apps and mobile medical apps that are subject to overt FDA regulation.[66] Apps that convert a mobile platform such as a smartphone or tablet computers into a medical device are regulated by the FDA.[63] The FDA regulates mobile apps that pose a greater risk to patients if they do not function as intended (e.g., apps that perform clinical tests such as blood or urine analysis, apps that display diagnostic images from x-rays and MRI, and apps that remotely display data from bedside monitors). The FDA focuses on technical issues related to patient safety and the security and integrity of information but not patient privacy.[62] Consumer-oriented apps for general health education are mostly unregulated.[66] In Europe, an Irish app (ONCOassist) for the iPhone and iPad that contains prognostic tools and calculators for oncologists at the point-of-care, has received Conformite Europeenne certification indicating that it complies with relevant European Union legislation.[67] The European Medical Device Directive MDD 93/42/EEC mentions software in its definition of a medical device.

In the United States, the Health Insurance Portability and Accountability Act (HIPAA) contains the primary set of regulations that guide the privacy and security of health

information.[68] HIPAA regulations require covered entities and their business associates (e.g., physicians, hospitals, health plans) to protect health information that identifies an individual and that relates to an individual's physical or mental health or health care services provided to the individual.[69] Developers of mobile apps and sensors must consider whether the software and information technology will be used by a covered entity and whether it will include any protected health information. For example, an app that assists a health care provider with following up patients must be designed to allow the provider to comply with HIPAA.[69] HIPAA requires that identifiable health information be encrypted so that only those authorized to read it can do so.[68] In the United Kingdom, the National Health Service established a Health Apps Library that endorses apps considered to be relevant to people in Great Britain and that provide trustworthy information, comply with data storage regulations, and do not pose potential risks if used improperly.[70] A recent assessment of 79 apps certified as clinically safe and trustworthy by the Health Apps Library found systematic gaps in compliance with data protection principles.[70] None of the 79 apps encrypted personal information stored locally, 66% (23 of 35) of apps sending identifying information over the internet did not use encryption, and 20% (7 of 35) did not have a privacy policy.[70] The authors noted that app users cannot see into the inner workings of apps or the services to which they connect; hence, they must trust developers to comply with privacy regulations and security best practices.[70] Medical information stored on apps or transmitted via the internet or Bluetooth should be secured using encryption.[71]

WHAT SHOULD CLINICIANS TELL THEIR PATIENTS ABOUT PRIVACY AND CONFIDENTIALITY?

Clinicians can only provide limited guarantees about privacy protection. Data collected on mobile phones can be subpoenaed as part of legal proceeds in civil or criminal cases.[57] Because of the potential for hacking of personal data from mHealth apps, the security of data collected via mobile phones cannot be guaranteed.[57] As stated, many mHealth apps do not use encryption when transferring data.[72] A further issue is that telecommunication companies record metadata and data transferred over their networks and sell them to third parties.

Patients' trust in their clinicians contributes to treatment adherence and continuity of care and, in turn, plays an important role in the adoption of mHealth technologies.[68] Clinicians should discuss the risks and benefits of using mHealth technologies as part of patient-centered care.[68] Providers should be aware of their institutions' privacy and security policies as part of their ethical obligation to ensure patient-physician confidentiality. Before using mHealth technologies, clinicians should obtain informed consent from patients so that they understand the benefits, risks, and potential harms. The rapid pace of development, early efforts at regulation, and the complex nature of the risks posed by using mHealth technologies raise challenges in communicating risks to patients.[57] Discussion of the potential risks (e.g., data harvesting, data breaches), benefits (e.g., self-awareness/self-management, attention to adherence and lifestyle behaviors, patient-provider communications), and unknowns (e.g., optimal balance of tech to touch) is warranted.

USING SOCIAL MEDIA AND MHEALTH APPS IN LOW-RESOURCE SETTINGS

Globally, by 2030, the burden of cancer is predicted to worsen significantly in low-income (82% increase in incidence) and lower-middle income (70% increase) countries.[73] The rise in mobile phone access worldwide[74] affords opportunity for delivering social media and mHealth technologies to improve cancer awareness, encourage timely screening, and secure follow-up care.[75] In the United States, mobile technologies have bridged the digital divide.[76] By ethnicity, African Americans and English-speaking Hispanics are just as likely as whites to own a mobile phone and use it for a wider range of activities.[76] In a survey of female public housing residents in Boston, nearly all reported mobile phone use for calls (97%) and texts (84%); recent use (past day) of the internet was 65%, social media 59%, and email 28%; 70% had a Facebook account and 12% a Twitter account.[77] Social media users were more likely to be Hispanic and Spanish speaking.

Broad reach, low or no cost, and high scalability make social media and mHealth apps particularly well suited for application in resource-poor settings. Social media can be used across platforms (i.e., Android, iOS, and personal computers) and can connect individuals over long distances, which can be valuable to individuals in rural areas with rare cancers who do not have peers or role models readily available otherwise. Even for those with more common cancers, online social media allows social interaction without the burden of travel to clinics or support group locations. Research indicates barriers to engaging in care among some low-income groups, such as residents in public housing.[78] Social media and mHealth technologies may aid outreach efforts with appropriate messaging and support for cancer prevention efforts.

Needed and worthy of evaluation is the extent to which people with lower levels of health literacy or numeracy find cancer-related use of social media and mHealth apps to be helpful or practical and whether apps are effective in helping culturally diverse groups to reduce their risk of cancer. Emphasized is the thoughtful development and use of mHealth applications to solve health disparities, not widen them.

To inform development of a social media smoking-cessation intervention, focus groups were conducted with 33 Hispanic, Spanish-speaking, current and former smokers in the San Francisco Bay area.[79] Most participants owned a smartphone (84%), and the majority of cell phone owners reported daily texting (81%) and Facebook use (69%). The participants valued the communal aspect of social media

and suggested strategically tailoring groups based on key features (e.g., age, gender, language preference). Participants reported preferring visual, educational, and motivational messages connected with existing services.

Development of social media and mHealth programs for diverse settings and communities can be achieved with limited investment by drawing upon existing resources. Content analyses of various social media groups (e.g., Facebook groups, individuals using the same Twitter hashtag) have identified several types of social support provided,[16,80] and numerous interventions have shown that behavior change techniques can be effectively delivered via existing social media tools.[7,23,81] Hence, expending resources to create new cancer-focused mobile apps or websites may not be necessary to deliver effective prevention and treatment interventions. Even if the long-term goal is to create an entirely new system, existing tools can provide a method for prototype testing. For example, combinations of personal emails and group sessions via social media can be used to test out the potential effects of face-to-face or app-based delivery of these techniques. An example of effective low-cost leveraging of mobile technologies comes from work in Ambanja, Madagascar, where smartphones were used to take and transmit high-definition images for the detection of cervical intraepithelial neoplasia of grade 2 or worse as an adjunct to standard on-site examination.[82]

CONCLUSION

Exciting innovations in mHealth and social media applications are occurring across the cancer spectrum, from primary prevention to screening, early diagnosis, treatment, survivorship, and end-of-life care. These new platforms and technologies avail social engagement and support as well as personalized data points for patients and providers to inform care decisions. Cancer-prevention applications include attention to tobacco use, diet, physical activity, and sleep; there are screening apps and cancer risk calculators to raise awareness; and links to patient communities or providers for symptom management. Advantages of social media and mHealth technologies include low or no cost, high scalability, self-tracking and tailored feedback functionalities, use of images and video for enhanced health literacy, broad reach, and data sharing for large-scale analytics. Although development efforts have been rapid and numerous, frameworks and investigations of efficacy for achieving and sustaining behavioral change and positive health outcomes are sorely needed, and regulation concerning data security issues is notably lacking. Targeted development is also needed for culturally diverse groups and for non-English speakers. Further investment in research to build the evidence base and identify best practices will help delineate and actualize the potential of social media and mHealth technologies for cancer prevention and treatment.

CARE DELIVERY AND PRACTICE MANAGEMENT

Challenges in Opening and Enrolling Patients in Clinical Trials

Julie M. Vose, MD, MBA, FASCO, Meredith K. Chuk, MD, and Francis Giles, MB, MD

OVERVIEW

Clinical trials are key elements of the processes that account for many of the recent advances in cancer care, including decreased mortality rates and increased survivorship; better supportive care; and improved understanding of cancer risk, prevention, and screening. This research also has led to the validation of numerous exciting new types of cancer treatments, such as molecularly targeted therapies and immunotherapies. Clinical trials, however, are becoming more and more challenging to conduct. Research programs must comply with legal and regulatory requirements that can be inefficient and costly to implement and often are variably interpreted by institutions and sponsors and sponsors' representatives, including contract research organizations. Some of these requirements are essential to protect the safety of trial participants, to promote the scientific integrity of research, or to ensure that trial conduct is efficient and adequately resourced. Such requirements are important to preserve. However, some requirements do not fulfill any of these goals and, in fact, hinder research and slow patient access to safe and effective treatments. This article discusses some of the identified issues that are slowing the process of cancer clinical trials, such as conservatively interpreted guidelines by pharmaceutical companies and contract research organizations; overprotective language for contracts; and patient protections by health systems and universities. The article also discusses possible solutions to these problems that are slowing down the cancer therapies that patients need.

Clinical trials are key elements of the processes that account for many of the recent advances in cancer care, including decreased mortality rates and increased survivorship; better supportive care; and improved understanding of cancer risk, prevention, and screening. This research also has led to the validation of numerous new types of cancer treatments, such as molecularly targeted therapies and immunotherapies.

Clinical trials, however, are becoming more and more challenging to conduct. Research programs must comply with legal and regulatory requirements that can be inefficient and costly to implement and often are variably interpreted by institutions and sponsors and sponsors representatives, including contract research organizations. Some of these requirements are essential to protect the safety of trial participants, to promote the scientific integrity of research, or to ensure that trial conduct is efficient and adequately resourced. Such requirements are important to preserve. However, some requirements do not fulfill any of these goals and, in fact, hinder research and slow patient access to safe and effective treatments.

To address the problem of administrative and regulatory burden on cancer clinical trials, the American Society of Clinical Oncology (ASCO) partnered with the Association of American Cancer Institutes on the Best Practices in Cancer Clinical Trials Initiative (the Initiative). The purpose of the Initiative is to promote practical solutions to meeting existing regulatory and administrative requirements on research. Both ASCO and the Association of American Cancer Institutes have previously explored various strategies to streamline the conduct of clinical trials, such as the development of supportive tools and templates, networking sessions, and the development of common guidelines and standards. This Initiative was an opportunity to expand on the current work in this area.

The Initiative was overseen by a multidisciplinary working group, including hematologists and oncologists, research nurses, administrators, managers, and industry representatives. Officials from the U.S. Food and Drug Administration (FDA) and the National Cancer Institute, contract research organization staff, and patient advocates attended. The main elements of the project included (1) a stakeholder survey to identify the most pressing issues in clinical trials that could be addressed by the Initiative and to gather data on use of existing tools and resources, (2) an invitational workshop, which convened many leading oncology professionals and policy makers to identify potential solutions for improving the efficiency and conduct of cancer clinical trials, and (3) dissemination of the recommendations from the workshop through publication; the ASCO Annual Meeting; and the

development of practical resources, toolkits, and follow-up meetings with relevant organizations and individuals. This article provides a summary of the stakeholder survey and of the workshop.[1]

ADVERSE EVENT REPORTING: FDA GUIDANCE

As stated in the Code of Federal Regulations (CFR), the primary objective of the FDA in reviewing an investigational new drug application (IND) is "to assure the safety and rights of subjects" (21 CFR §312). One of the principle ways that this is accomplished is by monitoring adverse events that occur during the course of clinical trials. Sponsors of clinical trials conducted under an IND are required under 21 CFR §312.32 to report any suspected adverse reaction that is both serious and unexpected as an IND safety report to the FDA and to all participating investigators.

In September 2010, the FDA published a final rule that amended the safety reporting requirements for INDs.[2] This rule became effective on March 28, 2011. This rule was adopted to clarify the requirements for safety reporting to improve the quality of reporting, reduce the number of uninformative reports, expedite the FDA review of important safety information, and improve the ability to detect valid safety signals. Sponsors often submitted IND safety reports of individual events that were a result of the underlying disease—events that occurred often in the population evaluated, or events that were study endpoints. This resulted in submission of a large number of uninterpretable and uninformative safety reports that strained the limited resources of the FDA, investigators, and institutional review boards and did not contribute meaningfully to the development of a drug safety profile.

The FDA published two guidance documents to help sponsors and investigators comply with the requirements of the 2010 final rule: Safety Reporting Requirements for INDs and BA/BE Studies, in December 2012,[3] and Safety Assessment for IND Safety Reporting, in December 2015 (Draft Guidance).[4] A brief review of the these guidance documents with a focus on reporting events from clinical trials is below, followed by a review of results of an internal FDA audit about the quality of safety reporting in oncology and efforts to improve the problem of ongoing uninformative safety reporting.

KEY POINTS

- **Some steps that have been shown to dramatically improve the efficiency of the clinical research process include establishing clear timelines; developing transparent metrics; and defining the appropriate role for center clinical investigators.**
- **Another key step is the development of standardized study budgets, based on fair market value as applicable to the center's level and location, with dynamic benchmarking with comparable centers.**
- **The ratio of and relative priority given to commercially sponsored studies, investigator-initiated studies/trials, the National Clinical Trials Network, or federally funded trials should be addressed.**
- **The FDA guidance documents on adverse event reporting should be followed by all sponsors, contract research organizations, and investigators for cancer clinical trials.**
- **Health care institutions should work with the investigators and the sponsors on reasonable terms for master contracts that should be universally accepted.**

Review of FDA Guidance on IND Safety Reporting

The final rule clarified the following definitions to be used for reporting purposes:

- Adverse event: any untoward medical occurrence associated with the use of a drug, whether it is considered drug related or not
- Suspected adverse reaction: any adverse event for which there is a reasonable possibility that the drug caused the adverse event (i.e., evidence to suggest a causal relationship between the investigational drug and the adverse event)
- Life-threatening adverse event or life-threatening suspected adverse reaction: an event that, in the view of either the investigator or sponsor, places the patient at immediate risk of death
- Serious adverse event or serious suspected adverse reaction: an adverse event that, in the view of either the investigator or sponsor, results in any of the following outcomes: death, a life-threatening adverse event, inpatient hospitalization or prolongation of existing hospitalization, a persistent or significant incapacity or substantial disruption of the ability to conduct normal life functions, or a congenital anomaly/birth defect. Important medical events that do not meet the above criteria may be considered serious when, based upon appropriate medical judgment, they may jeopardize the patient and may require medical or surgical intervention to prevent one of the outcomes listed in this definition.
- Unexpected adverse event or unexpected suspected adverse reaction: An adverse event is considered unexpected if it is not listed as occurring with the particular drug in the investigator brochure or other risk information, or is not listed at the specificity or severity as the current event.

Sponsors of clinical trials conducted under an IND application must notify the FDA and all participating investigators in an IND safety report (a 7- or 15-day report, depending on the type of event) of potential serious risks from clinical trials or other sources. In the IND safety report, the sponsor must identify all reports of similar events previously submitted to FDA, and the sponsor should take these events and any other relevant information into consideration for the assessment of causality and significance of the suspected adverse reaction being reported.

Sponsors must report suspected adverse reactions that are both serious and unexpected. Reports that do not satisfy all three criteria should not be submitted to the FDA as IND safety reports.

The issue of causality is often the most difficult to assess, but it is the most critical to avoid uninformative reporting. The regulations state that there must be a reasonable possibility that the adverse event was caused by the drug. This should be interpreted as the presence of enough evidence to suggest a causal relationship. Per FDA regulations, the determination of causality for the purposes of reporting rests with the sponsor, not the investigator. The sponsor has access to the most up-to-date and comprehensive information available about the drug and is best able to make informed and consistent decisions about causality. This is a difference between the FDA regulations and the ICH E2A guideline,[5] which allows the determination of causality to be made by the investigator or the sponsor. Sponsors should consider the following when assessing causality:

- Single adverse events usually are uninterpretable and would not meet the criteria for expedited reporting except in cases of events that are uncommon and known to be associated with use of a drug, such as Stevens-Johnson syndrome or angioedema.
- Multiple occurrences of events not commonly associated with drug exposure but otherwise not common in the population (e.g., tendon rupture), may be informative. Single events with strong evidence of causation, (i.e., a strong temporal relationship or recurrence on rechallenge) may constitute sufficient evidence for an expedited report, but generally more than one similar event is needed to suspect a causal relationship.
- Adverse events that are likely to occur (i.e., are anticipated) in the population under evaluation, whether as a result of the age of the patient, nature of the disease, or concomitant therapy (e.g., cardiac disease in older patients with risk factors or fever and neutropenia in patients receiving cytotoxic chemotherapy) should not be reported as single events, because there is inadequate information to determine a reasonable possibility of causality. These events require aggregate analysis across the development program to determine if they truly occur more often in patients exposed to the drug. These aggregate analyses require that the sponsor have a system in place for ongoing review and analysis of safety data throughout the development of the drug. If these analyses reveal there is an imbalance between patients who did and those who did not receive the investigational drug, this information should be reported in an IND safety report.

An event is considered unexpected if it is not listed in or if it occurs at a severity or frequency that is unusual from that listed in the investigator brochure or other risk information. The investigator brochure should contain a list of adverse events that have been observed with use of the drug and for which a causal relationship is suspected or confirmed. Clinical judgment is required to establish and then maintain this list after periodic review of safety information from ongoing clinical investigations.

Adverse events that qualify for IND safety reporting must be submitted to the FDA and participating investigators as soon as possible, but no later than 15 calendar days after the sponsor determines that the information qualifies for reporting. Unexpected fatal or life-threatening suspected adverse reactions must be reported as soon as possible, but no later than 7 days after the sponsor receives the information. Follow-up reports are only required for relevant information that is necessary to evaluate the suspected adverse reaction.

For clinical trials that are blinded, the blind generally should be broken for IND safety reports submitted to FDA and investigators, because information about drug exposure is necessary to interpret the event, treat the patient, and institute any changes in trial conduct, such as increased monitoring or changes to the informed consent document. This unblinding should not affect the integrity of the trial, because it should be infrequent for single events. A data monitoring committee or independent safety team should review safety data to determine if aggregate reporting of any particular adverse event is appropriate.

Sponsors also are required to submit safety information from other clinical studies, epidemiologic studies, and pooled analyses of multiple studies; findings from in vitro studies that suggest a notable risk in humans; and any increased rate of serious suspected adverse reactions other than that listed in the protocol or IB. Clinical judgment is required to determine what is a clinically meaningful increase on the basis of the trial population(s), nature and severity of the adverse event, and the magnitude of increase. The submission of an IND safety report for the findings listed above should be enough to require a change to the protocol (e.g., monitoring or eligibility criteria) or to the informed consent document.

Internal Audit of Expedited Safety Reports in the Office of Hematology and Oncology

From the years 2006 to 2014, the Office of Hematology and Oncology Products received an average of 17,686 expedited safety reports per year. Additional analysis of the number of reports per IND per year that were submitted before and after the implementation of the 2010 final rule on IND safety reporting showed that, not only was there no change since the implementation of the final rule, there was actually a slight increase.[5] In 2015, medical officers in the Office of Hematology and Oncology Products who were responsible for evaluating IND safety reports conducted a review of 160 initial safety reports submitted to commercial INDs and concluded that only 14% met criteria for reporting.[6] The remaining 86% of the reports were determined to be uninformative for a variety of reasons: 54% of the reports were for adverse events that were expected on the basis of information in the investigator brochure or product labeling, in 50% of the reports, the sponsor did not conclude that the adverse event was related to the drug; and, of the reports that met all three criteria of serious, suspected, and unexpected events, 42% of the events were determined to be anticipated on the basis of the FDA review (e.g., febrile neutropenia in a patient who received a backbone of cytotoxic chemotherapy).

Steps Toward Process Improvement

The FDA has been encouraging sponsors to develop mechanisms to reduce uninformative reporting. Several sponsors have been successful at dramatically decreasing the number of initial and follow-up safety reports through a variety of measures, including establishing dedicated teams of physicians to review safety reports, implementing consistent thresholds for determination of causality, and identifying and reporting only clinically relevant follow-up information that directly contributes to the assessment of the suspected adverse reaction.[7]

In addition, 21 CFR § 312.32 (c)1(v) allows for submission of IND safety reports in an "electronic format that FDA can process, review, and archive." The FDA is exploring the digital submission of expedited safety reports based on ICH E2B guidelines—Technical Requirements for Registration of Pharmaceuticals for Human Use—for postmarket safety report submissions[5] on the basis of a successful pilot study conducted by the Office of Hematology and Oncology Products and the Office of Surveillance and Epidemiology.[7] This move to standardize reporting and submit safety information as data sets uses mechanisms already in place for safety reporting in the postmarket setting. This method of submission will allow for a more consistent and streamlined way to receive, process, and analyze safety information, the ability to better detect safety signals and ensure the protection of patients, and the identification of relevant events at time of reporting.

Efficient and timely submission and review of relevant safety data are imperative to ensure patient safety in clinical trials. Unfortunately, revisions to the IND safety reporting requirements instituted in the final rule in 2010 did not result in the desired decrease in the number of uninformative safety reports, which continue to be burdensome for the FDA, investigators, and investigational review boards to process and review; these reports also make the detection of genuine safety signals more difficult. Perceived barriers by sponsors to implementation of the provisions of the 2010 final rule include a lack of international harmonization on all elements of reporting as well as concerns related to unblinding during the course of clinical trials and to thresholds for reporting serious and unexpected adverse reactions.[8] Efforts to improve and streamline the reporting process are ongoing, but successful implementation will require all sponsors to identify barriers to and institute mechanisms for decreasing uninformative IND safety reporting; efforts also will require regulators to continue to engage with all stakeholders to optimize the process for IND safety reporting.

BREAKING DOWN THE BARRIERS: THE PATH FORWARD

The barriers to patient participation in cancer clinical studies are numerous; less than 5% of patients participate in a clinical trial. Conducting relevant public education campaigns; addressing financial and other study access barriers; and increasing physician advocacy for, and conduct of, clinical trials are important ways to address this major challenge.

In cancer centers where the conduct of clinical studies is an important core activity, there is increasing concern about the escalation of attendant financial and personnel costs of study conduct. Efforts to standardize and streamline the process of opening, conducting, and closing studies at cancer centers are ongoing. Some key steps that have been shown to dramatically improve the efficiency of this process include:

1. Map the institutional processes used to open, conduct, close, and report a study. The involvement of all relevant stakeholders and of professional process improvement colleagues is critical to the success of this step. It is important to leverage an underlying proven, data-driven, process-improvement methodology, such as Define, Measure, Analyze, Improve, Control (i.e., DMAIC), that can be scaled according to the scope and depth of current and desired clinical study activity.
2. Eliminate all unnecessary duplicative steps in the process, and pay particular attention to steps that are necessary for full compliance with applicable mandatory standards (e.g., National Cancer Institute–designated cancer centers). Establish clear timelines for—and definitions of roles, responsibilities, and deliverables of those involved in—the remaining essential steps. Develop an ongoing dynamic feedback system to monitor the efficiency of these key steps.
3. Develop transparent metrics for expected productivity and outcomes of key administrative, financial, and research staff.
4. Define the appropriate role for center clinical investigators in study budget development and study institutional resource allocation, with appropriate consideration of conflict-of-interest issues, academic freedom, and operational efficiency. Develop standardized study budgets that are based on fair market value as applicable to the level and location of the center. Ensure that such fair-market-value budgets are dynamically benchmarked with comparable centers and are offered in a transparent manner to all sponsors for all studies, regardless of whether the study is offered directly from a sponsor or via intermediary entities.
5. Develop policies, in conjunction with comparable clinical research sites, on institutional responses to site evaluation/screening questionnaires; on responses to sponsor/contract research organization requests for site evaluation/qualification visits; on minimal qualifications/experience levels of external staff who conduct or monitor the study; on the nature and frequency of remote and on-site study monitoring activities; and on standards for authorship/acknowledgment expectations in study-related publications.
6. A specific issue that merits the development of institutional policies is the ratio of, and relative priority given to, studies or trials that are commercially

sponsored and investigator initiated, that are National Clinical Trials Network studies, or that are federally funded. Additional specific issues include the role of central institutional review boards, participation in multicenter groups with common consensus administrative and budget policies, and the development of specific alliances with sponsors to improve the investigator-initiated studies/trials process.

Major opportunities for standardization of approaches to clinical research conduct between cancer centers exist. Key steps will involve central registers/repositories of commonly requested study conduct documents and central records of investigator and institutional research capabilities, interests, infrastructure/resources and productivity. Increasing the role of central key organizations, such as ASCO, in developing, monitoring, and refining policies and procedures to optimize clinical research conduct also will be crucial.

mHealth: Mobile Technologies to Virtually Bring the Patient Into an Oncology Practice

Nathan A. Pennell, MD, PhD, Adam P. Dicker, MD, PhD, Christine Tran, MS, Heather S. L. Jim, PhD, David L. Schwartz, MD, FACR, and Edward J. Stepanski, PhD

OVERVIEW

Accompanied by the change in the traditional medical landscape, advances in wireless technology have led to the development of telehealth or mobile health (mHealth), which offers an unparalleled opportunity for health care providers to continually deliver high-quality care. This revolutionary shift makes the patient the consumer of health care and empowers patients to be the driving force of management of their own health through mobile devices and wearable technology. This article presents an overview of technology as it pertains to clinical practice considerations. Telemedicine is changing the way clinical care is delivered without regard for proximity to the patient, whereas nonclinical telehealth applications affect distance education for consumers or clinicians, meetings, research, continuing medical education, and health care management. Technology has the potential to reduce administrative burdens and improve both efficiency and quality of care delivery in the clinic. Finally, the potential for telehealth approaches as cost-effective ways to improve adherence to treatment is explored. As telehealth advances, health care providers must understand the fundamental framework for applying telehealth strategies to incorporate into successful clinical practice.

Telehealth encompasses a broad variety of technologies with clinical applications to deliver virtual health care services. Because there is no universal definition, the terms telehealth, telemedicine, eHealth, digital health, or mobile health (mHealth) often are used interchangeably. However, the U.S. Department of Health & Human Services defines telehealth as the use of electronic information and telecommunication technologies to support and promote long-distance clinical health care, patient and professional health-related education, public health, and health administration.[1] Although this broad definition includes both clinical and nonclinical applications, the term telemedicine is confined to clinical services in remote locations and is defined as allowing health care professionals to remotely evaluate, diagnose, and treat patients using telecommunications technology.[2] These clinical applications encompass services that support remote electronic clinical consultation, such as diagnosis, patient communication, disease management, remote monitoring, and clinician support. Meanwhile, nonclinical applications can include distance education for consumers or clinicians, administrative meetings, research, continuing medical education, or health care management.[3] Telehealth innovations enable the delivery of care irrespective of geographic location, bringing about a fundamental shift in U.S. health care by bringing health care to the patient. Moreover, the need to improve quality, access, equity, and affordability of health care supports the utilization of telehealth across several medical disciplines. The potential shortage of oncology services is pointed out in ASCO's report, *The State of Cancer Care in America: 2016*[4]; evidence-based health research supports the use of telehealth in the oncology setting and its ability to increase access to patients with cancer.[5-7] For example, in a systematic review of experiences for patients with cancer who have participated in telehealth interventions, telehealth was noted to be an advantageous approach to reduce treatment burden and disruption to patient lives.[8] Health care professionals who use telehealth to export their clinical expertise enable patients to experience decreased travel time, immediate access to care, early detection of health issues, increased patient autonomy, reduced caregiver burden, and increased patient satisfaction with health care.

TELEHEALTH TECHNOLOGY

The most commonly used telehealth technology employs video conferencing to connect a patient to a health care provider.[9] Video conferencing integrates telecommunications

technology to allow patients and providers to "electronically collaborate face to face, in real time, and share all types of information, including data, documents, sound, and picture."[9] This type of interactive video conferencing environment allows for patient-provider consultation, discussion, education, and patient monitoring. The use of telehealth technology offers great promise and currently is being used in health care in a number of ways. The clinical applications of telehealth range from drug formulary apps to reference programs, educational apps, medical tools (patient documentation apps, patient monitoring apps, nursing apps, imaging apps, and clinical apps), payer tools, decision support tools, and patient support tools.[10] The technological advances of telehealth include wearable sensors (pedometer/accelerometer, or sensors of sleep, weight, blood pressure, heart rate, temperature, environment exposure, blood levels, falls, and geolocation), data entry technologies (exercise testing, diet, mood/stress levels, symptoms, health-related quality of life, functional status, social support, medication, tobacco use, pillbox sensors, and alcohol use), ingestible/implantable sensors, biometric sticker sensors, and the ability of smartphones to be used as otoscopes, ophthalmoscopes, and microscopes. This technology can be used to remotely collect and send data for interpretation by a health care provider.[11] Telehealth interventions also have been expanded to social media sites such as Twitter to foster healthy lifestyles through the use of wearables for self-monitoring and social media to facilitate support for behavioral changes.[12] The U.S. Food and Drug Administration also has approved imaging apps, which allow radiologists to interpret images or ophthalmologists to use color vision plates for clinical evaluation when a more traditional outlook is not available. Digital images also are a type of store-and-forward technology, which permits the electronic transmission of medical files to be used at the convenience of providers to then make diagnoses, recommendations, and treatment plans. Whether the device exists as a standalone item, such as a smartphone, wearable, or hybrid (e.g., smartwatch), the information can be used by remotely monitoring health, medical behavior (e.g., compliance, movement, symptoms, vital signs, diet) or a person's location.[11]

Moreover, the demand to satisfy uniform quality of telehealth services has been met recently through the American Telemedicine Association. These practice guidelines and technical standards include practice guidelines for videoconferencing-based telemental health, evidence-based practices for telemental health, core standards for telemedicine operations, practice guidelines for teledermatology, telehealth practice recommendations for diabetic retinopathy, home telehealth clinical guidelines, and clinical guidelines for telepathology.[13] The standardization of telehealth guidelines may help reduce the cost of equipment and increase adoption by making telecommunication independent of hardware used.

HEALTH CARE CONSUMER AND PROVIDER PERSPECTIVES

The goal of telehealth is equal efficiency with in-person care, and physician-patient encounters via telehealth recently have reported consistent performances compared with standard face-to-face care.[14] In a randomized, controlled trial for patients with prostate cancer that used telehealth after radical prostatectomy to assess the efficiency, satisfaction, and cost of remote virtual visits versus traditional office visits, telehealth was equivalent in patient and provider satisfaction and time allocated to care.[15] In another study to evaluate the opinion on the use of telehealth in oncology, a majority of responders cited advantages of oncologic apps that included better documentation, improved and continual care for patients, enhancement of communication between provider and patient, improved patient compliance, possible use of data for scientific evaluation, and potential for patient-independent information.[16] Overall, 84.3% supported the use of oncologic apps complementary to traditional treatment.[16] Critics of telehealth cited issues related to legal uncertainty, data privacy, and insecure data transfer and storage.[16] Moreover, in a group of surveyed health care professionals, the most common medical app functions included drug-referencing tools, clinical decision-support tools, communication, electronic health record (EHR) access, and medical education materials.[17] The amount of scientific material that clinicians must memorize is large, so reference programs and educational apps help enable clinicians to choose clinically appropriate and cost-effective drugs, quickly search and access information/textbooks, perform calculations, log experiences, communicate, and input specific patient information for diagnosis.[10]

The adoption of telehealth technology relies on patient participation and the motivation of patients to become partners in their health care. With a consumer-based foundation, telehealth shifts medicine to more participatory care and an improved health care system composed of patient empowerment. This paradigm shift in responsibility allows patients to manage their health, health network, and heath information, and it leverages emerging technologies for a patient-centered ecosystem. In a survey to assess patient

KEY POINTS

- **Oncology health care is ripe for digital health disruption with the convergence of mobile technology, platforms, networks, and the introduction of machine learning.**
- **Digital platforms that include telemedicine, internet of things, and wearables are scalable.**
- **mHealth technology, including virtual scribes, real-time location systems, and peer-to-peer messaging apps, has the potential to improve the efficiency and quality of clinical cancer care.**
- **Treatment nonadherence in oncology occurs at a high rate and is associated with worse outcomes.**
- **Innovative, collaborative research will be pivotal to transform mHealth into a standard part of modern cancer care relevant to the 21st century health care marketplace.**

attitudes toward telehealth, patients had a positive overall attitude and cited an opportunity for improved self-efficacy and improved provider-driven medical management.[18] Moreover, respondents mentioned comfortableness in being remotely monitored with confidence in privacy protection. Findings about telehealth from the experience of a cancer survivor illustrated analytic themes that included how telehealth limited the disruption to people's lives, how telehealth could enable close and personalized relationships between cancer survivors and service providers, and how survivors felt that they had immediate access to professional advice, which acted as a safety net for possible issues in treatment.[8] Nevertheless, individual differences in digital literacy (i.e., the competency and technical skills to operate digital devices and conceptually understand their functionality) have the potential to widen health disparities and must be addressed as telehealth becomes more widespread.[19,20]

TELEHEALTH CHALLENGES FOR CLINICAL PRACTICE

Despite its potential, telehealth issues of privacy and security remain ongoing concerns for health care professionals and patients alike. For telehealth to complement traditional approaches in the delivery of health care, it must be delivered to both clinicians and patients with confidence that the privacy, confidentiality, and security of their data will be safeguarded within compliance of the Health Insurance Portability and Accountability Act (HIPAA). In an emerging field, the means for securing data includes understanding the roles of cybersecurity and developing a mobile technology policy to ensure that protected health information data are safe. Moreover, patient portals tethered to EHRs include advanced technology as part of their system to provide scheduling, billing, and clinical support, but there is no policy for telehealth applications to be fully integrated into health information systems in hospitals or provider organizations.[21] The variation in telehealth data and a patient's EHR displays the difficulty of management for telehealth and need for integration. In the progression of telehealth, health care institutions must establish a method for health care providers to access the EHR at the time of a telehealth encounter and establish a foundation of interoperable standards.

Multiple factors on both the individual and organizational levels are crucial to clinician acceptance and adoption of telehealth technology. Clinician acceptance of telehealth technology depends on a full integration into the workflow, added value to patient care, administrative convenience, and facilitated communication among multidisciplinary teams.[22] Although usefulness and ease of use were cited as important factors to the adoption of telehealth, the argument of whether it is an affordable option is still in discussion among health care professionals, who have referenced cost issues as limiting the adoption of telehealth tools.[23,24] Elements related to costs (e.g., the question of how to bill for telehealth) act as barriers to its adoption. Reimbursement regulations for medical services were planned before telehealth technology, which thus gives each state the option of whether to cover telehealth. These variations in reimbursement relate to service coverage, payment methodology, distance requirements, eligible patient populations, authorized technology, and patient consent.[25] Moreover, traditional concepts of liability and malpractice still apply to telehealth practitioners, who are more vulnerable to legal issues and who may face an additional fee for malpractice insurance.[26]

Despite technological advances, legal and regulatory challenges concerning provider licensure, credentialing, and privileging processes remain an obstacle for all allied health professionals. Mutual recognition models such as the multistate Nurse Licensure Compact or the Interstate Medical Licensure Compact are just beginning to develop to help facilitate telehealth interactions across state boundaries and into the mainstream. Additionally, the mandate for credentialing and privileging in multiple, separate health care facilities offer similar challenged for health care providers to deliver telemedicine.

FUTURE DIRECTIONS FOR TELEHEALTH

Telehealth is the future to improved access to specialized medicine, preventive care, monitoring of chronic conditions, and improved patient outcomes and satisfaction. It has the potential to reduce fragmentation of care and allow access to care despite the distance from major medical centers. In a 2014 study, telehealth industry growth and its potential to decrease care costs within the health care system were demonstrated; the study outlined $5 billion in savings on the basis of an estimated 100 million telemedicine visits across the world.[27] Demands for improved access to care in rural areas or to underserved populations that have been a challenge historically because of a shortage of clinicians or because of financial or geographic barriers also create the potential for a new telehealth ecosystem and novel health care model. Telehealth can overcome many of these barriers; it already has increased the quality of care and reduced costs by reducing the readmissions and emergency visits in rural communities.[28] Telehealth effectiveness also has been demonstrated through research in rural and remote areas, where telehealth satisfaction reached 94%.[29] These findings suggest a general acceptance of therapies delivered via telehealth, which advocates for its unparalleled opportunity. Growing interest in tele-oncology also shows the potential to increase access from a comprehensive cancer center to patients in rural areas by offering consultations, supervision of chemotherapy administration, oral medication adherence, or symptom management.[30]

THE POTENTIAL OF MHEALTH TECHNOLOGY TO IMPROVE EFFICIENCY AND CLINICAL CARE

mHealth technology has a tremendous potential to improve clinical care; its uses range from telemedicine patient encounters to the collection of patient-reported outcomes and improved adherence to therapies with apps and mobile devices. However, there is a lack of research about what patients will benefit the most, what the efficiency of telehealth

is at saving costs or time, and whether its contribution to a greater provider burden significantly hinders the advancement of telehealth. Apps for electronic patient-reported outcomes are available now from the Apple and Android app stores. One example is the Strength Through Insight app (Fig. 1).[31] The Strength Through Insight study aims to assess the feasibility of collecting survey data from patients through digital technologies and hand-held devices.[31] Practitioners may worry about the impact these technologies have on their day-to-day workflows and how demands for increasing technological innovation may interfere with their primary job of caring for patients. To what extent are these changes taking into account improvements in the efficiency of patient care? Efficiency has not been a major consideration in the design of much of health care technology, but there are a number of areas in which mHealth tools can be used not just to improve compliance or billing but also to benefit day-to-day practices.

REDUCING THE BURDEN OF DOCUMENTATION IN THE EHR WITH VIRTUAL SCRIBES

The primary components of health care technology that practitioners interact with on a day-to-day basis are the EHR, clinical decision support tools, and clinical physician order entry.[32] The primary intent behind adoption of these tools has been the reduction in preventable medical errors, as outlined in the Institute of Medicine report "To Err is Human; Building a Safer Health Care System,"[33] and their use is encouraged through the Health Information Technology for Economic and Clinical Health (HITECH) Act.[34] Although much time and money have been spent on their adoption, little time has been spent making these systems user friendly or efficient. Additional requirements specific to oncology, such as meeting criteria for participation in the Oncology Care Model,[35] only worsen the bureaucratic burden. There is a growing realization that documentation in the EHR places a substantial time burden on practitioners and is drastically reducing the amount of time physicians can spend face to face in direct patient interaction. This has consequences in reduced patient and physician satisfaction as well as in reduced clinical productivity and income.[36]

The need for documentation in an EHR is not going away anytime soon, so a workaround, the medical scribe, has allowed practitioners to spend more time with patients. Scribes, who usually are unlicensed professionals hired to retrieve from and transcribe data into the EHR, have been shown in various clinical settings to decrease time spent in documentation and to improve both the quality of documentation and patient satisfaction.[37] Scribes introduce challenges too, including space issues in the exam room, patient discomfort with a stranger in the room during sensitive conversations, and—of course—expense and availability of trained scribes issues. However, the capacity of telemedicine for instantaneous, real-time communication anywhere in the world now means that the scribe does not have to be in the same room or even in the same country as the practitioner.

Virtual scribes, connected by audio and video to the patient and practitioner through a wireless connection such as Google Glass,[38,39] could provide the same advantages as an in-person scribe but without the space issues or intrusiveness of an additional person in the room. There could also be cost advantages, such as reduced expense in hiring and training scribes in a HIPAA-compliant location that can link out to clinics around the world, even, potentially, in countries where highly educated individuals are available at reduced cost. Patients would still have to consent to this service, and there are important issues related to protection of protected health information and data security that must be addressed, but hospital systems around the country already are adopting this model with some success.[39] A pilot study to investigate the impact of virtual scribes on documentation time and on patient and physician satisfaction is planned (unpublished observation).

REAL-TIME LOCATION SYSTEMS

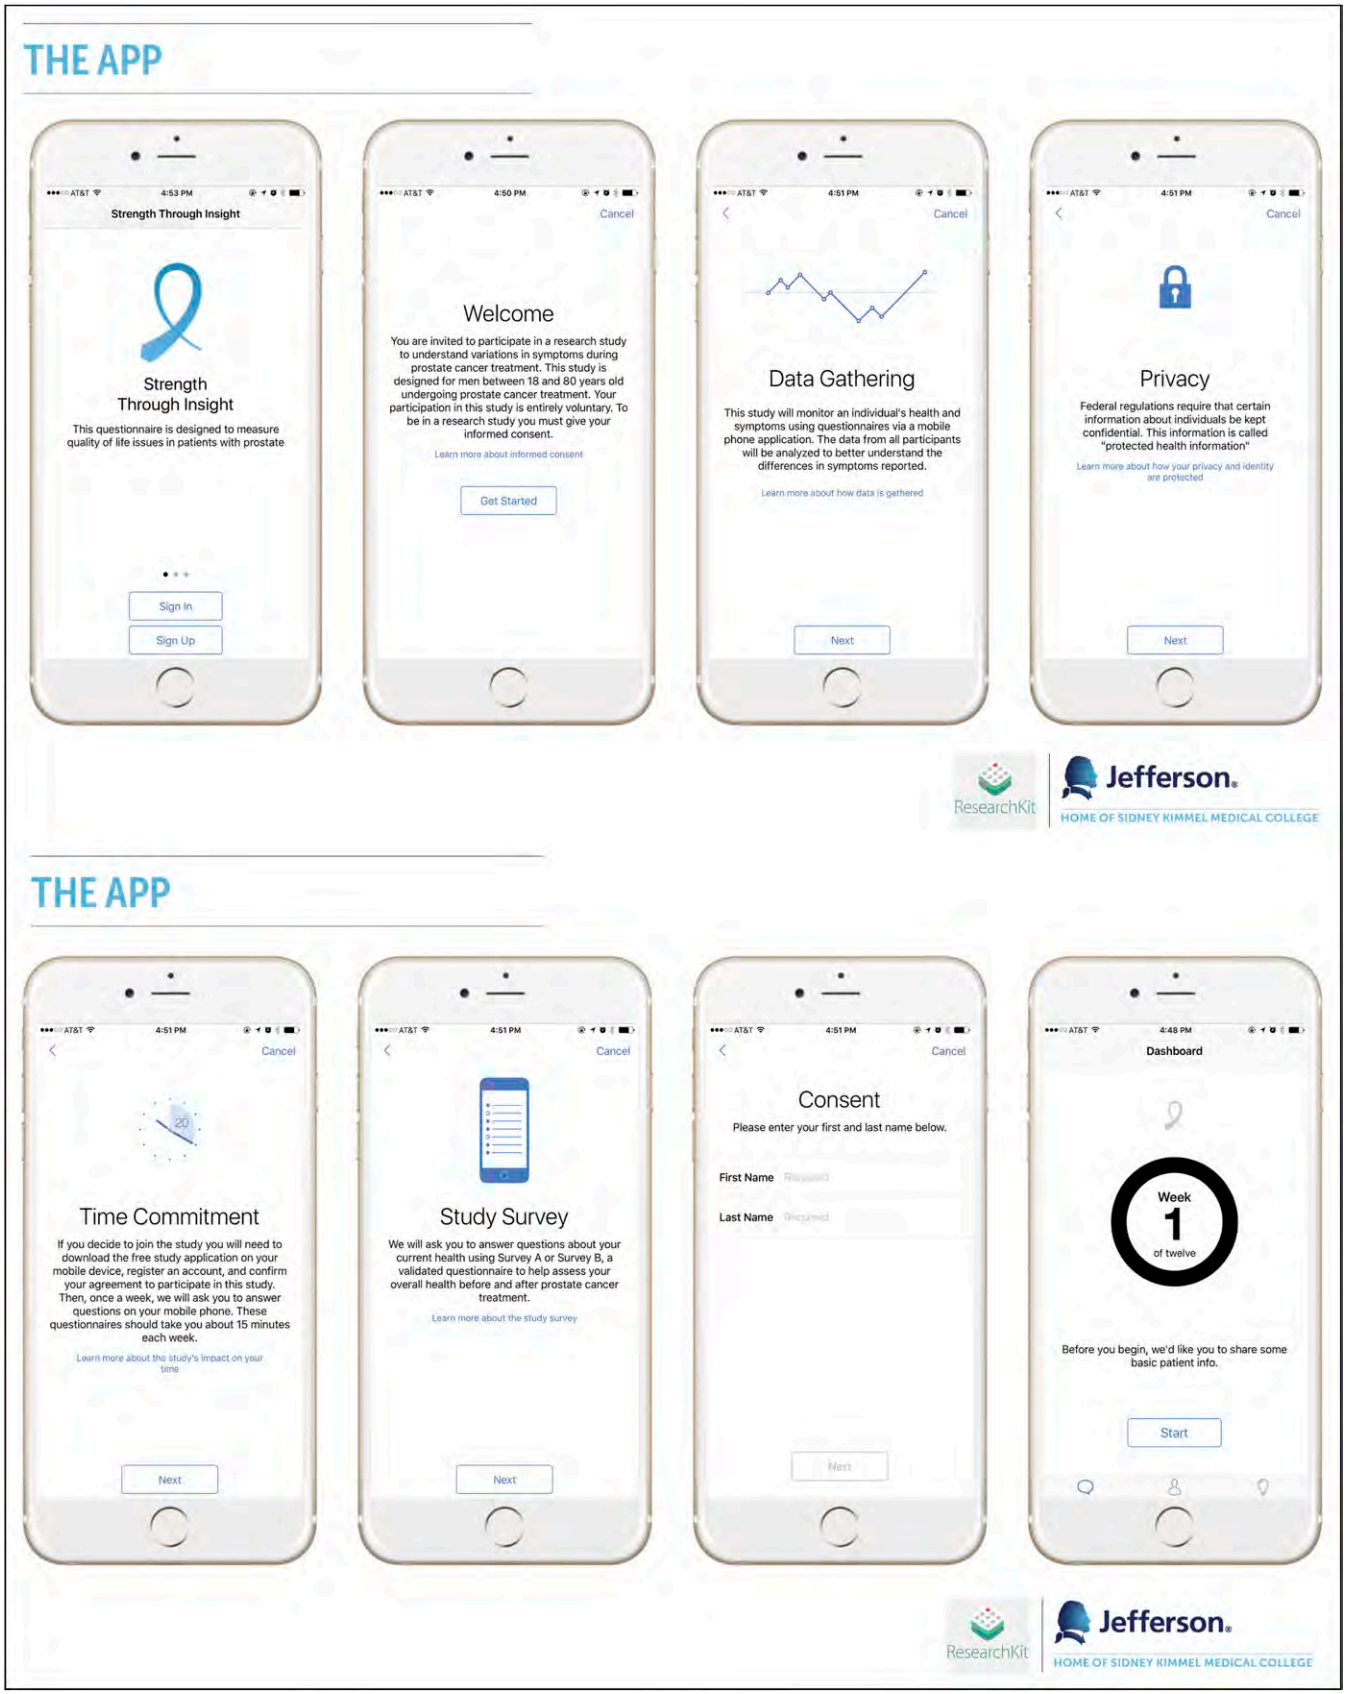
mHealth technology does not always have to connect to the outside world. Real-time location system (RTLS) technology is emerging as a useful tool to help improve patient flow within clinics and hospitals by allowing real-time localization of patients and practitioners.[40,41] In general, patients or practitioners wear a badge that allows them to be tracked in real time by a variety of possible means (e.g., wireless local area networking (Wi-Fi), radio-frequency identification (RFID), or global positioning system (GPS), and the patterns of movement and time spent in a particular location can be recorded. This can help with clinic flow and treatment chair management, and it can decrease room turnover time.[40,42] RTLS also can allow rapid localization (which can be a tedious process) of individual practitioners to sign orders, for example. Some RTLS systems allow hands-free verbal communication through the badges.[43]

Although little data exist specifically in the oncology field about the use of RTLS to improve efficiency, data in other health care settings supports RTLS as a viable option, and a number of prominent institutions, including a cancer center affiliation of one author (N. A. P.), has adopted this technology.[44,45] In an example of how RTLS can be used, a timer starts when patients are roomed; if no practitioner enters the room within 15 minutes, a nurse is alerted to find the practitioner and to reassure the patient. As a result of the positive effect on clinic flow as well as the possible impact of the Hawthorne effect (i.e., that watching someone tends to influence their behavior), studies have shown the patient wait times can be lowered and satisfaction scores can be improved by RTLS.[42]

USE OF MOBILE TECHNOLOGY FOR PHYSICIAN-TO-PHYSICIAN COMMUNICATION

Communication between health care practitioners is critically important to high-quality health care, especially in a field as multidisciplinary as oncology. This is true whether it occurs between nurse and physician, between resident and supervising physicians on a health care team, or between

FIGURE 1. The Strength Through Insight App



The app allows patients and their caregivers to build a partnership for communication throughout their cancer treatment. The survey uses standard questions that can be answered digitally via an app at a set schedule.

consulting services. Although there are a great many ways that practitioners communicate, ranging from alphanumeric pagers to email, the ubiquity of mobile phones and texting/instant-messaging apps opens up a whole new arena of opportunity for communication.

Mobile phones have been tested in medical settings and compared with pagers in terms of speed of communication and reduction in medical errors; results generally are in favor of mobile phones.[46] However, the speed and ease with which practitioners can be reached with mobile phones has drawbacks. Although replacement of pagers with mobile phones has been shown to improve efficiency and decrease the time needed to reach physicians, it may not improve nursing satisfaction with communication. In fact, in one study, use of mobile phones reduced face-to-face communication of nurses with doctors. Instead communication primarily occurred by texting or phone calls, which were considered less meaningful.[47] Studies also have suggested that the ease of mobile phone–based communication significantly increases the number of messages, which can be disruptive to workflow.[48] Finally, questions about the security of protected health information depend on the specific application used for texting; institutions that choose texting as a preferred communication method must provide a properly secure environment.[49]

Despite the risks of increased interruptions and security, mobile phones seem likely to replace pagers and other types of physician-to-physician communication, given their prominence in all other aspects of our lives. In middle-income countries, mobile phones may represent the best available means of communication. An example of the use of mobile technology in this manner is the widespread use of the web-based messaging app, WhatsApp (WhatsApp, Inc., Mountain View, CA), which has approximately one billion users worldwide and has been tested in a number of health care settings.[50]

WhatsApp has advantages compared with short message service texting in that closed groups can be created, and all communications can be viewed securely by all group members, which allows supervision of team communications. Notifications can be sent when a message has been read, and the app is fairly inexpensive, because practitioners can use their own phones and communicate with the wireless network of the institution. In some countries, such as Israel, WhatsApp is used by up to 96% of physicians, and up to 71% use it for communication of patient information and for consultations.[50] Several studies have shown WhatsApp to be a viable method of communicating patient information, asking questions of supervising physicians, and getting feedback among members of a health care team.[51,52]

Given the importance of teamwork and multidisciplinary care to oncology,[53] the availability of a secure and rapid method for team communication would have tremendous potential to aid patient care. However, there are concerns about the security of WhatsApp for communicating protected health information,[54] because the app security is end-to-end encrypted only if all members of a communication group have the most up-to-date version of the software. WhatsApp represents an intriguing illustration of the potential for web-based messaging for clinical communication. However, before adoption of a specific app for professional communication, the policy of the institution about the use of such technology must be clear.

Many oncologists and other practitioners view health information technology as a burden that decreases their face-to-face time with patients and contributes to burnout, but it is important to point out that technology also has the potential to improve efficiency and reduce time spent on low-value tasks. Although this is by no means a comprehensive list, the examples of virtual scribes to reduce time spent typing on the EHR, RTLS to reduce time spent moving patients or searching for providers, and use of mobile apps for better team communication should illustrate how technology may reduce burdens in caring for patients with cancer. As these technologies advance, however, it will be critically important to study their effects on patient care and practitioner well-being and to make sure that the rapid pace of technological development does not conflict with laws in place to protect patient confidentiality.

MHEALTH APPROACHES TO IMPROVING TREATMENT ADHERENCE

Decreased adherence to treatment is well documented for many chronic diseases. Adherence rates vary across diseases and patient factors, with an overall nonadherence rate of 24.8%.[55] This is an important topic, given that decreased treatment efficacy is a consequence of nonadherence.[56] The empiric data specific to adherence in oncology is more limited. Innovative use of mobile technology is well suited to support strategies to improve adherence in oncology, although study of these approaches is still limited. Given that use of telehealth approaches may provide a cost-effective way to improve outcomes for patients with cancer, validated approaches to use of this technology are highly desirable.

Although there are decades of experience in measuring and improving adherence in many chronic diseases, this topic has not received the same attention in oncology. Given the historical dominance of infused therapies in oncology, the concept of adherence as understood in other therapeutic areas was not relevant—antineoplastic treatment was delivered in direct view of the health care team. Empiric work conducted to understand adherence to cancer treatment is more limited, and strategies to optimize patient adherence have not been incorporated into usual care. A preponderance of the empiric work on treatment adherence in oncology has focused on imatinib for chronic myeloid leukemia, or on hormonal therapy for breast cancer (e.g., tamoxifen, aromatase inhibitors), because these were among the first widely used oral medications to require long-term administration in oncology.[57] Adherence rates in these indications are similar to those documented in other therapeutic areas; adherence to oral chemotherapy has ranged in empiric studies from 50% to 89%, depending on the definition of adherence and the study methodology.[57-59]

An important methodologic consideration in adherence research is the measure of adherence used. Measures can be described as direct measures (e.g., blood levels, provider observation) or indirect measures that are further subdivided into objective (e.g., prescription fills) or subjective (e.g., patient self-report) measures. Comparison of objective and subjective measures shows that patients systematically over-report adherence behavior.[60]

Treatment adherence is a critical issue for oncology, because studies consistently have shown that nonadherence leads to worse outcomes, including decreased survival.[61] Data from studies of infused therapies are instructive to define the risk of missed doses. A study of relative dose intensity of adjuvant chemotherapy delivered to patients with breast cancer found that the cohort of patients who received a relative dose intensity of less than 65% achieved an overall survival equivalent to a control group who received no adjuvant chemotherapy.[62] Increased mortality underscores another difference between the consequences of poor adherence in oncology and those in other diseases, in which the risk is limited to increased morbidity.

Nonadherence also leads to increased health care utilization and increased cost.[63] Predictors of nonadherence include patient factors (e.g., age, gender, amount of social support), treatment factors (e.g., frequency and severity of adverse effects), and health care team factors (e.g., education from physician about disease linked to treatment information).[58] Cost of treatment also has been linked to decreased adherence rates.[64,65] Given the emerging focus on improving outcomes while containing health care costs, the need to implement cost-effective strategies to improve treatment adherence is paramount. In addition, the ability to connect to patients outside clinical settings is a compelling approach, given the importance of patient engagement and symptom management in promoting adherence for patients with cancer. For both of these reasons, research into mHealth approaches to manage treatment adherence is desirable.

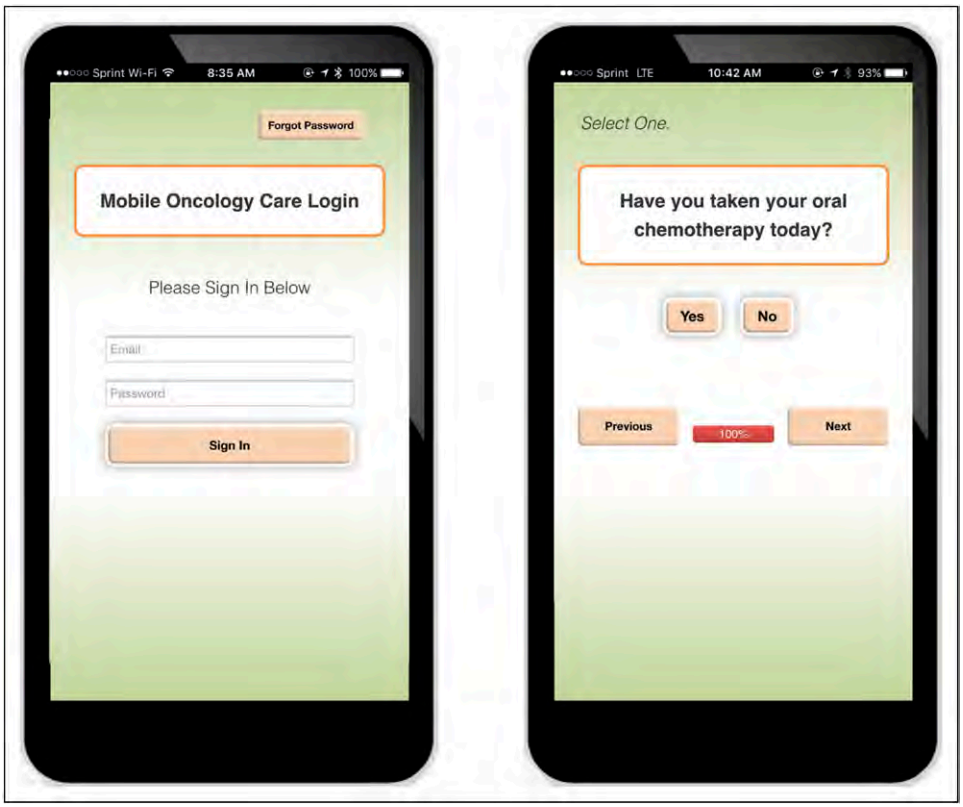
Given that smartphones are becoming ubiquitous, interventions to improve medication adherence through smartphone applications are broadly available.[66] Greater than 90% of American adults owned a cell phone in 2015, an increase from 65% in 2005.[67] There is a growing body of evidence that even simple interventions, such as text message reminders, improve adherence in a variety of chronic diseases.[68] Greater than 80% of cell phone users report sending or receiving text messages.[69] Essentially all (99%) texts are opened, and 90% are read within 3 minutes.[70] Short message service–and multimedia message service–based texting programs and smartphone applications are being introduced into the health care setting.[71-73] Prospective research remains limited, but early studies indicate that digital mHealth interventions can improve patient engagement and adherence to treatment.[69,74] Real-time mobile links between patients and providers can relieve logistic burdens of facility-based care, improve symptom tracking, enhance patient compliance, and shift symptom control to the at-home setting.[75] However, it is also true that the features present in basic smartphone apps vary enormously; therefore, not all apps can be expected to have the same usability or outcomes.[76] An evaluation of the features of 272 mobile phone apps purported to promote medication adherence, and readily available in an app store, found that only six of these apps had even half of the desirable features.[76] For example, flexible scheduling was the most common feature found across the 272 apps but was still available in only 56.3% of the apps. Password protection, as desired to optimize data privacy, was available for only 13.2% of these apps. Standard approaches to evaluate the quality of apps as required to meet their stated goals are needed to facilitate decision making by patients and providers.

In contrast to standard treatments for many chronic diseases, treatments in oncology are often associated with risks for toxicity. This cause of nonadherence may require a different approach than those effective in other therapeutic indications. That is, a text message reminder may not increase treatment adherence in a patient with severe diarrhea who is electing not to take his oral chemotherapy in response to treatment-related symptoms. Instead, approaches that include symptom monitoring of emerging toxicity that prompt the health care team to conduct proactive management would be expected to provide value to improve adherence in oncology. Basch et al[77] used an electronic system to routinely collect patient reported outcomes on common symptoms as part of usual care. Patients in this experimental condition continued to receive therapy for an average of 2 months longer, and they experienced increased 1-year survival, compared with a control group treated with usual care. These data provide evidence that symptom assessment and management may help improve outcomes in the context of oncology care.

A recent pilot study combined symptom monitoring and adherence assessment in patients with early-stage breast cancer who initiated treatment with aromatase inhibitors (Fig. 2).[78] Patients were stratified to receive text and/or email alerts reminding them to complete surveys or to a group that logged onto a website to complete surveys on an ad lib schedule. The group receiving text/email alerts completed 74% of surveys compared with 38% in the ad lib group. Post-study interviews found a high level of acceptance for the mobile surveys; patients stated that they felt that weekly surveys better captured their symptoms compared with waiting for their in-clinic appointment. Additionally, the alert group had nominally better quality of life than the ad lib group.

Beyond systemic therapy, patient-facing technology also may improve broader patient acceptance of their complex care journey, including locoregional treatment. Adherence to immediate postoperative care is ripe for mHealth engagement. Surgical recovery is a traumatic part of the overall cancer care continuum and is punctuated by discomfort, disability, and anxiety. For example, the emotional burden of cancer surgery in the head and neck region is heightened by disfigurement and debilitation. Surgeons and allied

FIGURE 2. Screen Shots From the Patient Care Monitor (Vector Oncology, Memphis, TN) Used for Mobile Health Adherence Monitoring



providers field drop-in visits to manage minor problems, but these visits distract from their urgent duties. Real-time or asynchronous mobile communication could empower appropriate patient self-care, preempt needless anxiety, and decompress clinic schedules. A pilot study that involved a surgical specialty team was conducted at an academic referral center and used a commercial automated text-based intervention to address the immediate postoperative care engagement needs of patients with head and neck cancer.[79] Thirty-two patients were approached, and 23 patients (72%) enrolled. All enrolled patients texted their providers, although frequency (median, seven texts; range, two to 44 texts) varied. Socially isolated patients and those who faced surgical complications used the platform more frequently. Patient satisfaction with the platform was high (mean,3.8 on a four-point Likert scale).

Radiation treatment is complex, lengthy (often 30 to 35 daily treatments during 6 to 7 weeks), costly, and toxic. It has been shown that gaps in treatment yield poorer outcomes for patients as a result of accelerated tumor regrowth during breaks in treatment. Compliance is crucial to ensure the best chance for local control and cure; unfortunately, adherence to radiation is a challenge. A review of 564 patients with head and neck cancer who received radiotherapy at a tertiary academic center was conducted to quantify the extent of this problem in a modern patient population covered by a spectrum of private insurance and public indigent care.[80] Three-hundred sixteen patients (56% of all enrolled) suffered a treatment break; 114 missed a single session, 202 missed multiple treatments. Seventy percent of uninsured patients had treatment delays compared with 47% of privately insured patients ($p \leq .0001$). Uninsured patients most often missed treatment because of nonmedical/logistic reasons. Delay was predictive for local recurrence ($p = .0002$) and overall survival ($p < .0001$). Among noncompliant patients, there was a higher likelihood for local recurrence in indigent patients. Our results highlight cancer control needs specific to disadvantaged communities at risk for poor radiotherapy adherence. A complex mix of social and human elements—including patient trust in providers, effectiveness of toxicity management, and quality of patient support—create a constellation of determinate factors. Emerging research has shown that mHealth informatics platforms can positively affect health care delivery in indigent cancer populations.[74,75] Interestingly, a pilot study published by Percac-Lima et al[81] found that telephone navigation directed to at-risk patients significantly improved cancer clinic visit adherence.

In summary, early patient-centered studies leveraging mHealth applications to engage patients with cancer about their treatments confirm an exciting beginning. However, these are just the first steps in a longer journey, on which all hype will wear thin quickly. Careful work is needed to refine personalized telehealth tools/utility measures, propel

stakeholder enthusiasm, and secure sustainable reimbursement models. Momentum toward mobile consumer self-fulfillment in our modern economy is undeniable. Our patients soon will demand dependable, useful, and thoughtfully designed mobile tools to optimize the acute, recuperative, and long-term survivorship phases of their cancer care. Inclusive multidisciplinary teams will be necessary to keep the cancer care experience relevant to the 21st-century patient, and the changes will require the buy-in and expertise of clinicians, social scientists, computer/data scientists, product designers, health systems experts, and health care policy makers among others. Additional work must focus on best practices to improve outcomes and balance patient and provider burden. Comparing approaches will be challenging because of the variability in features of apps and tools grouped under the mHealth label. Attention to scientific methodology will be especially important to ensure that potentially cosmetic improvements in patient satisfaction and adherence that we engender with technology actually lead to meaningful downstream clinical outcome improvements.

Perspectives on the Use of Clinical Pathways in Oncology Care

Anne C. Chiang, MD, PhD, Peter Ellis, MD, and Robin Zon, MD

OVERVIEW

Pathways and guidelines are valuable tools to provide evidence-based care in oncology. Pathways may be more restrictive than guidelines because they attempt (where possible) to reduce cost, add efficiency, and remove unwarranted variability. Pathways offer an opportunity to measure, report, and improve quality of care; they can drive to evidence-based targeted therapy where appropriate; they can enhance efficiency through standardization; and, finally, they can be a vehicle to enhance participation in clinical trials. Pathway implementation requires understanding and commitment on the part of the physician and leadership as they may initially disrupt workflow, but ultimately have the ability to enhance patient care. ASCO criteria have been published for the development and implementation of high-quality oncology pathway programs. Future challenges for pathways include incorporation of molecular testing and appropriate targeted care in a real-time precision oncology approach.

Pathways have been used for more than a decade in the oncology space, with the aims of improving patient care and communication while focusing on outcomes and maximizing resource utilization by reducing unwarranted variation and promoting the use of higher value therapy. However, the magnitude and growing importance of pathways is evident in the role of reimbursement, already implemented by some payers, and pathway utilization expansion, such as in the Oncology Care Model. Additionally, with the statutory implementation of the Medicare Access and CHIP Reauthorization Act of 2015 (MACRA), the U.S. health care system of reimbursement is transitioning away from a volume-incentivized, provider-centric model to a value-based, patient-centered model. Well-designed pathways have the potential to help us adapt to this transformation by serving as a foundation for comprehensive patient care, while promoting efficient, higher quality care. This in turn can potentially control costs and better position practices to assume financial risk for our patient populations, while assuring best care for the patient. Pathways could possibly serve as a central component of oncology practice and as a cornerstone of future payment methodologies.

DEFINITION: GUIDELINES VERSUS PATHWAYS

The terms "guidelines" and "pathways" are used frequently in discussions regarding quality and cost-effective oncology care. A guideline is a listing of all treatments that are considered (by a panel of experts) to be within a "standard of care" for a given presentation of disease. Practice guidelines assist practitioner and patient decisions about appropriate care, defined by empirical evidence, addressing specific clinical circumstances and aligning practice with state of the art oncology. Guidelines do not formally address cost and resource utilization. The primary aim for guidelines is not standardization, but rather to ensure that care delivered has been demonstrated to be effective by evidential review. In a Venn diagram, pathway treatment recommendations would be included within the scope of the guidelines, but with a much smaller numerical set. An exception to this might be when a pathway is updated more frequently than a guideline, incorporating new evidence.

Pathways are also known as care pathways, critical pathways, care maps, or integrated care pathways. A pathway references the same literature sources, but attempts to choose a single therapy from the acceptable options that is best for a given presentation of disease. This process involves committees of physician peers with disease expertise and uses consensus to determine the best option based on a platform of efficacy, toxicity, and cost. Characteristics of a pathway program include the pathway serving as a multidisciplinary management tool, based on high-level evidence applicable to a specific group of people, wherein interventions are defined, optimized, and sequenced. Generally, pathways will support the Triple Aim of health care, which is better perception of care by the patient, improved professional effectiveness and coordination of care, while

Disclosures of potential conflicts of interest provided by the authors are available with the online article at asco.org/edbook.

Corresponding author: Anne Chiang, MD, PhD, Yale University School of Medicine, Smilow Cancer Hospital, 20 York St., NP-304, New Haven, CT 06520; email: anne.chiang@yale.edu.

controlling/reducing costs. Ideally, pathways should be available at the point of care for a patient for real-time clinical decision support. The pathway system should also be able to document the decision making of the clinician for future study, reporting, and compliance.

RATIONALE FOR USE OF PATHWAY PROGRAMS

Whereas access to the ASCO and the National Comprehensive Cancer Network guidelines is open, pathway systems are currently only commercially available and thus require substantial commitments of time and resources for practice implementation. However, there are multiple compelling reasons to support pathway use. First, the status quo of relying upon the individual expertise of any one physician to decide appropriate care is no longer acceptable in our current age of accountability. There is now a need to prove the quality of care to stakeholders (e.g., patients, referring providers, and payers) rather than the "trust me" mantra of old. Measuring care is an indispensable part of care delivery, but, unfortunately, our current electronic platforms for documenting care are not up to the task as they cannot have the innate flexibility needed to react to the rapidly changing science of oncology. Pathway systems can provide such data demanded by new legislation, such as MACRA and Merit-based Incentive Payment System.

Second, the costs of all medical care are rising faster than inflation with oncology care contributing significantly to this increase. By standardizing care—where feasible and appropriate—to best evidenced-based care, pathways programs offer the possibility of driving down costs, increasing quality, and improving outcomes. Standardization also offers the potential for improved patient flow, error reduction, and cost savings without compromising patient access or care. Limiting "unwarranted variability" is in everyone's best interest.

Finally, as oncology care becomes more personalized, the options for care more numerous, and the volume of information that informs decision making ever more complex, it becomes increasingly difficult for a single provider to remember the nuanced details of treatment of every state and stage of disease presentation. At the same time, restrictions in provider availability will likely tighten as the baby boomers continue to age and patients live longer and better lives with their cancer diagnoses. The need for a point-of-care decision support tool is increasingly becoming self-evident. For institutions committed to advancing the knowledge-base of cancer treatment through research, a pathway can simplify and potentially enhance accrual of patients by being able to incorporate open clinical trials into the treatment algorithm.

KEY POINTS

- **Pathways are a subset of guidelines designed to standardize care with best evidence and reduce unwarranted variability and cost.**
- **Pathways offer the hope of improved quality by standardization around best evidence, enhancing clinical trial availability, offering decision support at the point of care, and providing measurable outcomes.**
- **Implementation of pathways requires significant understanding and commitment of the provider institution, but has the promise of being an important quality and cost tool.**
- **Pathways may be influenced by the viewpoint of the developer. ASCO members are often most comfortable with the implementation of provider-based pathways in clinical care.**
- **Pathways may enhance the use of appropriate targeted (personalized) care.**

THE ROAD MAP TO SUCCESSFUL PATHWAY IMPLEMENTATION

After the decision has been made to proceed with the adoption of clinical pathways, there are several key aspects to a successful launch. The initial "big picture" buy-in of all of the clinicians in the institution is critical; they must understand and agree that a provider-based solution is preferable to a payer- or government-based solution both for patient care and provider satisfaction. The big picture will necessarily look different to an academic physician compared with a clinical physician, but can be equally compelling.

Once buy-in is obtained, the system chosen for use should be integrated into the normal physician workflow as seamlessly as is possible. Clinician expectations have to be managed, stressing that all efforts are being made to minimize disruption in the clinic, but that it is impossible to add a variable without some alteration in flow. Adjustments to workflow or the product should not be based upon a perception of what it will be like, but rather upon the experience of hands-on usage and subsequent thoughtful adjustment to obtain the goal of quality patient care and good workflow. This iterative process is possibly the single most important aspect of implementation. Each clinic may have its own uniqueness and character demanding slight variations in rollout that are often easily accommodated.

After initial implementation, giving feedback to the physician and monitoring that feedback are vital to success. Clinician feedback regarding the advantages of a decision support tool and data collection are helpful in maintaining compliant use of the system. For example, the ability to provide data on eligible patients throughout a network to academic physicians for screening or clinical trials development is an immediate positive byproduct. Facilitating workflow by offering all the information necessary for patient care in one location is appreciated by busy clinicians trying to get through a busy clinic. Saving time to look up side effects or dose reductions allows for more time spent with each patient. Changes in workflow are always difficult to manage, especially when physicians already have their own established care preferences. Attempting change in a stepwise fashion is preferable to allow time for adoption.

The content of a pathway may differ based upon the principles and priorities of the pathway developer. A transparent

SIDEBAR 1. ASCO Recommendations to Improve the Development and Use of Clinical Pathways in Oncology

1. Pursue a collaborative, national approach to reduce the unsustainable administrative burdens associated with the unmanaged proliferation of oncology pathways.
2. Adopt a process for development of oncology pathways that is consistent and transparent to all stakeholders.
3. Ensure that pathways address the full spectrum of cancer care, from diagnostic evaluation through medical, surgical, and radiation treatments, and include imaging, laboratory testing, survivorship, and end-of-life care.
4. Update pathways continuously to reflect new scientific knowledge and insights gained from clinical experience and patient outcomes, to promote the best possible evidence-based care.
5. Recognize patient variability and autonomy and allow physicians to easily diverge from pathways when evidence and patient needs dictate.
6. Implement oncology pathways in ways that promote administrative efficiencies for both oncology providers and payers.
7. Promote education, research, and access to clinical trials in oncology clinical pathways.
8. Develop robust criteria to support certification of oncology pathway programs; pathway programs should be required to qualify based on these criteria, and payers should accept all oncology pathway programs that achieve certification through such a process.
9. Support research to understand the effect of pathways on care and outcomes.

and evidence-based development process of pathways is vital to assure the confidence of those affected by the pathway: the provider, patient, and payer. Many practices have found that implementation of a well-designed pathway program is both doable and advantageous in the delivery and measurement of quality oncology care.

THE ASCO PERSPECTIVE OF CLINICAL PATHWAYS

On January 12, 2016, the ASCO Policy Statement on Clinical Pathways on Oncology[1] was released with recommendations to ensure that clinical pathways in oncology enhance—and not diminish—patient care (Sidebar 1). The intent of the statement was to elevate awareness about clinical pathways in oncology and to convey a cautionary note that no current mechanism exists to ensure the integrity, efficient implementation, and outcome assessments for these treatment management tools. The release came within 1 year of the establishment of the Task Force on Clinical Pathways, which was charged with better understanding the concerns and barriers to providing high-quality, evidence based care, as articulated by ASCO members and other stakeholders. Specifically, ASCO's State Affiliate Council and Clinical Practice Committee cited a number of concerns, including: lack of transparency in disclosing conflict of interest and disclosure describing the methodology used in development, a focus on cost savings with efficacy and safety as secondary considerations, a cumbersome appeals process and lack of reimbursement for off-pathway treatment, lack of pathways for rare and in-patient–treated cancers, implementation concerns, as well as lack of publicized analytics supporting pathway utilization. Members especially highlighted the associated unsustainable administrative burdens related to the multitude of oncology pathways some providers are required to track and manage, as well as the continued requirement of pre-authorization when pathway compliant.

The Clinical Pathways Task Force has continued its efforts to ensure that pathways are consistently developed and transparent to all stakeholders, and used in the way they are intended—to guarantee quality care while helping to reduce unwanted variations in care and controlling costs. Recently, the Task Force developed and published ASCO criteria for the development and implementation of high-quality oncology pathway programs while actively seeking and respecting input—through direct stakeholder meetings and interviews—with patient advocates, payers, vendors, and providers (Table 1).[2] The criteria focus on three key areas: development, implementation/use, and analysis and are intended for use by multiple stakeholders to evaluate clinical pathway programs and guide their future development.

TABLE 1. ASCO Criteria for High-Value Pathways

Development	Implementation and Use	Analytics
Expert driven and reflects stakeholder input	Clear and achievable expected outcomes	Efficient and public reporting of performance metrics
Transparent, evidence-based, patient-focused, clinically driven, and up-to-date	Integrated, cost-effective technology, and decision support	Outcomes-driven incentives
Comprehensive and promotes participation in clinical trials	Efficient processes for communication and adjudication	Promotion of research in value and effect on pathways and care transformation

BENEFITS OF USING ASCO CLINICAL PATHWAY CRITERIA FOR PRACTICING ONCOLOGISTS

Regardless of the site of service, ASCO criteria are intended to be used in a manner that enhances the ability of the provider to evaluate pathway programs for their practice. Because providers are becoming increasingly focused on optimizing efficiencies, including reducing costs while preserving high quality care for the patient, the criteria may help in assessing programs that may best attain practice management goals. Furthermore, as various stakeholders collaborate to improve the delivery of care, pathway utilization may intensify. Cancer care is generally a multidisciplinary effort, and pathways, if comprehensively developed as proposed in the criteria, can be widely used by the caregiver team to optimally coordinate patient care. Reducing redundancy and unnecessary testing while assuring the necessary evaluations and treatments are delivered would be paramount to the success of a pathway program in this collaboration. On a broader scale, there are differences between payer- and provider-facing pathways. Collaboration between payers and providers regarding pathway utilization and criteria compliance may offer opportunity to help minimize some of the administrative issues for both stakeholder groups, be leveraged as a measure to control costs, and inform reimbursement discussions.

EVOLUTION OF CLINICAL PATHWAYS: CHALLENGES OF PRECISION ONCOLOGY

The ASCO criteria promote a much needed benefit of continually updated comprehensive pathways to help with the management of rapidly developing clinical advances. All stakeholder groups, including payers and patients, are quick to point out variation of care and resource utilization between providers. As pathways integrate scientific advances, including precision medicine and rapid learning system–validated evidence, there should be opportunity to maximize resource alignment and promote value. In addition, informed pathways will assist the provider in delivering appropriate, equitable care for all patients. To serve as example, pathway programs can potentially assist providers in ensuring the growing complexity of molecular testing is used optimally so patients can receive targeted and other personalized care to achieve best outcomes. Currently, the utilization of U.S. Food and Drug Administration–approved and National Comprehensive Cancer Network guideline-approved tests, such as EGFR testing in patients with newly diagnosed advanced lung cancer, is not known. One study estimates 18% of patients with newly diagnosed lung cancer undergo testing within 6 months of diagnosis, with 37% patients with presumed nonsquamous histology (receiving bevacizumab or pemetrexed) undergoing EFGR testing.[3] Certainly, pathway use can help to ensure and track the use of appropriate molecular tests.

Precision oncology now refers to the use of molecular testing to identify mutation-based treatment options such as vemurafenib and dabrafenib for patients with BRAFV600 mutations or erlotinib for EGFR mutations. With the increasing uptake of genomic testing, in part enabled by reduced cost, many clinicians and patients are faced with trying to understand the implications of molecular testing results on treatment decisions. For example, should patients with various disease types who have BRAFV600 mutations receive targeted therapy, even if the drugs have not yet been tested or approved for those specific disease-types? Two meta-analyses have shown that trials utilizing molecularly-based treatments led to better outcomes compared with those with nontargeted therapies.[4,5] However, the prospectively randomized French SHIVA trial did not show benefit in progression-free survival for patients who were treated with molecularly targeted agents versus investigator's choice. In this trial, patients with any metastatic solid tumor that had progressed on standard treatments underwent mandatory tumor biopsy to obtain tissue for genomic testing. Patients who had molecular alterations that mapped to the PI3K/AKT/mTOR, or RAF/MEK, or hormone receptor pathways were randomly selected to receive standard of care versus molecularly targeted agents including erlotinib, lapatanib plus trastuzumab, sorafenib, imatinib, dasatinib, vemurafenib, everolimus, abiraterone, letrozole and tamoxifen. Of 741 patients screened, 293 (40%) had at least one molecular mutation identified; 92 patients were randomly selected to receive the control standard-of-care arm and 99 patients to the experimental molecularly targeted arm. The median progression-free survival was 2.0 months compared to 2.3 months (HR 0.88; p = 0.41) in the control versus experimental arms, respectively.[6]

There are several reasons for the lack of benefit seen in patients receiving targeted therapy in the SHIVA trial. Mutations in driver genes identified by sequencing may be silent passenger mutations or mutations that are resistant to therapies, such as EGFR exon 20 insertions that are not associated with response to EGFR inhibitors. Alternatively, some cancers may require multiple hits in different signaling pathways or involve epigenetic or post-transcriptional control. Finally, discrepancies between commercially available tests or discordance between primary, metastatic, or just heterogeneous tumors may complicate the use of molecular alterations for treatment. Although there is no doubt that some molecularly based treatments based on single mutations (e.g., erlotinib and crizotinib in lung cancer) can improve patient outcomes and should be incorporated into clinical pathways, much work remains to be done before large-scale genomic testing and subsequent targeted therapies becomes standard of care.

VALUE-BASED CARE AND PATHWAYS: FUTURE CHALLENGES

Several current initiatives aim to improve quality of care and care delivery, including the development of learning health care systems and value-based frameworks. These initiatives, along with pathways, are influenced by the different perspectives and needs of the stakeholders. For example, the definition of value may differ between health systems,

payers, patients, oncologists, and manufacturers. Similarly, the perspectives of payer- and provider-facing pathways may differ. Because there is limited published data regarding pathway performance, escalation of widespread pathway program analysis as it pertains to patient outcomes and the financial aspects surrounding cost and value, is needed. Additionally, learning health care systems have challenges pertaining to data sharing, interoperability of electronic health care systems, and patient-reported outcomes. These initiatives, although currently being developed independently, have the potential to enhance patient-centered care as an integrated strategy while still achieving the goals of quality, value, and cost control. As pathway programs continue to evolve, improvements in patient care will be achieved as value and learning health system learnings are integrated as essential components.

Precision Oncology: Who, How, What, When, and When Not?

Lee Schwartzberg, MD, Edward S. Kim, MD, David Liu, MD, MPH, and Deborah Schrag, MD, FASCO

OVERVIEW

Precision oncology, defined as molecular profiling of tumors to identify targetable alterations, is rapidly developing and has entered the mainstream of clinical practice. Genomic testing involves many stakeholders working in a coordinated fashion to deliver high-quality tissue samples to high-quality laboratories, where appropriate next-generation sequencing (NGS) molecular analysis leads to actionable results. Clinicians should be familiar with the types of genomic variants reported by the laboratory and the technology used to determine the results, including limitations of current testing methodologies and reports. Interpretation of genomic results is best undertaken with multidisciplinary input to reduce uncertainty in clinical recommendations relating to a documented variant. Non–small cell lung cancer has emerged as a prototype disease where genomic data from at least several well-documented alterations with approved targeted agents are essential for optimal treatment from diagnosis of advanced disease. Due to the development of resistance to targeted therapies, resampling and retesting of tumors, including using liquid biopsy technology after clinical progression, may be important in making treatment decisions. The value of molecular profiling depends on avoiding both underutilization for well-documented variant target-drug pairs and overutilization of variant-drug therapy without proven benefit. As techniques evolve and become more cost effective, the use of molecular testing may prove to add more specificity and improve outcomes for a larger number of patients.

The goal of precision medicine is simply to deliver the right cancer treatment to the right patient at the right dose and the right time. Several lines of investigation came together nearly simultaneously to usher in the beginning of the precision oncology era. In 1998, the *BCR-ABL* rearrangement in chronic myeloid leukemia was successfully targeted by the small molecule imatinib, leading to dramatic clinical remissions and U.S. Food and Drug Administration approval in 2001. The first draft sequence of the human genome was accomplished the same year,[1] followed by the first cancer genome.[2] Rapid discovery of multiple, nonoverlapping driver mutations and tyrosine kinase inhibitors with clinically effective inhibitory properties in non–small cell lung cancer and melanoma led to assays of alterations performed by polymerase chain reaction (PCR) quickly and inexpensively. Use of these biomarkers to drive treatment decisions in solid tumors raised expectations and interest in molecular profiling. Sequencing technology and costs improved rapidly during the early 2000s, particularly with the advent of NGS on formalin-fixed, paraffin-embedded tissue whereby massive parallel sequencing allows determination of alterations in a large number of genes through a timely, cost-effective process.

Underpinning precision oncology is the concept of somatic mutations as the foundation of cancer development.[3] Mutations in oncogenes rendering them constitutively active are considered driver mutations and are central control points for progression of malignancies. Conversely, tumor suppressor genes, involved naturally in controlling tumor pathogenesis, can cause cancer progression when inactivated through mutation or allele loss. Multiple processes result in dysregulation of the genetic machinery in DNA RNA or protein, leading to altered expression of the protein coded for by the gene. To capture the entire spectrum of potential alterations, multiple technologies, termed a multi- or pan-omic approach, are best considered. The vast number of choices of technologies, commercial entities offering testing, and sometimes conflicting results have overwhelmed clinicians looking to obtain molecular information that will result in clinical utility for their patients. Even in academic centers, oncologists report varying confidence in their ability to use the genomic findings appropriately.[4]

At its most fundamental level, a genomic test with clinical utility should be predictive of a treatment response from a targeted agent. An early example in solid tumor oncology was the ability to test for *HER2* positivity as defined as fluorescent in situ hybridization–based gene amplification or immunohistochemistry to demonstrate overexpression of the protein. Positive results predicted response to

trastuzumab-based therapies, whereas *HER2*-negative tumors did not derive benefit from this approach. As we have moved into multiplex testing of many genes or other biologic species, including messenger RNA and proteins, the same criteria should apply—is the variant alteration sufficiently predictive of response to a paired agent?

To date, success in using precision approaches to treatment have been mixed. A prospective phase II study of molecular profiling to assign matched therapy did not show superior outcomes for the matched group but suffered from serious methodologic design issues.[5] Large retrospective series have documented that 80%–90% of patients tested will have potentially actionable genomic alterations, although the definition of actionable can vary substantially.[6-9] However, only a minority of patients to date actually receive genomically directed therapy, usually on a clinical trial.

TECHNICAL ASPECTS OF NGS TESTING FOR THE CLINICIAN

Types of Alterations Detected

A range of genomic somatic variants can be ascertained with NGS, including single nucleotide variants (SNVs), also known as point mutations, and small insertions or deletions of bases (indels), which can lead to a nonfunctional or absent protein. Additionally, copy number variants, which reflect amplifications and deletions of genes and/or larger portions of a chromosome, gene rearrangements and fusion genes can be detected.

Read Depth and Coverage

This criterion refers to the number of times a particular base position in the DNA is read during the NGS analysis. The greater the coverage of a particular alteration, the more likely it is to be detected, which is especially important in tumor samples with low tumor content. By covering the same area of the gene fragment multiple times, the likelihood of picking up a variation of low allelic frequency is enhanced.

KEY POINTS

- **The goal of precision oncology has begun to be realized through multiplex molecular testing including NGS.**
- **Oncologists should be familiar with technical aspects of NGS to facilitate selecting the most appropriate and cost-effective testing platform.**
- **Considerations for molecular testing include which tissue type to utilize, timing of profiling in the disease course, extent of panel to order, and degree of clinical annotation reported.**
- **Actionable biomarkers of non–small cell lung cancer make this disease a paradigm for precision oncology at diagnosis of advanced disease, during therapy, and at time of progression.**
- **Interpretation of molecular data to facilitate best practice remains a challenge; clinical trial participation and sharing of linked molecular/clinical data sets are strongly encouraged.**

For hot spot testing, coverage of at least 100–300X is recommended.

Breadth and Scope of Testing

How many genes are included and what areas of the gene are analyzed. The most frequent NGS offerings today are hot spot testing, where alterations in exons or intron/exon junction areas of a preselected panel of cancer genes, including known activating oncogenes and tumor suppressor genes, are analyzed. Targeted hot spot panels focus on the best-annotated cancer genes, typically 35 to 350 genes, and provide high depth of coverage. The greater depth allows for assessing lower allele frequency and can account for intratumoral heterogeneity and low allele frequency of the alteration. NGS panels are not ideal for large-scale rearrangements and/or deletions and certain fusion genes. Addition of RNA sequencing can help identify these alterations.

Recently, whole-exome sequencing and whole-transcriptome sequencing have become available at academic and some commercial laboratories. At the moment, the value of whole-exome sequencing information is largely confined to the translational research space, where it offers enormous potential to produce novel variant-pathogenic associations leading to clinical trials investigating new agents. Lengthy turnaround time and lack of clinical associations for the large majority of genomic alterations preclude current effective clinical use.

Variant Calling

The bioinformatics approach to lining up the vast amount of information obtained in an NGS sequence, and accurately calling variants, is important to achieve quality results. Variant quality scores are generated for each test within a laboratory. Technical validity results can be provided to the practitioner upon request and may be useful in determining which assay to use due to interlaboratory differences. Federal guidelines for technical validity do not currently exist for NGS tests, which are classified as laboratory developed tests.

Variant Allele Frequency

This reflects the percentage of reads identifying a variant divided by the overall coverage of that locus. If tumor cells represent 100% of the sample DNA analyzed, heterozygous loci such as seen in germline mutations should be near 50% variant allele frequency, homozygous loci should be near 100% and reference loci should be near zero. In actual practice, the contamination from normal cells, local copy number alterations and tumor heterogeneity often yield unpredictable variant allele frequency.

Variant Meaning

Particularly for single nucleotide variants, it is not always easy to determine if a mutation is pathogenic or not. Publicly available databases, such as the Catalogue of Somatic Mutations in Cancer (COSMIC),[10] and the laboratory's internal databases, are reviewed by the evaluating pathologist, and a

determination is made whether the alteration is pathogenic, probably pathogenic, probably benign (meaning that it is likely a single nucleotide polymorphism without functional significance), benign representing a known single nucleotide polymorphism or a variant of unknown significance. As panel testing grows larger, the reporting of a variant of unknown significance has grown dramatically. It is hoped that in the future, sharing of genomic data will settle the issue for the growing number of alterations without a clinical correlate to call pathogenic or not. At the moment, utilizing a laboratory with deep molecular expertise, including molecular pathologists and geneticists on staff to help make the call, is extremely important. Alternatively, third-party organizations like N-of-1 use extensive resource capabilities to perform this function for laboratories or health care systems. Their role is to generate content relevant to the spectrum of variants so that clinically appropriate decisions can be made.

Tumor Only Versus Tumor Normal

When a tumor alone is tested, variants are compared with databases such as COSMIC and ClinVar[11] to determine whether the variant is a known pathogenic variant or a known single nucleotide polymorphism. Simultaneously sequencing tumor and normal tissue allows more precise calling of somatic mutations. Moreover, germline cancer predisposition genes can be clearly distinguished from somatic mutations in the same genes. As bioinformatics improves, value from the additional cost and complexity of sequencing both tumor and normal tissue routinely appears to be diminishing.[12] Though advances in bioinformatic techniques and reference germline databases are improving the accuracy of tumor-only sequencing, matched-tumor and normal-tissue sequencing is still the gold standard for somatic mutation detection.

IMPLEMENTING PRECISION ONCOLOGY TESTING AND INTERPRETATION IN PRACTICE

Doing precision oncology optimally depends on getting operational issues of testing right. Many considerations factor into selecting the right molecular test (Sidebar 1). Communication between medical oncologists and local pathologists becomes more critical than ever, particularly when the material will be sent to an outside facility. Local pathologists control the tissue, and the rationale for testing and the technical needs of the outside laboratory must be clearly stated. Standard operating procedures for molecular testing are useful to facilitate the process and improve the likelihood of timely, successful and accurate molecular result reporting. Importantly, tissue blocks must be assessed for adequate tumor tissue so that the results are interpretable and infrequent mutations can be characterized. Formalin-fixed, paraffin-embedded samples, including fine-needle aspirates and cytology samples with sufficient cellularity, can be used for NGS. The amount of DNA needed, expressed either in nanograms or the number of slides necessary to do testing, should be considered upfront to avoid a quantity-not-sufficient result. NGS technology requires at least 10 to 20 slides for a complete analysis, so the pathologist may have to evaluate multiple blocks to pick the sample with the most tumor tissue likely to yield an interpretable result.

SIDEBAR 1. Diagnostic Considerations in Molecular Testing

- Choice of assay and design
- Cost
- Tissue quality
- Turnaround time
- Clinical Laboratory Improvement Amendments and/or College of American Pathologists certification
- Bioinformatics analysis
- Clinical interpretation

Many patients undergo fine-needle aspiration or core biopsies for histologic diagnosis of malignancy, so remnant tissue may be sparse and careful decision making weighing the risks and benefits of biopsy for the express purpose of genomic testing is essential. For patients likely to require molecular testing at some point in their course, it is helpful to plan the initial biopsy of metastatic disease with this need in mind, so that tissue will be available later. Decisions to rebiopsy are complex and include morbidity and cost associated with the procedure versus the value of assessing the current tumor biology, particularly after exposure to genomic-altering agents.

Typically, specific informed consent for testing in the context of clinical decision making is not required for molecular profiling. An oncology clinic's general consent form for testing and treatment should cover molecular testing under the scope of medical practice. If patient results will be used in a prospective registry maintained by the practice, the institution, the testing laboratory or an academic consortium, informed consent based on a collection and analysis protocol is advisable. Should molecular alterations render a patient eligible for a clinical trial, the patient will be required to provide consent again to use this information for the study.

Who and When?

Many patients with metastatic disease may be good candidates for genomic testing at varying times in their clinical course. Patients with disease with fewer or no standard treatment options are candidates for early molecular profiling in the hope that they will be a candidate for a clinical trial evaluating a particular alteration. Such trials are called basket studies and typically are agnostic to the tissue of origin as long as specific variants are identified. When no trial is available or the patient is not eligible, using an approved agent for a specific alteration in another disease state (e.g., BRAF V600E mutation) might be appropriate after failure of standard therapy. Often there is no definitive trial data to base decisions on appropriateness of molecular targeted therapy in noninvestigational settings, and a balance of risks and benefits of an unknown approach should be carefully

weighted. One potential hierarchy for decision making is presented in Table 1. Emerging evidence suggests overall tumor mutational load, analyzed in either large target gene panels of 300 to 600 genes or utilizing whole-exome sequencing, can be predictive of response to immune checkpoint inhibitors.[13,14] Additionally, mismatch repair deficiency assessment through genomic analysis is another valuable molecular assay with applicability to immune-oncology therapies.[15]

In general, early-stage patients undergoing definitive treatment do not typically require somatic gene panels. They will not have actionable alterations provided by NGS beyond what can be ascertained from standard histologic evaluation (e.g., estrogen receptor, progesterone receptor, and HER2 in the case of early-stage breast cancer). Broader molecular information will be of research use only.

For certain diseases where a first-line decision depends on multiple molecular markers, such as advanced non–small cell lung cancer, the use of a multiplex NGS panel at diagnosis becomes increasingly attractive given the growing number of targetable genes, the ability to simultaneously obtain the information from one sample and the ever lower cost of multiplex testing. Conversely, when other disease states exhaust evidence-based lines of standard therapy, panel testing is often appropriate if the patient remains a good candidate for further treatment.

A decision must be made whether to send a new biopsy or use archival tissue. Discordant genomic results may be seen between primary tumors and metastases, although this is highly disease site specific. For instance, *RAS* mutations in colorectal cancer are an early event in tumorigenesis, and reliable actionable information regarding use of anti-EGFR antibodies in the metastatic setting can obtained from the primary tumor.[16] Conversely, estrogen receptor 1 mutations conferring resistance to aromatase inhibitors in breast cancer appear to occur as a consequence of exposure to aromatase inhibitors and are unlikely to be present in the primary tumor.[17]

Molecular evolution of the tumor has been documented in many cancers under the selective pressure of prior therapy. This is most apparent in patients receiving targeted therapy whereby one of the mechanisms of resistance is secondary mutations in the gene of interest or along the relevant pathway.[18] In these circumstances, repeat biopsies may be very informative. Currently, the degree of heterogeneity exhibited by metastatic lesions in various sites is unclear. When heterogeneity is suspected, liquid biopsies for circulating tumor DNA or circulating tumor cells may reflect the clinical situation better, presumably integrating tumor status from a variety of sites and reflecting a composite mutational landscape.[19] This concept is attractive but far from established and requires further study. However, minimal invasive tissue sampling using blood samples to yield components such as circulating tumor DNA and circulating tumor cells is likely to become standard as an alternative to biopsy in clinically risky situations and in monitoring progressive alterations over tumor during exposure to targeted agents.

Molecular Tumor Board

As precision oncology expands, there is an increased need to include multiple domain experts in decision making to best harness the massive amount of information wisely. In the community setting where generalist oncologists now have to add management of genomic data to the clinical information, having access to additional expertise is enormously valuable. Either virtual or real-time molecular tumor boards can be accomplished in a practice setting. Ideally, members would include medical, surgical, and radiation oncologists as would be found in any conventional tumor board complimented by pathologists, genetic counselors, and research staff. Additional expertise is often available from commercial laboratories in the form of molecular pathologists and molecular geneticists. In more robust practice settings, access to biostatisticians, bioinformaticists, epidemiologists, and translational scientists may be available to participate. Multiple databases are publicly available for searching during molecular tumor boards to help in making variant-therapy associations. A number of free, frequently updated, and deeply curated websites offer information on a large number of variants and can be very useful to the practicing clinician in helping ascertain whether a particular therapy is right for a patient (Table 2). Archived, online molecular tumor boards such as those provided by ASCO are a good reference source.[20]

Data Integration

Integration of molecular data into electronic health records remains in the infancy of development. Typically, genomic results are sent to the oncologist in Portable Document Format and are therefore not available in structured fields that are searchable, filterable, and linked to clinical data. Integration of clinical and genomic data are a necessary goal to aid electronic matching of patients to molecular-based trials and to aggregate multiple N-of-1 experiments on individual patients to develop real-world evidence of benefit. Custom interfaces can be developed through relationships with third-party genomic laboratories and information technology companies or as a standalone in larger institutions that possess deep bioinformatics and information technology resources. Several laboratories now offer resources, such as the Caris Life Sciences Molecular Intelligence portal[21] and the Foundation Medicine Interactive Cancer Explorer

portal,[22] which allow result searches with some data-basing capability, and provide documentation of available preclinical and clinical research pertaining to observed variants and therapies. The clinical interpretation of molecular alterations is at the heart of providing the value of precision oncology.

NON–SMALL CELL LUNG CANCER AS THE PARADIGM OF PRECISION ONCOLOGY

Recently, lung cancer, after several decades of choosing platinum-based doublets for every patient, has undergone a transformation integrating precision medicine. There are now numerous biomarkers needed for treatment assessment in patients with lung cancer (Table 3), and this number will continue to increase as new molecularly defined subsets are identified. When diagnosing a patient, measuring *EGFR* mutation, and *ALK* or *ROS1* fusions, will help determine whether a tyrosine kinase inhibitor (TKI) should be used in lieu of cytotoxic chemotherapy.[23] Recently, PD-L1 expression (tumor proportion score ≥ 50%) has proven to be effective in enriching patients with lung cancer who may benefit from immunotherapy (pembrolizumab) instead of chemotherapy.[24] When considering patients who are diagnosed with non–small cell lung cancer, these biomarkers may alter treatment decisions in approximately 50% of patients to biologic agents instead of cytotoxic chemotherapy.

Increasing utilization of targeted therapies also brings to the forefront the growing clinical challenge of acquired drug resistance, currently a very active area of research. This is best exemplified by the emergence of the EGFR T790M mutation, which occurs in 50% of patients previously treated with an EGFR-TKI.[25] These gatekeeper mutations, which directly interfere with drug-target interactions, are a recurring theme across many kinase-driven tumors treated with kinase inhibitors.[26] Propelling their significance is the accompanying development of (1) therapies designed to target these mutations and overcome resistance (e.g., T790M/osimertinib), and (2) noninvasive assays that can monitor status of the resistance mutations (e.g., cobas EGFR Mutation Test v2), sequentially and in real time.

The complexity associated with acquired resistance is compounded by intra- and intertumor heterogeneity[27] and adaptive tumor biology that is facilitated by genetic instability.[25] The selective pressure of kinase inhibition can lead to the disappearance of drug resistance mutations,[28] emergence of varying resistance mechanisms at different metastatic sites,[29] histology transformation to small cell lung cancer,[30] or emergence of new resistant clones (e.g., C797S, Leu792).[31] Each of these situations presents unique treatment approaches. For example, there are reported responses to specific small cell lung cancer treatments for tumors that have transformed into small cell lung cancer.[30] Rechallenge with first-generation EGFR TKIs in patients where the T790M clone disappearshas also been successful.[32]

The utilization of the evolving genetic landscape of tumors to inform treatment decisions will be made possible through sequential and real-time monitoring of the patient. Rebiopsy with traditional biopsy techniques at time of progression, which may occur at multiple time points through the treatment course, is not safe for the patient, nor feasible from a practical perspective. Furthermore, patients may have multiple tumors. Therefore, the challenge is also identifying the tumor that would yield the best-quality biopsy; however, that approach still does not address the potential for intertumor heterogeneity.

Much progress has been made to address these complex and evolving issues through the development of noninvasive plasma-based assays for the detection of emerging

resistance mutations. The U.S. Food and Drug Administration approved the first liquid biopsy–based companion diagnostic to detect the T790M resistance mutation in patients whose disease is progressing on erlotinib, gefitinib or afatinib, for consideration of osimertinib. Furthermore, the search for assays, utilizing PCR- or NGS-based detection methods, that have high sensitivity and specificity, are cost-effective, and have high concordance with tumor biopsies is intensifying.[33-35] Some studies note, however, that liquid biopsy is still not ready for replacement of tumor biopsies but, in some instances, such as monitoring response or progression, may be prioritized.[36,37] Therefore, in cases in which a liquid biopsy test is negative for a resistance mutation, guidelines recommend a tissue biopsy.[23]

Collectively, these research efforts are converging to create a new paradigm in precision medicine in oncology. The discovery of resistance mutations, designing new drugs that target these resistance mechanisms, and development of noninvasive techniques to monitor emergence of resistance are all integral components advancing the field forward. The following case highlights the precision medicine revolution occurring in lung cancer.

Case Example

Mr. G, a 55-year-old man, has felt fatigued during the last couple months. A persistent cough led to a doctor's appointment. He did not have a history of smoking, although his parents did smoke cigarettes. His performance status was good, and he did not have any other chronic medical conditions. Radiographic imaging with CT identified several lesions in the lungs bilaterally. A CT–guided biopsy revealed a well-differentiated adenocarcinoma. The rest of the staging scans revealed stage IV disease in the bilateral lungs. Molecular testing was performed and revealed an exon 19 deletion. The patient started treatment with afatinib 40 mg daily. He had grade 1 acne and grade 1 diarrhea. Follow-up CT after 2 months of treatment revealed significant response of the tumors. He continued treatment, eventually dose reducing to 30 mg after several months of treatment. The patient continued taking afatinib for 20 months when a restaging scan revealed new disease bilaterally. The disease was peripherally located, with the largest lesion approximately 1 cm. Performing a tissue biopsy would be challenging but feasible. A serum circulating tumor DNA test revealed a T790M mutation. The patient then started treatment with osimertinib 80 mg daily. Restaging after 2 months revealed shrinkage of the tumors. He is tolerating the therapy well and continues at this time.

PRECISION ONCOLOGY IN THE ERA OF VALUE-BASED MEDICINE

The goal of precision testing is to identify the optimal therapy for the patient that will maximize their survival and quality of life. In some cases, there are well-validated biomarkers in a specific tumor context with high-quality clinical evidence (often approved by the U.S. Food and Drug Administration) of improved efficacy using a specific targeted agent or class of agents vis-à-vis an unselective therapy. For example, every new diagnosis of metastatic non–small cell lung cancer should undergo molecular testing for *EGFR* mutation, *ALK* rearrangement, *ROS1* rearrangement and *PD-L1* expression, all of which have demonstrated improved benefit with targeted agents for tumors positive for these biomarkers compared with chemotherapy in the first-line setting. In contrast, mutated *RAS* is a contraindication for the addition of anti-EGFR therapy for metastatic colorectal cancer due to well-demonstrated lack of efficacy in this setting. Testing for these biomarkers in the appropriate clinical context is the standard of care and is covered by insurance. With proven benefits, clear indications and financial coverage, the major challenge in this subset is underutilization of testing and dissemination and implementation of timely adoption to maximize benefits for all patients. The National Comprehensive Cancer Network, ASCO, and other tumor-specific societies provide regularly updated guidelines and are good references for evidence-based testing. Examples of these validated context-biomarker-drug combinations are listed in Table 3.

However, there is a much longer list of context-biomarker-drug combinations without sufficient evidence to make standard of care (Table 4). The cost of NGS has decreased by orders of magnitude in recent years. Cancer centers and other academic medical centers often have their own "home-grown" panels of cancer genes, anda number of companies offer gene panel sequencing for several thousand dollars within a few weeks. Given the reasonable cost, rapid turnaround time, and the potential for discovery of

Biomarker	Drug	Tumor Context
EGFR L858R	EGFR TKI	Non-NSCLC tumor
BRAF V600E mutation	BRAF and MEK inhibitors	Nonmelanoma
BRAF L597 mutations	BRAF and MEK inhibitors	Any tumor
ATM mutation	PARP inhibitor + alkylator	Any tumor

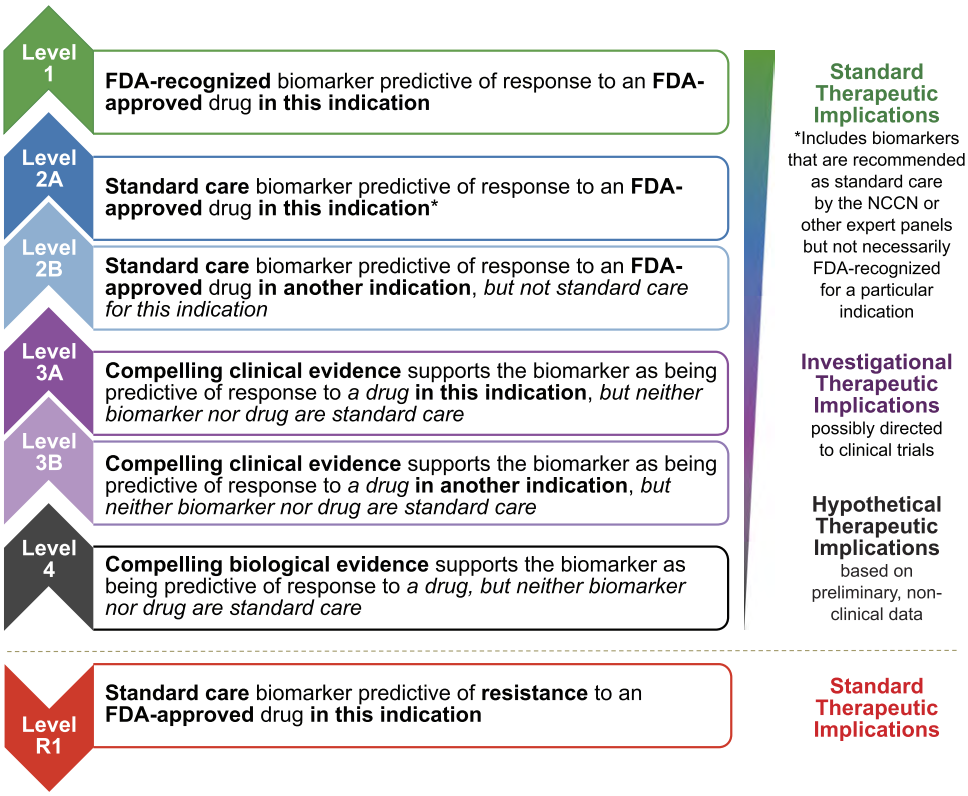
Abbreviations: NSCLC, non–small cell lung cancer; TKI, tyrosine kinase inhibitor.

new biomarkers that are targetable, the use of panel testing has proliferated in academic medical centers and the community. Standard biomarkers are tested in these gene panels, but in addition, alterations in genes without sufficient evidence of corresponding efficacious therapy are also routinely presented.

Interpretation and communication of this data to patients and translation into therapeutic interventions is a daunting challenge for clinicians. For example, *BRAF* V600E–mutated melanomas respond exceptionally well to *BRAF* and *MEK* inhibitors, but the response in colorectal cancers to these drugs as monotherapies has been disappointing.[38,39] Closely curated databases of genomic alterations such as OncoKB[40] and MyCancerGenome[41] have developed frameworks to assist prioritization of therapies for genomic alterations (Fig. 1). However, use of these biomarkers to select therapy is still largely experimental and should be done in the setting of a clinical study at an experienced center, where structured support is available for the patient and data can be appropriately collected and aggregated to answer clinical and research questions. It should be emphasized that in communication with patients, clinicians should make clear that beyond the limited set of validated tests with corresponding validated therapies, selection of therapy based on tumor genomic profiles is experimental and with no clearly established benefit.

Whenever possible, patients should be encouraged to participate in clinical studies. Molecular stratification of patient tumors increases the challenge of accruing sufficient patients to power detection of benefit (or lack thereof) in these tumor subsets. A variety of clinical trial designs have been developed to validate predictive biomarkers, including random assignment of patients stratified by biomarkers (IPASS,[42] MARVEL[43]), enrichment studies with assignment to study arms by biomarker status (BATTLE,[44] I-SPY 2[45]) and adaptive trial designs.[46] NCI-MATCH (NCT02465060) is a National Cancer Institute–sponsored clinical trial designed to

FIGURE 1. Example of Hierarchy of Evidence of Genomic Alterations



Used with permission.[40]

handle the problem of low accrual by combining multiple tumor types as a basket trial based on molecular alteration rather than tumor type, as well as to maximize the number of participating sites to optimize enrollment.[47] ASCO has initiated the Targeted Agent and Profiling Utilization Registry Study (TAPUR), which will collect real-world data on use of approved agents to treat molecular targeted variants across disease types.[48] Umbrella trials, such as the National Cancer Institute–sponsored Lung MAP trial (NCT02154490), recruit patients of a given tumor type (recurrent metastatic squamous cell carcinoma) and place them into arms based on biomarkers (e.g., *PI3KCA* mutation) with targeted therapies (e.g., taselisib).[49]

The vast majority of patients do not participate in biomarker-driven clinical studies, and their genomic and clinical data would be a huge boon for research if able to be collected, aggregated and structured appropriately. This has prompted initiatives to share and pool data between multiple institutions, such as the American Association for Cancer Research–sponsored GENIE project[50] and ORIEN.[51] Further, direct patient collaborations such as the Metastatic Breast Cancer Project,[52] in which individual patients directly give permission for clinical data and tumor tissue to be collected from disparate medical centers and centrally analyzed, could provide important data in low-frequency disease. ASCO is further developing the CancerLinQ[53] program to create a data platform in which clinical (and genomic, where available) data from the much larger group of patients treated in a broader range of settings can be collected and analyzed both for clinical and research benefit. The Cancer Moonshot Initiative[54] identified data aggregation and a common data ecosystem as key components of accelerating the pace of cancer research.

Beyond the current set of existing tests, new promising technologies are being developed. Cell-free tumor DNA found in blood plasma has been detected in multiple metastatic tumor settings[19]; a liquid biopsy avoids the morbidity of traditional biopsies and allows more frequent monitoring, enabling earlier detection of response or development of resistance. Further, tumor genomic heterogeneity has been demonstrated between primary and metastatic lesions and [55] different metastatic lesions[56,57] and even in different regions[58] of the same lesion. A liquid biopsy may thus present an integrated profile of the tumor. Further, novel techniques using bio-informatic approaches to infer deficiencies in DNA repair pathways from genomic data[59] may predict response to DNA-damaging therapies. Single-cell RNA sequencing,[60] or deconvolution of bulk RNA sequencing[61] to identify specific immune cell subsets in the tumor microenvironment,[62] may assist in predicting which tumors are likely to respond to immune therapy. It is likely that in the future mulitple omic approaches including genomic DNA alterations, epigenetic modifications, transcriptome-based expression of mRNA, proteomic expression, and alterations in regulatory molecules such as microRNA and immune factors will provide a more integrated portrait of the tumor and microenvironment.

In a value-based reimbursement world, where quality is defined by outcome/cost, it is essential for oncology practices to maintain up-to-date lists of biomarker/target–driven pairs for which there is compelling evidence that biomarker testing identifies an important therapeutic opportunity (e.g., crizotinib for *ALK*-rearranged lung cancer) or allows for avoidance of a toxic therapy (e.g., cetuximab in *KRAS* mutant colorectal cancer). Quality metrics will increasingly focus on avoiding underutilization of these established tests, as clinical evidence has already established biomarker selected therapy as a superior strategy.

In contrast, use of broad panel tests is more complex. Payers may have prior authorizations built in to limit use of panel testing in certain clinical circumstances. Panel tests may be valuable if they are used to identify a batch of validated biomarker/target–driven pairs as well as to support investigation. However, overuse of panel tests should also be avoided. It is critical that when these tests are obtained, oncologists have access to the necessary support for interpretation. Finally, it is anticipated that linking these genomic reports with detailed treatment histories and clinical outcomes such as response, duration of response and survival will accelerate discovery of efficacious therapeutic strategies.

CONCLUSION

Precision oncology has clinical utility in the here and now, but the promise for the future is much greater. With rapid improvements in technology, enhanced ability to probe beyond single DNA alterations to other molecular components that influence tumor behavior and represent targets for new therapeutics is clearly in sight. Responsible use of this remarkable technology will depend on generating evidence through new clinical trial designs, aggregation of molecular and clinical data in real-world databases and careful analysis to determine relevant target-agent associations. Ultimately, the approach must prove value across specific patient populations. The practicing oncologist should make an effort to understand the power and limitations of the current testing and treatment landscape to help patients make the best informed decisions.

CENTRAL NERVOUS SYSTEM TUMORS

American Society for Radiation Oncology 2016 Annual Meeting: Central Nervous System Abstracts

Samuel Chao, MD

OVERVIEW

The American Society for Radiation Oncology's (ASTRO) 2016 scientific program presented a number of excellent abstracts focusing on brain and spine tumors. Selected abstracts will be reviewed in this article.

There were a number of excellent abstracts regarding central nervous system tumors presented at ASTRO's 2016 Annual Meeting. This review will highlight some of these abstracts, but is not meant to be comprehensive. The exclusion of some abstracts does not reflect on the quality of those abstracts, as all abstracts presented were superb.

GLIOBLASTOMA/GLIOMA

EORTC 26981-22981 defined the current standard of care for glioblastoma, showing that the addition of temozolomide resulted in a survival advantage.[1] In a secondary analysis, Hegi et al[2] demonstrated that the methylation of O-6-methylguanine-DNA methyltransferase resulted in better survival and response to temozolomide. However, there has not been an updated nomogram to help predict survival that incorporates O-6-methylguanine-DNA methyltransferase methylation. Gittleman et al[3] used data from the Radiation Therapy Oncology Group (RTOG) 0525 and 0825 studies to develop this nomogram. They found that older age at diagnosis, male gender, lower Karnofsky performance status (KPS), lack of a gross total resection, and unmethylated O-6-methylguanine-DNA methyltransferase predicted for worse survival. A nomogram was developed and can be accessed through this website: http://cancer4.case.edu/rCalculator/rCalculator.html.

Treatment options for recurrent glioblastoma are limited. A phase I trial was conducted at Yale looking at mibefradil and reported by Lester-Coll et al.[4] This drug is a calcium channel blocker, but was found to have activity in gliomas as a radiation sensitizer. In this study, mibefradil was given 5 days prior to resection, and the tissue was analyzed for the presence of drug. Radiation was given to a total dose of 30 Gy in five fractions. Drug dose was escalated in a 3 + 3 design. The study was able to escalate to a final dose level of 200 mg per day. Median progression-free survival was 5.25 months, and median overall survival (OS) was 12.75 months. One patient had a complete response. Drug levels in the tumor correlated to what was required for tumor cell sensitization. The researchers are currently doing a phase I trial in upfront glioblastoma.

Other studies included one that looked at salicylic acid (Zhang et al[5]), which appears to affect growth inhibition and apoptosis related to c-Jun-N-terminal kinase and AMPK (AMP-activated protein kinase) activation and arrest in the G2/M phase in vitro. This may have promise for a future study.

A couple of studies specifically looked at institutional data regarding low-grade gliomas. The Mayo Clinic looked at their series of patients with low-grade glioma. Kreofsky et al[6] found that the median OS was 11.8, 8.1, 14.2, and 14 years for observation, radiation therapy (RT) alone, chemotherapy alone, and RT and chemotherapy, respectively ($p = .02$). They recommended that observation is reasonable for appropriately selected patients with low-grade glioma, in particular those younger than age 40 and with a gross total resection. Wahl et al[7] looked at patients treated at the University of California, San Francisco, and found that patients with 1p19q codeletion and pretreatment tumor volume of less than 68 cc had 0% risk of progression during treatment. Median progression-free survival was 4.9 years, and median OS was not reached. This suggests that there may be a subgroup of patients who can avoid radiation.

BRAIN METASTASES

Studies to date looking at stereotactic radiosurgery (SRS) alone versus SRS with whole-brain RT (WBRT) have failed to demonstrate a strong role for WBRT upfront given its effect on neurocognitive function and quality of life.[8,9] It is recognized, however, that there might be patients who may benefit, as a subset analysis of a prospective trial

From the Department of Radiation Oncology, Rose Ella Burkhardt Brain Tumor and Neuro-oncology Center, Cleveland Clinic, Cleveland, OH.

Disclosures of potential conflicts of interest provided by the author are available with the online article at asco.org/edbook.

Corresponding author: Samuel Chao, MD, Department of Radiation Oncology, Rose Ella Burkhardt Brain Tumor and Neuro-oncology Center, Cleveland Clinic, 9500 Euclid Ave., T28, Cleveland, OH 44195.

demonstrated a potential survival benefit to WBRT.[10] Churilla et al[11] performed a secondary analysis of EORTC 22952-26001 that randomly selected patients who received SRS or surgical resection to observation versus WBRT. They asked the question whether WBRT translates into a survival benefit for patients with a limited competing risk from their extracranial disease. They found no interaction from the effect of WBRT and time to extracranial progression. There was no difference in OS between patients with favorable versus unfavorable graded prognostic assessment, so the patients with the best survival did not seem to benefit from WBRT. The study authors concluded that WBRT could be omitted in patients undergoing SRS or surgical resection.

It is clear from these studies, however, that withholding WBRT does increase the risk for intracranial recurrence.[8,10,12-14] Thus, patients who do not receive WBRT have a higher rate of needing salvage therapies, including more SRS. Given the costs of SRS, there is concern that withholding WBRT will increase the overall costs of brain metastases management in a patient. Miller et al[15] used single-institutional data comparing various costs including cancer-specific costs, brain metastases–specific cost, and cumulative total costs of health care between those receiving SRS alone and those receiving SRS and WBRT upfront. The study authors showed that there was no difference in the various costs between the two cohorts. Additional sensitivity analyses and modeling were recommended by the authors to identify if there is a subset of patients for which SRS with WBRT is most cost-effective.

Brown et al[16] reported as a late-breaking abstract the results of NCCTG N107C. This was a phase III trial comparing WBRT and SRS to the resection cavity for patients with resected brain metastases. In total, 194 patients were enrolled in this study. Median follow-up was 15.6 months. There was shorter cognitive deterioration-free survival of 2.8 months in those receiving WBRT compared with 3.2 months for those that received SRS to the resection cavity ($p < .0001$). As expected, overall intracranial tumor control at 12 months was 78.6% with WBRT and was better compared with SRS alone, which was 54.7% ($p = .0001$). However, quality of life was better in the SRS arm. One interesting result was that surgical bed relapse at 12 months was rather high at 44.4% compared with SRS at 21.8% for WBRT. The final manuscript is eagerly awaited to see if these factors contributed to a higher than expected surgical bed relapse rate for the SRS-only group.

Mahajan et al[17] reported the results of an MD Anderson Cancer Center prospective study comparing observation and SRS to the resection cavity for completely resected brain metastases. In this phase III study, 132 patients with 140 resected brain metastases were randomly selected to receive SRS to cavity versus observation. Median follow-up was 12.6 months. The authors found that local control was better in the SRS arm at 72% at 12 months compared with 45% for observation. There was no difference in distant brain metastasis control. OS was the same in both arms. Those with a preoperative tumor size of more than 3 cm in diameter benefitted the most. Adjuvant SRS is recommended postresection for local control over no additional therapy.

There has been interest in using systemic agents to manage brain metastases upfront. Magnuson et al[18] performed a multi-institutional analysis comparing upfront epidermal growth factor receptor tyrosine kinase inhibitor therapy compared with upfront RT. From four institutions, 162 patients were pooled. Median OS was longer in the upfront RT group at 29.4 months compared with upfront epidermal growth factor receptor tyrosine kinase inhibitor therapy at 20.5 months ($p = .0015$). Upfront SRS had significantly improved survival, but upfront WBRT did not. Median intracranial progression-free survival was improved in patients receiving upfront RT compared with upfront epidermal growth factor receptor tyrosine kinase inhibitor therapy (21.1 vs. 13.4 months; $p = .003$). The authors stressed the importance of a prospective study given these results.

KEY POINTS

- **For gliomas, and in particular glioblastoma, there is a need to better determine prognosis for treatment selection.**
- **Systemic therapies need further study. This includes a better understanding of patients who may avoid radiation, particularly in low-grade gliomas.**
- **More studies seem to prove stereotactic radiosurgery alone is the best approach for patients with a limited number of brain metastases. In this era, an understanding of the costs of stereotactic radiosurgery is necessary.**
- **Resection cavity radiosurgery may be an alternative to whole-brain radiation for patients with resected brain metastases. Systemic agents need further study in the management of brain metastases.**
- **Spine stereotactic radiosurgery has become an established technique in treating spine metastases. The presented abstracts focused on understanding the toxicities and survival rates following spine radiosurgery.**

SPINE STEREOTACTIC RADIOSURGERY

The role of spine stereotactic radiosurgery is being studied by RTOG 0631, a phase II/III study with the phase III component comparing single-fraction conventional radiation with spine SRS.[19] One toxicity that has been noted by those treating with SRS is vertebral compression fractures (VCF). Prior studies have shown that a dose of 20 Gy and more per fraction increases the risk of VCF.[20] Thibault et al[21] used CT-based segmentation to assess the volume of lytic vertebral body metastatic disease and predict the risk of VCF for spine radiosurgery. In 55 patients, 100 spine segments were analyzed. Of these, 56% had lytic disease. Median dose was 24 Gy in two fractions. Those who developed fractures had pre-existing osteolytic disease. The threshold for VCF was a lytic tumor burden of 11.6% or more. One may consider prophylactic stabilization or vertebral augmentation in this group of patients.

Using the patients treated at MD Anderson Cancer Center, Deegan et al[22] looked at long-term toxicities from spine SRS. This includes grade 4 myelopathy in 1.7%, sensory radiculopathy in 8.5%, and vertebral body collapse in 13.6%, with 10.2% requiring vertebroplasty or surgery. Most of these occur within 2 years of treatment. The only toxicity that occurred after 4 years was a VCF.

There is no good way to predict how patients receiving spine SRS will do with regard to survival. This is important, as spine SRS is a relatively expensive treatment but is felt to improve local control with good pain relief compared with conventional RT. Spine SRS may be offered to patients with better survival, but those who have short anticipated survival may be best treated with conventional RT. Balagamwala et al[23] used a database comprising 444 patients and looked at factors that contribute to survival. On univariate analysis, patients with a KPS higher than 70, controlled systemic disease, single-level spine disease, absence of visceral metastases, and longer time from diagnosis of primary had improved survival. The authors did recursive partitioning analysis. Class I patients were defined as KPS higher than 70 and controlled systemic disease and had a median OS of 26.7 months. Class II patients were defined as KPS higher than 70 and uncontrolled systemic disease or KPS 70 or lower, age 54 or older, and no visceral metastases. These patients had a median OS of 13.4 months. Recursive partitioning analysis class III patients had KPS 70 or lower, age 54 or older, and visceral metastases or KPS 70 or less and age younger than 54. The median OS was only 4.5 months in this group. The authors felt that spine SRS as upfront treatment is best reserved for patients who are recursive partitioning analysis class I and II. For class III patients, conventional RT may be favored, and spine SRS can be reserved as salvage treatment.

CONCLUSION

There were numerous excellent abstracts presented at ASTRO's 2016 Annual Meeting. Only a few of these were reviewed in this summary. With continuing research like this, better treatments with lower toxicities and improved survival may be discovered.

Beyond Alkylating Agents for Gliomas: *Quo Vadimus*?

Vinay K. Puduvalli, MD, Rekha Chaudhary, MD, Samuel G. McClugage, MD, and James Markert, MD

OVERVIEW

Recent advances in therapies have yielded notable success in terms of improved survival in several cancers. However, such treatments have failed to improve outcome in patients with gliomas for whom surgery followed by radiation therapy and chemotherapy with alkylating agents remain the standard of care. Genetic and epigenetic studies have helped identify several alterations specific to gliomas. Attempts to target these altered pathways have been unsuccessful due to various factors, including tumor heterogeneity, adaptive resistance of tumor cells, and limitations of access across the blood-brain barrier. Novel therapies that circumvent such limitations have been the focus of intense study and include approaches such as immunotherapy, targeting of signaling hubs and metabolic pathways, and use of biologic agents. Immunotherapeutic approaches including tumor-targeted vaccines, immune checkpoint blockade, antibody-drug conjugates, and chimeric antigen receptor–expressing cell therapies are in various stages of clinical trials. Similarly, identification of key metabolic pathways or converging hubs of signaling pathways that are tumor specific have yielded novel targets for therapy of gliomas. In addition, the failure of conventional therapies against gliomas has led to a growing interest among patients in the use of alternative therapies, which in turn has necessitated developing evidence-based approaches to the application of such therapies in clinical studies. The development of these novel approaches bears potential for providing breakthroughs in treatment of more meaningful and improved outcomes for patients with gliomas.

The past decade has seen important breakthroughs in the treatment of newly diagnosed gliomas with the publication of mature and practice-changing results of several clinical trials. However, nearly all these trials have been based on the combination of radiation therapy and alkylating agents. The promise of targeted therapies, which has resulted in notable successes in several other cancers, has not been realized in patients with gliomas despite numerous trials of agents targeting the most common signaling pathways altered in these tumors.[1] Although ongoing studies are actively examining the mechanisms for the failure of targeted therapies in gliomas, alternative approaches that seek to attack tumor cells in ways that circumvent tumor resistance and heterogeneity are being increasingly explored. One of the more exciting of therapeutic strategies that has emerged in recent years involves immunotherapy involving a variety of methods including cell-free and cell-based vaccines, antibody-drug conjugates, and checkpoint blockade, which exploit the expression of tumor-specific antigens and neutralize tumor-mediated immunosuppression.[2] Another emerging area is the identification and targeting of tumor-specific metabolic and protein-processing pathways that act as hubs for converging cellular processes vital for tumor cell survival.[3] Targeting such hubs has the potential to disable the complex signaling networks that tumor cells depend on for survival and resistance to therapy. However, the slow progress in developing effective therapies against gliomas has also resulted in patients seeking alternative and often untested therapies that are used concurrent with or as alternatives to standard therapy[4]; the rigorous assessment of such treatments through systematic studies is emerging as an equally important aspect of cancer care. The following sections examine the current state of these varied approaches and their impact on the treatment of patients with gliomas.

NEW APPROACHES TO GLIOMA THERAPY: TARGETED THERAPIES AND BEYOND

Current Standards of Care for Gliomas

Recent studies have established new standards of care for patients with gliomas. For adults with World Health Organization (WHO) grade II glioma after maximum safe resection, radiation therapy (RT) followed by chemotherapy using a combination of procarbazine, lomustine, and vincristine resulted in improvement of survival compared with RT alone, particularly for patients with low-grade oligodendroglioma.[5] The same regimen also resulted in improved overall survival (OS) in patients with WHO grade III (anaplastic) oligodendrogliomas that had codeletions of chromosome 1p and 19q.[6,7] Further characterization of this benefit is being

explored in a randomized CODEL trial that seeks to compare the benefits of RT with procarbazine, lomustine, and vincristine with that of RT with temozolomide (TMZ) against 1p/19q codeleted anaplastic gliomas.[8] The optimal standard of care for patients with anaplastic gliomas without 1p/19q codeletion is currently being explored in a multicenter CATNON trial that randomly assigned patients to four different treatment arms to assess the benefit of adding TMZ as adjuvant or concurrent therapy with RT. Recently reported interim results of this study indicated that the two arms with adjuvant TMZ had a better outcome compared with the two without.[9] Based on these data, the trial has been modified to eliminate the arms without adjuvant TMZ and now continues with two arms (RT followed by TMZ vs. RT with TMZ followed by TMZ), the results of which are awaited. In the setting of recurrent grade II or grade III gliomas, there are no clear new standards of care; currently used treatments include reirradiation, alkylating agents, and treatment of secondary glioblastoma (GBM) with bevacizumab. Lastly, the current standard of care for adults up to age 70 with newly diagnosed GBM after maximum safe resection consists of chemoradiation therapy (6 weeks) with concurrent daily TMZ followed by up to six monthly cycles of adjuvant TMZ, which improved survival particularly in the subgroup of patients in whom tumors have promoter methylation of methyl-guanyl methyltransferase (*MGMT*).[10,11] Efforts to intensify adjuvant TMZ dosing or to add bevacizumab to this regimen have failed to improve survival in this setting. However, recent data showed that the addition of low-intensity alternating electrical fields to the standard of care therapy along with adjuvant TMZ, using transducer arrays applied to the scalp for more than 18 hours a day (tumor-treatment fields; Optune) improved OS in adults with newly diagnosed GBM independent of the *MGMT* promoter status.[12] In elderly patients, a shortened course of chemoradiotherapy (3 weeks) followed by up to 12 months of adjuvant TMZ was both tolerated and improved OS compared with RT alone.[13] Treatments for recurrent GBM includes bevacizumab, nitrosoureas, tumor-treatment fields, and several other chemotherapeutic agents that are currently less frequently used given their limited benefit. None of these treatments have provided a survival benefit, although bevacizumab received regulatory approval based on response rate and improved progression-free survival (PFS).[14,15]

KEY POINTS

- **Alkylating therapies remain the cornerstone of standard-of-care therapy for gliomas despite advances.**
- **Identification and targeting of specific signaling pathways most commonly altered in gliomas have failed to yield improvement in outcomes in patients with these tumors.**
- **There is urgent need for a broader targeting of the diverse pathways that mediate adaptive resistance to treatment and facilitate tumor recurrence.**
- **Novel strategies include immunotherapeutic approaches, targeting of metabolic pathways, and harnessing of newer insights into the biology of gliomas.**
- **Additionally, the lack of curative therapies for gliomas has also increasingly encouraged patients to use alternative therapies with little scientific support. Critical assessment and systematic study of such treatment options is essential for providing the best care for patients with gliomas.**

Targeted Therapies Against Gliomas: Rationale and Limitations

Extensive genetic, epigenetic, and molecular studies have been conducted to delineate the key signaling pathways and alterations in gliomas.[16-20] Early studies had identified key roles for three major pathways in gliomagenesis and progression including (1) the receptor tyrosine kinase/phosphoinositide 3-kinase (PI3K)/Akt pathway, including alterations in *EGFR*, *Her2*, *PDGFR*, *FGFR*, and *cMET* (approximately 90%), (2) the p53 pathway including alterations in *TP53*, *MDM2*, and *MDM4* (approximately 85%), and (3) the Rb and cell cycle–related pathways including defects in *RB, CDKN, CDK,* and cyclins (approximately 80%).[16] More in-depth analysis has revealed the striking complexity of genetic and epigenetic changes in both low- and high-grade gliomas.[19,20] These data provided strong rationale for several clinical trials targeting key GBM relevant pathways, especially those of receptor tyrosine kinase inhibitors initially in the setting of recurrent GBM and subsequently in the newly diagnosed setting; however, it was soon evident that single-agent trials of these agents were largely ineffective in providing benefit in either PFS or OS for this patient population.[21-23] Focusing on the strategy of overcoming bypass pathways that the tumor cells deploy to establish resistance to the action of single agents, combination strategies targeting multiple pathways were subsequently tried but were again strikingly unsuccessful in providing an improvement in outcome.[24] These results point to limitations in our understanding of the complexity of survival and resistance mechanisms adopted by glioma cells and the need for more concerted effort to delineate the adaptive mechanisms of these cells that can be new targets for therapy.

Recent Advances in Understanding the Biology of Gliomas

In-depth genetic and epigenetic analyses of large numbers of low- and high-grade gliomas have recently yielded novel insights into the complexity of the alterations in these tumors.[25] From a clinical perspective, this has also provided evidence that histologic diagnosis may not accurately correlate with outcome; this has led to a revision of the WHO classification of brain tumors with modifications that allow incorporation of such molecular markers into conventional diagnostic approaches to align better with clinical outcome.[26] Although some of these markers have shown potential to be predictive markers that can help selection of treatment options, most are prognostic in nature and inform largely of the intrinsic behavior of the tumors without

specificity to the treatments used.[6,7,11,27-29] From the perspective of the basic biology of the tumors, the studies have shown that tumor heterogeneity is one of the most critical factors that dictates tumor behavior. Such heterogeneity is seen to be not only spatial (with different regions of the same glioma evolving along distinct pathways) but also temporal (with emergence of new mutations and hence biologic behavior with tumor treatment and progression).[30-32] It is also becoming clear that treatments can induce mutations that can contribute to clonal evolution of gliomas.[33] Such heterogeneity has provided an explanation for why therapies targeting single or even multiple pathways in gliomas fail to uniformly affect the majority of tumor cells or eliminate emergent clones during the course of tumor growth and therapy.

Emergent Targets for Antiglioma Therapies

Novel therapies for gliomas must overcome tumor heterogeneity and disable resistance mechanisms to treatment to be effective in improving outcome. The search for such strategies has resulted in the identification of novel targets that promise to change conventional approaches and are in advanced clinical studies or in early stages of investigations. Immunotherapy has emerged as one of the most promising strategies against gliomas currently in clinical trials and is aimed at either disabling immunosuppression induced by tumor cells or enable tumor targeting of immune cells by identification of overexpressed proteins or neoantigens. Several other emerging areas that bear promise to change therapeutic outcome of patients include targeting signaling hubs, use of biologic agents, disabling tumor-specific metabolic pathways, and activating death pathways that can eliminate tumor cells independent of internal tumor heterogeneity. The following sections briefly review these approaches and outline ongoing or potential clinical trial strategies related to these approaches.

The high frequency (approximately 80%) of mutations in isocitrate dehydrogenase 1 (*IDH1*) in WHO grade II and III gliomas as well as secondary GBM[34] associated with increased levels of 2-hydroxyglutarate (2HG), a putative oncometabolite that is believed to drive gliomagenesis,[35] has provided a strong rationale for targeting mutant IDH1 as a therapy against gliomas[36]; this has led to development of pharmacologic inhibitors of IDH1 that are currently in early clinical trials. A phase II trial of IDH-305, a selective R132H-IDH1 inhibitor against progressive WHO grade II and III gliomas, is due to open shortly (NCT02977689). Another trial aimed at low-grade gliomas that have high 2HG as measured by magnetic resonance spectroscopy proposes to assess changes in 2HG in tumor tissue and clinical outcome in terms of tumor response (NCT02987010). Another agent, AGI-5198, was shown to inhibit the ability of mutant IDH1 to produce 2HG in glioma cells, suggesting a potential for clinical activity in these tumors.[37]

Tumor cells including glioma cells, unlike normal cells, when subject to hypoxic environments, preferentially continue to use the anaerobic tricarboxylic acid cycle even after normoxic conditions are restored, the so-called Warburg effect.[3] Hypoxic regions are a key feature of GBMs and associated with areas of pseudopallisading necrosis, which also show increased expression of hypoxia-inducible factor α (HIF1α), a key player in inducing the Warburg effect.[38] HIF1α is stabilized in the setting of hypoxia and acts as a transcription factor that triggers a number of changes in gene expression and protein signaling aimed at increasing levels of tumor cell defense mechanisms include resistance pathways, accelerated metabolism, and angiogenic factors.[39] Therapeutic agents that target upstream effectors that stabilize HIF1α such as PI3K and mTOR have failed to yield substantial responses or improved outcome in early trials, likely because of activation of bypass pathways. Agents that directly target HIF1α have been tested in early trials, but data regarding their efficacy have not been promising.[39] More recently, the identification of phosphokinase M2 (PKM2) as being highly expressed in cancers, being transcriptionally upregulated by HIF1α, and promoting the Warburg effect,[40,41] has triggered efforts to develop PKM2 inhibitors as anticancer agents.[42,43] Depletion of PKM2 in cancer cells reverses the Warburg effect and inhibits tumor formation, providing a strong rationale for targeting PKM2 to inhibit cancer metabolism and tumor growth. Novel inhibitors to inhibit PKM2 are currently under development and may provide a novel therapeutic option against GBM (Fig. 1).[42,43]

Targeting basic cellular processes common to oncogenic pathways could potentially disable resistance mechanisms deployed by GBM cells and overcome the effect of heterogeneity. Heat shock response is one such highly conserved process that protects cells against adverse environmental stresses (e.g., oxidative stress, acidosis, or metabolic stress).[44] Heat shock response is mediated by the heat shock protein (HSP) family, which directs protein folding, oligomerization, and secretion, enabling the cell to generate potent resistance and survival mechanisms. Hsp90, a key member of this family, regulates folding and stabilization of several oncoproteins and is overexpressed in cancer cells; a high-affinity form of the protein is specifically expressed by cancer cells, allowing them to rapidly process proteins unlike normal cells.[45] Targeting Hsp90 can destabilize client oncoproteins, leading to their proteosomal degradation disabling crucial defense mechanisms used by GBM and sensitizing them to treatment.[46] Several Hsp90 inhibitors that block ATPase activity in a tumor-selective manner are in clinical trials.[47] Their use against GBM has been limited due to their inability to cross the blood-brain barrier, short duration of action, or unacceptable toxicity profile.[48] Second-generation Hsp90 inhibitors such as AUY922,[49] Onalespib,[50,51] and Debio0932,[52] some of which cross the blood-brain barrier, are currently in clinical trials against cancer and being considered for clinical trials against gliomas.

Another central regulator of protein processing involves the unfolded protein response (UPR), which is an evolutionally conserved central defense mechanism activated when protein that protects allows cells to adapt to endoplasmic reticulum (ER) stress.[53] ER stress results in the incorrect

folding and improper glycosylation of newly synthesized proteins. UPR allows cells to re-establish homeostasis by inducing a cell cycle arrest and blocking of protein translation, which prevents new protein formation during the period of ER stress.[53] Cancer cells including glioma cells are frequently subject to hypoxia and nutrient deprivation triggering tumor-specific ER stress, as a result of which they become highly reliant on the UPR for survival, making it an ideal target for therapeutic targeting.[54] Given that the UPR has also emerged as a mechanism for resistance to conventional therapies in solid tumors,[55] inhibitors of the UPR may serve to overcome resistance to standard antiglioma treatments and enhance their antitumor efficacy. The UPR is mediated by the dissociation of GRP78 from its inhibitory association with three transducer proteins—protein kinase R–like ER kinase, inositol-requiring enzyme 1, or activating transcription factor 6—allowing it to bind to and chaperone unfolded proteins.[55] Once released, protein kinase R–like ER kinase, inositol-requiring enzyme 1, or activating transcription factor 6 initiate downstream signals that cause transcriptional arrest and assist in alleviating ER stress. Inhibitors of GRP78 can disrupt signaling through the UPR, facilitate the reversal of ER, and consequently sensitize tumor cells to conventional treatments. AR-12, a novel orally bioavailable agent, has been reported to downregulate GRP78 and affect the UPR.[56] Inhibitors of the mitogen-activated protein kinase kinase/extracellular signal–regulated kinase pathways also decrease levels of GRP78 and can potentially inhibit the UPR. Novel inhibitors of GRP78 pathway are in continued development, and these agents are expected to enter clinical trials.[57]

Several novel and unconventional agents are currently entering clinical trials that have shown promising preclinical data against gliomas. BXQ-950 is a first-in-class agent that is a lipid-protein complex composed of Saposin C (SapC), a lysosomal protein, and a phospholipid (dioleoylphosphatidylserine [DOPS]) assembled into nanovesicles (SapC-DOPS), which selectively kill tumor cells through targeting of phosphatidylserine on the cancer cell surface, activating the ceramide cell death pathway as demonstrated in recent preclinical studies in gliomas.[58] The agent is currently in a first-in-human phase I trial including in patients with recurrent GBM (NCT02859857). G-202 (mipsagargin) is another novel prodrug that is activated by prostate-specific membrane antigen, which is expressed by GBM and tumor-associated vasculature but not in normal tissue, and is currently in phase II trials against recurrent GBM (NCT02876003 and NCT02067156). Glioma stem cells have also been assessed as novel targets in GBM; BBI608 (napabucasin), an orally bioavailable STAT3 inhibitor that targets cancer stem cells,[59] is currently in a phase I/II trial against recurrent GBM in combination with TMZ (NCT02315534).

IMMUNOTHERAPY FOR GLIOMA

Immunotherapy has emerged as one of the most exciting of therapeutic strategies against gliomas with a variety of approaches that harness the recent insights gained into cell based and humoral immune responses against cancer. The following section outlines several key strategies and associated ongoing clinical trials including a summary or early results available to date (Table 1).

Checkpoint Inhibitors

Checkpoint inhibitors (CPIs) work by interacting with molecules involved in the normal immune-inhibitory pathways of the body, tasked with limiting immune responses and avoidance of autoimmune reactivity.[60] A phase III trial (Checkmate 143; NCT02017717) is underway, looking at treatment of patients with recurrent GBM with nivolumab, a PD-1 inhibitor, and ipilimumab, a CTLA-4 inhibitor.[61] Preliminary data for this trial showed 90% of patients receiving a combination of nivolumab and ipilimumab having grade 3 or 4 adverse events in response to treatment. Preliminary efficacy results showed a 12-month OS of 40% for nivolumab (3 mg/kg), 30% for nivolumab (1 mg/kg) plus ipilimumab (3 mg/kg), and 25% for nivolumab (3 mg/kg) plus ipilimumab (1 mg/kg). Another phase III trial (Checkmate 498; NCT02617589) is investigating treatment with nivolumab combined with RT in adults with newly diagnosed MGMT promoter unmethylated GBM compared with standard therapy. KEYNOTE-028 is a phase I trial looking at the use of pembrolizumab (PD-1 inhibitor) for solid tumors and includes a GBM cohort of 26 patients.[62] A total of 73.1% of patients experienced treatment-related adverse events, with 15.4% experiencing grade 3 or 4 adverse events. One patient exhibited a partial response to treatment, whereas 12 patients exhibited stable disease. Results regarding PFS and OS did not show noteworthy improvements from current standard therapy. Additional studies are underway. The relatively modest effect of CPIs in trials to date may be because of the fact that GBM is not generally primed for immune response. Future studies using CPIs in combination therapies that may increase the degree of immune activity against GBM cells may provide better outcomes

T-Cell Therapies

Adoptive T-cell therapy is a novel approach to glioma immunotherapy that allows the targeting of treatment to a patient's specific tumor-associated antigen (TAA) profile, thus limiting the off-target effect to surrounding nonmalignant cells. Autologous lymphocytes are harvested and grown ex vivo, allowing for modification and recognition of specific TAAs prior to implantation in the patient.[64,65] Another novel approach uses chimeric antigen receptor (CAR) T cells, which uses autologous T-cell extraction and transduction to express modified tumor antigen T-cell receptors on the cell surface, allowing for chimeric T-cell activation independent of surface major histocompatibility complexes.[66] Brown et al[67] recently published a case report of one patient involved in a phase I trial (NCT02208362), treating patients with recurrent GBM using CAR T-cells targeting the TAA interleukin-13 receptor alpha 2 (IL-13Rα2). The patient exhibited tumor regression from 70%–100% in all lesions, an effect that was maintained for 7.5 months. Furthermore, this group

TABLE 1. Active Clinical Trials for Immunotherapy in Glioma

Intervention (Target/Origin)	Phase	Population	Design	Estimated Primary Completion Date	NCT Identification
Peptide Vaccines					
IMA950 (multiple tumor antigens)	I/II	Newly diagnosed GBM	Open-label, single-group assignment	March 2016	NCT02343406
PEPIDH1M (IDH1)	I	Recurrent grade II glioma	Open-label, single-group assignment	May 2017	NCT02193347
IDH1 peptide vaccine (IDH1R132H)	I	Grade III/IV glioma	Open-label, single-group assignment	August 2018	NCT02454634
HSPPC-96 (heat shock protein)	II	Recurrent GBM	Randomized, open-label, parallel assignment	July 2017	NCT01814813
DC Therapies					
ICT-107 (allogenic TAAs)	III	Newly diagnosed GBM	Randomized, double-blind, parallel assignment	December 2019	NCT02546102
DC vaccine (allogenic tumor lysate)	I	Newly diagnosed or recurrent GBM	Nonrandomized, open-label, parallel assignment	October 2018	NCT02010606
DC vaccine (autologous tumor lysate)	Pilot	Newly diagnosed GBM	Open-label, single-group assignment	November 2016	NCT01957956
DC vaccine (tumor lysate)	I	Recurrent GBM	Nonrandomized, open-label, parallel assignment	July 2018	NCT01808820
Human CMV pp65-LAMP mRNA-pulsed DC vaccine	II	Newly diagnosed GBM	Randomized, double-blind, parallel assignment	March 2019	NCT02366728
ICT-121 (CD 133)	I	Recurrent GBM	Open-label, single-group assignment	November 2017	NCT02049489
DCVax-L (autologous tumor lysate)	III	Newly diagnosed GBM	Randomized, double-blind, parallel assignment	November 2016	NCT00045968
CPIs					
Pembrolizumab (PD-1 inhibitor)	I	Solid tumors (Recurrent GBM)	Open-label, single-group assignment	August 2017	NCT02054806
Nivolumab (PD-1 inhibitor) with/without ipilimumab (CTLA-4 inhibitor)	III	Recurrent GBM	Randomized, open-label, parallel assignment	February 2017	NCT02017717
Durvalumab (PD-1 Inhibitor)	II	Newly diagnosed or recurrent GBM	Nonrandomized, open-label, parallel assignment	July 2017	NCT02336165
Pembrolizumab	II	Recurrent GBM	Randomized, open-label, parallel assignment	August 2016	NCT02337491
Nivolumab	III	Newly diagnosed GBM	Randomized, open-label, parallel assignment	March 2019	NCT02617589
Indoximod (IDO inhibitor)	I/II	Recurrent GBM	Nonrandomized, open-label, parallel assignment	December 2016	NCT02052648
T-Cell Therapies					
Genetically modified T cells (IL-13Rα2)	I	Recurrent GBM	Nonrandomized, open-label, parallel assignment	December 2018	NCT02208362
CAR T cells (EGFRvIII)	I/II	Recurrent GBM	Nonrandomized, single-group	December 2018	NCT01454596
CAR T cells (CMV, HER2)	I	Recurrent GBM	Open-label, single-group assignment	June 2014	NCT01109095
CAR T cells (EphA2)	I/II	Newly diagnosed or recurrent GBM	Randomized, open-label, parallel assignment	September 2016	NCT02575261
Viral Therapy					
MV-CEA (measles virus)	I	Recurrent GBM	Nonrandomized, open-label, parallel assignment	June 2017	NCT00390299
PVSRIPO (poliovirus)	I	Recurrent GBM	Open-label, single-group assignment	January 2017	NCT01491893
DNX2401 (adenovirus)	I	Recurrent GBM	Open-label, single-group assignment	December 2015	NCT01956734
Toca 511 (retrovirus) + Toca FC	II/III	Recurrent GBM	Randomized, open-label, parallel assignment	November 2017	NCT02414165

TABLE 1. Active Clinical Trials for Immunotherapy in Glioma (Cont'd)

Intervention (Target/Origin)	Phase	Population	Design	Estimated Primary Completion Date	NCT Identification
Combination Therapy					
DNX2401 + pembrolizumab	II	Recurrent GBM	Open-label, single-group assignment	December 2019	NCT02798406
DC vaccine + nivolumab	I	Recurrent GBM	Randomized, open-label, parallel assignment	May 2018	NCT02529072
Nivolumab + galunisertib (TGF-βR1K inhibitor)	I/II	Refractory solid tumors (recurrent GBM)	Nonrandomized, single group, open label	April 2018	NCT02423343
Pembrolizumab + HSPPC-96	II	Newly diagnosed GBM	Randomized, parallel assignment	May 2018	NCT03018288

Abbreviations: NCT, National Clinical Trial; GBM, glioblastoma; DC, dendritic cell; TAAs, tumor-associated antigens; CPIs, checkpoint inhibitors; IDO, indoleamine 2,3-dioxygenase; CAR, chimeric antigen receptor; CEA, carcinoembryonic antigen; TGF, transforming growth factor.
Data derived from https://clinicaltrials.gov.

reported 10 patients currently undergoing treatment, with minimal side effects, and CAR T cells detected in cerebrospinal fluid or tumor cyst fluid for more than 7 days.[68] These findings suggest that CAR T cells may be well tolerated by patients and are capable of producing a relevant treatment response in vivo. Other early-stage CAR T-cell trials include NCT01454596 (National Cancer Institute), treating patients in whom GBM expresses EGFR type III (EGFRvIII), a known tumor-specific antigen, and NCT01109095, testing the safety of CAR T cells targeting HER2, a tumor-specific antigen expressed on 87% of GBM cells.[69,70] For this second study, the gene expressing the HER2 antibody was transduced into T cells selected for their reactivity to cytomegalovirus (CMV), postulating that these cells would be more reactive as they would respond to both tumor cells and CMV, a viral antigen found in many patients with GBM.

Peptide Vaccine Therapies

Vaccination strategies for GBM are aimed at creating vaccines targeting specific tumor antigens, such as EGFRvIII and isocitrate dehydrogenase 1 (IDH1).[60,66,71] The ACT III trial was a phase II trial of newly diagnosed patients with GBM treated with rindopepimut (CDX-110), a vaccine targeting EGFRvIII. Early results showed a survival benefit, with patients exhibiting a PFS at 5.5 months of 66% and median OS of 21.8 months.[72] However, the phase III trial (ACT IV) was terminated early when it failed to show a survival benefit.[73] It has been speculated that the results may have been influenced by the patients in the control arm faring better than would be expected of typical control subjects with GBM.[66,73] Reardon et al[74] reported the results of a phase I/II trial of SL-107, a peptide vaccine targeting three tumor antigens—IL-13Rα2, Ephrin A2 (EphA2), and Survivin—in patients with recurrent GBM. Early results showed a partial response in one patient (more than 33 weeks in duration) and stable disease in 15 patients (median duration 8 weeks). Migliorini and Dutoit[75] reported results of a trial using IMA950, a peptide vaccine composed of 11 tumor-specific peptides.[66] For the six patients treated under the initial protocol, median OS was 17.5 months (range 11–21 months). Another target of interest under investigation for potential vaccination therapy is HSP.[76,77] A phase II trial (NCT01814813) is evaluating heat shock protein–peptide complex 96 (HSPPC96) with bevacizumab in patients with recurrent glioma. Similarly, IDH1 is a novel target for vaccine therapy, with one phase I trial in patients with grade III/IV glioma testing an IDH1 vaccine (NOA-16; NCT02454634).

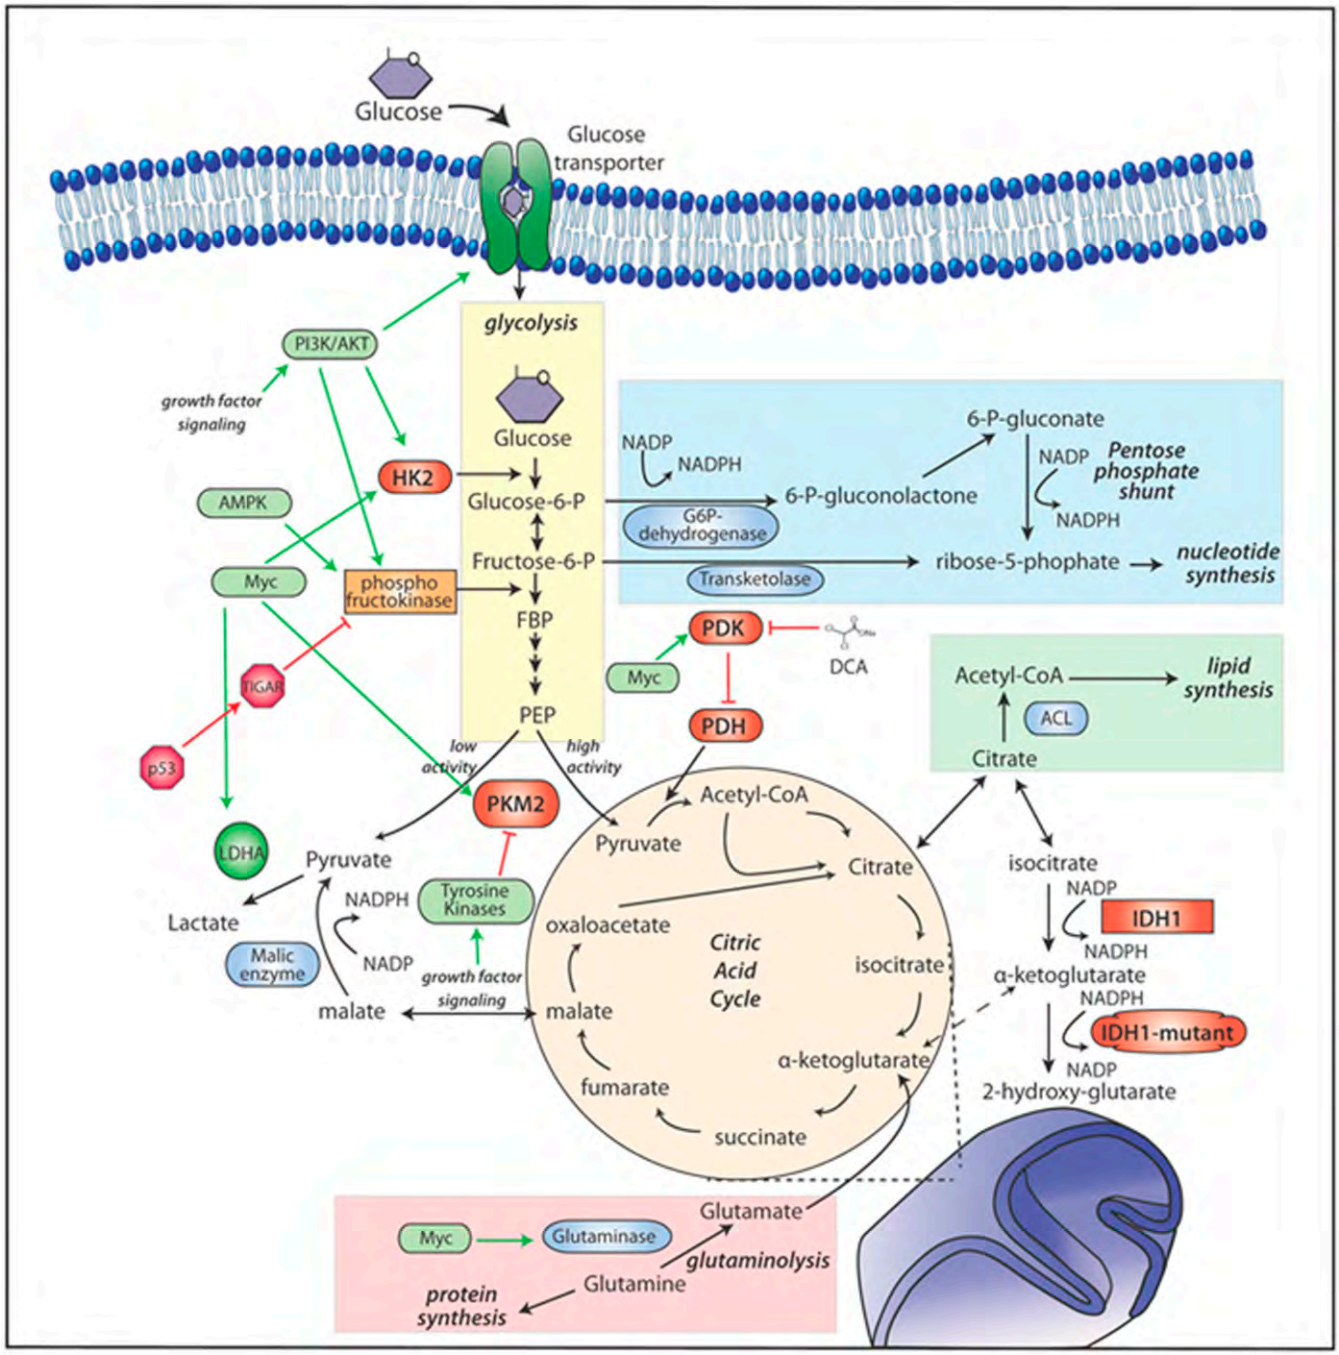
Dendritic Cell Therapies

Dendritic cell (DC) therapies function by harvesting DCs from the patient and exposing them to the tumor-specific peptides or tumor lysate ex vivo, prior to being injected back into the patient.[5,18] Previous clinical trials using DC therapy have shown encouraging results, with improvement in OS and 2-year survival compared with the current therapy.[60] Santos et al[78] published data from a phase II (NCT01280552) trial using ICT-107, a DC vaccine encompassing autologous DCs incubated ex vivo with six tumor-specific peptides. The data showed a relationship between HLA-A2–positive patients and an immune response to treatment, associated with both OS and PFS. The Mayo Clinic group reported a trial (MC1272; NCT01957956) of DC therapy in patients with newly diagnosed GBM.[79] Autologous DCs were pulsed with allogenic tumor lysate from two human GBM cell lines. Mean follow-up was roughly 1 year (range 0.19–1.77), with 80% OS. The University of California, Los Angeles group reported recently on a phase IIa trial (NCT01635283) of DC therapy in patients with grade II glioma treated with autologous DCs pulsed with autologous tumor lysate.[80] No difference was noted in time to progression between study patients and a matched cohort. One phase III trial (NCT00045968) using a tumor-lysate pulsed DC vaccine (DCVax-L) was recently completed in December 2016 with results not yet reported.

Oncolytic Viral Therapies

Oncolytic virus therapy uses genetically modified viral vectors that have the ability to both directly attack malignant cells as well as produce a durable host immune response to them.[81,82] NCT00390299 is a phase I trial for patients with recurrent GBM, assessing the safety and efficacy of measles virus transfected with human carcinoembryonic antigen as a marker for replication in vivo.[66] The PVSRIPO trial (NCT01491893) is evaluating a recombinant poliovirus (PSVRIPO) and has shown promising early results.[83,84] Patel

FIGURE 1. Metabolic Pathways Active in GBM Involving Enzymes of Glycolysis, the Pentose Phosphate Pathway, Fatty Acid and Glutamine Metabolism, and Their Regulation by Known Oncogenes and Tumor Suppressor Genes in Proliferating Cells



Growth factor/PI3K/AKT signaling stimulates glucose uptake and flux through the early part of glycolysis. Tyrosine kinase signaling negatively regulates flux through at PKM2, making glycolytic intermediates available for macromolecular synthesis. Myc has been found to promote glutamine metabolism and inhibit oxidative metabolism by activating pyruvate dehydrogenase kinase (PDK). p53 decreases metabolic flux through glycolysis in response to cell stress.

Abbreviations: Acetyl-CoA, acetyl coenzyme A; ACL, ATP citrate lyase; AMPK, 5' adenosine monophosphate–activated protein kinase; DCA, dichloroacetate; FBP, fructose 1,6-bisphosphate; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate; PDH, pyruvate dehydrogenase; PEP, phosphoenolpyruvate.

et al[85] recently reported on a new clinical trial using a recombinant oncolytic herpes simplex virus that functions through direct oncolytic action against malignant cells and transfection of a viral payload causing malignant cells to secrete IL-12. Tejada et al[86] reported preliminary results from a phase I trial (NCT01956734) using an oncolytic adenovirus (DNX-2401) and TMZ with noteworthy results: one patient alive 30 months after treatment with no evidence of progression and two further patients alive at 23 months. Aghi et al[87] also reported the preliminary results of three phase I trials using replicating retrovirus Toca 511 in patients with recurrent GBM, delivered via three distinct methods. Toca

511 is a recombinant retrovirus that transfects yeast cytosine deaminase into malignant cells, allowing for subsequent treatments with Toca FC (a 5-fluorocytosine derivative) to convert to 5-fluorouracil within the malignant cells.[87,88] Median OS for all three trial groups was 12.1–13.6 months.

Combination Immunotherapy Approaches

Several trials are investigating the use of combinations of immunologic agents to elicit the synergistic effects of such therapies. These include the CAPTIVE trial (NCT02798406), a phase 2 trial combining pembrolizumab with DNX-2401 (oncolytic adenovirus), the AVERT trial (NCT02529072), a phase I trial testing a combination of nivolumab and a DC vaccine (pp65) against recurrent glioma, a phase I/II trial (NCT02423343) for several solid malignancies, including recurrent GBM, testing nivolumab in conjunction with galunisertib, a transforming growth factor-beta receptor I kinase inhibitor, and a trial (NCT03018288) using pembrolizumab in conjunction with HSPPC96, an HSP peptide vaccine. Further research is likely needed to understand the critical interplay of immunosuppressive mechanisms within GBM, but combination trials such as these will hopefully provide us with useful information regarding concurrent immunotherapy treatments.

INTEGRATIVE MEDICINE AND ALTERNATIVE THERAPIES AGAINST GLIOMAS

Scope and Definition of Integrative Medicine

Integrative medicine, a new name for an ancient field of medicine, was previously known as alternative medicine, but because the term "alternative" implies in lieu of traditional medical therapy, the name has been recently been changed to the more inclusive name. Practitioners in oncology often encounter patients seeking advice about integrative oncology practices but whom are often ill equipped to address such questions, which may result in minimizing or avoidance of discussion regarding these queries. This common practice could lead to the patients becoming reluctant to discuss such therapies with their clinical team and potentially withholding information about the integrative techniques that they may be using. It is noted that up to 65% of cancer survivors report using integrative medicine practices at some time during their clinical course,[89] making it a highly relevant issue in the management of oncology patients. It has hence become important for practitioners in oncology to address this issue, encourage a discussion with the patients related to integrative therapy, and provide evidence-based information to help them make appropriate choices. Although reducing the potential for unreported use of integrative medicines by patients and encouraging open dialogue is a major reason for practitioners to educate themselves about integrative medicine, there are also evidence-based practices that demonstrate not only improvement in quality of life measures but also an increase in OS and PFS in patients with cancer.

Role of Stress and Mitigation of Stress

Stress and stress reduction is one of the most difficult fields to study in medicine because of often-subjective measures but is also the most interesting of all integrative medicine fields. Thaker et al[90] used a validated stress model to test the hypothesis that stress can induce tumorigenesis through stimulation of the B-adrenergic receptor on tumor cells. Nude mice were placed in a stress-inducing restraint system, and human ovarian carcinoma cells were inoculated into the peritoneal cavity. As compared with the control nonstressed mice, the ovarian cancer cells grew by up to 275% in the stressed-out mice. The pathophysiology of this response is poorly understood but is thought to be secondary to stimulation of the B-adrenergic receptor on tumor cells and transcriptional upregulation of VEGF. A legitimate question hence is whether decreasing stress can cause a decrease in tumor burden and improve survival. In this context, a randomized trial showed a considerable survival benefit of stress reduction in patients with metastatic breast cancer.[91] Patients undergoing adjuvant breast cancer therapy were randomized to an intervention arm that taught strategies to "reduce stress, improve mood, and alter health behaviors" for 1 year (26 sessions). At 11 years of follow-up, there was a striking improvement in median survival in the intervention arm (6.1 years) versus the assessment-only arm (4.8 years). Multivariate analyses confirmed that patients randomized to the intervention arm had a significantly lower risk of death because of breast cancer (hazard ratio 0.44; $p = .016$). Although there is a paucity of such trials, the importance of mental health in patients with cancer, often minimized in routine care, has been shown to improve quality of life measures and now even survival in a statistically meaningful way. Incorporating stress reduction techniques such meditation, psychologic therapy, and psychiatric intervention to address issues such as anxiety and depression into routine oncological clinical practice hence must be an integral part of the management of the patient with cancer in a modern era of medicine.

Exercise and Its Impact on Cancer

All areas of medicine accept that regular exercise is important for maintaining mental and physical health, but the question of whether exercise can actually affect cancer growth has only recently been systematically addressed. In a laboratory study, mice were randomized to a cage with a wheel for running or into a cage without a wheel, and mice in both groups were inoculated with B16F10 melanoma cells. Strikingly, after 4 weeks of running, the exercise mice had a 61% ($p < .01$) reduction in tumor as compared with the mice that were not exercising. Exercised mice had increased natural killer cell mobilization that was believed to be the pathophysiology due to which tumor progression was decreased.[92] In an era of immunotherapy, these data suggest that exercise may have an important part in therapy.

Primary brain tumors such as high-grade gliomas are highly aggressive and treatment resistant. A very interesting trial examined the role of exercise in patients with

recurrent grade III and grade IV malignant gliomas in which 243 patients with a Karnofsky performance status 70 or higher were prospectively given a self-administered questionnaire that assessed exercise behavior and performed a 6-minute walk test to assess functional capacity.[93] Exercise was an independent predictor of survival (p = .0081), although, interestingly, functional capacity was not. Exercise was also a better predictor of survival than Karnofsky performance status, age, sex, grade, and number of prior progressions. The adjusted hazard ratio mortality was 0.64 (95% CI, 0.46–0.91) for patients reporting strenuous exercise. That strenuous exercise was an independent predictor of survival is a striking finding in an extremely treatment-resistant tumor given that to date, no chemotherapy, radiation therapy, nor surgical therapy have been shown to improve survival in a meaningful way in recurrent high-grade gliomas. Patients often stop exercising after the diagnosis of cancer because of several factors, including fatigue and concerns regarding the impact of physical exercise on their fragile health status, an attitude that may be inadvertently encouraged by clinicians. The data presented above and in many animal models point to the contrary and suggest that patients should continue to exercise as vigorously as possible not only to maintain performance status but also for its potential effect on controlling tumor growth and improving survival.

Diet and Nutrition

One of the most controversial areas of integrative oncology is related to diet and nutrition and its effect on cancer. There are often concerns about weight loss and poor protein intake in patients with a hypermetabolic state. The prevalent belief among clinicians that diet has no notable effect on tumors has been challenged by emerging data in animals as well as humans. This is highlighted by the intriguing results of a randomized, double-blinded, placebo-controlled study assessing the role of flax seed in postmenopausal patients with breast cancer conducted by Thompson et al.[94] After initial biopsy, patients were randomized to a diet taking 25 grams of flaxseed daily in a muffin versus one with no flaxseed and with no other changes in their regular diets. At the time of lumpectomy, the flaxseed arm was found to have a considerable decrease (median 34.2%) in Ki-67 labeling index and considerable increase in apoptotic index (30.7%). No quantifiable changes on these indices were noted in the placebo group. Other similar studies have shown that even small changes in diet for a short period of time can induce changes at a cellular level. However, the question of whether diet can change tumorigenesis in a clinically meaningful way has been challenging to answer because of the difficulties in evaluating the effect of diet in an evidenced-based manner. Randomized controlled trials are virtually impossible, and so clinicians have to often rely on retrospective trial data, which are fraught with statistical bias. One large randomized control trial, the PREDIMED study, conducted in Spain on 4,282 women age 60 to 80 at high cardiovascular risk, showed compelling results in this context. These subjects were randomized to a Mediterranean diet with olive oil, a Mediterranean diet with nuts, or a low-fat control diet and monitored for development of breast cancer. There were 35 cases of breast cancer in a median follow-up of 4.8 years; intriguingly, the multivariable-adjusted hazard ratios for the Mediterranean diet plus olive oil group versus the control group was 0.32 (95% CI, 0.13–0.79).[95] The impact of these results can be considered in the context that a chemotherapy agent that showed similar results in preventing breast cancer would have been considered highly successful.

Other specialties in medicine such as cardiology have willingly embraced the impact of stress reduction, exercise, and diet in the prevention and treatment of disease. In oncology, such acceptance has lagged behind despite cumulative data that support the direct beneficial effects of such modalities on quality of life and survival. The reasons for the resistance in accepting the value of such measures in the therapeutic strategies against cancer are unclear. It can be speculated that this may be due to the lack of a direct and verifiable logical link between cancer and, for instance, exercise. It is also possible that the lack of conventionally accepted evidence based on robust clinical trials raise skepticism about the results of small uncontrolled studies or anecdotal experience. Further, in the era of highly specific and targeted therapies, it is possible that the role of a broader and less specific intervention such as diet or exercise may have lesser acceptance as a legitimate anticancer therapy. Perhaps clinicians also have concerns that patients may choose integrative practices in lieu of traditional medical therapy with potential medical consequences. Equally likely, however, is that clinicians trained in oncology receive little or no training in aspects of integrative medicine given the traditional stigma and biases associated with this field in traditional training programs as being a nonspecific science. However, it is highly encouraging that Integrative Oncology as a field is moving forward and that there is a growing recognition of the obligation in clinicians to familiarize themselves with the fundamentals of this field and to critically examine the evidence in the field as well as generate carefully designed studies, including through new study designs and clinical trial approaches to provide evidence-based results on which practice can be based. This is imperative for the benefit of our patients who are currently bombarded with nonevidence-based recommendations from a variety of nonmedical sources, including the internet and social media, every day.

CONCLUSION AND FUTURE DIRECTIONS

Recent advances in treatment have yielded incremental improvement in the outcomes of patients with gliomas; however, paradigm-shifting therapies that provide considerable prolongation of survival and improvement in quality of life for these patients have been elusive. The need for unconventional approaches to targeting gliomas has led investigators to explore targets and strategies that go beyond traditional chemotherapeutic agents, including the ones outlined in the sections above. A variety of other strategies,

including gene editing, noncoding RNAs, biologic therapies including viral and nonviral vectors, in addition to cell-based therapies, heat-based therapies, novel surgical techniques, and local delivery using blood-brain barrier disruption and convention-enhanced deliveries, as well as novel approaches with radiation therapy techniques, are under development. An exhaustive coverage of these techniques is outside the scope of this review, but it is recognized that these equally cutting-edge approaches are under active study. These novel strategies bear great promise in providing the long overdue improvement in quality of life and survival for patients with gliomas.

Practice-Changing Abstracts From the 2016 Society for Neuro-Oncology Annual Scientific Meeting

Marta Penas-Prado, MD

OVERVIEW

The most relevant practice-changing presentations at the 2016 Society for Neuro-Oncology (SNO) Annual Scientific Meeting revolved around the topic of the new 2016 World Health Organization (WHO) classification of central nervous system (CNS) tumors. The most notable change in this new classification is the introduction of molecular markers into the morphologic classification of diffuse gliomas (isocitrate dehydrogenase [IDH] mutation, 1p19q codeletion, and H3K27M mutation), ependymomas (RELA fusion), medulloblastomas (WNT- and sonic hedgehog–activated), and other embryonal tumors (C19MC amplification), thus allowing for more precise diagnosis of these entities compared with the use of morphologic features alone. Among the clinical trials presented, only one phase III trial evaluating a device therapy for treatment of newly diagnosed glioblastoma (EF14; tumor-treating fields) met prespecified statistical criteria for success, showing a modest benefit in progression-free survival and overall survival in patients without progression after radiation and concurrent temozolomide. Other topics of interest included the spatial and temporal heterogeneity of primary brain tumors and the prevalence of burnout among neuro-oncologists.

The new 2016 WHO classification of CNS tumors and its practice-changing implications were discussed in detail in several presentations during the 2016 SNO Annual Scientific Meeting.[1-6]

Historically, gliomas and other primary brain tumors have been classified based on morphology, with glioma grading depending on cellularity, nuclear pleomorphism, and presence of microvascular proliferation and necrosis. It is widely accepted that tumor grade is the primary predictor of biologic behavior and prognosis. However, recent data demonstrate that the molecular marker IDH mutation provides better prognostication than grade in malignant gliomas, and anaplastic gliomas without IDH mutations (IDH wild-type) have a similarly dismal prognosis as glioblastoma. Additionally, the presence of 1p19q codeletion is linked to the oligodendroglioma lineage and also associated with better prognosis and response to therapy than tumors of astrocytoma lineage.

This current 2016 update of the WHO classification of tumors of the CNS is the result of the collaboration of 117 contributors from 20 countries and discussion of the most controversial issues by a working group of 35 neuropathologists, neuro-oncological clinical advisors, and scientists at a 3-day consensus conference. The changes introduced in this 2016 update to the 2007 edition are detailed by Louis et al.[7]

The 2016 WHO CNS tumor classification moves beyond the classic histology description toward an integrated diagnosis, adding molecular-genetic markers to define many CNS tumors, although the grade determination is still being defined primarily on histologic criteria. As a result, the classification now includes a major restructuring of diffuse gliomas, with incorporation of new molecularly defined entities and deletion of some variants lacking diagnostic and/or biologic relevance (Table 1). The WHO grade II diffuse astrocytomas, WHO grade III anaplastic astrocytomas, and WHO grade IV astrocytomas (glioblastoma), are now each divided into IDH-mutant, IDH wild-type, and not otherwise specified (NOS) categories.

The diagnosis of WHO grade II oligodendroglioma and WHO grade III anaplastic oligodendroglioma requires the demonstration of both an IDH mutation and combined whole-arm losses of 1p and 19q (1p/19q codeletion). In the absence of testing or the setting of inconclusive genetic results, an otherwise histologically typical oligodendroglial tumor should be diagnosed as NOS. In instances in which histology and molecular genetic features are discordant (e.g., a diffuse glioma with morphologic features of astrocytoma, but harboring an IDH mutation and 1p/19q codeletion, or a tumor with appearance of oligodendroglioma, but with IDH, ATRX, and TP53 mutations), the genotype features determine the final diagnosis. Importantly, a molecularly defined

TABLE 1. 2016 WHO Changes to the Classification of Diffuse Gliomas

New Molecularly Defined Entities	Entities or Variants Deleted	Variants Added
Diffuse astrocytoma, IDH-mutant	Gliomatosis cerebri	Epithelioid glioblastoma
Diffuse astrocytoma, IDH wild-type	Protoplasmic and fibrillary astrocytoma variants	
Diffuse astrocytoma, NOS		
Anaplastic astrocytoma, IDH-mutant		
Anaplastic astrocytoma, IDH wild-type		
Anaplastic astrocytoma, NOS		
Glioblastoma, IDH wild-type		
Glioblastoma, IDH-mutant		
Glioblastoma, NOS		
Diffuse midline glioma, H3K27M-mutant		
Oligodendroglioma, IDH-mutant and 1p/19q-codeleted		
Oligodendroglioma, NOS		
Anaplastic oligodendroglioma, IDH-mutant and 1p/19q-codeleted		
Anaplastic oligodendroglioma, NOS		
Oligoastrocytoma, NOS*		
Anaplastic oligoastrocytoma, NOS*		

Abbreviations: WHO, World Health Organization; IDH, isocitrate dehydrogenase; NOS, not otherwise specified; CNS, central nervous system.

*The diagnosis of mixed gliomas is strongly discouraged in the 2016 WHO classification of CNS tumors. Diagnostic molecular testing should be used for further classification as a "molecularly" astrocytic or oligodendroglial tumor, whenever possible.

NOS is to be used in the absence of diagnostic molecular testing or when results are inconclusive; for oligoastrocytomas, NOS category should also be used in the very rare instance of a dual genotype oligoastrocytoma.

group of tumors, diffuse midline gliomas, H3K27M-mutant, has been introduced in the new 2016 WHO classification. These are tumors primarily seen in children (but also in adults), characterized by K27M mutations in the histone H3 gene *H3F3A* (or less commonly in the *HIST1H3B* gene) and a diffuse growth pattern, midline location (thalamus, brain stem, or spinal cord), and poor prognosis.

Even though the changes in the classification of diffuse gliomas are the most relevant due to the frequency of diffuse gliomas in clinical practice, other important changes have been introduced in this 2016 classification. New glioma variants have been included, such as epithelioid glioblastoma and anaplastic pleomorphic xanthoastrocytoma, as well as a new mixed neuronal-glial tumor entity, diffuse leptomeningeal glioneuronal tumor. A genetically defined ependymoma variant has also been included that is called ependymoma, RELA fusion-positive, which accounts for the majority of supratentorial ependymomas in children.

Medulloblastomas and other embryonal tumors are also being reclassified based on molecular subtypes when possible, and the general term PNET, or primitive neuroectodermal tumor, has been removed and substituted by the wastebasket diagnosis of CNS embryonal tumor, NOS, to be used when further histologic and/or molecular characterization is not possible (Table 2). Resembling the new classification of diffuse gliomas, medulloblastomas should also be classified following an integrated diagnosis model, with incorporation of both molecular group and histologic phenotype. The classification of embryonal tumors is expected to continue to evolve when molecular markers allow more precise cataloguing of these tumors and their subtypes in the near future. Other noteworthy changes to the 2016 WHO classification of CNS tumors include the introduction of brain invasion as a criterion for atypical meningioma and a soft tissue-type grading system

KEY POINTS

- **The new 2016 WHO classification of CNS tumors introduced molecular markers into the morphological classification of diffuse gliomas, ependymomas, medulloblastomas, and other embryonal tumors, allowing for more precise diagnosis of these entities.**
- **The 2016 CNS WHO classification includes a major restructuring of diffuse gliomas; WHO grade II diffuse astrocytomas, grade III anaplastic astrocytomas, and grade IV astrocytomas (glioblastoma) are now each divided into IDH-mutant, IDH wild-type, and NOS categories.**
- **Only one randomized phase III non–placebo-controlled trial was presented that met prespecified statistical criteria for success, evaluating the role of tumor-treating fields for treatment of newly diagnosed glioblastoma in combination with maintenance temozolomide.**
- **Recognition of spatial and temporal hetereogeneity of gliomas is key for the development of the new generation of clinical trials.**
- **A survey among SNO members revealed a high prevalence of symptoms of burnout and high levels of stress, and showed that patient care was the most satisfying career aspect.**

for the new combined entity of solitary fibrous tumor/hemangiopericytoma.

The WHO CNS tumor classification remains a work in progress. Of note, only markers with widely recognized diagnostic value and standardized, widely available methods of detection have been incorporated. Prognostic markers such as MGMT promoter methylation in glioblastoma have therefore not been incorporated, because of the lack of diagnostic value and lack of consensus on methods for detection. One of the major shortcomings is the difficulty to rapidly incorporate diagnostically relevant new molecular findings into standard WHO updates. For this reason, a new initiative will soon commence that will facilitate input and consensus review of novel molecular data, perhaps facilitating incorporation into future CNS tumor classifications. This initiative has been named cIMPACT-NOW (the Consortium to Inform Molecular and Practical Approaches to CNS Tumor Taxonomy) and is sponsored by the International Society of Neuropathology.[8]

FINAL ANALYSIS OF TUMOR-TREATING FIELDS PHASE III CLINICAL TRIAL FOR NEWLY DIAGNOSED GLIOBLASTOMA

The final results of NovoCure EF-14, an industry-sponsored, multicenter, non–placebo-controlled, randomized phase III trial in newly diagnosed glioblastoma testing the efficacy of tumor-treating fields (TTFields) in combination with maintenance temozolomide after initial treatment with chemoradiation were presented at this 2016 SNO meeting.[9]

TTFields are low-intensity (1–3 V/cm), intermediate-frequency (200 kHz) alternating electric fields applied to the shaved scalp via transducer arrays, connected to a portable device set to generate the electric fields (Optune; Novocure Ltd.). In preclinical models, TTFields have been shown to cause mitotic arrest and apoptosis by disrupting mitotic spindle formation during metaphase.[10] Notably, a prior randomized phase 3 trial in 237 patients with recurrent glioblastoma comparing treatment with TTFields to physician's choice standard chemotherapy failed to demonstrate an improvement in overall survival (OS) or progression-free survival (PFS), although adverse effects were generally minor.[11]

The current study in newly diagnosed glioblastoma aimed to evaluate the efficacy and safety of TTFields used in combination with maintenance temozolomide after completing therapy with radiation and concurrent temozolomide. The interim results were previously reported at SNO 2014 and published in *JAMA* in 2015.[10] Randomization was 2:1 favoring the experimental arm. The primary endpoint of the study was PFS in the intent-to-treat population, assessed by a blinded central review panel, with OS in an as-treated population as a powered secondary endpoint. OS was to be tested statistically only if the primary was met to avoid an increase in the risk of a false-positive result. The as-treated population was defined as patients who were able to receive at least one adjuvant cycle of temozolomide (i.e., started cycle 2) and also excluded patients in the control arm who received TTFields therapy outside the protocol (a total of 35 patients were removed for analysis of OS at the time of interim analysis). Blinded central review was not performed in real time to dictate treatment decisions, and some discrepancies in interpretation between local and central review were identified in both the experimental and standard arm.[10] An unusual feature of this trial was that, in the TTFields arm, patients were allowed to continue TTFields in combination with second-line chemotherapy until the second radiologic progression or clinical deterioration, for a maximum of 24 months.

At the published prespecified interim analysis, which included data from 315 patients,[10] the difference in PFS was 4.0 versus 7.1. months (i.e., an increase in 3.1 months favoring the TTFields arm, with a hazard ratio of 0.62), whereas the final analysis with 695 patients[9] found the difference was 4.0 versus 6.7 months with a hazard ratio of 0.63 (i.e., an increase of 2.7 months favoring the TTFields arm). In terms of OS in an as-treated population (powered secondary endpoint), there was a difference of 5 months both at interim and final analysis with a hazard ratio of 0.65, although the difference in intent-to-treat population at interim analysis was smaller (3 months). The respective 2-, 3-, and 4-year OS rates (secondary objective) were 43% (CI, 38%–47%) versus 30% (CI, 24–37), 24% (CI, 19–29) versus 16% (CI, 11–23), and 17% (CI, 13–23) versus 10% (CI, 6–18), respectively

TABLE 2. 2016 WHO Changes to the Classification of Medulloblastomas and Other Embryonal Tumor

New Molecularly Defined Entities	Entities or Variants Deleted	Entities Added
Medulloblastoma, WNT-activated	Primitive neuroectodermal tumor	CNS embryonal tumor, NOS
Medulloblastoma, SHH-activated and TP53-mutant		
Medulloblastoma, SHH-activated and TP53 wild-type		
Medulloblastoma, non-WNT/non-SHH		
Medulloblastoma, group 3		
Medulloblastoma, group 4		
Medulloblastoma, NOS		
Embryonal tumor with multilayered rosettes, C19MC-altered		
Embryonal tumor with multilayered rosettes, NOS		

Abbreviations: WHO, World Health Organization; CNS, central nervous system; NOS, not otherwise specified; SHH, sonic hedgehog.

TABLE 3. Comparative Outcome Data From RTOG 0525, RTOG 0825, EF-14 Interim Analysis, and EF-14 Final Analysis

			EF-14†	
	RTOG 0525 (2013)*	RTOG 0825 (2014)**	Interim (*JAMA* 2015)	Final (SNO 2016)
Median PFS (Months) Standard/ Experimental	5.5/6.7	7.3/10.7	4.0/7.1	4.0/6.7
Median OS (Months) Standard/ Experimental	16.6/14.9	16.1/15.7	15.6/20.5‡	16/21
***N* (Standard/Experimental)**	411/422	309/312	105/210	695

Abbreviations: JAMA, *Journal of the American Medical Association*; SNO, Society for Neuro-Oncology; PFS, progression-free survival; OS, overall survival.

*Randomization after chemoradiation.

**Randomization by day 10 of chemoradiation.

†Randomization after chemoradiation.

‡Defined as per protocol population (prespecified analysis). Median OS in intent-to-treat population also reported: 16.6 vs. 19.6 months.

($p < .05$ for all time points). Therefore, this phase III trial met prespecified statistical criteria for success, with a modest improvement in both PFS and OS. This is in striking contrast with the negative results of the previous phase III trial in recurrent glioblastoma.[11]

Table 3 summarizes EF-14 outcome data (median PFS and median OS) and provides the results of two other recent phase III trials, RTOG 0525 (standard vs. dose-dense temozolomide)[12] and RTOG 0825 (bevacizumab vs. placebo in addition to chemoradiation),[13] both large, multicenter randomized trials in newly diagnosed glioblastoma. Although direct comparison of patient outcomes among different trials is not statistically appropriate, RTOG 0525 and RTOG 0825 provide a reference of expected outcome of patients with newly diagnosed glioblastoma treated in clinical trials, and it is worth discussing in some detail to highlight potential limitations of this trial.

In RTOG 0525 and EF-14, patients were randomly assigned after chemoradiation, whereas in RTOG 0825, random assignment occurred at the beginning of chemoradiation (patients had to be randomly assigned by day 10 of chemoradiation). In all three trials, PFS and OS were measured from random assignment. When comparing outcome data, notably, the temozolomide control arm in EF-14 trial showed worse PFS than in RTOG 0525 and RTOG 0825, whereas OS seemed equivalent. In both RTOG 0525 and RTOG 0825, patients with suspected treatment effect rather than true tumor progression (pseudoprogression) were allowed to continue therapy, unless there was a new lesion or clinical decline. In the EF-14 trial, patients with suspected progression after chemoradiation were excluded from participation.

One potential factor that can account for differences in PFS in a given trial or among trials is the misclassification of true early tumor progression and pseudoprogression. Unfortunately, both traditional imaging criteria and clinical criteria are often misleading when trying to differentiate true progression from early treatment effect, thus being challenging to correctly include or exclude patients from trial participation and to estimate PFS. It is known that the peak of pseudoprogression happens within 3 to 4 months of completion of chemoradiation. Unfortunately, a blinded central radiologic review does not eliminate the problem of having inadequate tools to determine true versus false tumor progression. If, inadvertently, more patients with true progression right after chemoradiation were included in the temozolomide-only control arm of EF-14 (as suggested by worse PFS than in previous RTOG trials), this may have introduced an involuntary source of bias into the randomized study, favoring the experimental arm.

In summary, the positive results of EF-14 bring one additional therapy (TTFields) into the treatment arsenal against newly diagnosed glioblastoma. However, in view of the previous negative phase III trial in recurrent glioblastoma and the modest differences found in PFS and OS, it is still unclear which patients truly derive most benefit from this therapy, a question particularly relevant in the context of globally increasing health care costs. Unfortunately, patients with the most aggressive tumors (i.e., showing rapid tumor progression early during their course) are still lacking valid treatment options. In many cases, these tumors are also likely to have high MGMT activity as well as other unfavorable molecular markers. Additional research to investigate novel therapies for newly diagnosed and recurrent glioblastoma must continue to achieve much better improvement in survival, in the order of years rather than several months, as is the reality today. We must see the progress in OS for high-grade gliomas that has occurred in other malignancies like chronic myeloid leukemia or her2$^+$ metastatic breast cancer.[14,15]

OTHER TOPICS OF INTEREST

Spatial and Temporal Heterogeneity of Tumors

It is well known that gliomas represent a group of highly heterogeneous tumors, not only spatially (with different areas of the same tumor demonstrating different morphology, grade, or even molecular findings), but also temporarily, with an evolving molecular makeup during tumor treatment and evolution.[16] In this regard, Costello[17] presented intriguing data regarding IDH mutations during glioma evolution. Despite being an early oncogenic molecular event, IDH status can change during subclonal evolution and tumor recurrence via epigenetic mechanisms.

It is becoming increasingly clear that the failure of molecularly targeted therapies for recurrent tumors may be due, at least in part, to dynamic changes in the molecular alterations

driving the growth of the recurrence as compared with the original tumor. In consequence, taking therapy decisions based on molecular analysis on original tumor tissue is likely inappropriate in most cases. Recognition of this phenomenon should lead to changes in research practice, obtaining new tumor tissue for analysis whenever feasible before enrollment to clinical trials. In addition, it is also apparent that we do not have targeted drug therapies today that are sufficiently brain penetrant to access infiltrating cells, able to inhibit cellular targets long enough to exert sufficient antitumor activity, or specific enough in their action to be safely combined with other targeted therapies,[18] and a summary of the 2nd CNS Anticancer Drug Discovery and Development Conference will be published in *CNS Oncology* in the next few months.[18]

Investigating Burnout and Career Satisfaction Among Neuro-Oncologists

Professional burnout is common among U.S. physicians, but prevalence, root causes, and consequences of burnout syndrome in the neuro-oncology community had not been studied until now. Barbara O'Brien, MD, Shlomit Yust-Katz, MD, and Alvina Acquaye, MS, spoke on Education Day at the SNO meeting about their ongoing study on burnout in neuro-oncology and its preliminary findings.[19] Among 324 SNO members from the U.S. and Canada who completed an anonymous online survey, 30% reported current symptoms of burnout and 45% reported experiencing burnout in the past. More than 70% of the participants reported working more than 50 hours per week and administrative burden was high. Nearly half of participants reported significant stress and did not meet exercise and sleep recommendations for a healthy lifestyle. Interestingly, despite the unique challenges of caring for patients with brain or spinal cord tumors, patient care was reported as the most satisfying career aspect. Data collection and analysis are still ongoing, but these preliminary results reflect a high prevalence of burnout and stress in the neuro-oncology community and point toward the need for interventions to reduce undue administrative burden.

DEVELOPMENTAL THERAPEUTICS AND TRANSLATIONAL RESEARCH

Adoptive T-Cell Therapy for Solid Tumors

Oladapo Yeku, MD, PhD, Xinghuo Li, and Renier J. Brentjens, MD, PhD

OVERVIEW

Chimeric antigen receptor (CAR) T-cell therapy is an innovative form of immunotherapy wherein autologous T cells are genetically modified to express chimeric receptors encoding an antigen-specific single-chain variable fragment and various costimulatory molecules. Upon administration, these modified T cells traffic to, and recognize, cancer cells in an HLA-independent manner. CAR T-cell therapy has shown remarkable success in the treatment of CD-19–expressing B-cell acute lymphocytic leukemia. However, clinical gains to the same magnitude have not been reported in solid tumors. Several known obstacles to CAR T-cell therapy for solid tumors include target antigen identification, effective trafficking to the tumor, robust activation, proliferation, and in vivo cytotoxicity. Beyond these T-cell intrinsic properties, a complex and dynamic immunosuppressive tumor microenvironment in solid tumors hinders T-cell efficacy. Notable advancements in CAR design to include multiple costimulatory molecules, ligands, and soluble cytokines have shown promise in preclinical models, and some of these are currently in early-phase clinical trials. In this review, we discuss selected solid tumor malignancies and relevant preclinical data and highlight clinical trial results that are available. Furthermore, we outline some obstacles to CAR T-cell therapy for each tumor and propose strategies to overcome some of these limitations.

CAR T-cell therapy for solid tumor malignancies is an exciting frontier in cancer immunotherapy. The general architecture of a CAR consists of a single-chain variable fragment (scFv) derived against a predetermined tumor-associated antigen (TAA) followed by a CD3ζ domain required for provision of signal 1 and T-cell activation upon antigen recognition.[1] Upon transfection into autologous T cells, first-generation CAR T cells targeting *HER2*/*Neu*-expressing breast and ovarian cancer cell lines showed increased interleukin-2 (IL-2) production and cytotoxicity.[2] However, it was subsequently realized that sustained activity and proliferation after receptor engagement required a secondary signal, or signal 2.[1] Additional genetic modifications to include costimulatory molecules, such as CD28[3] and 4-1BB,[4] to the CD3ζ signaling domain led to second-generation CARs (28ζ and 4-1BBζ, respectively). Acting in concert, provision of both signal 1 and signal 2 mitigated the anergy and activation-induced cell death observed with first-generation CAR T cells.[5] Direct comparison of first- and second-generation CARs directed against CD19, a TAA expressed on malignant B cells, revealed superior expansion, tumor infiltration, and persistence in favor of the second-generation CAR design.[6] Additional genetic modifications have yielded third-generation CARs composed of two distinct costimulatory domains, such as CD28/4-1BB/CD3ζ or CD28/OX-40/CD3ζ, all with varying degrees of efficacy.[7-9] More recently, other approaches to optimize CAR T-cell efficacy via engineered expression of tethered or soluble ligands, cytokines, or scFvs[10,11] also have been reported.

However, despite ongoing success in the management of CD19+ B-cell hematologic malignancies, progress in the solid tumor landscape has been met with many obstacles. One is the identification of suitable neoantigens or TAAs to serve as targets for CAR T-cell therapy. The biologic heterogeneity of solid tumor malignancies does not lend to an approach of one antigen fits all. This difficulty is compounded by the frequent expression of putative target antigens on normal tissues that leads to on-target, off-tumor toxicity.[12] Despite this, acceptable antigens, such as EGFR variant III (EGFRIII),[13] GD2,[14] mucin 1 (MUC-1),[9] mucin 16 (MUC-16),[15] carcinoembryonic antigen,[16] mesothelin,[17] CA-IX,[18] and prostate-specific membrane antigen (PSMA)[19] have been characterized and are in various stages of clinical development (Table 1). Besides identification of a suitable TAA, trafficking of administered CAR T cells to the tumor is another challenge to effective therapy. Consequently, experimental models to improve innate CAR T-cell trafficking via coexpression of chemokine receptors[20] and compartmental/intercavitary administration of CAR T cells are being investigated.[21] Perhaps the most notable limitation lies in the dynamic, complex, and often inhibitory tumor microenvironment present in many solid tumor malignancies. For instance, myeloid-derived suppressor cells and tumor-associated macrophages (TAMs) decrease local tryptophan levels in

the tumor microenvironment,[22] depriving CAR T cells of an essential amino acid necessary for optimal function. In addition, regulatory T cells, myeloid-derived suppressor cells, and TAMs elaborate inhibitory cytokines such as IL-4, IL-10, leukemia inhibitor factor, and transforming growth factor β—all of which further repress T-cell function.[23-25] Strategies aimed at overcoming these limitations are currently areas of intense investigation.

GLIOBLASTOMA

IL-13 receptor α2 (IL-13Rα2) and EGFRIII are two major targets that have been investigated for CAR T-cell therapy against glioblastoma. IL-13Rα2 is overexpressed in more than 50% of glioblastomas, but limited expression on normal brain tissue is retained.[34] Importantly, IL-13Rα2 expression has been reported on both stem-like and more differentiated malignant cells, making it a favorable target with the potential to eliminate tumor-initiating cells and prevent tumor recurrence. Kahlon et al[35] generated a first-generation IL-13Rα2–specific CAR that redirected human CD8+ cytotoxic T lymphocytes to eradicate established glioblastoma tumor in an orthotopic xenograft model. In a separate study, IL-13Rα2–specific CAR T cells targeted glioma stem–like cancer-initiating cells and abrogated their tumor-initiating activity in mice.[36] A phase I trial was conducted in three patients with recurrent glioblastoma who received repetitive intracranial infusions of first-generation IL-13Rα2–specific CAR T cells without nonmyeloablative preconditioning.[26] Only transient antiglioma responses were observed in two patients. The unsatisfactory response may be explained by poor expansion and persistence of CAR T cells in vivo, because the trial used first-generation CAR T cells. As previously mentioned, first-generation CAR T cells show diminished expansion upon repeated antigen stimulation.[37] In a recent case report, a patient showed tumor regression after multiple intracranial infusions of second-generation IL-13Rα2–specific CAR T cells.[38] Interestingly, CAR T cells with intracavitary administration prevented only local tumor recurrence but failed to control tumor progression at distant sites. In contrast, intraventricular infusions resulted in tumor regression in all intracranial and spinal tumors. *EGFRIII* is a tumor-specific, mutated form of wild-type *EGFR* and is commonly expressed in glioblastoma. Because of an absence in normal tissues, EGFRIII is ideally suited to minimize on-target, off-tumor toxicity. Multiple preclinical studies demonstrate that EGFRIII-specific CAR T cells recognize and eliminate antigen-positive glioblastoma tumors in vitro and in vivo without cross-reacting with wild-type receptors present on normal tissues.[13,39-41]

KEY POINTS

- **CAR T-cell therapy has emerged as a promising immunotherapeutic approach for solid tumor malignancies and several promising candidates are in early-phase clinical trials.**
- **Despite tumor and antigen heterogeneity, several TAAs such as MUC-16, GD2, EGFRIII, mesothelin and PSMA have been identified as targets for CAR T-cell therapy.**
- **Clinical responses have been reported in a small subset of solid tumor malignancies; however, increased response rates and responses across a broader range of tumor types are required.**
- **CAR T-cell efficacy is limited by various intrinsic and extrinsic factors, including poor trafficking to tumor site and an immunosuppressive tumor microenvironment.**
- **Further genetic engineering to optimize CAR design (armored CAR T cells) or combinatorial approaches with cytotoxic, targeted therapy, and immunomodulatory agents are currently under investigation.**

NEUROBLASTOMA

In contrast to glioblastoma, neuroblastoma originates from immature neurons and mostly occurs in infants and young children. Multiple targets, including GD2 and CD171, have been identified and tested for development of CAR T-cell therapy. GD2 is expressed on tumors of neuroectodermal origin, including neuroblastoma and melanoma.[42] In a preclinical study, GD2-specific CAR T cells exhibited potent cytotoxicity and cytokine production in response to antigen stimulation.[43] A phase I clinical trial by Louis et al[27] reported a complete remission rate of 27% (three of 11 patients) in patients treated with first-generation GD2-specifc CAR T cells without lymphodepletion. Furthermore, CAR T-cell persistence was observed for up to 192 weeks in this study.[27] CD171 is a surface antigen expressed on many types of cancer, including neuroblastoma. Functionally, CD171 has been reported to enhance tumor cell activity.[44] The first CD171-specifc CAR was developed by Gonzalez et al,[45] and the engineered T cells displayed robust antitumor activity in vitro. However, subsequent treatment with first-generation GD2-targeting CD8+ lymphocytes in clinical trials failed to control disease progression, and CAR T-cell persistence was inversely correlated with disease burden.[28] The authors speculated that the minimal antitumor response was due in part to the lack of coadministration of IL-2, which is especially critical to support the function of first-generation CARs. It is also worthwhile to note that absence of a CD4+ subset in transferred T cells may have compromised function and persistence; emerging data indicate that optimal CAR T-cell efficacy requires both CD4+ and CD8+ compartments.[46]

Prospects

Efficient CAR T-cell trafficking and localization to the tumor site are prerequisites for optimal antitumor efficacy. This is especially challenging for neuro-oncological malignancies such as glioblastoma because of limited T-cell infiltration in brain. CAR T cells modified to express chemokine receptors, such as chemokine receptor 2, have shown improved trafficking and tissue homing in a neuroblastoma model.[47] An alternative strategy is to target the tumor vasculature. Local delivery of tumor necrosis factor α (TNF-α) has been reported to upregulate the expression of adhesion molecules, such

Abbreviations: CAR, chimeric antigen receptor; CEA, carcinoembryonic antigen; CR, complete response; EGFRIII, EGFR variant III; FcR, fragment crystallizable receptor; GD2, disialoganglioside GD2; IL-13Rα2, interleukin-13 receptor α2; MUC-16, mucin 16; N/A, not applicable; NED, no evidence of disease; PD, progressive disease; PR, partial response; PSA, prostate-specific antigen; PSMA, prostate-specific membrane antigen; SD, stable disease.

as vascular cell adhesion protein 1 and intracellularadhesion molecule 2 on endothelial cells, and to enhance T-cell infiltration.[48] Therefore, genetically modifying CAR T cells to secrete TNF-α is one potential approach to overcome this limitation and improve CAR T-cell efficacy. Combining CAR T cells with lenalidomide has been reported to enhance the formation of immune synapses and improve persistency of CAR T cells in vivo,[49] providing a rationale for combinatorial approaches for CAR T-cell therapy.

HEAD AND NECK CANCER

A target of particular interest is the ErbB receptor family, which contains four members, designated EGFR (or ErbB-1), ErbB-2 (HER2 or neu), ErbB-3, and ErbB-4.[50] ErbB receptors are transmembrane tyrosine kinase proteins that promote cell growth and inhibit apoptosis. Overexpression of these receptors, especially ErbB1 and ErbB2, have been observed in many malignancies, such as head and neck, breast, and lung cancers.[51-53] ErbB receptors can exist either in homodimeric or heterodimeric configurations,[54] and it has recently been appreciated that the transforming potential of the heterodimeric configuration is superior.[55] In addition, targeting individual ErbB receptors often results in acquired resistance because of enhanced activity of nontargeted receptors. In light of this, Davies et al[56] developed a second-generation CAR that incorporates a chimeric polypeptide, T1E, designed to achieve broad specificity for the ErbB network. ErbB-specific CAR T cells recognized and lysed several ErbB-positive tumor cell lines in vitro. These cell lines showed expression of a broad range of receptor combinations. In SCID-beige mice, CAR T-cell administration led to the eradication of established xenografts derived from ErbB1/2-overexpressing and ErbB2/3-overexpressing tumors. All four ErbB receptors are widely expressed in normal tissues, albeit at lower levels, which could lead to on-target, off-tumor toxicity. Van der Stegen et al[57] examined treatment toxicity in SCID-beige mice after delivery of the ErbB-specific CAR T cells via different routes. Compared with the intraperitoneal route, intratumoral delivery promoted tumor regression without eliciting any cytokine release syndrome. Consideration of intratumoral delivery has been proposed in clinical trials.[58]

Prospects

Multiple mechanisms have been exploited by cells in head and neck squamous cell carcinoma to escape immune surveillance. Data suggest that 55% to 65% of head and neck squamous cell carcinomas express PD-L1, which binds to its cognate receptor PD-1 on T cells, and suppress immune responses.[59] The presence of infiltrating regulatory T cells also contributes to the immunosuppressive tumor microenvironment via secretion of IL-10 and transforming growth factor β and via direct inhibition of T cells.[60] Therefore, strategies to optimize T-cell efficacy for head and neck squamous cell carcinoma could involve rational combinations of anti-PD-1/PD-L1 antibody with CAR T cells or armored CAR T cells modified to secrete blocking PD-1/PD-L1 scFvs.

BREAST CANCER

HER2 and mesothelin are two TAAs currently under investigation. Amplification of *HER2* oncogene leads to uncontrolled cell proliferation and occurs in approximately 20% of breast cancers.[61] Globerson-Levin et al[62] generated a HER2-specific, second-generation CAR containing CD28 and fragment crystallizable receptor (FcγR) signaling domains and tested its efficacy in a syngeneic mouse mammary tumor model. Transduced T cells exhibited potent cytotoxic capacity and cytokine secretion upon antigen recognition.[62] In addition, repeated injections of HER2-directed CAR T cells eliminated spontaneous HER2-positive tumors and enhanced survival in transgenic mice. Mesothelin is a glycoprotein expressed on a broad range of solid tumors, with limited expression on normal tissues.[63] Mesothelin expression has been shown to be enriched in triple-negative breast cancer and is associated with poor outcomes.[64] Patients with triple-negative breast cancer are not suitable for targeted therapy or hormone therapy, so adoptive transfer of mesothelin-specific CAR T cells offers an alternative option. Tchou et al[65] engineered mesothelin-specific CAR T cells and reported a cytolytic capacity against primary breast tumor cells in vitro. However, in vivo antitumor activity was not evaluated in this study.

Prospects

A major therapeutic challenge to therapy in breast cancer is acquired resistance that results from antigen escape. For instance, under selective pressure, HER2 can undergo proteolysis to cleave the extracellular domain without compromising kinase activity. One approach to overcome this limitation is to use a dual-targeting CAR system, in which engineered T cells coexpress two CARs that recognize two distinct antigens. Redirected T cells can be activated in the presence of either antigen, in essence creating an or-switch, to mitigate antigen-loss escape.[66] Alternatively, CAR T cells can be modified to secrete inflammatory cytokines, such as IL-12, or costimulatory ligands, such as 4-1BB ligand, to stimulate an endogenous immune response against tumor cells via epitope spreading.[67,68]

NON–SMALL CELL LUNG CANCER

Overexpression of *EGFR* is commonly seen in patients with non–small cell lung cancer, and small molecules inhibiting EGFR kinase activity have shown therapeutic benefits. Feng et al[29] reported efficacy of second-generation EGFR-specific CAR T cells that incorporate CD137 and CD3ζ signaling domains. In vitro antitumor efficacy was demonstrated via potent cytotoxicity and by interferon γ (IFN-γ) and IL-2 secretion in response to EGFR-positive lung carcinoma cells. In a phase I clinical study, two of 11 patients with refractory non–small cell lung cancer experienced a partial response after treatment with second-generation EGFR-specific CAR T cells after lymphodepletion. CAR T cells were detected in the peripheral blood of treated patients along with detection of CAR T cells at tumor sites, and eradication of EGFR-positive tumor cells was noted in post-treatment biopsies.[29] Mesothelin and carcinoembryonic antigen are also two attractive targets because of their elevated expressions in non–small cell lung cancer.[69,70] Multiple preclinical studies have reported antitumor efficacy of mesothelin- and carcinoembryonic antigen–specific CAR T cells against antigen-positive tumors, such as ovarian and liver cancers. However, direct evidence of antitumor efficacy against primary tumor samples or lung cancer cell lines has not been evaluated.[71-74]

MESOTHELIOMA

In addition to breast and lung cancer, mesothelin is overexpressed on the majority of mesotheliomas. Carpenito et al[71] engineered several mesothelin-specific CARs that used different combinations of costimulatory domains and compared their antitumor efficacy. Despite equivalent cytotoxicity in vitro, third-generation CARs, which contained CD137 and CD28 costimulatory domains in tandem, showed marginally superior tumor rejection in a subcutaneous mesothelioma tumor model compared with second-generation CARs that had either costimulatory domain alone. In a separate study, a fully humanized second-generation anti-mesothelin CAR mediated tumor elimination in vitro and in vivo.[72] Importantly, CAR T-cell activation was not subverted by soluble tumor-secreted or recombinant mesothelin. This mitigates the concern that CAR T cells could be blocked or preoccupied by the soluble portion of mesothelin detected in some patients. In addition to CAR development, identifying an optimal route of administration has been explored. Using an orthotopic mesothelioma xenograft model, Adusumilli et al[73] showed that intrapleural delivery of second-generation mesothelin-directed CAR T cells vastly outperformed intravenous delivery, requiring 30-fold fewer CAR T cells to induce tumor eradication. In a phase I clinical trial, four patients with advanced mesothelioma or pancreatic cancer were treated with repetitive intravenous infusions of second-generation mesothelin-specific CAR T cells. Moderate antitumor responses were observed, and CAR T cell persistence and trafficking to the tumor site were detected. Interestingly, this study also reported induction of an antitumor humoral immune response after CAR T-cell therapy, evidenced by an elevated antibody response to a variety of tumor-associated proteins. This observation highlights the potential of CAR T-cell therapy to elicit a systemic immune response targeted to a broader range of antigens mediated via epitope spreading.[17] One patient experienced anaphylaxis and cardiac arrest after the third infusion on this trial, and this adverse event was believed to be associated with the development of antibodies against the murine-derived scFv.[75]

Prospects

Like many other solid tumors, lung cancer and mesothelioma possess an immunosuppressive microenvironment. Overexpression of inhibitory molecules, such as PD-L1 and indoleamine 2,3-dioxygenase (IDO) by tumor cells and myeloid-derived suppressor cells have been reported in patients with non–small cell lung cancer or mesothelioma.[76-78] Multiple strategies, including additional modification of CAR T cells and combinatorial approaches, can be adopted to overcome these obstacles and enhance CAR T-cell efficacy. For instance, CAR T cells can be engineered to express dominant negative PD-1 receptors[79] or anti–PD-1/PD-L1 agents to promote resistance to such inhibition.[11] In addition, rational combinations with PD-1/PD-L1 blockade antibody or IDO inhibitors may restore CAR T-cell activity.

OVARIAN CANCER

Several antigens have been exploited as targets for CAR T-cell therapy in ovarian cancer. Barber et al[80] engineered a first-generation NKG2D receptor CAR that recognizes the cognate NKG2D ligand expressed on ovarian cancer cell lines and patient-derived primary ovarian cancer samples. In both cell lines and primary samples, these CAR T cells were activated, secreted proinflammatory cytokines, and lysed tumor cells in an NKG2D-dependent fashion. In vitro efficacy and repression of flank-implanted ovarian cancer cells in a xenogeneic model using HER2/neu-directed second-generation CAR T cells also have been reported.[81] The Lewis-Y (Le^{Y+}) antigen is a carbohydrate molecule that has been shown to be overexpressed on 70% of epithelial-derived tumors.[82-84] Westwood et al[85] designed a CD28ζ

second-generation CAR directed against Le^{Y+} tumors, one of which included ovarian cancer in an OVCAR-3 tumor model. These CAR T cells showed significantly enhanced IFN-γ production, proliferation, and cytotoxicity when exposed to Le^{Y+} OVCAR-3 cells.[85] Furthermore, treatment with Le^{Y+}-specific CARs inhibited growth of flank-implanted OVCAR-3 in immunodeficient NOD-SCID mice. Another TAA under development is MUC-16. MUC-16 is a membrane-associated molecule that belongs to the mucin family of glycoproteins.[86] The extracellular domain of MUC-16 is cleaved into a soluble antigen (cancer antigen 125 [CA-125]), leaving a retained portion (MUC-16-CD) that can be targeted by adoptively transferred engineered T cells.[15] Chekmasova et al[15] engineered a second-generation (CD28ζ) MUC-16-CD–directed CAR that showed efficacy against OVCAR-3 and patient-derived tumor samples. Armored CAR T-cells which have been engineered to secrete IL-12 directed against MUC-16-CD have been shown to be superior in vitro and in vivo to second-generation MUC-16-CD–directed CARs.[87] Similarly, mesothelin, a glycoprotein molecule expressed on pleural, pericardial, and peritoneal cells[88] has been explored as a TAA in ovarian cancer. Carpenito et al[71] reported notable in vitro cytotoxicity using mesothelin-directed third-generation (CD28/4-1BBζ) CAR T cells. Folate receptor α(FRα) is a cell surface–anchored glycosylphosphatidylinositol molecule[89] that is highly expressed on ovarian cancer cells,[90] and it has been shown to be predictive of negative outcomes in patients with ovarian cancer.[91] On the basis of the preclinical efficacy of folate receptor–directed CAR T cells,[92] Kershaw et al[32] conducted a phase I clinical trial using first-generation FR-positive–specific CAR T cells with or without exogenous IL-2 in patients with relapsed/refractory epithelial ovarian cancer. All 14 patients treated in this study had progressive disease. There was no reported decline in CA-125 or antitumor response.[32] In one of the cohorts in this study, the adoptively transferred cells were labeled with indium-111 to facilitate in vivo imaging. After intravenous administration, most of the labeled T cells persisted in the lungs, without any evidence of specific localization to the tumor sites. This finding partially explained the decreased systemic persistence and lack of efficacy in this trial.

Prospects

The inhibitory tumor microenvironment in ovarian cancer, including the highly suppressive ascitic microenvironment,[93] is an important obstacle that needs to be addressed for CAR T cells to be successful in this disease. One approach is to armor the CAR T cells with soluble cytokines, such as IL-12,[21] a proinflammatory cytokine that has been shown to enhance the cytotoxic capability of effector T cells[94] and to reprogram dendritic cells and myeloid-derived suppressor cells.[95] Potential combinations of checkpoint blockade with second-generation or armored CAR T cells also could be explored as a means to augment CAR T-cell efficacy via recruitment of endogenous effector T cells.[96,97]

PROSTATE CANCER

Prostate stem-cell antigen and PSMA are two of the most commonly used target antigens for CAR T-cell therapy for prostate cancer. Predominantly found on prostate tissue, prostate stem-cell antigen is a glycosylphosphatidylinositol-anchored antigen located on the cell surface.[98] In contrast, PSMA is a type II transmembrane protein that reportedly is present at low levels on the cytosolic/apical surface of normal prostate tissue.[99] However, during malignant transformation to prostate adenocarcinoma, it translocates to the extracellular/luminal side of the epithelium.[100] Zhong et al[8] generated a PSMA-directed third-generation CAR by engineering the 4-1BB receptor costimulatory molecule in tandem with CD28 and CD3ζ (named P28BBζ) and tested its efficacy against a human prostate cancer cell line in an SCID/beige mouse model. These CAR T cells showed robust proliferation and cytotoxicity in vitro. In tumor-bearing mice, treatment with P28BBζ greatly enhanced survival compared with control mice. Mechanistically, these T cells showed increased intracellular signaling and enhanced production of granzyme, IFN-γ, TNF-α, and granulocyte-macrophage colony-stimulating factor. Hillerdal et al[101] also have reported efficacy of a prostate stem-cell antigen–directed third-generation CAR that uses CD28 and OX-40 costimulatory molecules. In addition to robust proliferation, cytokine production, degranulation, and cytotoxicity upon recognition of prostate stem-cell antigen–expressing cells, these CAR T cells also were able to significantly delay subcutaneous tumor growth and prolong survival in nude mice. A phase I clinical trial by Junghans et al[102] reported a response rate, by prostate-specific antigen level, of 40% (two of five patients) with a first-generation PSMA-directed CAR after nonmyeloablative preconditioning and concurrent IL-2 administration. In another phase I report, Slovin et al[30] reported tolerability and systemic persistence of up to 2 weeks with second-generation PSMA-directed CAR T cells.

Prospects

TAMs have been implicated in prostate cancer.[103] Specifically, TAMs are recruited to and infiltrate the tumor stroma in a colony stimulating factor-1 (CSF-1)/CSF-1 receptor (CSF-1R) –dependent fashion,[104] where it has been shown to promote tumor and vascular growth[105] and to mediate resistance to hormonal therapy.[106] In experimental models, clodronate-mediated depletion of TAMs led to notable inhibition of tumor growth.[105] One approach to optimize CAR T-cell therapy for prostate cancer might involve preconditioning therapy with either pharmacologic (AZD6495) or antibody-mediated (anti–CSF-1R) depletion of TAMs before CAR T-cell administration. Alternatively, second-generation CAR T cells can be armored via additional genetic modifications to secrete soluble CSF-1R inhibitors.

RENAL CELL CARCINOMA

Carboxy-anhydrase-IX (CA-IX) expression in metastatic renal cell carcinoma has been exploited as a target for adoptive transfer of engineered T cells.[18] CA-IX is a metalloprotease

that reversibly catalyzes the hydration of carbon dioxide.[107] Although it is useful as a TAA in renal cell carcinoma, it also is expressed on several normal tissues, such as the gastric mucosa epithelium, small intestine epithelium, duodenum, and biliary tree.[108] In addition, expression of CA-IX is inducible in many other tissues under hypoxic conditions.[109] In preclinical studies, Weijtens et al[110] showed robust cytokine production and cytotoxic activity of first-generation CA-IX–directed engineered T cells against renal carcinoma cells. Lamers at al[31] initially treated three patients with CA-IX–positive metastatic clear cell renal cell carcinoma with first-generation CA-IX–specific CAR T cells and exogenous IL-2 administration without nonmyeloablative preconditioning. Two of these patients developed grade 2 to 4 liver enzyme toxicity, and liver biopsies showed cholangitis that involved T-cell infiltration around bile ducts and confirmation of CA-IX expression on the biliary ductal epithelium. Furthermore, all three patients developed antibodies against the murine-derived scFv. To abrogate any more toxicity, the investigators pre-administered unmodified antibody from which the scFv was derived (cG250) to saturate and protect the liver before CAR T cell administration. With this amended approach, Lamers et al[18] successfully eliminated treatment-associated hepatoxicity in all four patients who received antibody pretreatment. Curiously, they were unable to detect any human anti-mouse antibodies against the cellular product in patients who underwent antibody pretreatment, which suggests that perhaps the nonspecific inflammation caused by the cholangitis contributed to the generation of human anti-mouse antibodies. Despite CAR T-cell persistence of 3 to 5 weeks, there were no clinical responses.[18]

Prospects

Myeloid-derived suppressor cells[111,112] have been shown to facilitate T-cell suppression via arginase-mediated downregulation of the T-cell receptor ζ chain.[113] Increased levels of circulating regulatory T cells also have been reported in patients with renal cell carcinoma[114] and are inversely correlated with survival.[115] Sunitinib is a U.S. Food and Drug Administration–approved multikinase inhibitor for the treatment of metastatic renal cell carcinoma, and it has been shown to decrease myeloid-derived suppressor cells,[116] enhance type-I IFN responses, and decrease regulatory T cells function in patients with renal cell carcinoma.[117] Could sunitinib be used as preconditioning and maintenance therapy after CAR T-cell administration? This hypothesis could readily be subject to testing with a second-generation or armored CARs in a syngeneic model of metastatic renal cell carcinoma.[118]

SARCOMA

Although sarcomas represent a heterogeneous group of mesenchymal-derived neoplasms, there has been some success in identifying TAAs that are expressed across different sarcoma subtypes. Ahmed et al[119] exploited the expression of HER2 on osteosarcomas by engineering a second-generation HER2-directed CAR construct. These HER2-specific T cells showed robust cytokine production, proliferation, and cytotoxicity in vivo. Adoptive transfer of these genetically modified T cells effectively treated both localized and metastatic osteosarcoma in SCID mice. Second-generation (CD28ζ) NKG2D ligand-directed CAR T cells also have shown efficacy in preclinical in vitro models of Ewing sarcoma.[120] Another approach reported by Huang et al[121] involved generation of an anti–IL-11 receptor α chain (IL-11Rα) second-generation CAR. IL-11Rα expression has been reported on multiple tumor types, including osteosarcoma,[122] prostate cancer,[123] and breast cancer.[124] Signaling via the IL-11/IL-11Rα pathway has been shown, among many other things, to promote osteoclastogenesis.[125,126] IL-11Rα–specific CAR T cells were effective against both primary tumors and pulmonary metastasis in a nude mouse model of osteosarcoma.[121] In a phase I/II trial by Ahmed et al,[33] 19 patients with HER2-positive sarcoma were treated with second-generation HER2-specific CAR T cells without nonmyeloablative preconditioning. Adoptively transferred cells were detectable for up to 9 months in a fraction of treated patients. Furthermore, in patients who underwent metastatectomy 9 to 15 weeks after CAR T-cell therapy, HER2-specific CAR T cells were detected in the tumor samples by qualitative polymerase chain reaction.[33] Of the 17 evaluable patients, four had stable disease for as long as 12 weeks to 14 months. Three patients who underwent metastatectomy after CAR T-cell therapy remained in remission for up to 16 months.

Prospects

The importance of angiogenesis and vascular invasion in sarcoma has been well described.[127] In addition, the presence of M2-polarized TAMs has been reported, and these cells also could contribute to pathologic vasculogenesis via VEGF production.[128] Could CAR T cells be additionally modified to secrete soluble VEGF inhibitors? Perhaps they could be used in combination with anti-VEGF antibodies or multikinase inhibitors like pazopanib or sunitinib? Preconditioning or combination with immune-modifying agents, such as trabectedin[129] or mifamurtide, which act against monocytes/macrophages, could be explored as a means to optimize CAR T-cell efficacy for this disease.

CONCLUSION

Despite enthusiasm for adoptive immunotherapy, many obstacles must be addressed before CAR T-cell therapy joins the armamentarium for management of solid tumors. In tumor types that have more than one TAA, there is the question of which is the optimal target to minimize tumor escape via antigen loss/downregulation. When more than one TAA is expressed, could scFvs against both antigens be engineered in an or-activation or and-activation configuration to combat tumor heterogenicity or to improve safety, respectively? The prerequisite for nonmyeloablative preconditioning also must be rigorously assessed in syngeneic solid tumor models and clinical trials. There might be a hypothetical benefit to remodeling the endogenous lymphoid populations in anticipation of activation/recruitment

by specifically armored CAR T cells, but this remains to be tested. Appropriate preclinical models and mechanisms of efficacy and resistance to CAR T-cell therapy also should be explored, ideally before clinical development. Driven mostly by the importance of demonstrating antitumor efficacy against human cancer cell lines, the clear majority of preclinical CAR T cell validation experiments have been in the context of SCID/beige or other immunodeficient tumor models. These models potentially could underestimate the immunomodulatory effect of the endogenous immune systems of the hosts and the effects of the immunosuppressive tumor microenvironment on adoptively transferred T cells. Consequently, more effort is being directed at understanding the interaction of the tumor microenvironment and the endogenous immune system in immunocompetent mouse models in addition to the prerequisite xenogeneic research. The route of CAR T-cell administration also could be tailored to each solid tumor malignancy according to what is known about each tumor's biology. For example, clinical trials of intrapleural and intraperitoneal administration of CAR T cells for mesothelioma and ovarian cancer, respectively, are in progress. Lingering issues with toxicities in the form of cytokine release syndrome, neurotoxicity, and off-tumor cytotoxicity also are being investigated. Ultimately, knowledge of how best to mitigate these toxicities, coupled with rational combinations of chemotherapy, surgery, radiotherapy, or immunomodulators, will pave the way for the next breakthroughs in CAR T-cell therapy for solid tumor malignancies.

Biomarkers for Checkpoint Inhibition

Jeffrey S. Weber, MD, PhD

OVERVIEW

The identification of predictive biomarkers for the benefit of cancer immunotherapy is the holy grail of the burgeoning immunotherapy field. Recent work has shown that there are a core of concepts that establish the presence of an immune cell–infiltrate, an inflammatory signature of the tumor microenvironment, and the availability of target antigens defined by mutated neoantigens, as critical for the success of the checkpoint blockade. Genetic analyses have shown that resistance to PD-1 blockade, either innate or adaptive, may be due to existing or de novo mutations in signaling pathways critical for T-cell function in a modest proportion of cases. Major hurdles in the field that remain to be overcome are the difficulty of obtaining tumor biopsies for biomarker assessment, the heterogeneity of biomarker expression within tumors and within different tumors from the same patient, and the inducibility of some biomarkers by disease-related processes. Although assessment of peripheral blood or serum biomarkers would be ideal, few data suggest that they would reliably predict outcome with checkpoint blockade. Ultimately, some amalgamated biomarker that includes tumor and host factors will be required to predict which patients are likely to benefit from, or be resistant to, the effects of checkpoint inhibition.

The field of cancer immunotherapy has expanded enormously over the last decade, with many new trials and multiple new approvals of checkpoint inhibitors for solid tumors in 2016. Ipilimumab, nivolumab, and pembrolizumab have become mainstays of treatment for metastatic melanoma,[1-6] lung cancer,[7-10] and other solid tumors, and numerous combination trials are underway in efforts to optimize the use of checkpoint inhibition. Recently, atezolizumab, the first anti–PD-L1 antibody to be approved by the U.S. Food and Drug Administration for the treatment of platinum-resistant bladder cancer.[11] Lessons learned from evaluating biomarkers of toxicity and outcome in patients with melanoma will undoubtedly help accelerate the development of checkpoint inhibition for other cancers, and may suggest new strategies for overcoming innate and adaptive resistance to checkpoint inhibition.

The most critical question in the field of cancer immunotherapy is whether biomarkers can be defined that predict benefit from the use of these drugs and allow oncologists to choose patients most likely to respond to them. In melanoma and non–small cell lung cancer (NSCLC), a variety of studies have suggested that tumors have three potential immune profiles: (1) those that are infiltrated with T cells and express an "inflammatory" signature of genes, which could be amenable to checkpoint inhibition; (2) tumors that are devoid of any T-cell or inflammatory infiltrate on histologic examination and have a noninflamed, or "cold" gene expression profile and could be amenable to adoptive cell therapy; (3) and tumors that have T cells and other immune cells present, but only at the periphery or within the stromal tissue and not within the tumor itself and might be amenable to antiangiogenic therapy.[12] The "hot" tumors are most likely to respond to PD-1/PD-L1 blockade and have been associated with a previously primed immune response, but have been infiltrated with T cells with high levels of PD-1. Cold tumors that lack a T-cell infiltrate may be good candidates for an adoptive cell therapy strategy, and tumors that have immune cells that fail to infiltrate the tumor tissue may be appropriate for strategies employing antiangiogenesis agents or other drugs that promote T-cell migration.

PD-L1

PD-L1 is the critical ligand for the checkpoint molecule PD-1 on T cells. Its overexpression on tumor cells is a form of adaptive resistance to the presence of T cells that are infiltrating tumors.[13,14] A number of studies have evaluated the association of PD-L1 expressed on tumor cells and/or immune cell expression assessed by immunohistochemical staining and its clinical effect on the efficacy of PD-1/PD-L1 blockade.[15] Although most studies are in agreement that the higher the level of tumor cell membrane PD-L1 expression, the better the outcome with PD-1/PD-L1 blockade, it is clear that patients whose tumors stain negatively for PD-L1 may still gain benefit from checkpoint inhibition.[16]

This compromises the utility of PD-L1 as a biomarker to choose patients for therapy, because the investigators are unable to define patients who should not receive immunotherapy. In current studies, no less than three different antibodies are routinely used for PD-L1 staining assays, with three different scoring systems. The Ventana SP263, Dako 22C3, and Dako 28-8 antibodies have been most commonly used, and when evaluated for the pathologists' concordance in scoring using NSCLC specimens, a 90% rate was achieved.[17]

Nonetheless, some trials include tumor staining, others allow staining of tumor and immune cells, and yet others include staining of the immune-infiltrating cells only within the scoring system. Nonetheless, PD-L1 is an important biomarker for some tumors, and it has been used as a companion biomarker for the approval of pembrolizumab in patients with NSCLC.[9,10] In NSCLC and melanoma, patients with the highest levels of PD-L1 tumor staining have an excellent chance of achieving a response to PD-1 blockade. PD-L1 expression, a cytolytic or gamma interferon–related gene expression signature, CD8 density, and mutational load have been evaluated for their utility as biomarkers for the efficacy of PD-1 blockade, and mutational load appeared to be independent of the expression of T-cell and PD-L1 markers (Weber et al, unpublished data, 2017).

T-CELL INFILTRATION

The number of CD8 T-cells infiltrating the tumor microenvironment and expressing PD-1 and/or CTLA-4 appears to be a key indicator of success with checkpoint inhibition, and both PD-1 and CTLA-4 blockade may increase the proportion of infiltrating T cells. The best parameter associated with response to PD-1 blockade was a high density of CD8+ T cells at the invasive tumor margin.[18] Assessment of CD8+ cells in the tumor itself were less useful, as was tumor and invasive margin PD-1 expression or the expression of PD-L1 on the tumor cells and invasive margin cells. The number of intratumoral CD8+ T cells that were PD-1+ may also be associated with response to PD-1 blockade. In a different study, the number of double positive PD-1+/CTLA-4+ CD8 T cells within the tumor-infiltrating population was most strongly associated with outcome.[19] In patients receiving sequential PD-1 then CTLA-4 blockade with a planned switch, the CD8 T-cell infiltrate detected by immunohistochemistry was strongly associated with response to treatment in the cohort that received PD-1 antibody first (Weber et al, unpublished data, 2017).

Immune T-cell receptor (TCR) DNA sequencing utilizes a multiplex polymerase chain reaction (PCR) assay with forward primers specific for each V-gene segment and reverse primers specific for each J-gene segment. The TCR repertoire from circulating peripheral blood T cells was determined prior to and after anti–CTLA-4 antibody therapy. There was a substantial increase in the diversity (the number of unique TCR V-beta sequences) of the peripheral blood T cells. This increase demonstrated that no specific clone or subgroup of clones was expanded preferentially. These data suggest that a number of important clones have been disinhibited and allowed to proliferate by CTLA-4 blockade.[20,21] Interestingly, the immune-related toxicity associated with anti–CTLA-4 antibodies was also associated with increases in the TCR diversity, suggesting that some of the clones that were disinhibited and allowed to proliferate generated proinflammatory or autoimmune hyper-responsiveness. In another study, tumor biopsies from patients with metastatic melanoma were analyzed by TCR V-beta chain immune sequencing before anti–PD-1 antibody therapy.[18] Patients whose tumors had more clonal T-cell repertoire were most likely to respond to PD-1 blockade. When a metric of T cell number and clonality of the TCR was calculated, those with progressive disease had the lowest values. Analysis of tumors obtained after starting anti–PD-1 therapy showed that patients whose tumors exhibited high expansion of preexisting T-cell clones were most likely to respond to therapy.

A "focused" TCR repertoire, defined by DNA sequencing of the rearranged beta chain variable regions of the TCR within tumors, was associated with a good outcome with PD-1/PD-L1 blockade,[18] whereas a more "diverse" repertoire infiltrating tumors was associated with benefit from anti–CTLA-4 antibodies, as indicated above.[20-22] The focused repertoire would seem likely to encode TCRs specific for neoantigens, and many of the TCR sequences associated with a good outcome with PD-1 blockade can be found in the periphery in patients with melanoma. TCR diversity is also independent of the T-cell infiltrate or PD-L1 staining, both of which are dependent variables as a marker of outcome.

KEY POINTS

- **PD-L1 staining of tumors is associated with response and survival after treatment with PD-1 blockade.**
- **The magnitude of the CD8 T-cell infiltrate is an important correlate of benefit from anti–PD-1 therapy.**
- **An inflammatory tumor signature is also associated with benefit from anti–PD-1 therapy.**
- **T-cell receptor diversity is associated with benefit from CTLA-4 blockade; in contrast, T-cell receptor clonality is associated with benefit from PD-1 blockade.**
- **Mutational and neoantigen load have a modest association with benefit from PD-1 blockade.**

MUTATION AND NEOANTIGEN LOAD

The T-cell repertoire reflects the host immune response to cancer, but the tumor itself is a key determinant of success with checkpoint inhibition because there is a relationship between increased nonsynonymous variants or somatic mutations in tumors and outcome with checkpoint inhibition.[23] Patients who had tumors, which, like melanoma, possessed a high frequency of somatic mutations,were more likely to respond to checkpoint inhibition with anti–CTLA-4 and anti–PD-1 antibodies. In lung cancer, the number of smoking-related mutations,[24] and in gastrointestinal cancers,[25] the level of mutations dictated by the presence of mismatch repair deficiency were associated with the benefit of PD-1 blockade. Mismatch repair deficiency occurs in a small proportion of colorectal cancers as well as cancers

of the uterus, stomach, biliary tract, pancreas, ovary, prostate, and small intestine. Tumors that possess defects in the mismatch repair pathway have thousands of somatic mutations in regions of repeated DNA, known as microsatellites. Many different mismatch repair deficient tumors possess a prominent immune infiltrate and a cytokine-rich tumor microenvironment in which the tumors express PD-L1 and the effectors express different immune checkpoints including PD-1, CTLA-4, and LAG-3, which is consistent with a primed immune response.[26] The number of neoantigens—mutated proteins that are expressed and could be recognized in the context of MHC class I or II molecules as a processed peptide antigen by T cells, which is related to the total mutational burden—is critically associated with outcome for checkpoint inhibitors. However, the correlation between the burden of neoantigens and clinical benefit was less clear-cut when increasing rigorous thresholds for the binding affinity of peptides were applied and the neoantigens thus defined did not possess any shared sequences or features that were preferentially observed in patients who were responding.[27] These data suggest that the clinical relevance of neoantigens depends on the proper antigen processing and affinity of the neo-epitope peptide and HLA expression by the tumor, which is frequently aberrant. An additional issue is that of clonality, the likelihood that the majority of tumor cells express the neo-epitope in question, as opposed to a "branched" mutation that might be expressed by a small proportion of tumor cells and not clinically relevant. Better algorithms might also be needed to assess the immunogenicity of mutation-derived neo-epitopes.[28,29]

Interestingly, *BRCA2* mutations, which are associated with increased rates of DNA damage and a higher mutational load, are also associated with response to PD-1 blockade.[30]

TUMOR GENE EXPRESSION PROFILE

The nature of the tumor microenvironment also plays an important role in resistance or susceptibility to checkpoint inhibition. A tumor gene expression signature that reflects a series of gamma interferon–inducible genes may define a "hot," inflamed tumor, and is associated in several studies with a good outcome with checkpoint inhibition; its loss is associated with resistance to ipilimumab therapy.[30,31] Melanomas that are class II MHC–positive respond to PD-1/PD-L1 blockade and may share the interferon responsive signature.[31] In a recent study that included whole-exome sequencing of tumors from 16 patients with melanoma, multiple copy-number alterations resulted in the loss of interferon gamma pathway genes in 12 patients whose disease did not respond to ipilimumab.[32] Mice bearing melanoma tumors that lacked one of these genes, *IFNGR1*, also had an impaired response to anti–CTLA-4 therapy and substantially reduced overall survival compared with their counterparts whose tumors had wild-type *IFNGR1*. Tumor samples were collected from patients with melanoma treated with CTLA-4 blockade followed by PD-1 blockade at progression at multiple time points during therapy. Tumor biopsies during CTLA-4 blockade demonstrated higher density of CD8+ T cells in responders compared with nonresponders, suggesting a pharmacodynamic effect of the treatment that was associated with benefit.[33] When tumor gene expression profiling for patients exposed to either PD-1 or CTLA-4 blockade was performed, there was only a modest overlap in the genes that were increased at baseline or during early therapy and associated with outcome with either therapy, indicating a very different mode of action of the two antibodies. Response to PD-1 blockade was associated with pathways of cytolytic activity, antigen processing, and interferon gamma signaling. Expression of *VEGFA* was decreased in responders and increased with therapy in nonresponders, suggesting a mechanism of therapeutic resistance, as observed by others, and a potential target for therapy. In contrast, resistant tumors displayed a transcriptional signature (called the innate anti–PD-1 resistance, or IPRES), which was associated with increased expression of genes involved in the regulation of the epithelial-mesenchymal transition, cell adhesion, extracellular matrix remodeling, angiogenesis, and wound healing.[30] In addition to mesenchymal transition genes, immunosuppressive genes including *IL10*, *VEGFA*, *VEGFC*, and monocyte and macrophage chemotactic genes such as *CCL2*, *CCL7*, *CCL8*, and *CCL13* were associated with a poor outcome with PD-1 blockade. Those signatures of mesenchymal-invasive transition, angiogenesis, and wound-healing signatures have been detected in the resistant melanomas from patients receiving BRAF-inhibitor therapy, suggesting that induction of these signatures may negatively impact responsiveness to combinatorial anti–PD-1/PD-L1 therapy.[30,34] The IPRES signature was found to be increased in metastases compared with primary melanomas and was also detected in most different types of malignancy. Deletion of the *PTEN* gene, commonly found in melanoma, has a deleterious effect on antitumor immunity with checkpoint inhibition, and leads to a "cold" tumor with high levels of immune suppressive cytokines with sparse and inactive T cells.[35] The *PTEN*-deleted population had increased Akt signaling, and consistent with that finding, high levels of *p*-Akt expression in pretreatment tumor cells. In addition, CTLA-4 expression on the tumors and infiltrating T cells of patients with melanoma was associated with poor response rate and overall survival.[36]

There is also an association between tumor activation of the WNT/β-catenin signaling pathway and absence of a T-cell gene expression signature, which leads to deficiencies of infiltrating dendritic cells and a "cold" tumor microenvironment.[37] This might be overcome with the use of a STING agonist, which can augment expression of interferon gamma pathway genes.[38] Clinical examination of host biomarkers from large clinical trials of PD-1 blockade has shown that neutrophil-to-lymphocyte ratios, baseline lactate dehydrogenase, and eosinophil numbers are associated with outcome to checkpoint blockade, although none of these markers can reliably identify a patient who will not benefit from treatment.[39-41]

When tumors become resistant to PD-1 blockade after an initial response, exhibiting adaptive resistance to therapy, the induction of tumor *JAK1* and *JAK2* mutations, or deletion of beta 2-microglobulin may be responsible, leading to

impaired T-cell immunity and inability to detect tumor antigens.[42] In patients with innate resistance to anti–PD-1 antibodies that never respond to treatment, inactivating *JAK1/JAK2* mutations are not common, but are associated with low PD-L1 expression and lack of antitumor response.[43]

PERIPHERAL BLOOD AND MICROBIOME

The definition of serum biomarkers associated with the benefit of PD-1 blockade is still immature. In one series of patients receiving either nivolumab or pembrolizumab, a mass spectrometry–defined signature of proteins included those associated with acute phase reactant, complement, and wound-healing pathways.[44] The complement pathway has not been clearly shown in the past to play a role in T-cell activation, but recent work suggests that, in murine models, T cells have complement receptors, and that C5a and C3a can inhibit T-cell proliferation and activation.[45,46] High pretreatment serum levels of angiopoetin-2 was found to be associated with reduced overall survival in patients who were treated with anti–CTLA-4 or anti–PD-1 antibodies.[47] CTLA-4 and PD-1 blockade increased serum angiopoietin early after treatment initiation in a cohort of patients, whereas the addition of bevacizumab to ipilimumab resulted in decreased serum concentrations of angiopoietin. Increased angiopoietin levels were associated with reduced response to checkpoint inhibition.

Although immune populations detected in the peripheral circulation may not reflect events in the tumor microenvironment, a recent study demonstrated that baseline frequencies of myeloid-derived suppressor cells, CD4+/DF25+/FOXp3+ T regulatory cells, and high levels of eosinophils were associated with clinical benefit in patients with melanoma treated with ipilimumab.[40] High baseline frequencies of circulating CD4+/CD25-high/FOXp3+ T regulatory cells were associated with improved overall survival in this cohort.

There is a long history of work suggesting that the composition of the host microbiota in mice is associated with a favorable outcome with immunotherapy and checkpoint blockade, and recent data suggest that both clinical outcome and the immune-related adverse events often seen with checkpoint blockade may be associated with specific microbial taxa.[48-51]

CONCLUSION

In conclusion, there is no clear-cut and clinically useful single biomarker associated with the benefit of checkpoint blockade, or which could be used to select patients that would not benefit from this treatment. Developing the tools to define pathways of benefit, and that have the negative predictive value to predict innate and adaptive resistance to PD-1/PD-L1 and CTLA-4 inhibition, will undoubtedly require an amalgamated biomarker that combines tumor cell–intrinsic and host T-cell specific determinants. Current efforts in which peripheral blood cells, tumor and serum, as well as microbiome specimens are routinely collected in patients before and after treatment with checkpoint inhibition will be critical to research in defining biomarkers of response and resistance to immunotherapies.

Pharmacokinetic/Pharmacodynamic Modeling for Drug Development in Oncology

Elena Garralda, MD, Rodrigo Dienstmann, MD, and Josep Tabernero, MD, PhD

OVERVIEW

High drug attrition rates remain a critical issue in oncology drug development. A series of steps during drug development must be addressed to better understand the pharmacokinetic (PK) and pharmacodynamic (PD) properties of novel agents and, thus, increase their probability of success. As available data continues to expand in both volume and complexity, comprehensive integration of PK and PD information into a robust mathematical model represents a very useful tool throughout all stages of drug development. During the discovery phase, PK/PD models can be used to identify and select the best drug candidates, which helps characterize the mechanism of action and disease behavior of a given drug, to predict clinical response in humans, and to facilitate a better understanding about the potential clinical relevance of preclinical efficacy data. During early drug development, PK/PD modeling can optimize the design of clinical trials, guide the dose and regimen that should be tested further, help evaluate proof of mechanism in humans, anticipate the effect in certain subpopulations, and better predict drug-drug interactions; all of these effects could lead to a more efficient drug development process. Because of certain peculiarities of immunotherapies, such as PK and PD characteristics, PK/PD modeling could be particularly relevant and thus have an important impact on decision making during the development of these agents.

High drug attrition rates in oncology have been a major concern during recent years.[1] Only 5% of agents that show anticancer activity in preclinical development ultimately are approved upon demonstration of efficacy in a phase III clinical trial. Although the advent of molecular targets has led to a reduction in attrition rates—to 55% in the case of kinase inhibitors—rates remain unacceptably high,[2] which has led to an unsustainable economic model of drug discovery for the pharmaceutical industry and to spiraling costs of drugs that finally receive approval.[2,3]

These high attrition rates compared with those of other therapeutic areas can be explained in part by particular characteristics of oncology drugs,[4] including a narrow therapeutic index, complex pharmacology, the lack of data from healthy patients, a sparser PK sampling, high interindividual variability, and frequent use of therapies in combination to achieve maximum efficacy. Also, major differences in cancer targets and mechanisms of action of anticancer drugs (from conventional cytotoxic chemotherapies to small-molecule targeted agents to immune checkpoint targeted therapies) reject a one-size-fits-all model for PK and PD analyses.

Different solutions, including adaptive trial design[5]; a more extensive use of biomarkers from the early stages[6-8]; and novel tools, such as PK/PD modeling and simulation to aid the different steps of drug development, have been discussed.[9,10]

PHARMACOLOGICAL AUDIT TRAIL

The Pharmacological Audit Trail (PhAT) is a conceptual framework developed by Banerji and Workman[11] to facilitate rational decision making during drug development. By integrating PK and PD data, this tool allows for the codification of a series of biomarker-driven questions that should be raised in a sequential way at the appropriate stages of drug development. When these relevant issues or benchmarks are addressed, the likelihood of failure of a drug would decrease. The PhAT allows us to address critical aspects though out all the process, from the identification of the population most likely to respond and thus to define the target population, to the development of biomarkers of response, to understand the mechanisms of resistance once the treatment fails and finally to establish potential mechanisms to overcome such resistance (such as defining a new combination regimen or the identification of a potential new target).

Pharmacokinetics

PK is the study of the drug concentrations in the body during a period of time, and it includes the processes by which the drug is absorbed, distributed, metabolized, and excreted (also known in colloquial terms as what the body does to the drug).

From the Early Drug Development Unit, Vall d'Hebron University Hospital and Vall d´Hebron Institute of Oncology, CIBERONC, Universitat Autònoma de Barcelona, Barcelona, Spain.

Disclosures of potential conflicts of interest provided by the authors are available with the online article at asco.org/edbook.

Corresponding author: Josep Tabernero, MD, PhD, Early Drug Development Unit, Vall d'Hebron University Hospital and Vall d´Hebron Institute of Oncology, CIBERONC, Universitat Autònoma de Barcelona, Barcelona, Spain; email: jtabernero@vhio.net.

Both the importance and utility of PK studies in early drug development have long been recognized.[4,12] Different questions must be addressed. Are we reaching an appropriate PK exposure in humans? What is the correct schedule of administration? What is the correlation of the PK values with the toxicities observed during the trial? The answer to this specific question, for example, could help manage different toxicity profiles that could correlate with the maximum drug concentration and the area under the curve, which could help determine a different schedule of administration.[7] Finally, is there a relevant food effect or drug-drug interaction?

Pharmacodynamics

PD is the study of the relationship between drug concentration and its biologic effects (also known in colloquial terms as what the drug does to the body). Overall, there are two main types of biomarkers in this field[13]: (1) predictive biomarkers that constitute any measurement associated to response/lack of response or toxicity and (2) mechanism-of-action biomarkers that reveal insights into the PD effects of a drug.

Selection of the correct biomarker remains an important challenge, and the bottom-line questions surely must be these: are we modulating the intended target, and does this modulation translate into clinical benefit? Just one example to illustrate this point is the phase I trial of the protein tyrosine kinase Src inhibitor saracatinib.[14] The maximum-tolerated dose was achieved, and the recommended phase II dose was determined. Importantly, different schemes of treatments were tested, and PK analysis confirmed the proposed dose as optimal for PD effects in the tumor, with substantial reduction in Src activity. Another example is a PD study performed to evaluate the effects of different doses and schedules of cetuximab.[15] Results showed that every-other-week dosages of cetuximab had the same functional PD effect as weekly administration in patients with metastatic colorectal cancer; these results confirmed that the every-other-week dosage could be the appropriate one to treat this patient population.

KEY POINTS

- **There is a clear need to improve the speed and efficiency of clinical drug development in oncology.**
- **A deeper, more systematic knowledge of the PK and PD properties of a particular drug is required to better guide rational decision making during drug development.**
- **The use of computational models and simulation can help quantify and understand the relationship between exposure (i.e., PK) and response (i.e., PD).**
- **PK/PD modeling is a useful tool throughout all stages of drug development, and applications differ during the preclinical and clinical stage.**
- **Given the particular characteristics of immune therapies, PK/PD modeling could be particularly relevant during the immune therapy development.**

Despite the fact that PK/PD biomarkers remain crucial for phase I trials, incorporation of the use of predictive biomarkers from the outset clearly could be crucial for acceleration of drug development.[16] This is especially true with molecular targeted therapies, for which the cancer patient subpopulations that are most likely to respond to treatment can be identified to increase the probability of success. The development of anaplastic lymphoma kinase inhibitors in patients with *ALK* rearrangements,[17] or BRAF inhibitors in patients with mutant V600E *BRAF* melanoma,[18] is a clear example of this molecular enrichment approach. Complete validation of the biomarker probably will be carried out in subsequent phase II and III trials; incorporation of the biomarkers earlier, though, will potentiate more informative study designs about the biology of the tumor and treatment resistance mechanisms.

Pharmacokinetics/Pharmacodynamics Modeling

Model-based drug development employs mathematical and statistical models to describe disease progression, PK, and PD; to improve study design; and to better enable decision making.[19] It works as a tool to respond more certainly to the questions raised in the PhAT at a lower cost.

The term PK/PD modeling refers to a PK- and PD-driven exploratory analysis, which is based on a mathematical model.[20] These models can help to better understand the relationship between exposure (PK) and response (PD) as well as the change between these relationships as a function of drug intake. The normal assumption for a study design is the linear relationship between exposure to a medication and its activity; however, this relationship is not always so simple. For example, many monoclonal antibodies exhibit nonlinear PK behavior.

PK/PD modeling can be used throughout all the stages of clinical development.[21] Because models work with data in an iterative manner, the PK/PD model will be more reliable and valuable when more data are available. For the tool to reach its full potential, the tool should be developed from the preclinical stages to incorporate new data as the drug moves forward, which thus refines and improves the model. The updated model will help with the next steps of development. At the end of this building process, a well-defined model will include different submodels, which will be able to predict trial outcomes through the use of data of hundreds of multiple individual patients and multiple trial designs (Fig. 1). PK/PD modeling allows us to address a number of key questions at the various stages of the drug discovery and development process (i.e., PhAT).

Pharmacokinetics/pharmacodynamics modeling in preclinical stages. The main objective of early drug development is to select promising compounds that will be screened for efficacy and safety. The most promising agents will be studied more, and those with an acceptable efficacy/safety profile will enter the clinic. However, the translation of the efficacy and safety results from a preclinical level to the patient population remains a major challenge.

One of the key aims of translational, mainly mechanistic, PK/PD modeling is to generate a priori simulations that help support predictions about efficacy between different species (e.g., in vitro-in vivo predictions and xenograft-to-clinical correlations); thus, the importance of this tool lies at the preclinical-to-clinical interface.[21,22] The biggest cost-saving potential of drug modeling would be a determination of which compounds should move forward and which should be dropped.

The use of these models in the preclinical setting has several potential advantages.[23,24] It can improve lead optimization and the selection of the optimal compound, predict clinical potency estimates (e.g., effective concentration of a drug that gives half-maximal response), and predict the drug exposure needed. It also can provide guidance about the initial tested dose in clinical trials, the dose range, the suggested administration scheme, and even the optimal sampling required in the trial (Fig. 2).[25] Other advantages include prediction of oral bioavailability and assessment of the potential for drug-drug interactions. Other types of modeling, such as synergy-response surface modeling, can help predict the result of drug combinations and can better define a whole development strategy.

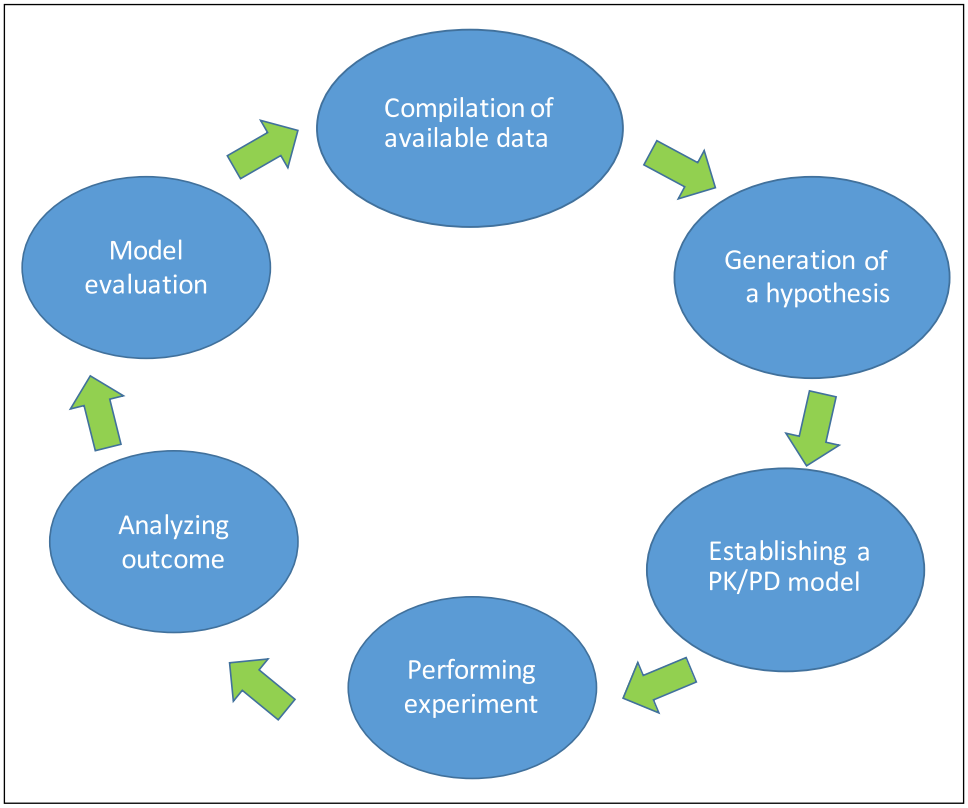
Pharmacokinetics/pharmacodynamics modeling in the clinical stage. There are several applications of PK/PD modeling in clinical development.[24,26] This include effective establishment of the relationship between exposure and biomarker, exposure and response, or biomarker and response relationships; earlier decision making about go or no-go plans on the basis of PK and PD characteristics of the drug; reduced numbers of phase II trials needed to obtain enough data for a phase III trial or for registration; and evaluation of different schemes of drug administration and study designs.

One important aspect of modeling is that it can increase prediction of drug-drug interactions. In the field of oncology, these interactions are a substantial problem, because many agents have a narrow therapeutic index and because most of the anticancer agents will be metabolized by cytochrome P450. The use of modeling can unmask these interactions and the importance of these interactions, and such data can be sent to the health authorities. With this approach, additional drug-drug interaction studies were avoided during the development of ceritinib, for example.[27]

Population PK/PD models also are becoming more important; in addition to the characterization of PK and PD, the models include relationships between covariates such as patient characteristics (e.g., age, body weight, renal function). This enables the assessment and the quantification of potential sources of variability in exposure and response within a specific target population, even under sparse sampling conditions. This approach is extremely relevant for assessments of special populations (e.g., pediatric population, frail patients, renal or liver impairment).[28]

A comprehensive example that illustrates the use of PK/PD modeling in the clinic is the development of everolimus. Everolimus blocks the mammalian target of rapamycin, or

FIGURE 1. The Model-Building Process



mTOR, pathway and inhibits the downstream S6 kinase 1. PK/PD models predicted that the inhibition of S6 kinase 1 in peripheral blood mononuclear cells was related to tumor effect and suggested that, although a weekly dose of 20 to 30 mg of everolimus already was associated with an antitumor effect, daily administration could cause a greater effect with higher dose intensity.[29,30] This supported the incorporation of S6 kinase 1 as a PD biomarker of mTOR signaling and guided the selection of the doses explored during the phase I studies. The phase I trial showed that everolimus administered as 10 mg daily or as 50 mg weekly would be the recommended phase II dosage, although the PD effect was more sustained with the daily dosage.[30,31] Subsequently, a phase III trial showed an increased overall survival in patients with renal cancer who received 10 mg of everolimus daily; approval for this indication was obtained.[32] Another phase III trial showed that 10 mg of everolimus daily increased progression-free survival in patients with pancreatic neuroendocrine tumors.[33]

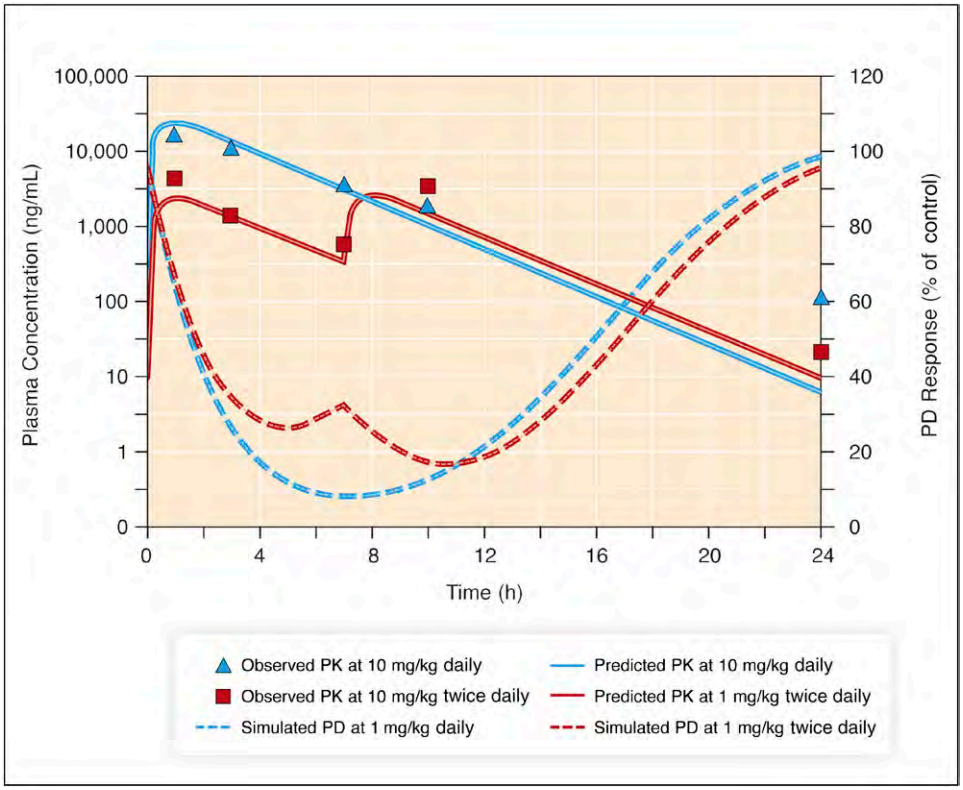
One area in which PK/PD modeling is especially reliable is that of biologics (drugs such as monoclonal antibodies that are produced by using biologic organisms or purified from a natural source) because of their ability to translate across species.[34] In general, the determination of the first-in-human dose is based mainly on toxicology properties and consideration of the no-observed-adverse-effect level, which is determined in preclinical safety studies and then reduced by an appropriate safety factor. However, with monoclonal antibodies, particularly agonist therapies, an additional approach is recommended—an approach that uses the minimal anticipated biologic effect level (MABEL) approach. The MABEL approach considers the pharmacological properties of the drug and the anticipated dose level that leads to a minimal biologic effect level in humans. MABEL is calculated mainly by integrating all of the available in vitro and in vivo information by PK/PD modeling.

DRUG MODELING WITH IMMUNOTHERAPIES

The advent of immune therapy represents a groundbreaking milestone for the treatment of patients with cancer, and the number of immuno-oncology agents entering drug development has continued to increase. However, because of the particular characteristics of these agents, their development has different challenges that must be considered.

Until recently, because most agents have had a direct dose-response curve, determination of the maximum-tolerated dose (MTD) has been the principal parameter for definition of the recommended phase II dose. However, the safety profile of most immunotherapies is different from those of targeted therapies or cytotoxic agents, and

FIGURE 2. Simulation of Exposure and Efficacy Data of Hypothetical Dosing Regimens in a Preclinical Mouse Model



A mouse xenograft model was treated with a drug with two different regimens: 30 mg/kg once daily or 1 mg/kg twice daily. Observed and predicted plasma levels were plotted with the simulated PD responses. This strategy can help determine what dose should be further tested.

Abbreviations: PD, pharmacodynamic; PK, pharmacokinetic.

Modified from Tuntland et al.[5]

the MTD generally is not reached; this provides an optimal setting for PK/PD-based dose recommendations. Moreover, the relationships between dose, response and toxicity are more complex with immunotherapies than with other drugs, so the old paradigms of the higher the dose the better, and the higher the dose the higher the toxicity profile is completely obsolete.[35]

To date, most of these immunotherapeutic agents are antibodies and have much more complex PK profiles than small molecules that have specific absorption, distribution, and metabolism characteristics. The size of an immunotherapy agent is much bigger, they are mainly administered intravenously, their distribution is more limited, and their elimination mainly depends on proteolytic degradation rather than biliary and renal excretion. The PD characteristics also are different. For example, although the toxicity of small molecules can be as a result of an on-target or off-target mechanism, the toxicity that has been observed with immunotherapies is mainly because of an activation of the immunogenicity, with a delayed onset of most of the immune adverse events. This will be especially relevant when combination therapies are considered.[36] Another potential advantage of immuno-oncology therapies is that, given their mechanisms of action, repeated PD measurements can be tracked for dynamic biomarker assessment and immunologic monitoring (e.g., $CD4^+$ and $CD8^+$ cells or the levels of different cytokines), which potentially could add value as predictive biomarkers or surrogates of tumor response. Despite these considerations, most phase I studies of immune agents lack PK and PD data. Additional knowledge of these parameters clearly would enrich PK/PD models and optimize the development of these treatments.[35]

A clear example of the importance of modeling in drug development is the case of pembrolizumab. The large phase I KEYNOTE 001 trial started with a standard 3 + 3 design, dose-escalation cohort to explore the MTD of pembrolizumab. Several dosages, from 2 to 10 mg/kg every 2 and 3 weeks, were evaluated.[37] Despite the safety of the higher dosage studied (10 mg/kg every 2 weeks), the mechanism-based translational model, which focused mainly on intratumor exposure prediction, suggested that robust clinical activity would be observed from a dosage of 2 mg/kg every 3 weeks.[38] This dosage, therefore,was recommended to be tested for clinical efficacy in additional clinical trials. Model-based characterization of the PK of pembrolizumab also was performed,[39] and it indicated an absence of covariate effects and supported the pembrolizumab dosage of 2 mg/kg every 3 weeks. Pembrolizumab at a dosage of 2 mg/kg every 3 weeks now is approved for non–small cell lung cancer tumors that express programmed death-ligand 1 and for metastatic melanoma. This clearly illustrates how drug modeling can transform early PK and PD results into a robust clinical trial design and can increase knowledge about the pharmacological properties of a drug. Given the costs of these agents and the challenge of reimbursement for health authorities and insurers, determination of the most appropriate dose is paramount. Notably, pembrolizumab was approved just 4 years after the phase I clinical trial started, through breakthrough designation by the FDA. This timeframe clearly contrasts with the 10 or greater years that former drugs traditionally took to be approved.[40]

CONCLUSION

As we progress in drug development, the importance of strategic thinking and rational decision making aimed at improvements of results remains clear. The PhAT represents a stepwise approach that allows for critical decision making that is based on biomarker and clinical endpoints, and it should be adopted and embraced more widely in clinical research.

Implementation of PK/PD modeling from early drug development promises a substantial impact on general efficiency as an excellent tool to help address critical questions and to evaluate different scenarios. For optimal modeling, the groundwork must begin early in preclinical development and the model must be finely tuned as results are obtained and sequentially analyzed.

Because of the common practice of using an MTD measurement, model-based drug development generally has not been considered during development decisions for anticancer therapies. This will probably change with novel drugs such as immunotherapeutics, because the MTD often is not reached. For PK/PD modeling to deliver on its promise the entire drug development community will need to learn and understand this approach in order to trust the models and be reassured of their utility.

As drug development evolves from determinations of MTDs to determinations of the optimal biologic (or immunologic) dose, the need for validated biomarkers will be of critical importance. Newer trial designs, coupled with new response and efficacy assessments, also will be required to optimize and expedite the development of novel agents, immunotherapies in particular.

Strategies to Maximize Patient Participation in Clinical Trials

Eric H. Rubin, MD, Mary J. Scroggins, MA, Kirsten B. Goldberg, MA, and Julia A. Beaver, MD

OVERVIEW

Despite considerable interest and success in oncology drug development, the minority of patients with cancer diagnoses enroll in clinical trials. Multiple obstacles account for this low enrollment rate. An improvement in patient participation in clinical trials could increase patient access to novel and potentially promising agents, provide faster trial results, and, with implementation of rational eligibility criteria, allow for a better understanding of the drug's safety and efficacy in a heterogeneous population. We present barriers and potential solutions to maximize patient participation, including a review of the ASCO and Friends of Cancer Research (FoCR) Modernizing Eligibility Criteria Project, U.S. Food and Drug Administration (FDA) regulatory considerations, an industry perspective, and a patient perspective.

The goal of oncology clinical trials is to understand the risks and benefits of a therapy and to facilitate and expedite the development of safe and effective drugs to treat patients with cancer. Clinical trials also provide patients with access to investigational agents; however, U.S. oncology clinical trials only enroll approximately 3% of patients diagnosed with a new cancer.[1] Multiple barriers can contribute to this low rate of enrollment, including those at the patient, physician, institutional, and protocol levels.[2,3]

Patient-level barriers to enrollment in clinical trials result from the fear that clinical trials will delay initiation of antineoplastic drugs (particularly if biopsy and genomic sequencing are required), fear of undergoing additional testing and procedures, or concerns about enrolling in randomized trials that might include a placebo or perceived inferior investigational or control arm. Other patient barriers include socioeconomic issues, such as concerns over travel costs with increased frequency of follow-up visits in a clinical trial. The lack of clinical trial access and/or a decline in functional status are additional commonly reported reasons that patients are not enrolled in clinical trials.[4] Physician-level barriers such as lack of knowledge about new agents and available clinical trials may also present obstacles to enrollment. Institutional-level barriers are reflected by the number of available protocols at one institution, and the fact that for many community practices, knowledge about the potential for referral to clinical trials may be limited. Overly restrictive eligibility criteria are a major protocol-level barrier. Given these obstacles, strategies are needed to maximize patient participation in clinical trials.

MAXIMIZING CLINICAL TRIAL PARTICIPATION AND IMPLEMENTATION OF MODERN ELIGIBILITY: INDUSTRY PERSPECTIVE

From an industry perspective, key parameters in clinical trial implementation and participation are as follows: (1) speed and efficiency in evaluating the safety and efficacy of an experimental oncology agent, (2) investigator and site experience with investigational drug trials (including obtaining patient informed consent and assessing adverse events), (3) speed of trial initiation at sites, (4) site accrual rates, (5) site data quality, and (6) investigator experience with the pathway targeted by the experimental agent.

Protocols for industry-sponsored clinical trials undergo a rigorous internal review process, typically involving multiple review committees with members possessing expertise in trial design, statistics, and regulatory, safety, data management, and operational aspects of clinical trials. During protocol development, industry sponsors typically obtain investigator input and ensure that the patient perspective is understood in order to confirm feasibility and maximize accrual rates.

Single-arm, personalized treatments (e.g., trials that select among various treatments based on a biomarker evaluation of a tumor biopsy) are often attractive to patients; thus, these trials tend to accrue rapidly. Single-arm trials may be sufficient for regulatory approval in some cases, such as rare cancers and/or where initial data suggest a remarkable improvement relative to existing treatment options. However, in most cases, randomized controlled trials will be necessary to demonstrate clinical benefit. In these trials, accrual rates can vary widely depending on patient perspectives on the potential benefits of the experimental and control arms.

Clinical Trial Designs to Improve Enrollment

Depending on the molecular target for an investigational agent, it may be preferable to use clinical trials that use enrichment designs (i.e., eligibility is dependent on having a "positive" result from a biomarker test performed on a tumor or blood specimen from the patient), particularly if the target is a mutated gene that has a low prevalence among a given tumor type. Using adaptive trials (e.g., trials that include prespecified changes based on accumulating data) may improve efficiency relative to use of multiple sequential trials, each requiring several internal and external committee reviews as well as separate site contracting and trial initiation efforts.[5-7] However, there may be tension in terms of the degree of flexibility desired by an industry sponsor versus prespecification of sample sizes based on statistical evaluations of efficacy and safety. In addition, adaptive trials increase protocol complexity, particularly if multiple amendments are required even if the adaptive changes are prespecified.

In some types of enrichment trials, it may be expected that that the biomarker test may identify responsive patients regardless of tumor type. In this case, "basket" trials have become increasing popular, in which eligibility is determined by the biomarker test rather than the tumor type.[8] However, this approach may create challenges in terms of selection of site principal investigators, because cancer centers are not organized by biomarkers but by tumor type. Thus, it may be difficult to identify an optimal principal investigator in terms of patient accrual to the trial.

KEY POINTS

- **Despite considerable interest and success in oncology drug development, the minority of patients with cancer diagnoses enroll in clinical trials, owing to barriers at the patient, physician, institutional, and protocol levels.**
- **An ASCO and FoCR Modernizing Eligibility Criteria Project, in collaboration with the FDA and other stakeholders, is working toward evaluating clinical trial entrance criteria that may unnecessarily restrict clinical trial access and providing recommendations for a more rational approach to determining inclusion and exclusion criteria.**
- **Working groups with representatives from ASCO, FoCR, FDA, patient advocacy programs, industry, and others have prioritized assessments on criteria for patients with brain metastases, organ dysfunction, history of prior malignancy, and HIV and for those younger than age 18 to come up with recommendations for a more nuanced approach to determining eligibility.**
- **Creative clinical trial designs such as enrichment designs, master protocols, and "basket" trials in the right clinical scenario can maximize patient participation and efficiency.**
- **Clinical trials hold the promise of providing benefit to patients/survivors and patient-level barriers to enrollment can be addressed through reasoned interventions.**

Master protocols are another trial design that has become increasingly popular as a means of improving efficiency of oncology drug development for a particular tumor type.[9] When testing multiple drugs with non-overlapping eligibility criteria (e.g., drugs targeting non-overlapping gene mutations), these designs have advantages over use of multiple two-arm randomized registration trials. First, grouping these trials under a single protocol, with a common control arm, reduces the overall screen failure rate. For example, assuming a prevalence of 20% for biomarkers A, B, C, and D in a given histologic cancer type (with no overlap among each subpopulation) and a need for 200 biomarker-positive patients each on an experimental arm and in the treatment-control arm, 8,000 patients would need to be screened in the case of four separate randomized studies, whereas only 2,163 would need to be screened in the case of a single five-arm study with four experimental arms and one control treatment arm. Second, process and operational efficiencies are improved through the ability to amend a single master protocol as needed as drugs enter and exit the trial. For example, after implementation, sponsors enrolling new drugs would benefit from the presence of a preexisting infrastructure. Although master protocols can improve the efficiency of drug development, they may not be fully endorsed by industry, particularly if trial arms include similar agents.

Implementation of Modern Eligibility

Although there are already examples of industry sponsors embracing changes in traditional eligibility criteria that have been suggested recently by various stakeholders (see section on modernizing eligibility criteria), challenges remain. Because industry typically desires to register new drugs in many different countries, registration trials usually involve sites from many different countries, and in certain countries, the view on reducing eligibility restrictions may differ from that of the United States, particularly as related to age. Furthermore, although mitigating factors have been described, allowing patients with impaired organ function or performance status may bias evaluation of safety and efficacy, potentially leading to premature discontinuation of the development of a particular agent. In some trials, accrual may be dominated by non-U.S. sites as a result of limited access of patients in some countries to investigational drugs or newly approved drugs. This can result in U.S. filing applications consisting of patient data from predominantly non-U.S. sites.

Strategies to Address Low Enrollment

Some studies enroll poorly, which may relate to several possible issues. These reasons may include lack of interest in the investigational agent or the control arm treatment, overly restrictive eligibility criteria, complex requirements (e.g., prolonged inpatient stays, uncomfortable procedures, or multiple invasive biopsies), or, in the case of enrichment trials, a low prevalence of biomarker positivity. Another possible reason for slow enrollment is the existence of similar studies competing for the same patient population,

particularly if the eligible population is uncommon (e.g., a biomarker-selected population in which the prevalence of biomarker positivity is low). Although many sites attempt to limit the number of trials competing for the same population, this does not address competition for patients between sites.

Sponsors may evaluate several options in cases of slow enrollment. A commonly used option is to simply add additional sites. If there is a high rate of screen failures, eligibility criteria may be re-evaluated, particularly if one criterion is a predominant reason for screen failures. For example, the number and types of previous treatment allowed may be too restrictive. In addition, for randomized trials, patients and investigators may not view the control arm as an attractive treatment option. In this case, adding additional treatment options to the control arm (e.g., allowing investigators to choose among a list of treatments), or allowing crossover to the investigation arm upon disease progression, may improve accrual rates.

MODERNIZING ELIGIBILITY CRITERIA FOR CLINICAL TRIALS

Historically, eligibility criteria were appropriately put in place because of concerns over safety in selected populations but, in many cases, clinical trial protocols are copied forward between and within drug development portfolios and are not always based on a rational analysis. It is critically important for developers of clinical trials to take a more thoughtful approach to the selection of eligibility criteria, not only to provide improved access to clinical trials for patients with cancer but also to understand a drug's safety and efficacy in a more representative population. Despite years of recognition of this issue, inclusion and exclusion criteria remain prohibitive for many patients.[10-13] Certain populations in particular are frequently excluded from oncology clinical trials, including patients with HIV, brain metastases, history of prior malignancies, poor performance status, and comorbidities and those younger than age 18.[13] Of approximately 300 commercial Investigational New Drug Applications submitted to the FDA's Office of Hematology and Oncology Products in 2015, only 3.7% included pediatric patients; 60% required Eastern Cooperative Oncology Group performance status of 0–1; 77% excluded known, active, or symptomatic central nervous system or brain metastases; 47% allowed treated or stable brain metastases; and 84.2% excluded patients with known or active HIV (with only 1.7% allowing patients to enroll with adequate CD4 counts).[14] Multiple stakeholders realize that taking a more rational approach to eligibility criteria will result in improved patient benefit.

ASCO/Friends of Cancer Research/FDA Modernizing Eligibility Criteria Project and Working Groups

The ASCO and FoCR Modernizing Eligibility Criteria Project, in collaboration with the FDA and other stakeholders, is working toward evaluating clinical trial entrance criteria that may unnecessarily restrict clinical trial access and providing recommendations for a more rational approach to determining inclusion and exclusion criteria.[13,15] Working groups were formed with representatives from ASCO, FoCR, FDA, patient advocacy programs, industry, the National Cancer Institute, biostatisticians, pharmacologists, and clinical investigators to come up with recommendations for a more nuanced approach to determining eligibility. These groups have prioritized assessments on criteria for patients with brain metastases, organ dysfunction, history of prior malignancy, and HIV and those younger than age 18.

Working Group Preliminary Recommendations

Publications from these working groups are pending; however, preliminary recommendations presented at the FoCR Annual Meeting in November 2016 detail current working group thinking.[16] The brain metastases working group endorsed the routine inclusion of patients with treated or stable brain metastases in all phases of clinical trials unless there is a compelling rationale for exclusion.[16] In certain instances, patients with new, active, or progressing brain metastases may also be included, taking the history of the patient's disease, trial phase and design, drug mechanism, and potential for central nervous system interaction into account. Patients with leptomeningeal disease may also have specific situations that warrant an eligible cohort in early-phase trials. The minimum age working group proposed that pediatric-specific cohorts be included in dose-finding studies in which strong scientific rationale is present. This rationale could be based on preclinical data or an understanding of the mechanism of the disease. In later stages of drug development, the group proposed that trials in diseases that span adult and pediatric populations should enroll pediatric patients, particularly patients age 12 and older. Others, including the FDA, have also suggested the inclusion of patients age 12–17 in appropriate adult disease-specific trials.[17] The working group also proposed that HIV-related eligibility criteria be rationally developed and focus on current and past CD4 and T-cell counts, a history of AIDS-defining conditions, and status of HIV treatment.[16] The working group advised that HIV should be considered a comorbidity and antiretroviral therapy should be considered a concomitant medication. The organ dysfunction working group proposed that eligibility regarding renal function should be based on creatinine clearance rather than serum creatinine levels, and knowledge of a drug's excretion by a specific organ system could inform exclusion criteria cutoffs. In addition, it was advised that exclusions based on prior malignancy be liberalized.

Regulatory Considerations of Eligibility

Regulatory incentives that might encourage a thoughtful approach to eligibility are also possible. For example, an expanded marketing claim could be granted if an adequately studied patient cohort included a previously excluded population such as patients with brain metastases. In addition, postmarketing requirements or commitments, such as the study of organ impairment, might be unnecessary if these

populations were included previously. Pediatric incentives include the ability to address requirements from the Pediatric Research Equity Act to study the effects of drugs on children. So that efficacy is not compromised in trials intended to support registration, a broader clinical trial population could include a prespecified, more narrowly defined population for the primary efficacy evaluation.

ASCO/FoCR/FDA Eligibility Criteria Future Directions

Appropriate eligibility criteria define a patient population that will result in patient protection, but strict eligibility criteria can negatively affect patient participation and result in failure to understand a drug's safety and efficacy in a representative population. Future endeavors of the ASCO/FoCR/FDA project will focus on approaches to appropriately defining drug washout periods, exclusion of concomitant medications, and inclusion of elderly patients.[16,18] The Modernizing Eligibility Criteria Project advocates for a culture shift in the approach to inclusion and exclusion criteria and will continue to pursue a broad implementation of this rational approach to eligibility.

IMPROVING ACCESS TO CLINICAL TRIALS: A PATIENT PERSPECTIVE

Although it is important to acknowledge that there is no single patient or patient advocate perspective or consensus on clinical trials. The views and suggestions offered here are those of an individual advocate informed and enriched by more than 20 years of active engagement across numerous advocacy groups.

A Goal of Patient Benefit

Simply put, clinical trials hold the promise—the enormously hopeful potential—of providing benefit to patients/survivors. Patient advocates, some as research advocates, support the clinical trial enterprise in numerous ways and participate in clinical trials for many reasons—one being the hope of personal benefit and another being the desire to contribute to the likelihood of benefit to future generations. Low trial enrollment decreases the speed and likelihood of trial progress and thus ultimate patient benefit (practice changing or incremental), wastes precious human and funding resources, and compromises confidence in the entire enterprise (thus becoming an additional barrier to enrollment).

Overview of Patient Barriers

Barriers to participation in clinical trials vary widely across institutions, professions, and populations. Low trial enrollment, relative to the available pool of participants, is a recurring topic or theme at nearly all conferences, meetings, and other gatherings of individuals involved in the clinical trial enterprise, seeking access to trials, or hoping to benefit from them. The long list of often-overlapping barriers includes (1) a history of unethical trials, (2) lack of understanding of clinical trials or the availability of specific trials, (3) lack of trust in the medical system, (4) uneven or unequal recruitment (including physician conscious and unconscious bias), (5) patient-physician communication (or the lack thereof), (6) access and logistical considerations (including financial, geographic, and educational considerations), and (7) the fear factor (e.g., of being randomized or of randomization not being so random and of being the object of unfettered experimentation).

These barriers and others combine to create limited and unequal participation in clinical trials, with differing effects on various populations, partially depending on their experience with the health care system. For example, "history" is often cited as a barrier to participation by populations described as vulnerable or "special" (a misnomer); however, history can be a barrier for any population and any individual who understands the medical misconduct and infamous studies that litter the research landscape. When known and understood, events such as the Nazi experiments (1940s), the Willowbrook studies (1956–1972), the Jewish Chronic Disease Hospital studies (1963), the AIDS trials (1980s), and the Tuskegee syphilis study (1932–1972), which is perhaps the most often cited example, prompt or exacerbate distrust in the system and increase reluctance to participate even with the potential of benefit to the participant or to others.

Distinguishing Myth From Reality

Important overarching concerns related to clinical trial participation include limited understanding of clinical trial terminology, standards, and protections. These concerns support the rise and maintenance of myths, such as those described in Table 1.

Trial Participation in the Age of Personalized Medicine

Clinical trial participation is the primary route through which biospecimens are obtained and banked, thus serving as a gateway for individual access to personalized medicine and health care. As such, it is increasingly important for all populations to be represented in the clinical trial enterprise. Because they are not equally represented, it is not surprising that banked biospecimens do not represent the diversity of the general population and that the findings derived from these biospecimens are not widely generalizable to segments of the population. Without trial participation across populations, underrepresented populations will have little or no "skin in the game." An unintended consequence is likely to be an increase in cancer health disparities. Therefore, with a substantial share of research efforts and research dollars focused on personalized medicine and health care, representative trial participation is a must.

Potential Strategies and Interventions

Like the barriers to clinical trial participation and low enrollment, potential solutions are frequently offered, if not implemented. The following potential solutions are offered as doable, feasible, and measurable:

1. Acting on what we know and have researched (including using best practices),

TABLE 1. Myths and Realities of Clinical Trial Participation

Myth	Reality
The Tuskegee syphilis study is the reason for low enrollment of black patients and perhaps other vulnerable populations.	The Tuskegee syphilis study or what it represents is a reason (i.e., one among many others), not the reason. In fact, it can become an excuse for the opportunity to participate not being offered.
Black and Hispanic patients are less likely to participate in clinical trials than white patients.	Although both groups are less likely to be invited to participate in trials than white patients, when asked, they are slightly more likely to enroll.
Trial participants are guinea pigs and may be experimented on in ways beyond their consent.	Numerous regulations and safeguards, including 45CFR46, ensure that human participants are protected and that research is ethical. All U.S. research involving human participants is reviewed and monitored by an institutional review board, whose focus is to protect participants.
Clinical trials are or should be an option only when potential participants have no other treatment options.	Clinical trial participation can and should be an option for any patient who meets specific trial eligibility requirements and wants to participate. Not all patients will choose to participate, but all should be given the option to do so when appropriate.
Some clinical trial participants will receive treatment inferior to standard of care, perhaps through randomization or placebo use.	All clinical trial participants will receive at least standard of care. Randomization and placebo strike fear in the hearts of potential participants. This fear can be educated away.

2. Focusing on recruitment of—as opposed to continuously studying—vulnerable and special populations (as a largely untapped resource and as a matter of good conscience and good science),
3. Funding and implementing bidirectional clinical trial education and awareness (to include a sustained public awareness campaign, communications skills, and cultural sensitivity training for the public, patients and survivors, health care providers, and researchers),
4. Developing trial-specific educational material (as well as trial-general material with substantial meaningful patient advocate involvement),
5. Instituting accountability relative to uneven/unequal recruitment and unmet goals (to include the requirement for rigorously reviewed population-specific recruitment goals and the implementation of consequences where warranted),
6. Reviewing and modernizing eligibility requirements (understanding, for example, that exclusion of potential participants with comorbidities—unless scientifically warranted—has a profound effect on eligibility by population and that trial participants should more closely align with the general population that might benefit from the trial),
7. Formalizing engagement of patient advocates beyond recruitment and throughout and beyond protocol development and review, and
8. Requiring an informed consent process as well as a signed informed consent document.

This may seem a smorgasbord or data dump of possibilities. It is not. Instead, it is a listing of potential solutions that can and should often be combined and fashioned into interventions that move from discussing low enrollment and the concomitant barriers to overcoming them.

In Summary—A Patient Advocate's Perspective

This cancer survivor and patient advocate's perspective focuses on the implementation of interventions old and new, alone and in combination. The breadth and depth of research on clinical trial participation have been extensive and the conversation is ongoing; however, to effect measurable change, we must move from conversation to research-based and best practice–informed action, that is, reasoned interventions.

CONCLUSION

Although restrictions on clinical trial entry for the protection of patients are appropriate and supported by all stakeholders, an examination of more nuanced eligibility is appropriate in many cases. This rational approach to defining eligibility will benefit patients by providing clinical trial access and ultimately resulting in a greater knowledge of a drug upon approval. Additional barriers can also be approached with similar efforts to expand and maximize patient participation in clinical trials. Through collaborative efforts across academia, government, industry, and advocacy, there is great promise and potential for maximizing patient participation in oncology clinical trials.

Tissue-Agnostic Drug Development

Keith T. Flaherty, MD, Dung T. Le, MD, and Steven Lemery, MD, MHS

OVERVIEW

The U.S. Food and Drug Administration (FDA) has approved drugs to treat patients with tumor types based on a single anatomic site, such as renal cell carcinoma or melanoma, rather than on a biomarker alone. This standard approach is based on a number of factors, including heterogeneity of drug effects in different biomarker-positive tumor types. Additionally, drug development for some drugs was primarily directed toward a specific genomic abnormality in a specific tumor type (e.g., drugs for anaplastic lymphoma kinase [ALK] fusion-positive non–small cell lung cancer). In such cases, differences in biology, differences in natural histories of different cancers, differences in mutation frequencies among cancers, or differences in concomitant therapies may have necessitated diverse development considerations. As described in U.S. regulations [21 CFR 201, CFR 201.57(c)(2)], the indications and usage section of drug labeling "must state that a drug is indicated for the treatment, prevention, mitigation, cure, or diagnosis of a recognized disease or condition or of a manifestation of a recognized disease or condition, or for the relief of symptoms associated with a recognized disease or condition." Such regulations, however, do not require that disease be defined solely as a specific tumor type. This manuscript will highlight scientific/biologic issues, clinical trial designs, and regulatory issues pertaining to the development of drugs agnostic of tumor type. Although the manuscript will discuss regulatory considerations as understood by the authors regarding tissue-agnostic drug development, it should not be considered formal or binding FDA guidance or policy.

Some of the earliest successes in developing targeted therapy for genetically defined subsets of cancer occurred by targeting genetic alterations that, in retrospect, were nearly restricted to one or two cancer types. This was the case for abl kinase targeting with imatinib, EGFR inhibitors for *EGFR* activating mutations, and ALK inhibitors for *ALK* fusions. As the tools to unravel the molecular biology of cancer have enabled complete characterization of the hundreds of cases of all common cancers and many uncommon ones, it is clear that cancers arise from common somatic genetic building blocks.

SCIENTIFIC/BIOLOGIC CONSIDERATIONS AND TARGET SELECTION FOR TRIALS TO IDENTIFY PATIENTS FOR TREATMENT AGNOSTIC OF TUMOR TYPE

The Cancer Genome Atlas project and other publicly funded studies rediscovered common genetic alterations that were variably represented across cancer types defined by site of origin (e.g., *PIKC3A*, *RAS*, *BRAF*, *Her-2*, *TP53*, *PTEN*, *CDKN2A*, etc.).[1] New insights were also gleaned into the commonness of genetic changes in components of complex, multicomponent molecular machinery (such as the SWI-SNF and spliceosome complexes). In the case of *Her-2* amplified and *BRAF* mutant tumors, it has become clear that the spectrum of efficacy observed in one tumor type can vary substantially when comparing various cancer types harboring a specific genetic alteration.[2-5] Perhaps most striking is the case of BRAF, where BRAF inhibitor monotherapy has profound efficacy in melanoma that is not yet equaled in colorectal cancer, even with triple-drug regimens targeting BRAF, MEK, and EGFR.[6] This precedent established the principle that one should assume heterogeneity, not homogeneity when investigating novel targeted therapy strategies. More recently, even immunotherapy has been subject to similar considerations. For the field-changing class of PD-1/PD-L1 antibodies, it has been established that higher mutation burden, infiltration of CD8+ T cells, and expression of PD-L1 on tumor and/or infiltrating immune cells can predict response.[7] But, the predictive accuracy varies across cancer types.[8] As new immunotherapies are being developed, the question arises as to whether their development would be accelerated by understanding whether new single agents or combinations building on a PD-1/PD-L1 antibody backbone might confer benefit similarly or differently in various cancer types that are profiled at the level of these analytes.

Preclinical models that might aid in predicting the most-responsive or most-resistant tumor types for a given therapy are poorly developed for many cancer types. Models that reflect the full genetic complexity of human cancer,

in a representative microenvironment, and in the setting of an intact immune system, are a particular unmet need in cancer therapeutic development. Thus, new therapies are brought into clinical development with little ability to predict which cancer types would be most impacted.

Principles of Variable Response to Oncogene/Signal Transduction Targeted Therapy

In cases of single-agent targeted therapy development, variable response within a single tumor type is the rule. The full spectrum of durable responses and de novo refractory disease has been well cataloged in the case of BRAF in melanoma, EGFR in *EGFR* mutant non–small cell lung cancer,[9] and ALK in non–small cell lung cancers harboring *ALK* fusions.[10] The addition of Her-2 antibodies to conventional cytotoxic chemotherapy in *Her-2* amplified breast cancer follows the same pattern.[2] Extensive investigation into the causes of de novo resistance and susceptibility have highlighted the contribution of cells in the tumor microenvironment providing growth factor-mediated survival signals, compensatory signaling as a consequence of dysregulated feedback mechanisms, and concomitant somatic genetic alterations present at baseline that mediate compensatory signaling. Even the contribution of tumor/immune interactions has been implicated in responsiveness of *BRAF* mutant melanomas to BRAF inhibitors.[11] It is logical to hypothesize that heterogeneity in one or more of these features would account for variable response to a new therapy being prospectively investigated. Taking the case of BRAF, sensitivity was equally demonstrated in melanoma and colorectal cancer (CRC) cell lines harboring V600 BRAF mutations.[12] But, only after observing widespread unresponsiveness in the colorectal population treated as one of two expansion cohorts in the phase I trial of vemurafenib were preclinical investigations launched that uncovered the ability of EGFR receptor signaling to rescue MAP kinase signaling and maintain PI3K pathway signaling in colon cancer models.[13,14] Interestingly, upregulation of EGFR has been implicated as a component of receptor tyrosine kinase–mediated resistance in melanoma, but as a component of acquired, not de novo, resistance.[15] Whereas the presence or absence of concomitant genetic alterations beyond the index alteration that is being therapeutically targeted can be assessed relatively easily in the era of clinical next-generation sequencing, predictive adaptive resistance mechanisms that do not have a hard-wired somatic genetic basis are not readily diagnosed a priori.

KEY POINTS

- **Most somatic genetic alterations in cancer are distributed across several to many cancer types.**
- **Preclinical model systems poorly predict relative sensitivity or resistance to therapies targeting these alterations.**
- **Early-phase clinical trials increasingly explore comparative efficacy across the spectrum of biomarker-defined tumor types.**
- **To date, durable objective responses have been observed in patients across different microsatellite instability–high/mismatch repair–deficient tumor types when treated with checkpoint inhibitors.**
- **If scientifically and clinically appropriate, investigating the effects of a drug agnostic of tumor type may be one pathway for drug development; however, every drug presents unique circumstances in regard to the population of patients who might benefit from it.**

Somatic Genetics Features

Concomitant genetic alterations that might mediate resistance to a targeted therapy (such as *PTEN* or *CDKN2A* loss in concert with a V600 BRAF mutation in melanoma) can be considered as effect modifiers. To mediate de novo resistance, such alterations must be present in the vast majority of tumor cell clones, presuming that cells that lack such alterations would be sensitive to therapy. Subclonal events that are present in a small minority of cells would be expected to account for resistance and disease progression following an initial period of disease control or response. Extreme examples of this are the presumed presence of gatekeeper mutations that impair drug binding to EGFR and ALK inhibitors that co-occur with an activating mutation that activates the kinase domain of EGFR or a translocation that drives ALK overexpression.[16,17] Such gatekeeper mutations are rarely found in the untreated state but commonly emerge under selective pressure of targeted therapy over the course of months. As such, these types of acquired resistance mechanisms seem to have little to do with variable initial response to treatment.

Another possibility has recently emerged in the targeted therapy development landscape: subclonal presence of the targeted oncogene itself. This appears to be the case in certain *PIK3CA* mutant cancers.[18,19] For years, *PIK3CA* mutant cancers were minimally impacted by the first generation of nonspecific PI3K inhibitors. With the emergence of inhibitors that are relatively selective for the alpha isoform of PI3K, which is the isoform that is activated by the mutation, muted responses have been observed across cancer types that harbor these common mutations (including breast cancers, head and neck cancers, and endometrial cancers). Genetic characterization of tumor specimens procured at baseline and at the time of disease progression has revealed that *PIK3CA* mutations are commonly subclonal and that *PIK3CA* wild-type tumors cells become over-represented in progression samples. In cases where mutant *PI3KCA* is clonal, concomitant genetic loss of PTEN can mediate resistance, providing a mechanism analogous to the other oncogene targeted therapy precedents described above. The *PIK3CA* case provides another dimension that may account for variable response and resistance across cancers that harbor genetic features: truncal versus subclonal target gene alteration.

Lineage-Specific Resistance

Beyond the somatic genetic makeup of cancers, the large remainder of resistance mechanisms to oncogene/signal

transduction targeted therapy lies in the epigenetic domain. On the surface, this refers to any de novo or adaptive resistance mechanism that reflects altered gene expression or signaling without requirement of an upstream genetic alteration that activates or inactivates. For the case of variable response to BRAF inhibitors in melanoma versus colorectal cancer, an epigenetic mechanism appears to underlie the utilization of EGFR signaling to maintain CRAF-MEK-ERK signaling in the face of BRAF inhibition.[14,20] Interestingly, this program does not appear to be as readily accessible to melanoma, raising the hypothesis that cell of origin might be an important factor for lineage-specific therapeutic resistance. Extensive research has highlighted the baseline transcriptional state of BRAF mutant melanomas and how that state is altered upon exposure to BRAF inhibitors. It appears that coordinated alteration in the melanocyte-specific transcription factor MITF and other TFE-3 family transcription factors can, but does not always, facilitate utilization of the beta-catenin signaling pathway and altered cellular metabolism.[21,22] These downstream consequences of BRAF inhibitor therapy might have their analog in other cancers that harbor BRAF mutations, but are almost certainly mediated by other transcription factors that play a role in the tissue-specific identity of those cells.

The relative contribution of concomitant genetic alterations and epigenetic phenomena is far from completely understood in any of the cases of successfully developed oncogene/signal transduction targeted therapy. In each case, it is only after a therapeutic effect has been observed that analysis of patients' tumor samples and parallel investigation in preclinical models have shed light on variable response within and across tumor types. It is this unmet need that, in part, informs the rise of functional diagnostics as an approach for judging response in minimally manipulated tumor samples ex vivo or, using novel microdevices for local delivery of drugs, in vivo.[23,24] These technologies are in their infancy with regard to use in cancer drug development. As such, it remains challenging to anticipate how the currently standard preclinical methods alone will enable prediction of therapeutic effects of a new class of therapies being brought forward.

The Clinical Trial Paradigm

In light of the current state of preclinical prediction, the standard paradigm for early-phase clinical trials is to perform dose escalation in unselected or biomarker-selected patients across tumor types followed by an exploration of efficacy in expansion cohorts. In the case of the vemurafenib phase I trial, unselected patients were enrolled in dose escalation (in part because diagnostic methods for *BRAF* mutation testing in real time were lacking), and two expansion cohorts were explored in which patients with melanoma and CRC were required to have a V600 BRAF mutation.[4,5] The target population was initially 20 patients. As opposed to formal phase II trials with statistical power to rule out a meaningful response rate, dose expansion cohorts of this size serve roughly the same purpose as the first stage of accrual in a Simon two-stage design. Depending on the clinical context with regards to unmet medical need, different threshold levels of response might be sought. The 20-patient CRC cohort was sufficient to declare vemurafenib as unworthy of further investigation as a single agent, whereas the response rate of greater than 60% in melanoma provided a clear signal that further single-agent development was warranted. Additionally, other cancer types in which BRAF mutations are less commonly found were investigated systematically in a dedicated phase II trial in which patients with any type of solid tumor could be enrolled.[25]

As in the vemurafenib example, a new oncogene/signal transduction targeted therapy is most commonly evaluated in the most-prevalent tumor-defined populations and/or the ones with the greatest unmet clinical need. With a path forward clearly established in melanoma, a parallel phase II investigation in other cancers harboring V600 BRAF mutations could be conducted while the confirmatory phase II trial in melanoma was performed for the purposes of regulatory approval. This approach effectively created a staggered drug development strategy, one that was driven by prevalence as well as observed efficacy. Out of an intention to streamline the process of drug development, pharmaceutical companies now typically embrace dynamic decision making and adaptation of phase I/II trials to enable broad exploration across cancer types and acceleration within cancer types in the setting of variable efficacy.[26] Of course, if heterogeneity is not seen, then the possibility exists of maintaining a tumor type–agnostic approach to development through phase II. This topic will be discussed in more detail later in the article.

One additional point in regards to drug development for oncogene/signal transduction targeted therapies is the difficulty in finding sparsely distributed, genetically defined populations. In the case of a genetic alteration that is present in 1% of a certain cancer type, it is both inefficient and costly to perform tests seeking alterations in such a single gene. Next-generation sequencing platforms for routine clinical use can solve this problem by simultaneously sequencing many cancer genes at one time, but have only recently been introduced and are used systematically in only a small number of major academic medical centers. Diagnostic companies have developed these platforms for centralized testing so that individual pathology laboratories need not develop their own capacity. However, in both scenarios, medical insurance payers are reluctant to cover the cost of these tests. Absent more widespread availability of next-generation sequencing tests, it becomes prohibitive to screen 100 patients to find one. The ongoing NCI-MATCH trial performs a sequencing analysis that identifies alterations in more than 150 genes for the purpose of empowering dozens of parallel phase II trials. But, with a total sample of only 6,000 patients, this trial simply demonstrates the efficiency of such an approach.

As originally conceived, NCI-MATCH placed priority on determining the genetic make-up of tumors at the time of study entry, rather than relying on archival tumor material

that might have been obtained at the time of primary tumor resection and potentially confounded by selective pressure of intervening therapy. To execute this, fresh biopsies were required at the time of study entry. This design decision reflects optimization of diagnostic accuracy, while introducing cost, risk associated with invasive procedures for research purposes, and a time delay while next generation sequencing is performed and analyzed. While this approach would have little impact on the representation of truncal mutations in a given tumor sample, it ensured that subclonal genetic alterations that may arise through tumor evolution and therapeutic resistance would be captured. During conduct of the trial, a modified approach was incorporated to allow submission of biopsies procured within the preceding 6 months prior to study entry provided that an intervening response to therapy had not occurred.

APPROACH TO THE DEVELOPMENT OF DRUGS FOR PATIENTS WITH MSI-H TUMORS

The promise of developing mismatch repair (MMR) deficiency as the first predictive biomarker across multiple tumor types for response to a novel therapeutic is supported by strong biologic rationale, availability of commercially used diagnostics for patient identification, and the urgent, unmet medical needs of patients with refractory cancers. The accumulation of evidence that PD-1 inhibition can provide durable benefit in patients with MMR deficiency, coupled with the explosion of technologies to identify these patients, leaves traditional approval pathways that require substantial evidence of effectiveness for each tumor type inadequate to help those in desperate need of therapy today.

MMR deficiency refers to the deficiency in proteins responsible in DNA repair when a mismatch occurs in the replication process. Specifically, these proteins are MLH1, PMS2, MSH2, and MSH6. Tumors deficient in these proteins accumulate many mutations because they lack the capacity to repair these mistakes. A tumor may acquire these deficiencies as part of an inherited disorder in one of these genes known as Lynch syndrome, a double somatic mutation in the tumor, or by hypermethylation of the MLH1 gene.[27-29] Immunohistochemistry testing for the absence of the MMR proteins can be used to identify these tumors.[30] Regardless of the mechanism for deficiency, this leads to the phenomenon of microsatellite instability. Microsatellites are repetitive DNA sequences that are prone to accumulation of mutations when tumors are MMR deficient. Microsatellite instability-high (MSI-H) refers to a tumor that, by polymerase chain reaction–based testing, has been shown to have shifts in more than 30% of specific microsatellite loci. As the shifts are compared with normal DNA, polymerase chain reaction–based testing does require normal tissue.

The recognition that MMR-deficient tumors were potentially immunogenic predated the current era of immune checkpoint blockade therapeutics. One of the pathologic characteristics of MSI-H CRC is the presence of immune infiltrating cells.[31-34] In particular, the presence of cytotoxic T cells in the tumor microenvironment suggests recognition of tumor antigen by these cells. The presence and progression of the tumor despite immune cell infiltration, however, support immune evasion by the cancer. The mechanism of immune recognition is not completely understood; however, these tumors are considered "hypermutated" due to accumulation of 10- to 100-fold the number of mutations as their microsatellite-stable counterparts.[35,36] These mutations can lead to the presentation of neoantigens to the immune system, making the prospect of immune recognition more likely.

Biologic Commonalities Among MMR-Deficient Tumors

The frequency of MSI varies across tumor types and stages within a tumor type but can be found in diverse histologies, ranging from those with higher frequencies such as colon, gastric, and endometrial cancers to those less commonly associated with MSI such as prostate cancer.[35,37] However, among those tumor types that have been studied histologically and by sequencing, the characteristics that may be predictive of response to immunotherapy are shared among MSI tumors: T-cell infiltration, PD-L1 expression, and high mutation burden. These features are found in both Lynch-associated and sporadic tumors.

CRC

MSI is present in 15% of CRC, with a majority of cases sporadic in etiology and 3% due to Lynch syndrome.[29] In advanced-stage disease, the frequency is 3% to 5%. Testing is already part of the National Comprehensive Cancer Network guidelines for CRC (version 1.2017).[38] Testing is recommended for the identification of patients with possible Lynch syndrome, a negative predictive marker for adjuvant therapy for stage II colon cancer, and now as a positive predictive biomarker for PD-1 inhibition. Better prognosis in early-stage disease is possibly due to immune recognition of these tumors. However, this is not true in metastatic disease, and MSI may portend a worse prognosis.[39,40] Pathologists can often identify these tumors without molecular diagnostics, as they tend to originate from right-sided primaries and have medullary differentiation, signet cell features, mucin production, poor differentiation status, and dense T-cell infiltration.[31,32,34] PD-L1 expression is also more frequent in MSI cancers than microsatellite-stable cancers.[41] In the Cancer Genome Atlas analysis of CRCs, 77% of the 30 hypermutated tumors with a complete data set were MSI-H.[42] Nineteen of these were due to MLH1 hypermethylation.

Endometrial Cancer

Universal testing of endometrial tumors for MMR deficiency is now recommended for the identification of patients with Lynch syndrome (National Comprehensive Cancer Network guidelines, version 1.2017). Data correlating MSI status to patient outcomes has been mixed. In a Japanese study, 40% of 191 cases of surgically resected endometrial cancer were found to be MMR deficient by IHC and this correlated with

better OS.[43] However, in a study of patients younger than age 40, MMR deficiency was associated with worse outcomes.[44] Similar to CRC, MSI-H endometrial cancers have higher CD3+ and CD8+ T-cell infiltrates than their microsatellite-stable counterparts.[45,46] Furthermore, PD-L1 expression is also mostly seen on immune-infiltrating cells.[45] Integrated genomic analysis of 373 endometrial cancers including MSI testing found MSI in 40% of endometrioid tumors and 2% of serous tumors.[47] MSI tumors fell into the hypermutated group, with most of them falling into the MLH1 hypermethylated group.

Gastric Cancer

Although MSI testing is not routinely performed in gastric cancer, some studies report an MSI-H frequency as high as 30%.[37] In a post hoc analysis of a large trial of perioperative chemotherapy versus surgery alone, MMR deficiency was a positive prognostic factor in those undergoing surgery alone but negative in those treated with chemotherapy.[48] This is reminiscent of the adjuvant story in colon cancer. Pathologically similar to other MSI-H cancers, they are associated with tumor-infiltrating lymphocytes and mucin phenotypes.[49,50] These tumors are predominantly intestinal in type. As part of the Cancer Genome Atlas analysis, 295 gastric cancers were analyzed. Four subtypes of gastric cancer were proposed: Epstein-Barr virus (EBV)–associated tumors that are associated with PD-L1 and PD-L2 amplification; microsatellite-unstable tumors; genomically stable tumors; and tumors with chromosomal instability.[51] The MSI-H cancers were again characterized to have high mutation rates. Likewise, PD-L1 expression on tumor and tumor immune infiltrates are more commonly associated with EBV+ or MSI-H gastric cancers.[50,52,53]

Other MSI-H Cancers

Microsatellite instability can be found across multiple tumor types at varying frequency.[35,37] These variations may be due to the baseline characteristics such as geographic region, stage of disease, and family history. Furthermore, the assay for detection of MMR or MSI varied as well. MSI can be detected in 2% of pancreatic adenocarcinomas, 10% of ampullary cancers, and 10% of ovarian cancers. The availability of data regarding the prognostic implications of MSI status varies among different histologies; however, once metastatic, the cancers are uniformly fatal. It is hypothesized that regardless of histology, the common features of immune cell infiltration, PD-L1 expression, and high mutation frequency will make MSI an important predictive marker for susceptibility to immune checkpoint blockade. Furthermore, routinely used assays are already being used to identify these patients, and MSI/MMR status is now also being reported on molecular profiling and next-generation sequencing panels.

Hints of PD-1 Antibody Activity in MSI-H Cancers

Intriguingly, PD-1 inhibition has shown some level of activity in these specific histologies known to have a subset of cancer with MSI. In CRC, single-agent PD-1 inhibition has only been active in MSI-H tumors. The single response in the first nivolumab study and the response in the PD-L1–positive selected study of pembrolizumab in CRC were found to be MSI-H.[54,55] PD-L1 was not a good predictive biomarker of response in the latter study. The overall response rate (ORR) was 13% in PD-L1–selected endometrial cancer.[56] MSI status has not been reported on these patients. However, in a study of pembrolizumab in PD-L1–positive gastric cancer, a 22% ORR was observed, with all eight responders achieving partial responses. Twenty-four tumors were tested for MSI and 17% (four tumors) were determined to be MSI-H. Of these, two MSI-H tumors were noted to have responded to treatment, accounting for at least 25% of the responses.[57,58]

In an analysis of 319 esophagogastric cancers by investigators at Memorial Sloan Kettering Cancer Center, they identified 12 patients with MSI-H tumors, of which three were treated with anti–PD-1 with best response of complete response, partial response, and stable disease. One patient with an EBV+ cancer had a complete response to combination PD-1 and cytotoxic T lymphocyte antigen-4 inhibition.[59]

MMR Deficiency as a Predictive Biomarker for PD-1 Inhibition

In a prospective study, MMR deficiency was explored as a predictive biomarker of response to pembrolizumab.[60] Patients with CRC were identified as MMR deficient based on immunohistochemistry testing for the MMR proteins or by polymerase chain reaction–based testing for MSI. An additional cohort of MSI-H non-CRC patients was also treated. The original article reported on 11, 21, and nine patients with MMR-deficient CRC, MMR-proficient CRC, and MMR-deficient non-CRC with ORR of 40%, 0%, and 71%, respectively. Importantly, in the MMR-deficient cohorts of patients who were all previously treated with standard therapies, the median duration of response and overall survival were not reached. Median follow-ups were 36 and 21 weeks for the MMR-deficient CRC and non-CRC cohorts, respectively. As expected, whole-exome sequencing resulted in a mean of 1,782 somatic mutations per tumor in MMR–deficient tumors and 73 in MMR-proficient tumors. Updated data reported at the 2016 ASCO Annual Meeting [61,62] showed the ORR was 57% with 11% complete response rate in the MMR-deficient CRC cohort and 53% with a 30% complete response rate in the MMR-deficient non-CRC cohort. The disease control rates were 89% and 73%, respectively. Responses were seen in CRC and endometrial, gastric, pancreaticobiliary, small bowel, and prostate cancers. At the same meeting, preliminary data with nivolumab was reported that showed an ORR of 26% with an additional 30% stable disease in MSI-H CRC.[63]

Based on a clinically significant response rate with longer-than-expected response duration in traditionally incurable advanced cancers, physicians and patients are optimistic that the evidence is accumulating that will allow access to these agents for patients outside of clinical trials and access programs.

REGULATORY CONSIDERATIONS REGARDING TISSUE-AGNOSTIC DEVELOPMENT

General Considerations

Federal regulations governing drug development do not require disease to be defined based on a single tumor type. Food-labeling regulations contain the following definition of disease: "… damage to an organ, part, structure, or system of the body such that it does not function properly (e.g., cardiovascular disease), or a state of health leading to such dysfunctioning (e.g., hypertension); except that diseases resulting from essential nutrient deficiencies (e.g., scurvy, pellagra) are not included in this definition."[64] Nevertheless, prior to determining whether a drug can be developed based on a molecular pathway, investigators or drug developers should determine whether the approach is scientifically and clinically appropriate. In the BRAF example cited above, tissue-agnostic development may not have been appropriate. Importantly, the mechanistic explanation for lack of response in CRC has been elucidated, and this has led to clinical trials that are investigating the effects of BRAF inhibitors in combination with other inhibitors of the MEK or EGFR pathways.[6,14,65]

Ultimately, determining whether a sponsor should develop a drug irrespective of histology will depend on several preclinical and clinical factors, including data supporting the scientific rationale (e.g., as discussed above) and the context of treatment of patients with different tumor types. For example, if a drug is most effective in combination regimens, tissue-agnostic development may not be appropriate given the differences in standard therapies administered to patients across tumor types. It may be more appropriate to consider tissue-agnostic development in situations where a drug-target combination appears to demonstrate very high activity (e.g., breakthrough-like) across multiple tumor types where the clinical effect can easily be demonstrated. Other developmental considerations may include differences in natural history across diverse cancers and how investigators or sponsors will propose to generate data in a sufficient number of patients with various tumor types.

Pediatric Development

An indication that is truly tissue agnostic would allow for the treatment of both adults and children. Such a tissue-agnostic approach, if appropriate, could therefore benefit children by bringing drugs to treat children with cancer more expeditiously. Sponsors who are assessing the effects of a drug across various tumor sites based on a biomarker should consider how they will address the needs of children who have a tumor that possesses that biomarker. For example, the FDA has recommended the inclusion of adolescents (age 12–17) in disease- and target-appropriate adult oncology trials.[66] Sponsors should determine whether additional formulations of a drug would be necessary to address the needs of younger children so that younger children can enroll in clinical trials and potentially benefit from that therapy.

Companion Diagnostic

A companion or complementary in vitro diagnostic (IVD) device provides essential information for the safe and effective use of a corresponding therapeutic product.[67] An analytically and clinically validated device reduces the risk of withholding appropriate therapy from a patient who is mutation/biomarker positive who receives a false negative test result or administering inappropriate therapy in the case of a false positive result.[67] From a practical perspective, for rare mutation-tumor combinations, it may be preferable to develop an IVD test as part of a larger panel of tests (e.g., as part of a next-generation sequencing panel). Factors unique to IVD development for tissue-agnostic use may include differences in amount of tumor collected at biopsy among different tumor types, differences in tumor heterogeneity among tumor types, and differences in stromal tissue surrounding tumors. The FDA recently published a perspective regarding both the potential benefits and challenges of complex IVD signatures.[68]

Sponsors are encouraged to meet with the FDA early to facilitate companion diagnostic development. FDA can provide advice to sponsors to determine whether an investigational device exemption is necessary to use an IVD in the trial and to provide guidance in regards to what data would be necessary to approve a companion IVD if the device is necessary for the safe use of the drug.

Residual Uncertainty

Uncertainty may arise in a development program about a drug's effectiveness in all tumor types with a specific fusion, mutation, or biomarker, particularly because some tumor-biomarker combinations may be exceedingly rare. The rarity of certain tumor-biomarker combinations may also make it impossible to conduct randomized trials, especially in settings where equipoise would not exist based on unprecedented antitumor activity observed in single-arm trials. For example, the FDA granted regular approval of crizotinib for ROS-1–positive non–small cell lung cancer based on the benefit of an objective response rate of 66% (95% CI, 51–79) by independent review and a median duration of response of 18.3 months.[69]

Depending on the strength of evidence across tumor types, multiple regulatory mechanisms exist to address this residual uncertainty. These range from requiring additional data in the premarket setting to requiring postmarketing data in the setting of accelerated approval. If data are adequately collected, "real-world" evidence also may provide supportive data regarding tumor response or lack thereof across rare tumor types.[70] Postmarketing requirements for drugs granted accelerated approval would not necessarily need to include randomized trials. Alternatively, if there is a histology-biomarker combination that is more common (e.g., ALK in lung cancer), a randomized trial (if necessary) in that dominant tumor type could be conducted to provide supportive evidence of safety and clinical benefit of a high (durable) response rate observed in other tumor types.

CONCLUSION

Ultimately, the goal of drug development is to bring effective drugs that benefit patients as quickly as possible.

Investigating the effects of a drug agnostic of tumor type may be one pathway for drug development; however, every drug presents unique circumstances in regard to the population of patients who might benefit from it. Furthermore, development agnostic of tumor type could actually slow drug development if there are differential effects across tumor types by diverting resources from enrolling patients in a predominant population or in the tumor type most likely to respond. Therefore, input from all stakeholders is recommended prior to embarking on such an approach.

GASTROINTESTINAL (COLORECTAL) CANCER

Personalizing Adjuvant Therapy for Stage II/III Colorectal Cancer

Nadine Jackson McCleary, MD, MPH, Al B. Benson III, MD, FACP, FASCO, and Rodrigo Dienstmann, MD

OVERVIEW

This review focuses on three areas of interest with respect to the treatment of stage II and III colon and rectal cancer, including (1) tailoring adjuvant therapy for the geriatric population, (2) the controversy as to the optimal adjuvant therapy strategy for patients with locoregional rectal cancer and for patients with colorectal resectable metastatic disease, and (3) discussion of the microenvironment, molecular profiling, and the future of adjuvant therapy. It has become evident that age is the strongest predictive factor for receipt of adjuvant chemotherapy, duration of treatment, and risk of treatment-related toxicity. Although incorporating adjuvant chemotherapy for patients who have received neoadjuvant chemoradiation and surgery would appear to be a reasonable strategy to improve survivorship as an extrapolation from stage III colon cancer adjuvant trials, attempts at defining the optimal rectal cancer population that would benefit from adjuvant therapy remain elusive. Similarly, the role of adjuvant chemotherapy for patients after resection of metastatic colorectal cancer has not been clearly defined because of very limited data to provide guidance. An understanding of the biologic hallmarks and drivers of metastatic spread as well as the micrometastatic environment is expected to translate into therapeutic strategies tailored to select patients. The identification of actionable targets in mesenchymal tumors is of major interest.

Although there is no uniform number at which physiologic aging occurs, there is little known about optimal treatment of colon cancer involving lymph nodes following surgical resection for adults age 75 or older.[1,2] A substantial number of patients with colorectal cancer (CRC; 40%) are adults age 75 or older.[3] Standards for adjuvant chemotherapy following resection of colon cancer were established based on results of three large randomized clinical trials: MOSAIC (Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer), NSABP C-07 (National Surgical Adjuvant Breast and Bowel Project), and XELOXA NO16968 (XELOX in Adjuvant Colon Cancer Treatment). Yet with less than 1% (MOSAIC) and 5% (NSABP C-07), respectively, of those trials including older adults, it proves difficult to extrapolate standards of adjuvant chemotherapy to older adults in the real-world setting (the proportion age 75 or older is not reported in XELOXA NO16968). Several pooled analyses show potential for survival benefit among some older adults; however, nearly two-thirds do not receive adjuvant treatment.[3,4] Nonreceipt of systemic chemotherapy is particularly prevalent among those older adults diagnosed with colon cancer who also have geriatric syndromes (e.g., delirium, frailty) or active comorbid medical conditions.[5] Expertise in delivering care to this growing subset of patients is predominantly driven by provider experience and possible bias, given the limited clinical trial data available to guide use of adjuvant chemotherapy in the older adult population. Here, we review the available data and recommendations for adjuvant treatment recommendations for adults age 75 or older diagnosed with stage III colon cancer.

TAILORING ADJUVANT THERAPY FOR THE GERIATRIC POPULATION

Adjuvant Chemotherapy for Stage III Colon Cancer

General population. The benefit of adjuvant chemotherapy has been clearly established in the adjuvant setting for node-positive colon cancer. Standard treatment options include fluorouracil (FU) or capecitabine with or without oxaliplatin (Table 1). The addition of FU to surgical resection led to 17% improvement in disease-free survival and 13% improvement in overall survival among patients with node-positive colon cancer.[6] The addition of capecitabine led to similar improvements in disease-free (hazard ratio [HR], 0.87; 95% CI, 0.75–1.00) and overall survival (HR, 0.84; 95% CI, 0.69–1.01) compared with bolus FU/leucovorin (p for equivalence < .001, with median follow-up of 3.8 years).[7] The addition of oxaliplatin to FU further leads to an absolute improvement in disease-free and overall survival at 10 years by an additional 8%.[8] The addition of oxaliplatin

Corresponding author: Al B. Benson III, MD, FACP, FASCO, Division of Hematology/Oncology, Robert H. Lurie Comprehensive Cancer Center, Northwestern University, 676 N. St Clair St., Suite 850, Chicago, IL 60611; email: a-benson@northwestern.edu.

to capecitabine results in a similar improvement, with reductions of 20% and 17% in the relative risk of recurrence or death (95% CI, 0.69–0.93; p = .004) and risk of death (95% CI, 0.70–0.99; p = .04), respectively.[9] The extent to which older adults derive benefit from adjuvant chemotherapy was not established in these trials, given that most trials limited participation to those younger than age 75[7,10] or limited the number of adults age 75 or older.[3,4]

Older adults. A number of pooled and subpopulation analyses have been conducted to fill the gap in knowledge regarding survival benefit of older adults receiving adjuvant chemotherapy for stage III colon cancer (refer to Table 1[23,24]). In a pooled analysis of seven randomized clinical trials of adjuvant chemotherapy included in the ACCENT (Adjuvant Colon Cancer End Points) study, older adults did not experience substantial benefit from adjuvant fluoropyrimidine or combination chemotherapy regimens regarding disease-free survival (HR, 1.05; 95% CI, 0.94–1.19), overall survival (HR, 1.08; 95% CI, 0.95–1.23), or time to recurrence survival (HR, 1.06; 95% CI, 0.93–1.22).[22] Older adults seemed to have a reduced overall survival benefit from oxaliplatin-based chemotherapy with a similar disease-free survival benefit compared with younger adults receiving oxaliplatin-based chemotherapy. There was no difference in rates of death within experimental or control arms, suggesting that it is unlikely that the substantial interaction noted between treatment and age would be explained by early deaths attributable to treatment-related toxicity.[22]

In contrast, comorbidity and age did not appear to affect disease-free or overall survival among older adults enrolled in four randomized clinical trials evaluating adjuvant fluoropyrimidine with or without oxaliplatin including comorbidity data defined by the Charlson Comorbidity Index or the National Cancer Institute Combined Index.[15] The ACCORE study evaluated 191 patients age 70 or older and 338 patients younger than 70 receiving adjuvant 5-fluorouracil (5-FU) or capecitabine with or without oxaliplatin for CRC in Denmark from 2001 to 2012.[25] Older adults experienced similar 10-year CRC-specific overall survival compared with younger patients but did experience higher rates of mortality owing to other causes after controlling for performance status and presence of comorbid medical conditions. Older adults received equivalent doses of capecitabine but fewer doses of oxaliplatin and 5-FU compared with younger patients. Disease-free survival and CRC-specific mortality were not affected by reductions in chemotherapy dose intensity. This and other pooled analyses from clinical trials are limited by the relatively small number of older adults enrolled. Despite this, rates of use of oxaliplatin found in the Surveillance, Epidemiology and End Results (SEER) database increased rapidly in adults age 65 or older diagnosed with stage III colon cancer (from 52% in 2004 to 73% in 2007, albeit at reduced rates among individuals older than 85 and those with comorbid medical conditions).[26]

In the general population of 5,489 adults 75 or older, 2,395 (44%) received chemotherapy within 120 days of surgery and 3,096 (56%) did not.[3] Rates of chemotherapy administration were higher in academic centers (75% in a National Comprehensive Cancer Network assessment [61% oxaliplatin]) versus nonacademic and community sites (42% in a SEER-Medicare analysis [42% oxaliplatin], 45% in a New York State Cancer Registry-Medicare study [28% oxaliplatin], and 52% in the CanCORS study). Oxaliplatin receipt decreased with increasing age, from 46% of adults age 75–79 to 7% among those age 85 or older. However, the benefit of adjuvant chemotherapy in this heterogeneous older population was comparable to that observed in pooled analyses of selected fit older adults participating in clinical trials, suggesting retention of survival benefit among subsets of older adults amenable to and receiving adjuvant chemotherapy within 120 days of surgical resection.

Older adults appear to receive a benefit from adjuvant chemotherapy in some, but not all, studies. Survival seems to differ across age categories, with decreasing survival benefit with increasing age. A review of the National Cancer Institute SEER database linked to the Medicare database (SEER-Medicare) noted a predicted increased 5-year survival benefit of 14% among patients age 70–74 compared with 8% among those age 80–84.[17] Survival benefit persists in older adults age 80–89, despite only 43% of the 8,141 octogenarians included in the National Cancer Database from 2006 to 2011.[4] Regardless of potential benefit for some older adults, older age remains the strongest determinant of initiation, duration, and completion of adjuvant chemotherapy.[3,27-29] Older adults are also more likely to have delays in initiation of adjuvant chemotherapy and are less likely to complete the full 6 months of adjuvant therapy, factors that also increase mortality risk.[25,30,31]

KEY POINTS

- **Age is the strongest predictive factor for receipt of adjuvant chemotherapy, duration of treatment, and risk of treatment-related toxicity.**
- **Available data support disease-free and overall survival benefit after adjuvant therapy among older adults age 70–74 years with colon cancer, but variable outcomes for those age 75 years or older.**
- **Attempts at defining the optimal rectal cancer population that would benefit from adjuvant therapy remain elusive.**
- **In stage II disease, microsatellite instability and/or high "immunoscores" associate with very good prognosis and support a no-adjuvant-treatment approach. On the other hand, empirical evidence for the addition of supervised gene expression classifiers to the clinical decision-making paradigm is scarce.**
- **Irrespective of tumor stage, activation of a gene expression signature of epithelial-mesenchymal transition correlates with an invasive-inflamed microenvironment infiltrated with stromal and immunosuppressive cells, which confers poor prognosis and limited benefit with standard adjuvant chemotherapies.**

TABLE 1. Survival Outcomes for Adjuvant Chemotherapy Among Older Adults

Trial (Year), Study Design	Treatment Arms	Older Adult Cohort, Age (No. of Patients)	Regimen-Specific Data	Disease-Free Survival	Relapse-Free Survival	Time to Recurrence	Overall Survival
NSABP C-06 phase III (2006[11])	UFT/LV vs. 5-FU/LV	≥ 60 (939)		1.41 (1.18–1.69); p = .002 (referent = age < 60)	N/A	N/A	1.40 (1.12–1.74); p = .03 (referent = age < 60)
National Cancer Database (2005[12]), retrospective study	Adjuvant chemotherapy	All (1990–1991: 12,413; 2001–2002: 14,187)	Receipt of chemotherapy (%):	N/A	N/A	N/A	Similar OS regardless of age
		70–79 (1990–1991: 4,103; 2001–2002: 4,086)	69	N/A	N/A	N/A	
		≥ 80 (1990–1991): 2,593; 2001–2002: 3,305)	39	N/A	N/A	N/A

Molecular Profile of CRC Among Older Adults

Could a molecular profile determine those older adults unlikely to benefit from adjuvant chemotherapy? We sought to identify a subset of molecular markers unique to older adults diagnosed with colon or rectal cancer. We examined the presence of the CpG island methylator phenotype; microsatellite instability (MSI); *KRAS*, *BRAF*, and *PIK3CA* mutations; and nuclear CTNNβ1 expression status by age at CRC diagnosis within a large prospective cohort study. Tumor nuclear CTNNβ1 appeared to be associated with higher mortality among older adults diagnosed with CRC.[32] However, subsequent examination of the impact of nuclear CTNNβ1 and a host of additional molecular factors on prognosis for older adults diagnosed with colon or rectal cancer did not confirm a particular molecular phenotype among older adults diagnosed with colon or rectal cancer (N. J. McCleary, MD, MPH, and A. J. Bass, manuscript in preparation, 2017). Additional study is underway to examine whether a particular molecular phenotype predicts survival among a cohort of older adults receiving chemotherapy for colon or rectal cancer.

Modifying Risk, Enhancing Benefit of Adjuvant Chemotherapy for Older Adults

Potential benefit from adjuvant chemotherapy in older adults must be balanced by the potential for risk attributable to increased toxicity, reduced organ function, sarcopenia, limited social support, or unanticipated decline in physical function.[33] Although prospective clinical trials cannot delineate patients most at risk for poor clinical or physical outcomes from specific adjuvant chemotherapy regimens, doses, or duration of treatment, we can glean recommendations for treatment decisions from a few notable studies.

First, we can predict treatment-related toxicity across multiple cancer types for older adults. Moving beyond the limitations of the Eastern Cooperative Oncology Group or Karnofsky performance status, the comprehensive geriatric assessment has been shown to predict those older adults at risk for toxicity across a number of cancer types and stages, including colon cancer.[34,35] The comprehensive geriatric assessment is a feasible, validated instrument that allows both patient and provider evaluation of functional status, medications, social support, cognition, nutrition, psychologic state, and comorbidity to better assess overall fitness. This assessment may identify issues affecting treatment decision making for both patient and provider. The geriatric assessment can predict overall morbidity and mortality but, more specifically, it can anticipate chemotherapy-related toxicity.[36-39] A cancer-specific comprehensive geriatric assessment has shown benefit in treatment selection for older adults diagnosed with lung cancer in the ambulatory setting[40] and for hospitalized older adults.[41] It is now being embedded within a prospective multicenter treatment clinical trial to assess its ability to risk-stratify patients (A. Hurria, personal communication, ALLIANCE meeting, Chicago, IL, November 2016). This and other indices of frailty,[42] or risk of increased morbidity and mortality associated with chemotherapy, will not only provide parameters for discussion with older adults regarding the additive risks versus benefits of adjuvant chemotherapy, but they will also potentially inform provider decision making regarding initiation and dosing of treatment.[43-45]

Second, we can consider the potential impact of particular adjuvant chemotherapy regimens on organ function and physical function absent from any specific comorbid medical condition. Common measures of performance status underestimate the physiologic changes in organ function occurring with aging.[24] Bone marrow reserves decrease with increasing age. Chemotherapy treatment can lead to depletion of the bone marrow, thereby increasing the risk of cytopenias and subsequent risks of bleeding or infection. Aging is also associated with decreases in renal and hepatic function, bone and muscle mass, and risks of altered cognition, potentially increasing the risk of treatment-related toxicity.[24] Exercise is recommended for secondary cancer prevention following resection of colon cancer and may serve as a useful adjunct during the postoperative treatment course.[46,47] However, older adults receiving chemotherapy are susceptible to a decline in physical function, potentially limiting their ability to exercise. Oxaliplatin-induced neuropathy further affects this physical decline and increases the potential risk of falls and limits independence.[24,48-50]

Third, we can discuss the relative benefit of adjuvant chemotherapy among those older adults with active, unmanaged comorbid medical conditions and competing risk of death or disability. Comorbid medical conditions appear to have a greater effect on older adults diagnosed with advanced CRC.[51] Comorbid medical conditions may impact drug absorption and clearance. The presence of comorbid medical conditions predict for concomitant medications and risk of drug interactions.[52] Regular careful review of patient medications, as promoted by geriatric assessment, can limit the potential risk of drug-drug interactions.[53] In the adjuvant setting, renal excretion of both capecitabine and oxaliplatin requires dose adjustment for creatinine clearance below 50 mL/min.[24] Capecitabine also requires dose adjustment for patients taking warfarin. Cognitive impairment increases the risk of nonadherence to capecitabine.

Finally, it is incumbent on us as oncology providers to understand the full impact of adjuvant chemotherapy on older adults beyond disease-free and overall survival.[54] Disease-free and overall survival are the primary outcomes used to determine the standards for adjuvant chemotherapy regardless of age at diagnosis. However, other clinical and quality outcomes may be of interest to patients. Although outcomes of interest have not yet been specifically identified for older adults, few clinical trials evaluate outcomes beyond traditional outcomes of disease-free and overall survival to include outcomes potentially pertinent to older adults, such as the impact of adjuvant chemotherapy on "quality of survival and functional independence."[34] Given this, we can consider the traditional outcomes as a measure of treatment response, but we cannot fully comment on other benefits that older adults may experience as a result of adjuvant chemotherapy. Adults age 65 or older reported greater decline in physical and mental health within the first 6 months of diagnosis of CRC compared with age-matched controls as part of the Medicare Health Outcomes Survey, particularly among patients diagnosed with stage III or IV CRC.[55] How do we best define "functional independence" and "quality of survival" over the course of adjuvant chemotherapy administration and afterward? What is an acceptable threshold for additional outcomes beyond which treatment should not be recommended regardless of potential disease-free or overall survival benefit? We must begin exploring those additional outcomes of importance to older adults to determine the full impact of adjuvant chemotherapy on older adults and develop strategies to improve outcomes globally.

CONTROVERSIES IN THE ADJUVANT SETTING

Adjuvant Chemotherapy for Rectal Cancer

For many years, the standard of care for patients with locally advanced clinical stage II to III rectal cancer included surgery, often resulting in a permanent ostomy, followed by adjuvant chemotherapy and chemoradiation.[11-14,16,18-21] This strategy improved both overall survival and the risk of locoregional failure. An example of the outcome benefits of combined adjuvant chemoradiation, published more than a decade ago, include the U.S. Intergroup 0144 trial, which evaluated the so-called sandwich approach of chemotherapy followed by chemoradiation followed by additional chemotherapy and compared bolus versus infusional 5-FU regimens for patients with T3-4N0M0 or T1-4N1,2M0 disease.[56] The locoregional failure rate for those who received low anterior resection was between 3% and 5%. Three-year overall survival was between 81% and 83%. A pooled analysis of North American phase III combined modality adjuvant trials identified three different risk groups defined by TN stage, including T1-T2N1 and T3N0 (intermediate); T1-2N2, T3N1, and T4N0 (moderately high); and T3N2, T4N1, and T4N2 (high), which correlated with survival and disease control.[57,58] Five-year overall survival rates for the intermediate group were 78%–85% compared with 25%–57% for those with high-risk lesions. Different treatment strategies depending upon risk were therefore implied. Subsequently there was a profound shift in the treatment approach for clinical stage II to III rectal cancer as data emerged supporting the use of neoadjuvant chemoradiation; however, this therapeutic evolution generated considerable controversy as to the role of adjuvant chemotherapy, a controversy that has persisted.

Neoadjuvant chemoradiation has become the preferred treatment of locally advanced rectal cancer because of evidence demonstrating improved outcomes, better tolerability, and, in many cases, considerable downstaging resulting in sphincter-preserving surgery and thus avoiding a permanent ostomy. A hallmark study from the Working Group of Surgical Oncology/Working Group of Radiation Oncology/Working Group of Medical Oncology of the Germany Cancer Society (CAO/ARO/AIO-94) compared preoperative chemoradiotherapy with postoperative chemoradiotherapy for locally advanced rectal cancer, demonstrating significant improvement in 5-year cumulative incidence of local relapse favoring a preoperative approach (6% vs. 13%; $p = .006$).[59] There were considerably less acute and long-term toxic effects in the preoperative group, although 5-year overall survival

rates were similar (76% vs. 74%). Patients also received four cycles of postoperative 5-FU. Long-term follow-up data showed improved outcomes for the preoperative patients who achieved complete and intermediate tumor regressions and the overall 10-year cumulative incidence of local relapse continued to favor the patients treated preoperatively (7.1% vs. 10.1%; p = .048); there was no change in overall survivorship (59.6% vs. 59.9%).[60,61] A recent meta-analysis of more than 10,000 patients who participated in randomized controlled trials confirmed the improved rate of local control with neoadjuvant chemoradiation, including after total mesorectal excision, although there was no improvement in long-term survival.[62]

Although incorporating adjuvant chemotherapy for patients who have received neoadjuvant chemoradiation and surgery would appear to be a reasonable strategy to improve survivorship as an extrapolation from stage III colon cancer adjuvant trials, attempts at defining the optimal rectal cancer population that would benefit from adjuvant therapy remain elusive. This paucity of consistent evidence has resulted in variability in practice patterns. For example, a National Comprehensive Cancer Network CRC database assessment of nearly 2,000 patients with stage II/III rectal cancer who received neoadjuvant chemoradiation showed that a sizable minority of patients did not receive adjuvant chemotherapy.[63] A SEER-Medicare database analysis noted that one in three patients did not receive adjuvant therapy after neoadjuvant chemoradiation and resection.[64]

Some investigations have attempted to select patients who may not require adjuvant therapy after neoadjuvant chemoradiation and surgery. For example, a study of 176 patients reported that those who achieved a complete response (15.3% of patients staged as ypT0M0) had 5-year disease-free and overall survival rates of 96% and 100%, respectively, suggesting that adjuvant therapy would provide no further meaningful benefit for these individuals.[65] In a retrospective study of 851 patients, 330 received preoperative short-course radiation (2,500 cGy administered in five fractions without chemotherapy) and 123 received adjuvant chemotherapy.[66] A subgroup analysis showed that adjuvant therapy improved disease-specific survival and overall survival only for those patients who had at least two high-risk features such as pT4 tumor, inadequate lymph node sampling, lymphovascular invasion, perineural invasion, poor differentiation, obstruction, or perforation.

EORTC 22921 was a randomized trial of 1,011 patients evaluating FU-based adjuvant chemotherapy after preoperative chemoradiation for patients with clinical stage T3 or T4 resectable rectal cancer.[67] Patients were assigned to one of four treatment arms including preoperative radiotherapy with or without chemotherapy and preoperative radiotherapy with or without chemotherapy followed by adjuvant chemotherapy. There was relatively poor adherence to adjuvant chemotherapy, because only 43% of patients received the planned dose. At a median follow-up of 10.4 years, there was no substantial difference in overall survival among the four treatment groups (48.4%–51.9%), nor were there differences in disease-free survival rates and cumulative incidence of distant metastases. Most recurrences were noted within 5 years. A recently reported Italian study of 634 evaluable patients concluded that adjuvant 5-FU did not improve 5-year overall or disease-free survival, including among those who obtained a complete pathologic response and overall downstaging rates; 28% of patients, however, never received the assigned adjuvant chemotherapy.[68] A Dutch study of 437 eligible patients closed prematurely for accrual reasons; however, there was no difference in 5-year cumulative incidence for either local regional recurrence or in 5-year distance recurrences after postoperative fluoropyrimidine monotherapy.[69]

Systematic reviews and meta-analyses also were recently reported to address the role of adjuvant chemotherapy after neoadjuvant therapy and surgery. An analysis of four phase III clinical trials of nearly 1,200 patients with ypTNM stage II and III rectal cancers and a R0 resection found no difference in overall survival comparing those who received adjuvant chemotherapy versus observation.[70] There were patients with tumors located at 10 to 15 cm from the anal verge who had improved disease-free survival and fewer distant metastases when treated with adjuvant chemotherapy. Another analysis of randomized controlled trials in retrospective studies of nearly 5,500 patients reported improvement in both 5-year overall survival and disease-free survival for those patients treated with neoadjuvant chemoradiation, surgery, and adjuvant chemotherapy.[71] The improvement in 5-year overall survival was largest among patients who were downstaged and in the retrospective series. A third systematic review and meta-analysis of five randomized trials including 2,398 patients did not show an advantage for those who received adjuvant chemotherapy although there was a substantial adjuvant chemotherapy effect for patients who were randomized after surgery (753 patients).[72] In two trials, there was a difference in disease-free survival for those who received FU and oxaliplatin compared with single-agent 5-FU; however, in two other trials, FU and oxaliplatin did not show a substantial difference. Overall, the authors concluded that adjuvant chemotherapy provided no "strong scientific evidence" to support its use for those who received preoperative chemoradiation.

A number of treatment strategies have been the subject of recent clinical trials and have informed current or planned global clinical trial portfolios[73,74] (Table 2). For example, there is interest in the "wait and watch" approach for patients who have obtained a complete response after chemoradiation and in strategies to encompass neoadjuvant chemotherapy while reserving radiation for those with suboptimal response.[73,74] The overall goal is to avoid more extensive intervention with the associated risk of toxicity and long-term sequelae for patients who may not need such an approach and to intensify therapy for those who are at highest risk for recurrence. Current National Comprehensive Cancer Network guidelines recommend a number of options for patients with clinical stage II and III rectal cancer, including (1) neoadjuvant therapy comprising long-course chemoradiation with either

capecitabine or infusional 5-FU, short-course radiation, or a preferred chemotherapy regimen with oxaliplatin and a fluoropyrimidine followed by chemoradiation; or (2) adjuvant therapy is recommended after surgery for those who have received neoadjuvant oxaliplatin and a fluoropyrimidine followed by chemoradiation surveillance, whereas adjuvant chemotherapy with oxaliplatin and a fluoropyrimidine is recommended as the preferred regimen for those treated with chemoradiation or short-course radiation.[75]

Adjuvant Therapy for Resectable Metastatic Disease

It has long been known that there is a subgroup of patients with colon or rectal cancer who have potentially resectable metastatic disease and can enjoy long-term survival after surgery. The introduction of combination chemotherapy for metastatic CRC has resulted in improvement in response, progression-free survival, and overall survival. In addition, there is a perceived benefit of combination chemotherapy for patients with resectable metastatic disease or those who obtain a substantial response to therapy rendering them with resectable disease. An advantage of preoperative chemotherapy for patients with resectable or potentially resectable metastatic disease is to determine "chemosensitivity" and also to identify those individuals who may be resistant to therapy and develop more rapid disease progression. For patients with rectal cancer and potentially resectable

TABLE 2. Select Current and Planned Rectal Cancer Trials

Trial	Treatment
NO148 PROSPECT phase III	FOLFOX × 6 → response ≥ 20% → TME → FOLFOX × 6
	FOLFOX × 6 → response < 20% → 5-FU/capecitabine RT → TME → FOLFOX × 2 *versus*
	5-FU/capecitabine RT → TME → FOLFOX x 8
NRG G1-002 (TNT) phase II	
High risk	FOLFOX × 8 → RT + capecitabine → surgery
	FOLFOX × 8 → RT + capecitabine + veliparib → surgery
	Additional arms planned

Low risk	Surgery → FOLFOX (pN+) *versus*
	Capecitabine RT → surgery → capecitabine
High risk	Capecitabine RT → surgery → capecitabine *versus*
	5-FU/oxaliplatin RT → FOLFOX → surgery
RENO	ChemoRT → cCR → watch and wait
RAPIDO phase III	ChemoRT → MRI/CT → response → TME → CAPOX *versus*
	RT → CAPOX → MRI/CT → response → TME

[a]ypT1^{Bad}, RI, high grade.

Abbreviations: 5-FU, fluorouracil; CAPOX, capecitabine/oxaliplatin; cCR, complete clinical response; chemoRT, chemoradiotherapy; FOLFOX, fluorouracil/leucovorin/oxaliplatin; pN+, pathologically node positive; RI, microscopic positive margin; RT, radiotherapy; TAMIS, transanal minimally invasice surgery; TEMS, transanal endoscopic micro-surgery; TME, total mesorectal excision.

metastatic disease, preoperative chemoradiotherapy is often considered to reduce the risk of local regional recurrence, particularly when the goal of surgery is curative intent.

A perioperative approach for those with resectable metastatic disease incorporates a total chemotherapy treatment period of approximately 6 months including preoperative therapy followed by surgery and adjuvant chemotherapy. The role of adjuvant chemotherapy, however, has not been clearly defined because of very limited data to provide guidance. A systematic review of 642 evaluable patients with liver metastases evaluated surgery versus surgery and chemotherapy, demonstrating improvement in disease-free and progression-free survival favoring chemotherapy without a survival advantage.[76] A meta-analysis of 10 studies including nearly 1,900 patients showed no survival benefit for patients who received perioperative chemotherapy for resectable liver metastases compared with surgery alone; however, a disease-free survival benefit was noted.[77] Similar results were observed in additional analyses.[78,79] EORTC 40983 evaluated six cycles of fluorouracil/leucovorin/oxaliplatin before and after surgical resection of liver metastases compared with surgery alone, demonstrating a 40% response to preoperative fluorouracil/leucovorin/oxaliplatin and improvement in progression-free survival for eligible patients who were resected with no overall survival benefit.[80] There is consensus in the National Comprehensive Cancer Network guidelines that adjuvant chemotherapy after resection of metastatic disease remains an option of care.[75]

MOLECULAR PROFILES AND THE FUTURE OF ADJUVANT THERAPY: MICROENVIRONMENT MATTERS

Retrospective biomarker analyses of multiple clinical trials in the adjuvant setting strongly support the feasibility of refining prognostic stratification in CRC by factoring in molecular features with pathologic tumor staging.[81] However, validated predictive markers of adjuvant therapy benefit for stage II or III CRCs are still lacking.[81] To date, the only molecular marker with proven clinical utility in early-stage CRC is MSI, which associates with very good prognosis in stage II disease irrespective of adjuvant chemotherapy, supporting a no-adjuvant-treatment approach.[82] On the other hand, patients with MSI stage III CRC derive benefit from adjuvant chemotherapy, with no differential benefit compared with the microsatellite stability (MSS) population in clinical trials assessing 5-FU or oxaliplatin-based regimens.[83] Interestingly, there is a possible interaction between MSI status and primary tumor location in stage III treated disease, with a better prognosis limited to right-sided tumors.[84] This association reinforces the known intrinsic biologic differences between proximal and distal CRC.[85]

Mounting evidence indicates that an enhanced lymphocytic reaction in CRC is a critical determinant of the risk of dissemination to distant metastasis.[86] A clinical translation of this finding was the establishment of a scoring system, called the "immunoscore," based on the abundance of two distinct lymphocyte populations ($CD8^+$ cytotoxic T cells and $CD3^+$ T memory cells) at the tumor center and at its invasive margin. In a large validation study, time to recurrence and overall survival were significantly longer for patients with stage II and III colon cancer with immunoscore high tumors, independent of clinicopathological factors.[87] MSI cancers characteristically exhibit strong infiltration of the tumor microenvironment with immune cells, which relates to hypermutation rates and higher neoantigen loads.[88] However, a subset of MSS tumors also have increased intratumoral adaptive immune gene expression and high immunoscores. These "immune-activated" tumors, irrespective of stage, have improved survival outcomes and the immunoscore was shown to be superior to MSI in predicting patients' disease-specific recurrence and survival in multivariable models.[89] These data strengthen the concept that reduced immune cytotoxicity is a major factor driving metastases in CRC. However, most patients with early-stage CRC have MSS and/or a medium/low immunoscore, which associate with an intermediate to poor prognosis and do not help prioritize adjuvant chemotherapy in stage II or III disease. The same is true for tumors harboring *BRAF* V600E mutations, which are an independent prognostic factor of reduced overall survival in multiple studies, particularly in MSS left-sided disease, but not a marker of chemosensitivity/resistance to 5-FU or oxaliplatin-based regimens in the adjuvant setting.[81]

In addition to microsatellite status and gene mutations, which did not demonstrate predictive value for standard chemotherapy benefit in early-stage CRC, different groups explored the potential clinical utility of gene expression signatures in this context. The transcriptomic profile of a tumor, encompassing cancer cell, immune, and stromal signals, is intimately linked to its phenotype and clinical behavior. Gene expression profiling has been used extensively to identify biologically homogeneous subtypes of the disease through unsupervised clustering. An international effort dedicated to large-scale data sharing and coordinated analytics cross-compared independent transcriptomic-based CRC subtyping systems and resulted in a consensus molecular classification that allows the categorization of most CRC tumors into one of four robust intrinsic subtypes.[90] The consensus molecular subtype (CMS) features are summarized in Table 3. There are striking differences in prognosis with this unsupervised gene expression signature, confirming that the biologic processes implicated in each subtype are clinically relevant.[90] The CMS4 mesenchymal group is associated with a significantly higher risk of distant relapse and death for patients diagnosed with early-stage CRC, irrespective of validated clinicopathological features, MSI status, and *BRAF* V600E mutations.[81] These tumors exert a proangiogenic and stromagenic influence on the microenvironment, which is highly infiltrated with endothelial cells and cancer-associated fibroblasts. In addition, CMS4 mesenchymal tumors are enriched with immunosuppressive cells, such as regulatory T cells, B cells, and myeloid-derived suppressor cells, which are negative regulators of cytotoxic T cells.[91-93] This effect is explained in part by high expression of transforming growth factor-β and chemokines attracting myeloid cells (C-C motif chemokine ligand CCL2) and related cytokines

(interleukin-23 and interleukin-17).[92,93] The proangiogenic/stromagenic/immunosuppressive phenotype of CMS4 mesenchymal tumors, with their invasive-inflamed microenvironment, is intimately linked to higher chances of metastatic spread and resistance to therapy.[94,95] Indeed, retrospective biomarker analysis of the NSABP C-07 randomized clinical trial showed poor prognosis and no benefit from adjuvant oxaliplatin-based chemotherapy in the subset of patients with stage III CRC whose tumors displayed a mesenchymal phenotype.[96] However, the clinical utility of using intrinsic CRC subtyping to identify patients for oxaliplatin treatment requires validation in independent clinical trial cohorts.

Similarly, the value of supervised gene expression classifiers for adjuvant chemotherapy selection remains to be proven. Different prognostic signatures, such as Oncotype DX Colon Cancer, ColoPrint, Veridex, and GeneFx Colon, have been widely evaluated retrospectively in clinical cohorts.[81] Irrespective of assay, gene panel size, and tissue source (fresh, frozen, formalin fixed, paraffin embedded), analysis of the various transcriptomes in CRC can effectively classify patients into subgroups at low and high risk of disease relapse. The original hypothesis was that patients whose tumors are categorized as high risk have increased benefit from adjuvant chemotherapy. In theory, the prognostic information provided by these signatures could have the greatest clinical utility when used as a complement to T stage and MSI status, specifically for patients who have pT3pN0 MSS disease.[97] However, the relative chemotherapy benefit for Oncotype DX Colon Cancer was shown to be similar across risk groups.[98,99] Despite the fact that gene expression–based risk scores seem to add little to risk models with known prognostic factors,[100] incorporation of the signature results into clinical practice was associated with changes in treatment recommendation for nearly 50% of patients with pT3pN0 MSS CRC compared with traditional clinicopathological assessment variables alone.[101] Prospective validation of these signatures has not yet been presented, and currently only one trial (PARSC [Prospective Study for the Assessment of Recurrence Risk in Stage II Colon Cancer Patients]) is comparing risk assessment using the ColoPrint profile versus a clinical risk assessment based on the investigator's judgment and American Society of Clinical Oncology recommendations for high-risk disease. Furthermore, economic studies assessing the cost-effectiveness of using gene expression signatures to select patients with CRC who have a high risk of relapse (and to base adjuvant chemotherapy decision making on this criterion) are not yet available. Given the fact that high risk scores in supervised signatures have substantial overlap with a mesenchymal phenotype,[102] it is understandable that these prognostic classifiers have limited predictive value for adjuvant chemotherapy selection. This finding is in stark contrast with prognostic gene expression classifiers in early-stage breast cancer, in which high risk scores associate with high proliferation rates and increased benefit from more aggressive adjuvant chemotherapy.[103]

In summary, pathways that coordinate the creation of an immunosuppressive microenvironment and stromal invasiveness are the key drivers of a prometastatic state in CRC.[86] These processes are strongly enriched in the CMS4 mesenchymal CRC population,[90] which is poorly responsive to standard chemotherapies.[95,96] The following investigations should be pursued by the scientific community: (1) correlating response patterns of targeted agents and immunotherapies with the CMS classification in existing clinical trials; (2) adapting the design of future trials, such as adding stratification factors or increasing their power to allow these retrospective correlative analyses to be performed; and (3) designing prospective clinical trials in CRC that incorporate new biomarkers with drug repositioning and/or novel matched targeted agents and immunotherapies.[91] Different academic groups are working on a practical and robust CMS classifier that works on formalin-fixed, paraffin-embedded primary CRC tissues (either gene expression or immunohistochemistry based).[104] Molecular classifiers based on

TABLE 3. Clinical and Molecular Features of Intrinsic Gene Expression–Based CRC Subtypes

Feature	CMS1 (MSI Immune)	CMS2 (Canonical)	CMS3 (Metabolic)	CMS4 (Mesenchymal)
Prevalence in early-stage CRC, approximate %	15	40	15	30
Primary tumor site	Enriched right side of the colon	Enriched left side of the colon and rectum	Enriched right side of the colon	Enriched left side of the colon and rectum
Cancer cell features	MSI, hypermutated, hypermethylated, enriched for *BRAF* mutations	MSS, chromosomal instability, EGFR, and ERBB2 upregulation	Mixed MSI/MSS status, chromosomal instability, metabolic deregulation, enriched for *KRAS* mutations	MSS, chromosomal instability, epithelial-mesenchymal transition and stemness
Microenvironment features	Infiltrated with cytoxic T, helper T, and natural killer cells	Limited immune cell or stromal cell infiltration	Limited immune cell or stromal cell infiltration	Highly infiltrated with stromal cells, regulatory T cells, B cells, and myeloid-derived suppressor cells
Prognosis	Better relapse-free survival and worse survival after relapse	Better relapse-free and overall survival	Better relapse-free and overall survival	Worse relapse-free and overall survival

Abbreviations: CMS, consensus molecular subtype; CRC, colorectal cancer; MSI, microsatellite instability; MSS, microsatellite stability.

intrinsic tumor phenotypes are already being investigated in prospective clinical trials in the metastatic setting, such as in the MoTriColor project, a large pan-European effort pioneering novel molecularly guided trials in metastatic CRC, but the biologic differences between micro- and macrometastatic disease must be taken into account when translating data garnered from advanced-stage CRC into early-stage disease regarding treatment decisions.[91] The recent failures with cetuximab and bevacizumab in adjuvant trials in stage III CRC exposed this challenge and call into question our traditional paradigm of drug development (namely, considering agents for testing in the curative setting only after they are found to be beneficial in the treatment of patients with metastatic disease). We believe that this new biologic understanding is expected to guide drug selection in future adjuvant clinical trials and is hoped to increase cure rates and survival in CRC.

Systemic Therapy for Metastatic Colorectal Cancer: From Current Standards to Future Molecular Targeted Approaches

Chloe E. Atreya, MD, PhD, Rona Yaeger, MD, and Edward Chu, MD

OVERVIEW

Over the past 20 years, substantial advances have been made in the treatment of patients with metastatic colorectal cancer (mCRC). In particular, there is now a wide range of options for the front-line treatment of mCRC. Sophisticated molecular technologies have been developed to identify novel prognostic and predictive biomarkers for CRC. DNA sequencing technology has made remarkable advances in recent years, primarily as a result of the development of next-generation sequencing and whole exome sequencing, which are powerful new tools for the discovery of predictive molecular biomarkers to facilitate the delivery of personalized medicine. In addition to tumor tissue, recent efforts have focused on analyzing circulating tumor DNA in peripheral blood. Herein, we review the evolution of standard chemotherapy and targeted therapy strategies for the treatment of mCRC in the front-line setting, the molecular technologies that are presently being used to facilitate our ability to practice individualized medicine, and the practical aspects of applying molecular biomarkers to everyday clinical practice.

CRC remains a major public health problem in the United States and worldwide. In 2017, there will be an estimated 135,000 new cases diagnosed in the United States.[1] CRC is the second leading cause of cancer deaths, with an estimated 50,000 deaths each year. Approximately 20% of newly diagnosed CRC is metastatic at the time of initial presentation. Perhaps more importantly, up to 50% of patients who initially present with early-stage CRC will eventually be diagnosed with metastatic disease. Substantial progress has been made in the treatment of mCRC during the last 2 decades, so that median overall survival (OS) is now in the 30-month range.

For patients with mCRC, systemic chemotherapy has been the main treatment approach.[2,3] For nearly 40 years, from the mid-1950s to 1996, the fluoropyrimidine 5-fluorouracil (5-FU) was the only agent approved for the treatment of mCRC. However, since 1996 with the approval of the topoisomerase I inhibitor irinotecan, considerable advances have been made with the approval of several cytotoxic, biologic, and targeted agents by the U.S. Food and Drug Administration. In addition to irinotecan, the cytotoxic agents include oxaliplatin, a third-generation platinum analog, and two oral fluoropyrimidines, capecitabine and TAS-102. Bevacizumab, an anti-VEGF antibody, was approved in 2004, along with cetuximab, an anti-EGFR antibody. In 2006, panitumumab, an anti-EGFR antibody, was approved for use in the disease-refractory setting, and in 2012, the anti-VEGF recombinant fusion protein, Ziv aflibercept, and regorafenib, a multikinase small molecule inhibitor, were approved.

OXALIPLATIN VERSUS IRINOTECAN

Four randomized clinical trials have directly compared the clinical efficacy of oxaliplatin-based chemotherapy with irinotecan-based chemotherapy in the first-line treatment setting.[4-7] The most well-known was the GERCOR C97-3 study conducted by Tournigand et al[4] in France, and this was the first large, randomized clinical trial investigating leucovorin plus 5-FU (46-hour infusion) and oxaliplatin (FOLFOX6) compared with leucovorin plus 5-FU and irinotecan (FOLFIRI) for the front-line treatment of mCRC. This study clearly documented the virtually identical clinical efficacy of FOLFOX6 and FOLFIRI chemotherapy with respect to overall response rate (ORR; 56% vs. 54%, respectively), median time to tumor progression (8.5 vs. 8.1 months), and median OS (20.6 vs. 21.5 months). Similar results were subsequently reported by the Gruppo Oncologico Dell'Italia Meridionale in Italy and the U.S. CALGB Cooperative Group (CALGB 80203).[5,6] The Hellenic Oncology Group in Greece conducted a clinical study in which the bolus weekly schedule of 5-FU was used instead of an infusional schedule as the backbone fluoropyrimidine regimen in combination with irinotecan or oxaliplatin, and they also showed no difference between irinotecan and oxaliplatin with respect to clinical efficacy.[7]

ORAL VERSUS INTRAVENOUS 5-FU

FOLFOX Versus XELOX

The NO16966 randomized phase III study was initially designed as a two-arm, open-label study to compare the clinical efficacy of leucovorin plus 5-FU (22-hour infusion) and oxaliplatin (FOLFOX4) with oral fluoropyrimidine plus capecitabine and oxaliplatin (XELOX).[8] When it was clear that bevacizumab was going to receive approval by the U.S. Food and Drug Administration, this study was subsequently amended to a two-by-two, placebo-controlled design with two of the arms including bevacizumab.[9] In the initial cohort of 634 patients who were treated with only FOLFOX4 or XELOX, no differences were observed with respect to ORR, progression-free survival (PFS), and OS. Both combination regimens were relatively well-tolerated. However, FOLFOX4 was associated with more grade 3/4 neutropenia (44% vs. 7%), febrile neutropenia (4.8% vs. 0.9%), and grade 3/4 venous thromboembolic agents (6.3% vs. 3.8%) than XELOX. In contrast, XELOX was associated with an increased incidence of grade 3 diarrhea (19% vs. 11%) and grade 3 hand-foot syndrome (6% vs. 1%) compared with FOLFOX4. Of note, the rates of grade 3/4 neurotoxicity were similar between XELOX and FOLFOX4.

Ducreux et al[10] conducted a randomized study of XELOX compared with FOLFOX6 in the first-line treatment of mCRC, and the primary endpoint of this study was overall ORR. The secondary endpoints were PFS, OS, quality of life, and pharmacoeconomics. No differences were observed between the XELOX and FOLFOX6 arms in terms of the clinical efficacy endpoints of ORR (42% vs. 46%, respectively), PFS (8.8 vs. 9.3 months, respectively), and OS (19.9 vs. 20.5 months, respectively). However, as had been previously reported in the N016966 study, the incidence of grade 3/4 myelosuppression was higher in patients treated with FOLFOX6 (47%) compared with XELOX (5%). Patients treated with XELOX experienced more grade 3/4 thrombocytopenia (12% vs. 5%) and diarrhea (14% vs. 7%) than those treated with FOLFOX6. In contrast to the NO16966 study, FOLFOX6 was associated with a higher incidence of neurotoxicity (26% vs. 11%) compared with XELOX.

KEY POINTS

- **Anti-VEGF and anti-EGFR antibodies can be effectively used in combination with cytotoxic chemotherapy for the first-line treatment of metastatic colorectal cancer.**
- **The sidedness of the primary tumor is an important factor in determining the potential role of anti-VEGF and anti-EGFR antibodies for the first-line treatment of metastatic colorectal cancer. Anti-EGFR antibody therapy should not be administered in patients with a right-sided primary tumor.**
- **Genomic testing should be performed at the time of diagnosis of metastatic disease to evaluate for potential alterations in the *KRAS*, *NRAS*, and *BRAF* genes, which will guide patient selection for anti-EGFR antibody therapy, and to also inform decisions about potential curative-intent resection of metastases.**
- **Induction chemotherapy with FOLFOXIRI, with or without bevacizumab, should be considered in patients with a *BRAF* mutation and good performance status.**
- **Treatment with the immune checkpoint inhibitors nivolumab or pembrolizumab should be considered in patients with microsatellite unstable/mismatch repair defective tumors, as per the 2017 NCCN guideline (U.S. Food and Drug Administration approval is pending).**

FOLFIRI Versus XELIRI

A meta-analysis of six clinical studies was conducted by Guo et al[11] to investigate the clinical efficacy of the oral capecitabine plus irinotecan (XELIRI) and FOLFIRI combination regimens in the first-line treatment of mCRC. No significant differences in clinical efficacy, as reflected in ORR, PFS, and OS, between XELIRI and FOLFIRI were identified. In terms of side effects, both treatment regimens were relatively well-tolerated with similar safety profiles.

The FNCLCC ACCORD 13/053 study was a randomized phase II clinical trial that investigated the efficacy and safety of XELIRI and FOLFIRI as first-line therapy of mCRC.[12] Patients were randomly assigned to receive XELIRI or FOLFIRI, and bevacizumab was included in both treatment arms. The 6-month PFS was 82% in the XELIRI arm and 85% in the FOLFIRI. In general, both XELIRI and FOLFIRI were well-tolerated with a manageable safety profile, and the most frequent toxicities were grade 3/4 neutropenia (18% vs. 26%, respectively) and grade 3 diarrhea (12% vs. 5%, respectively).

Triplet Cytotoxic Chemotherapy

In patients with good performance status and who are believed to be able to tolerate aggressive combination chemotherapy, it is clear that doublet chemotherapy has superior clinical efficacy over single-agent fluoropyrimidine chemotherapy, whether it is infusional 5-FU or oral capecitabine. The next issue to consider is whether triplet chemotherapy with all three of the active cytotoxic agents, 5-FU, oxaliplatin, and irinotecan, could provide improved clinical efficacy in the up-front treatment setting. To directly address this question, the Gruppe Oncologico Nord Ovest (GONO) of Italy conducted the first randomized phase III study to compare leucovorin plus 5-FU, oxaliplatin, and irinotecan (FOLFOXIRI) with FOLFIRI in the front-line setting.[13] A total of 244 patients were randomly assigned, and Falcone et al reported improved ORR, PFS, and median OS in patients treated with the FOLFOXIRI triplet combination regimen when compared with FOLFIRI. Moreover, treatment with FOLFOXIRI compared with FOLFIRI resulted in improved R0 surgical resection rate for all patients (15% vs. 6%, respectively) and for those specific patients with liver-limited disease (36% vs. 12%, respectively). The triplet combination regimen was fairly well-tolerated, although there was an increase in grade 2/3 neurotoxicity (19% vs. 0%) and grade 3/4 neutropenia (50% vs. 28%) compared with FOLFIRI. However, the incidence of febrile neutropenia and grade 3/4 diarrhea was not significantly different between the two treatment arms. A final analysis was conducted after a median follow

up of 5 years that confirmed the superiority of the FOLFOXIRI regimen.[14] In addition, a risk-stratified analysis based on the Köhne prognostic model was performed, which showed that FOLFOXIRI, when compared with FOLFIRI, was associated with improved PFS and OS in all risk subgroups.

FOLFOXIRI chemotherapy is associated with improvements in PFS and OS; the absolute benefit in OS is 7% at 5 years. In a relatively fit patient population, this triplet combination regimen is feasible and is associated with a manageable safety profile. Moreover, in patients who are able to undergo R0 surgical resection of liver-limited disease, there does not appear to be an increase in liver toxicity. Finally, initial treatment with FOLFOXIRI does not appear to have a negative effect on the outcomes of patients who received subsequent treatment in the second-line setting.

ANTI-VEGF VERSUS ANTI-EGFR THERAPY IN COMBINATION WITH CYTOTOXIC CHEMOTHERAPY

PEAK was a phase II study in which modified FOLFOX6 (mFOLFOX6) was used as the chemotherapy backbone, and patients were randomly assigned to receive the anti-VEGF antibody bevacizumab or the anti-EGFR antibody panitumumab.[15] A total of 285 patients were enrolled, and the primary endpoint of the study was PFS, with secondary endpoints of ORR, OS, and safety. Overall, ORR and median PFS were nearly identical between the arms treated with bevacizumab or panitumumab (54% vs. 58%, respectively, and 10.1 vs. 10.9 months, respectively). However, median OS was significantly improved in patients treated with panitumumab when compared with bevacizumab (34.2 vs. 24.3 months; hazard ratio [HR] 0.62; p = .009). When an extended *RAS* analysis was performed and the clinical data were re-analyzed, the improvement in OS was maintained with panitumumab compared with bevacizumab (41.3 vs. 28.9 months; HR 0.63). Moreover, median PFS in patients treated with panitumumab was found to be significantly improved by 4.5 months compared with bevacizumab (13 vs. 9.5 months; HR 0.65; p = .029).

FIRE-3 was a study conducted in Germany in which patients with previously untreated mCRC with wild-type *KRAS* were treated with the FOLFIRI chemotherapy backbone, and patients were randomly assigned to receive either bevacizumab or cetuximab.[16] The primary endpoint of this study was ORR, with secondary endpoints of PFS, OS, R0 surgical resection rate, and safety. In the original analysis of this study, ORR and PFS were virtually identical between the arms treated with bevacizumab or cetuximab (58% vs. 62%, respectively, and 10.3 vs. 10.0 months, respectively). However, a significant 3.7-month improvement in OS was observed in patients treated with cetuximab, which represented a 23% reduction in the risk of death (HR 0.77; p = .017). The safety profiles of the two arms of the study were as expected and manageable. This was the first direct head-to-head comparison of cetuximab and bevacizumab in the front-line treatment setting, and although ORR and PFS were identical, cetuximab treatment resulted in a potentially clinically meaningful improvement in OS. At the time of the initial publication and the presentation of this work at the 2013 ASCO Annual Meeting, the potential effect of the improvement of the FOLFIRI plus cetuximab combination remained unclear given the somewhat limited information relating to duration of second-line and subsequent salvage therapies.

In the United States, the CALGB/SWOG 80405 phase III randomized study compared the potential benefit of cetuximab and bevacizumab added to cytotoxic chemotherapy.[17] In contrast to the FIRE-3 study, the primary endpoint of this study was OS, and patients could receive either FOLFOX or FOLFIRI as their cytotoxic regimen depending on physician preference. Of note, 74% of patients received FOLFOX whereas 26% received FOLFIRI. Overall, no significant differences were observed in PFS (10.4 vs. 10.8 months, respectively) and OS (29.9 vs. 29.0 months, respectively) in patients treated with cetuximab compared with bevacizumab. When the specific chemotherapy regimen was analyzed, no significant differences in OS were identified among patients treated with FOLFOX or FOLFIRI chemotherapy. This was the largest randomized study in the front-line setting conducted to date, and the take-home conclusions were that FOLFOX/FOLFIRI in combination with either bevacizumab or cetuximab were effective treatment options and that an OS of approximately 30 months established a new benchmark for first-line treatment.

Venook et al[18] recently investigated the potential effect of primary tumor location on the clinical efficacy of patients treated on CALGB/SWOG 80405, and these findings were reported at the 2016 ASCO Annual Meeting. In a careful chart review, they determined that 68% of the primary tumors came from the left side of the colon or rectum and 27% of the tumors came from the right side. When OS was determined by sidedness of the primary tumor, there was an improvement in OS for patients with left-sided tumors compared with right-sided tumors (33.3 vs. 19.4 months, respectively), which was highly significant (p < .0001). For patients treated with bevacizumab, the improvement in OS was maintained in patients with left-sided tumors compared with right-sided tumors, albeit still higher for left-sided primary tumors (31.4 vs. 24.2 months, respectively). However, in patients treated with cetuximab, there was a striking 19.3-month difference in which OS was 36.0 months for left-sided tumors and only 16.7 months for right-sided tumors. These findings are important as they highlight the importance of sidedness as an important predictive marker and the role of sidedness in determining response to anti-EGFR antibody therapy and has now been confirmed in other clinical studies.[19,20] Patients with right-sided tumors clearly derive greater benefit from bevacizumab compared with cetuximab and, in fact, derive little benefit from cetuximab. In contrast, patients with left-sided tumors derive benefit from both cetuximab and bevacizumab, although it appears that the median OS is improved by nearly 5 months with cetuximab.

Triplet Cytotoxic Chemotherapy in Combination With Biologic Agents

TRIBE was a multicenter, phase III study conducted in 34 Italian oncology centers in which patients with mCRC were randomly assigned to receive FOLFOXIRI plus bevacizumab or FOLFIRI plus bevacizumab as first-line treatment.[21,22] A total of 508 patients were enrolled in this study. The median PFS was 12.1 months with FOLFOXIRI plus bevacizumab compared with 9.7 months with FOLFIRI plus bevacizumab (HR 0.75; p = .003), and ORR was increased to 65% compared with 53% for patients treated with FOLFIRI plus bevacizumab. The median OS was 31 months in the FOLFOXIRI plus bevacizumab group compared with 25.8 months in patients treated with FOLFIRI plus bevacizumab, and this difference approached significance (HR 0.79; p = .054). Of note, the FOLFOXIRI/bevacizumab combination was equally effective in wild-type and mutant *KRAS* tumors, and although the numbers were small, this combination appeared to be especially active in the mutant *BRAF* subgroup.

To date, only phase II studies have investigated FOLFOXIRI in combination with the anti-EGFR antibodies cetuximab and panitumumab. Saridaki et al[23] conducted a pilot phase II study of FOLFOXIRI plus cetuximab, and they reported an ORR of 70%, with median time to progression of 10.2 months and median OS of 30.3 months. In addition, R0 surgical resection was performed in 37% of patients. Although this combination regimen was relatively well-tolerated, the incidence of grade 3/4 diarrhea was 53%. The GONO group in Italy investigated the combination of FOLFOXIRI plus panitumumab in patients with wild-type *RAS* and *BRAF* mCRC, and they reported an 89% ORR and a median PFS of 11.3 months.[24] In addition, R0 surgical resection was achieved in 35% of the treated patients. Once the 5-FU infusion dose was reduced from 3,000 mg/m^2 to 2,400 mg/m^2 after two of the first three patients experienced grade 3/4 diarrhea, this combination regimen was found to be well-tolerated, and the most common grade 3/4 toxicities were neutropenia (48%), diarrhea (35%), asthenia (27%), mucositis (14%), and skin conditions (14%).

CURRENT TREATMENT OPTIONS FOR MCRC

In 2017, there is now a wide range of treatment options for the first-line therapy of mCRC.[25] The current standard of care for first-line treatment is combination cytotoxic chemotherapy using the fluoropyrimidine backbone (5-FU or capecitabine) with either oxaliplatin (FOLFOX or XELOX) or irinotecan (FOLFIRI or XELIRI) in combination with the anti-VEGF agent bevacizumab or anti-EGFR agents (cetuximab or panitumumab) for patients with wild-type *RAS* and *BRAF*. The choice between bevacizumab and anti-EGFR agents for the first-line setting in patients with wild-type *RAS* depends on clinical presentation and individual patient factors. Recent studies suggest that the sidedness of the primary tumor is an important predictive biomarker and that patients who present with right-sided primary tumors derive little benefit from anti-EGFR therapy. Patients with left-sided primary tumors derive clinical benefit from either bevacizumab or cetuximab, although it appears that the benefit may be greater with cetuximab.

MOLECULAR PROFILING OF CRC: WHAT, WHEN, AND HOW

Genomic analysis of mCRC provides both prognostic and predictive information. Genomic analysis should be performed in all patients with mCRC, including patients with limited tumor burden who are being evaluated for hepatectomy or other metastasectomy. The National Comprehensive Cancer Network (NCCN) guideline recommends genomic testing at the time of diagnosis of metastatic disease.[25] An array of sequencing tests, which differ in the number of genes analyzed, depth of sequencing, and evaluation of mutations and/or copy number alterations, are currently available.

For clinical care, genomic analysis should evaluate for the presence of activating mutations in the *KRAS*, *NRAS*, and *BRAF* genes to guide the selection of patients for the anti-EGFR therapies, cetuximab or panitumumab. The *KRAS*, *NRAS*, and *BRAF* are oncogenes that encode proteins involved in the classic mitogen-activated protein kinase (MAPK) pathway that regulates cell proliferation and survival, and mutations in these genes are found in about 45%, 4%, and 8% of mCRC, respectively.[26] Activating mutations in these genes occur as an early event in colorectal tumorigenesis[27] in defined hotspots, and *KRAS*-, *NRAS*-, and *BRAF*-activating mutations are nearly universally exclusive.[28] In mCRC, either the primary tumor or metastasis can be analyzed. Studies of paired tumors suggest near complete concordance for mutations in *KRAS*, *NRAS*, and *BRAF* between colorectal primaries and metastases.[29,30]

Genomic alterations in the *KRAS*, *NRAS*, and *BRAF* genes provide predictive information for the selection of patients for the anti-EGFR antibodies cetuximab or panitumumab. Activating mutations in these genes result in constitutively activated proteins, whose activation does not require upstream signaling, such as through EGFR, and whose activation leads to negative feedback loops that limit EGFR activation. Multiple clinical trials indicate that colorectal tumors harboring activating *KRAS* or *NRAS* mutations do not benefit from anti-EGFR therapies and may actually experience accelerated growth with use of these drugs.[26,31,32] Thus, prior to the consideration for treatment with the anti-EGFR antibodies, *RAS* mutation testing should be performed to analyze for mutations, both at the more common sites in exon 2 (codons 12 and 13) and outside exon 2 (exon 3 at codons 59 and 61, and exon 4 at codons 117 and 146). In colorectal tumors harboring BRAF V600E mutations, increasing evidence through subset analysis of clinical trial and retrospective data also suggest lack of response to EGFR inhibitors, both as single agents and in combination with chemotherapy. In addition, two meta-analyses found no PFS benefit for EGFR inhibitors in BRAF-mutant mCRC.[33,34] These data are limited by the overall low frequency of BRAF V600E mutation and the aggressive nature of mCRC with this mutation (see below).

Genotyping the *KRAS*, *NRAS*, and *BRAF* genes also provides important prognostic information. Several studies have evaluated the effect of *KRAS* mutations on the outcomes of patients with mCRC. Although early results were inconsistent, as some studies found no effect and others found harm associated with *KRAS* mutations, recent data increasingly suggest that the presence of a *KRAS* mutation is associated with worse outcomes. A retrospective analysis of 918 patients with mCRC at Memorial Sloan Kettering Cancer Center identified an HR of 1.6 (95% CI, 1.29–1.90; p < .001) for OS with the presence of a *RAS* mutation on multivariate analysis adjusting for age at diagnosis of metastatic disease, gender, location of primary tumor, synchronous or metachronous disease, and occurrence of metastasectomy or hepatic arterial infusion treatment treated as a time-dependent covariates.[35] Few series have looked at outcomes in *NRAS*-mutant mCRC. An updated analysis from Memorial Sloan Kettering Cancer Center found that, compared with *RAS*–wild-type mCRC, *NRAS*-mutant and *KRAS*-mutant mCRC had an HR of 2.0 (95% CI, 1.3–2.8; p < .01) and 1.5 (95% CI, 1.2–1.8; p < .01) for OS, respectively, on multivariate analysis (Rona Yaegar, unpublished data). The presence of the BRAF V600E mutation is a strong negative prognostic marker in mCRC. Data from the randomized phase III Medical Research Council COIN trial in mCRC, for example, identified an OS of 8.8 months for patients with *BRAF*-mutant mCRC, 14.4 months for *KRAS* exon 2–mutant mCRC, and 20.1 months for *KRAS* exon 2–wild-type mCRC.[36] Similarly, many series have reported median OS of less than a year for *BRAF*-mutant mCRC.[26,37] The presence of a *BRAF* mutation in mCRC has been associated with T4 primary tumors, poor tumor differentiation, and peritoneal metastasis.[37-40]

The presence of mutations in the *RAS* and *BRAF* genes may also influence recurrence risk after metastasectomy, and patients with *RAS*-mutated or *BRAF*-mutated tumors should be carefully selected for surgical treatment with curative intent. In patients undergoing hepatectomy for colorectal liver metastases, the presence of a *RAS* mutation, in comparison with wild-type the wild-type variant, was associated with significantly worse recurrence-free survival (RFS) and OS, with similar liver RFS at 3 years, but lower lung RFS at 3 years.[41] In *RAS*-mutant mCRC, there is a high risk of recurrence as well as shorter survival after hepatectomy in node-positive primary tumors, larger tumors, and after more than 7 cycles of preoperative chemotherapy. The presence of a *BRAF* mutation is associated with a high risk of recurrence after metastasectomy of liver, lung, or peritoneal disease, and patients with *BRAF*-mutant mCRC experience shorter survival after metastasectomy compared with patients with *BRAF*–wild-type disease.[42] Patients with *BRAF*-mutant mCRC should be carefully selected and informed of the increased risk of recurrence before metastasectomy; and, unless metastatic disease is truly limited, systemic clinical trial options (see below) should be considered rather than aggressive surgical debulking.

Prior to an appreciation for the need to perform extended *RAS* genotyping, clinical testing should focus on hotspot alterations in exon 2 of *KRAS*. Genotyping of codons 12 and 13 in exon 2 of *KRAS* was often done with Sanger sequencing or real-time polymerase chain reaction (PCR).[43] Sanger sequencing is limited by low sensitivity with a limit of detection of about 20% and is laborious. Real-time PCR is more sensitive, but requires unique primers for each possible mutation. PCR-based assays have been expanded to cover all hotspots in *RAS* and can be used for extended *RAS* testing. However, with the decreased cost of sequencing, many groups have shifted to multiplexed genotyping platforms that include more genes. A mass spectrometry based multiplatform assay can detect alterations with a sensitivity limit of detection of about 5%. For this assay, the target DNA is amplified, a single base extension is performed, and then the small DNA products with unique mass value according to the mutation generated are measured by a mass spectrometer. These assays can analyze several genes in a single sample and genotype multiple hotspots, but require prior knowledge of all potential mutation sites of interest. In recent years, target enrichment by hybrid capture has allowed next-generation sequencing (NGS) of subsets of the genome of clinical interest, as done by FoundationOne, Caris Life Sciences, and Tempus.[44] NGS assays are highly sensitive, can analyze a large panel of genes, and detect novel mutations, small insertions and deletions (indels), copy number alterations, and select gene fusions and rearrangements from small amounts of DNA.

In addition to providing predictive and prognostic information, when using a multigene NGS panel to perform molecular profiling of mCRC, the number of mutated genes identified can be used to discriminate between somatic mCRC and microsatellite-unstable mCRC.[45] Microsatellite instability–high (MSI-H) mCRC results from mutations in the mismatch repair (MMR) genes that cause a malfunctioning gene product or from promoter methylation causing epigenetic silencing of MMR protein expression and is diagnosed with a PCR assay to identify changes in length of dinucleotide/trinucleotide repeats or with immunohistochemical analysis for retained expression of the MMR proteins (MLH1, MSH2, MSH6, PMS2). MSI-H tumors exhibit a higher mutation burden. Using a small number of test cases with known MSI status, a mutation number cutoff to discriminate between microsatellite-stable (MSS) and MSI-H cases can be identified.[46] The mutation number cutoff varies by the assay and the number of genes analyzed. Information about MSI status of mCRC now has important clinical implications, and the updated 2017 NCCN guideline recommends that all mCRC be evaluated for MMR deficiency, and the anti-PD1 antibodies, pembrolizumab and nivolumab, have been added as treatment options for patients with unresectable MSI-H or MMR-deficient mCRC.[25] Use of a single assay may provide a cost-effective option to both evaluate *RAS* and *BRAF* mutation status and screen for microsatellite instability in mCRC.

Because activating mutations in the *KRAS*, *NRAS*, and *BRAF* genes are nearly universally exclusive, some groups use a hierarchical system of genotyping to improve cost-effectiveness

of genomic analysis. Genomic alterations are analyzed sequentially—usually first in *KRAS* exon 2, then extended *KRAS* testing, BRAF V600E, and finally *NRAS* testing based on frequency of these alterations—with the analysis halted if a mutation is detected. In tumors that are wild-type at all three genes, it may be worth considering alternative driver alterations that may impact response to EGFR inhibition and may be targetable. *ERBB2* amplification and *MAP2K1* mutations appear to predict resistance to EGFR inhibition and may be targetable.[46-49] NTRK fusions, although very rare in mCRC, are potentially targetable and early clinical trials with novel agents that target NTRK alterations have reported promising initial results.[50]

Cell-free fragments of DNA are shed into the bloodstream by cells undergoing apoptosis and necrosis, and the circulating free DNA (cfDNA) released by tumor cells can be collected and amplified to look for somatic mutations. Looking to the future, cfDNA may represent a novel method to perform molecular profiling in mCRC, obviating the need to obtain tumor tissue and potentially allowing for a noninvasive method to perform genomic analysis at multiple time points during therapy, evaluating for clonal evolution, as well as molecular mechanisms of response and resistance. Both focused analysis for several genes and multigene NGS assays have been applied to detect somatic alterations within circulating tumor DNA in mCRC.[51] Genomic analysis of cfDNA has been done most often in patients with response to targeted therapy who then acquire resistance.[52,53] The use of cfDNA to characterize *KRAS*, *NRAS*, and *BRAF* mutation status and guide the use of EGFR inhibitor treatment is not standard in mCRC and may be limited by the lower sensitivity of the assay.

TRANSLATING BIOMARKERS INTO CLINICAL PRACTICE

RAS Mutations

If a mutation is detected in *KRAS* or *NRAS* at codons 12, 13, 61, 117, or 146, the recommendation is for cetuximab or panitumumab to not be considered as potential treatment options.[54] RAS remains an elusive target, although many early phase trial strategies are aimed at targeting RAS and/or its downstream effectors. One study that has generated a great deal of interest is the phase 1B study of the MEK inhibitor, cobimetinib, combined with the anti-PD-L1 agent, atezolizumab.[55] Based on prior clinical data, neither drug along would be expected to produce responses in *KRAS*-mutated, MSS mCRC tumors. In combination, however, the ORR to cobimetinib plus atezolizumab was 20% in 20 *KRAS*-mutant tumors, with the majority of responses or disease stabilization persisting for more than 6 months. It is now hypothesized that MEK inhibitor–mediated intratumoral T-cell infiltration and MHC I upregulation is a *RAS* mutation–independent effect. For this reason, the follow-up phase III trial (NCT02788279) allows up to half of patients to have *RAS* wild-type tumors.

If a tumor is found to be *RAS* wild-type, additional biomarker testing should be considered to try to identify potentially actionable targets. It should also be noted that as per the 2017 NCCN guideline, cetuximab and panitumumab therapy are only recommended for left-sided tumors, further refining the appropriate patient population for anti-EGFR antibodies.[25]

MSI/MMR

The anti–PD-1 antibodies, pembrolizumab or nivolumab, have been included as treatment options for patients with unresectable MSI-H or MMR-deficient CRC in the recently updated 2017 NCCN guideline[25]; although, as of this writing, neither agent is U.S. Food and Drug Administration–approved for mCRC. The data to support the NCCN recommendation come from the interim results of KEYNOTE-016, a phase II study of pembrolizumab in MSI-H tumors (NCT01876511), and CheckMate 142, a study of nivolumab or nivolumab combinations in recurrent or mCRC (NCT02060188).[56-58] Given the limitations of cross-study comparisons, these results are summarized in Table 1. With immunotherapy, time to response may be long, such that response rates tend to increase as the data matures. Whereas primary progression occurs quickly, responses and stable disease are impressively durable.

KEYNOTE-164 is a phase II trial of pembrolizumab as monotherapy in patients with previously-treated MSI-H/MMR-deficient mCRC, and this study is now closed to accrual after reaching the planned enrollment of 120 patients.[60] For newly identified patients with MSI-H/MMR-deficient mCRC, KEYNOTE-177 is an ongoing phase III study of first-line pembrolizumab compared with standard of care chemotherapy with a planned enrollment of 270 patients (NCT02563002).[61]

In response to those patients with MSS mCRC who ask about immunotherapy, none of the 25 patients with MMR-proficient mCRC who received pembrolizumab during the phase II study achieved objective responses (median

*Patients were randomly assigned to treatment.

Abbreviations: ORR; objective response rate; DOR, duration of response; PFS, progression-free survival; OS, overall survival; NA, not available; NR, not relevant.

PFS, 2.4 months); comparable results were observed for the 20 patients with MSS mCRC treated with nivolumab with or without ipilimumab.[56,57] Research efforts are underway to identify a subset of patients with immune-infiltrated MSS tumors who may benefit from checkpoint blockade.[62] In addition, several combination strategies are being developed to prime MSS tumors for immunotherapy by first inducing intratumoral T-cell accumulation, including the cobimetinib plus atezolizumab trial discussed above.

BRAF Mutations

The presence of a BRAF V600E mutation predicts aggressive disease biology and poor response to standard therapies including anti-EGFR antibodies.[26,37,63-66] However, the potential treatment implications of favorable prognosis *BRAF* mutations at codons 594 and 596 are less clear.[67,68] With a BRAF V600 mutation, the ability to achieve disease control with first-line therapy may be a critical determinant of survival outcomes.[69] In patients with good performance status, induction therapy with FOLFOXIRI should be considered.[70] The TRIBE study showed that the median OS of 53 patients with *BRAF*-mutated CRC was 19 months when treated with first-line FOLFOXIRI plus bevacizumab compared with 10.7 months with FOLFIRI plus bevacizumab (HR 0.54; 95% CI, 0.24–1.20).[22] Additionally, approximately a quarter of BRAF V600E–mutated mCRCs also exhibit MMR/MSI. Responses to checkpoint inhibitor therapy have been observed in the presence of a *BRAF* mutation and MMR/MSI.[58,71] As such, immunotherapy options, such as enrollment on the KEYNOTE-177 trial (NCT02563002) and/or other immunotherapy-based clinical studies should be considered in this setting.

Several studies have investigated the role of BRAF inhibitors as single-agents and in various combination strategies, for the treatment of BRAF V600E–mutated mCRC[72-79] (Table 2). What we have learned thus far is that BRAF inhibitor monotherapy is ineffective, although inclusion of a BRAF inhibitor in a combination strategy appears to be important, and three-drug therapies are somewhat more active than doublets. In the first randomized comparison with a standard of care regimen, the S1406 cooperative group study found that the addition of vemurafenib to irinotecan plus cetuximab significantly improved PFS (HR 0.42; 95% CI, 0.26–0.66; p < .001).[76]

Some patients clearly benefit from targeted inhibitor strategies, although disease stabilization is more common than radiographic response. Early emergence of drug resistance remains a challenge. For newly identified patients with *BRAF* V600E-mutated mCRC, an ongoing phase III trial that is expected to enroll 645 patients, BEACON CRC, is testing the combination of binimetinib (MEK inhibitor) with encorafenib and cetuximab, as compared with standard therapy (NCT02928224).

HER2 Amplification/Overexpression

The presence of HER2 amplification or a HER2-activating mutation may predict resistance to anti-EGFR antibodies. However, the current NCCN guideline does not yet discourage the use of cetuximab or panitumumab.[25,48,80-82] Several HER2-directed treatment strategies have been, or are being, evaluated in mCRC.[49,83-85] HERACLES (HER2 Amplification for Colorectal Cancer Enhanced Stratification) was the first large, phase II clinical trial to evaluate the tyrosine kinase inhibitor lapatinib in combination with the HER2-targeted monoclonal antibody trastuzumab in patients with HER2-amplified mCRC. HER2 positivity was defined as 2+/3+ by immunohistochemistry or fluorescence in situ hybridization–positive. The HERACLES study found that 27 patients with HER2-amplified mCRC refractory to standard therapy, including anti-EGFR antibodies, had a 30% response rate to lapatinib plus trastuzumab, with an 8.9-month median duration of response and a median PFS of 4.9 months.[49] A follow-up study, HERACLES-RESCUE, is evaluating T-DM1 after progression during trastuzumab and lapatinib treatment is underway.[86] T-DM1 is an antibody-drug conjugate whereby trastuzumab (the T portion) is connected via a stable

thioether linker to emtansine (the DM1 portion), a potent microtubule chemotherapy agent. Once trastuzumab binds to HER2-expressing cells, the linker is broken down, releasing DM1 intracellularly.

Considerations for patients with newly identified HER2 overexpression include ongoing basket trials. NCI-Molecular Analysis for Therapy Choice (NCI-MATCH, NCT02465060) is testing T-DM1 in HER2-amplified cancers and afatinib, an irreversible tyrosine kinase inhibitor that targets HER2, EGFR, and HER4, in HER2-mutated cancers. The MyPathway study is testing the combination of trastuzumab with pertuzumab, a monoclonal antibody that inhibits HER2 homodimerization and heterodimerization with other HER family members, in HER2-amplified and mutated tumors (NCT02091141).[85] The interim efficacy data from 34 patients enrolled in MyPathway is similar to what has been reported with the HERACLES study: 38% ORR, with a 10.3-month median duration of response, and a median PFS of 4.6 months. Notably, none of the nine patients with mutant KRAS and HER2-amplified/overexpressed mCRC responded to trastuzumab plus pertuzumab.[85,86]

Emerging Biomarkers

The aforementioned basket trials and several smaller studies contain rational therapeutic options for a large number of genetic aberrations found in CRC, including *EGFR*, *AKT*, *PIK3CA*, and *MAP2K1* mutations, as well as *MET* and *FGFR* amplification. Additionally, PARP inhibitors may be effective for *BRCA1/2*-mutated CRCs. Other emerging CRC-relevant DNA damage response targets include ataxia-telangiectasia–mutated (*ATM*) and ataxia-telangiectasia and Rad3-related (*ATR*).[87] Oncogenic fusions are of particular interest, as their targeting has led to exquisite responses in other cancer types. As proof-of-concept, patients with mCRC with a *NTRK1* and an *ALK* gene rearrangement were treated with entrectinib, a selective pan-TRK, ROS1, and ALK inhibitor.[50,88] Both patients experienced partial responses. A basket study of entrectinib for the treatment of patients with NTRK, ROS1, or ALK fusions is ongoing (NCT02568267). For patients with high *RSPO3* gene expression, which may arise from translocations of *RSPO3* and *PTPRK*, a trial of the anti-RSPO3 antibody, OMP-131R10, is in progress (NCT02482441).

In 2017, *KRAS*, *NRAS*, *MSI/MMR*, and *BRAF* are the main molecular markers that currently influence standard-of-care practice. However, enrollment of patients with these and other potentially actionable biomarkers in clinical trials holds promise for making increasingly personalized and effective treatment options available to future patients with mCRC.

GASTROINTESTINAL (NONCOLORECTAL) CANCER

Best Practices and Practical Nuances in the Treatment of Gastric Cancer in High-Risk Global Areas

Federico A. Sanchez, MD

OVERVIEW

Gastric cancer is an aggressive disease that is very frequent in Latin America. The reasons for this increased incidence is not clear. Associated with the lack of minimum health care opportunities, lack of accurate statistics and reporting data beyond epidemiologic data, and raw nonreliable data, there is little known of the actual clinical course and treatment of these patients. Understanding epidemiologic data may allow us to encourage the adequate use and distribution of the meager resources that exist.

The incidence of gastric cancer in Latin America and in Central America is quite high. In the neighboring countries of Central America—Guatemala, El Salvador, and Honduras—the incidence of gastric cancer is high enough to be considered the most common malignancy. Actual statistics and information about the number of occurrences and the clinical course of this condition are unknown. In Central America, with the exception of Panama and Costa Rica, a mature, well-developed cancer registry program is sorely lacking.[1] Internet sites like www.WorldAtlas.com quote a gastric cancer incidence in Guatemala as high as 23.7 in 100,000. Limited information gathered through National Cancer Institute of Guatemala states that gastric cancer remains the leading cause of cancer-related deaths.[1] Regardless, gastric cancer is the second most common cause of cancer mortality worldwide and is the leading infection-associated cancer.[2,3] Gastric cancer has clear geographic and ethnic variability.[3,4] The highlands of the Pacific coast of Latin America have the highest incidence and mortality rates of the sites studied so far; the areas affected include Mexico, Guatemala, Honduras, Costa Rica, and Colombia.[5] As already mentioned, with the exception of Panama and Costa Rica, any type of information or literature about the epidemiology of gastric cancer in Central America is limited.[1,3]

Gastric cancer development has to be considered a multifactorial process, in which many conditions play a role; historically, the roles of diet, infection, ethnic background, socioeconomic conditions, and the altitude enigma[6] have been addressed. The impact of these factors may actually affect the histologic type of cancer (personal observation on the frequency of signet ring type histology) and the anatomic location of the sites of the cancer (proximal vs. distal). It should be noted that, without much data and on the basis of personal observations, at least in Guatemala, gastric cancers in lower socioeconomic populations tend to present with signet ring morphology and a more virulent behavior; anatomically, they tend to be distal cancers. This article attempts to outline the known facts associated with this condition in Guatemala and northern Central America.

RISK FACTORS

Dietary factors may induce cancer, but dietary habits also may be protective; diet is being studied aggressively. Historically, worldwide studies have documented protection from diets high in vegetables and fruit. Conversely, high intake of processed, red meat or smoked preserved foods seems to increase the risk of gastric cancer. A meta-analysis of Latin American studies done by Bonequi et al[4] showed that a trend toward this protection did exist, but the association was considered weak. Results for the association with the intake of red meat, processed meat, and salt did not vary from other global studies and did not indicate an increase in risk for the development of gastric cancer.[4] Smoking and drinking clearly showed a notable impact on the development of this malignancy. Smoking increased the incidence of gastric, overall risk increased 60% between smokers and nonsmokers. The dose response meta-analysis for this cancer documented an increase in gastric cancer risk of 12% per exposure of 10-pack years.[4] Alcohol use seemed to increase the risk of gastric cancer by 61%, but there was notable variability on the amounts of exposure reported.[4]

Education and ethnicity may go hand in hand as surrogate indicators of socioeconomic status and income potential in countries where the median income of the population is approximately $1.60 per day.[1] Clearly, ethnicity has been

studied worldwide, but, in Latin America, where 10% of the population is indigenous,[7] the lack of information is widespread, and even the more advanced economies of the area lack statistics and data with which to work.[1,8] We know that poverty is associated with poor outcomes of cancer care; this has been attributed to poor access to medical care either because of low availability or, probably more important, because of the high cost of care and the lack of accessible, affordable resources in these low-income countries.[7] Also, poverty and ethnic background fuel persistent cultural beliefs, which hinder both access and availability to medical care.[4,8] The lack of adequate educational and medical resources at the national level in these societies also affects the incidence of gastric cancer.

Other risk factors worth mentioning include the association with infections and the site of residence. We have known for some time that the presence of infections, in particular *Helicobacter pylori (H. pylori)*, clearly increases the risk of gastric cancer. This association, identified in the 1990s, has been aggressively studied worldwide.[9]

In association with presence of infections, the site of residence for this population may play a role. Interesting data have been published on the role of high altitude and the development of gastric cancer. Torres et al[6] reviewed published statistics and data that documented clearly higher gastric cancer mortality in the Americas and a higher incidence of disease concentrated in the nations along the Pacific Rim. Observational analysis cited in the article document notable changes in incidence of this disease in short distances, sometimes as small as 150 miles, but the most distinct difference between the communities was the altitude.[6] Implications of these observations are important; these observations have led to the development of the altitude enigma concept. Historically, geographic barriers like mountains or large bodies of water allow development of diverse genetic patterns in humans and in bacteria or other organisms. If we include the impact of population changes triggered by immigration, slavery, and historical events, the implications are staggering. Implications and associations studied so far include evaluation of *H. pylori* genotypes and haplotypes on the basis of altitude. The ancestral origin of the *H. pylori* strain studied by phylogenetic haplotypes has been documented by de Sablet et al,[10] who noted clear variation between the African ancestries populations that live in the coastal regions of Colombia compared with the mestizo population (European/Amerindian) in the highlands. It was determined that the incidence of *H. pylori* from European ancestry was more common in the highlands with the mestizo population, whereas the coastal populations had 66% African-originated *H. pylori*.[10] These researchers also observed an increase in more severe gastritis and DNA damage in the populations affected by the European-ancestry *H. pylori*, but they still could not explain, by this finding alone, the 25-fold difference in incidence of gastric cancer between coastal and mountain regions of Colombia. Clearly, other risk factors do exist. The possibility of coinfections, either chronic helminthiasis or Epstein-Barr virus, has been suggested.[11,12] Diet, as previously mentioned, also has been strongly evaluated.

KEY POINTS

- **In the Americas, the highest incidence of gastric cancer is found the mountain areas of the Pacific Rim.**
- **Gastric cancer has ethnic and geographic variability.**
- **Dietary issues may not play as large a role in the pathogenesis of gastric cancer.**
- **Altitude may be a surrogate for bacterial, dietary, and environmental factors that may predispose to gastric cancer.**
- **Interactions between *H. pylori* serotype and population genetic makeup could explain some of the epidemiological variability for gastric cancer.**

EPIDEMIOLOGY OF GASTRIC CANCER IN CENTRAL AND LATIN AMERICA

A difference in the type of gastric cancers according to socioeconomic status has been noted. As documented in all of the previously mentioned citations, gastric cancers in low-income countries tend to be noncardia, affect the poor more often, and have a male-to-female ratio of 2:1.[3] In contrast, the higher socioeconomic, more educated, and more affluent groups tend to suffer from cardia-based gastric cancer, which presents with a ratio of 5:1 in men to women and 2:1 in white to black individuals.[13] To explain the different pattern of development for gastric cancer in the cardia in the developed countries, other dietary behavioral issues—in particular, obesity and tobacco use—have been suggested.[14] These suggestions carry many concerns. Does the different carcinogenesis pattern develop a different kind of biologic behavior? Does the different pattern of development imply a different pattern of genetic amplification and overexpression that would affect how we treat this condition? Clearly, these are all good questions that, without adequate databases, will be hard to answer. Corral et al[3] observed that, as Hispanic people have migrated to the United States, there has been a slight shift proximal of the site of origin of the malignancy; however, malignancies remain noncardia in origin. Cancers of the antrum in Central America occurred in 73.6%; cancer of the corpus was slightly more common, at 54%, in the U.S. Hispanic population. Thus, there is either a genetic predisposition or a residual epidemiologic drift brought on by cultural and social affinities; it is hard to know which is true.

IMPLICATIONS

This brief review outlines the issues created by the inequities in medical care. Cancer is one of the most common medical conditions across all continents and social strata and should be considered a public health issue. The problem of adequate care is compounded by the multiple other social issues surrounding illness and public health cost that exist, in particular in low-income countries, which results in a lack of information worldwide. Few studies outside the

high-income countries have been done to provide indicators, to identify the magnitude and scope of this problem, and to plan an approach to tackle it. Treatment patterns and outcomes in Latin American countries, in particular in Central America, usually are underreported; any accurate static or information is elusive. Cancer control can be achieved only if we develop a system to acquire relevant data that could be analyzed to allow development of a systematic approach to address this problem across all countries and socioeconomic strata.

Gastric Cancer in Southern Europe: High-Risk Disease

Ramon Andrade De Mello, MD, PhD

OVERVIEW

Gastric cancer is an aggressive disease. Several risk factors are involved in gastric cancer pathogenesis, likely *Helicobacter pylori (H. pylori)* infection, genetic factors in hereditary syndromes, lifestyle, and diet. However, well-implemented screening strategies are lacking in most countries, including those in Southern Europe. Nevertheless, gastric cancer outcomes are better in some Southern European countries than in others, likely because of the incidence and distribution of different histologic types. Robotic surgery has been gaining favor as a treatment of early-stage disease, and the need for perioperative chemotherapy or adjuvant chemoradiotherapy (CRT) for locally advanced disease has been debated. In the metastatic setting, trastuzumab in combination with chemotherapy has helped to extend survival compared with chemotherapy alone for HER2-positive disease. This article will describe how gastric cancer is assessed and treated in Southern Europe in an attempt to correlate these approaches from a global perspective.

Gastric cancer is a very aggressive disease worldwide.[1] Specifically, it is the third most important cause of cancer-related death, and in Southern Europe, it is the sixth most common malignancy. Therefore, Southern Europe is considered a high-risk area for gastric cancer.[1-3] In Europe, the incidence of gastric cancer is not homogeneous, and the risk is low in some areas, such as Central Europe. The mortality rate is 9.7% in men and 4.6% in women.[1] Moreover, some familial syndromes, such as hereditary diffuse gastric cancer syndrome, which is related to the *CDH1* gene mutation, play an important role in the etiology of gastric cancer.[4,5] Furthermore, the incidence of *H. pylori* and genetic factors are responsible for a variety of related diseases and their presentation. Currently, *H. pylori* infection is considered a component of gastric cancer development. In addition, factors related to the improvement of the population's living conditions, a better diet, and improved food preservation may improve the course of the disease.[1,6] Although the incidence of gastric cancer continues to decrease in the United States and Europe, gastric cancer remains an important leading cause of cancer death worldwide.[7] Geographic differences in the disease burden of gastric cancer (highest in Japan, Korea, and regions of Latin America) suggest that environmental and dietary factors play major roles in gastric cancer risk. Histologically, gastric adenocarcinomas are classified as intestinal or diffuse; diffuse-type gastric cancers make up 15% to 10% of cases and are characterized by the submucosal spread of neoplastic signet ring cells. In this article, we discuss how gastric cancer is assessed and treated in Southern Europe in an attempt to correlate these approaches from a global perspective.

RISK FACTORS AND HEREDITARY SYNDROMES

Several genetic and hereditary factors have been identified to interact with gastric cancer pathogenesis. Nevertheless, environmental risk factors have been studied on a population basis because they can be modified to reduce the prevalence of this disease. Although Western Europe is considered an overall low-risk area, gastric cancer is a challenge for oncology health care professionals in Southern Europe, which is considered a high-risk area. However, gastric cancer mortality has been decreasing in recent decades (since 1971).[8] Although most gastric adenocarcinomas are presumed to be sporadic, approximately 5% to 10% arise in individuals with a family history of gastrointestinal cancer, and 3% to 5% of these cases are estimated to be associated with inherited cancer predisposition syndromes.[8] Following the decreases observed since the 1970s in Portugal, further declines in gastric cancer mortality were projected for 2015 and 2020, with an expected number of deaths of approximately 1,400 and 1,300 in men and 900 and 800 in women, respectively, corresponding to crude rates of 28.9/100,000 and 28.2/100,000 in men and 16.9/100,000 and 16.1/100,000 in women, respectively.[7-10] Another important issue is the prevalence of *H. pylori*, which increases with age, from childhood to age 45 to 50 in adults. In addition, the prevalence of *H. pylori* has not exhibited consistent trends in adults and children since the

1990s. Regarding overall survival (OS), some screening programs implemented in certain areas, such as Korea, may improve survival because of early diagnosis. Nevertheless, survival is higher in Portugal than in Europe overall. This difference is likely because of a higher incidence of tumors with a better prognosis, such as noncardia tumors and intestinal histologic type tumors and not because of generalized screening programs.[7,9,11] Furthermore, efforts to reduce the prevalence of *H. pylori* infection are important because such efforts reduce gastric cancer mortality, as reported in previous studies of developed countries such as the United States and Central Europe.

PATHOLOGY AND MOLECULAR PROFILE

Genetic alterations are closely associated with the development of neoplasia, and the body of evidence identifying molecular factors that affect gastric cancer is continuously growing. Specifically, approximately 140 genes have been identified to drive cancer, a subset of which have been implicated in hereditary cancer syndromes. However, the types and patterns of these mutations are highly variable and heterogeneous within a single entity as well as between different tumor categories. For example, the hyperactivation of the phosphatidylinositol-3 kinase (PI3K)/Akt/mTOR signaling pathway in gastric cancer has frequently been identified to be related to mutations and/or amplifications of the *PIK3CA* gene and a loss of function of PTEN, which play a crucial role in the regulation of this pathway. The PI3K/Akt/mTOR signaling pathway plays an important role in mediating multiple cellular functions including cell growth, proliferation, metabolism, survival, and angiogenesis. In 2014, researchers from The Cancer Genome Atlas (TCGA) research network studied 295 stomach tumors and found that 80% harbor different grades of mutations in the *PIK3CA* gene and amplifications of receptor tyrosine kinase genes, such as *ERBB3*, *ERBB2*, and *EGFR*, which increase the activities of these proteins in gastric cancer.

Akt acts as a central regulator of cell survival by transcriptionally and post-translationally interacting with antiapoptotic signals. In addition, Akt phosphorylates Bad, a member of the BCL2 family of antiapoptotic proteins, at SER136 and Caspase9, a protease, and at SER196, which partially inhibits cell death and supports cell survival signals. Akt also regulates antiapoptotic transcriptional functions by translocating to the nucleus and regulating the transcription of the forkhead box O (FoxO) family of transcription factors. The FoxO family of transcription factors regulates cell death signals by expressing various members of both intrinsic and extrinsic modes of apoptosis as well as cyclin-dependent kinase inhibitors. Upon nuclear translocation, Akt represses the transcription of FoxO1, FoxO3, and FoxO4, thereby enhancing cell survival signals.

In 2014, researchers from TCGA examined 295 stomach tumors and identified subtypes using complex statistical analyses of molecular data obtained from six molecular analysis platforms. Thereafter, they described a new molecular characterization that defines four major genomic subtypes of gastric cancer: positive for Epstein-Barr virus, microsatellite instability, chromosomally instability, and genomic stability. At least three of these subtypes, which includes 80% of the studied gastric cancer cases (Epstein-Barr virus–positive, microsatellite instability, and chromosomally instability subgroups), house different grades of mutations in the *PIK3CA* gene and amplifications of receptor tyrosine kinase genes, such as *ERBB3*, *ERBB2*, and *EGFR*. In a recent Chinese study, the authors suggested that a mutation in the GTPase *RHOA* gene and its oncogenic signaling pathway represent a strong biomarker-driven therapeutic target for Asian gastric cancer. This comprehensive strategy represents a promising approach for the development of hit compounds. *RHOA* is frequently overexpressed in the gastric cancer tumors of Japanese and Chinese patients, whereas gastric cancer datasets from TCGA depository exhibited *RHOA* mutations, not mere overexpression, in diffuse-type gastric cancer tumors. More recent evidence suggests that changes in PHOSPHO2-KLHL23 mRNA expression were the most significant in gastric adenocarcinoma. PHOSPHO2 is important for metabolism and the vitamin B6 metabolism pathway, and KLHL23 is implicated in cone-rod dystrophy and the vitamin B6 metabolism pathway. Ribosomal protein L17 (RPL17), also known as RPL23, is a component of the large 60S ribosome subunit and promotes multidrug resistance in gastric cancer cells by suppressing drug-induced apoptosis. In a Korean study, Choi and colleagues[12] screened read-through transcription events from stomach adenocarcinoma RNA-seq data and selected three candidates, PHOSPHO2-KLHL23, RPL17-C18orf32, and PRR5-ARHGAP8, to assess their biologic role in gastric cancer. They suggested that PHOSPHO2-KLHL23 was the most significantly upregulated transcript in stomach tumor tissues ($p < .0001$), and our investigation revealed that the KLHL23 protein is related to this tumorigenic effect.

One to three percent of all gastric cancers may be considered hereditary diffuse gastric cancer.[13] Furthermore, consistent with the biallelic *CDH1* inactivation and consequent E-cadherin loss of function, E-cadherin protein expression,

KEY POINTS

- **Gastric cancer is a very aggressive disease with a higher incidence in Latin America, Southern Europe, and Asia compared with other areas.**
- **Several genetic and hereditary factors have been identified to interact with gastric cancer pathogenesis.**
- **The eradication of *H. pylori* reduces the incidence of gastric cancer and peptic ulcers as well as the prevalence and cost of managing dyspepsia.**
- **Minimally invasive surgery has been demonstrated to improve the short-term outcomes in selected patients compared with open surgery, especially the rate of perioperative complications.**
- **Irinotecan in combination with 5-FU (FOLFIRI or IF) is an option for the treatment of patients with chemotherapy-naive disease with a poor performance status.**

as assessed by immunohistochemistry, is almost always abnormal in hereditary diffuse gastric cancer, in contrast to the normal complete membranous expression in adjacent normal (nontumoral) epithelium.[3,5,14-16] The E-cadherin gene, *CDH1*, is located on chromosome 16q22.1, and heterozygous germline *CDH1* mutations have been described in 18% to 40% of hereditary diffuse gastric cancer families.[4,17] The 120 kDa glycoprotein encoded by *CDH1* features a large extracellular domain, a transmembrane segment and a short cytoplasmic domain. E-cadherin is a transmembrane calcium-dependent protein that is mainly expressed at the basolateral membrane of epithelial cells, where it plays important roles in cell-cell adhesion at the adherens junctions to maintain epithelial integrity. Furthermore, several other genes are involved in hereditary diffuse gastric cancer predisposition, including *CTNNA1*. Like *CDH1*, *CTNNA1* is involved in intercellular cell adhesion, and *CTNNA1* encodes the protein α-E-catenin, which functions in a complex with β-catenin, where it binds the cytoplasmic domain of E-cadherin to the cytoskeleton.[14,18]

CLINICAL APPROACHES AND TREATMENT

Currently, screening strategies are not well implemented throughout European and Latin American countries. Nevertheless, the eradication of *H. pylori* reduces the incidence of gastric cancer and peptic ulcers as well as the prevalence and cost of managing dyspepsia. Specifically, economic analyses suggest that the eradication of *H. pylori* is cost-effective in controlling gastric cancer for high-risk populations.[19-21] Table 1 summarizes current clinical trials involved in gastric cancer prevention and/or early detection.

In terms of molecular approaches, a single molecular alteration that has been universally accepted as an independent prognostic factor in gastric cancer has not been identified. Instead, many gene expression signatures have been used to classify tumors into intrinsic subtypes and predict the survival of patients with gastric cancer,[22,23] and carriers of germline mutations in different genes associated with cancer predisposition have an increased risk for various tumor types.[24] The identification of germline mutations in families offers the opportunity for early intervention in relatives as yet unaffected by cancer who may be at high risk. Specifically, 25 frequently mutated genes have been identified in gastric adenocarcinoma (e.g., *PIK3CA*, *RHOA*, *ARID1A*, *KRAS*, *MUC6*, *RNF43*, *CNGA4*, *TP53*, *SMAD4*, *CDH1*, *APC*, *MLH1*, *MSH2*, *MSH6*, *STK11*), and these mutations correspond to four tumor subtypes: positive for Epstein-Barr virus, microsatellite stable (hypermutated), genomically stable (predominantly diffuse subtype), and chromosomally instable.[25] However, well-implemented strategies and policies to correlate these data with screening tools to avoid familiar gastric cancer cases are lacking. Furthermore, populations at a low risk for gastric cancer may also benefit from screening and treatment because of the effects on nonmalignant upper gastrointestinal diseases. However, public health authorities have been slow to consider the benefits of population-based screening and treatment as a means of reducing the morbidity and mortality associated with *H. pylori* infection.[21]

Nevertheless, novel techniques are revolutionizing approaches for the treatment of gastric cancer. For example, robot-assisted surgery has recently improved conventional minimally invasive surgery. Specifically, Ceccarelli and colleagues[26] reported an interesting retrospective Italian review of 363 consecutive patients undergoing robot-assisted surgery at an Italian general surgery unit from September 2012 to June 2016. The entire cohort and subgroups that underwent three of the most-performed surgeries (i.e., gastric resections, right colectomy, and liver resections) were analyzed. This analysis suggested that the benefits of minimally invasive surgery compared with open surgery have improved short-term outcomes in selected patients, as evidenced by lower perioperative complication rates and earlier recovery, resulting in an improved quality of life. These benefits were also suggested in elderly populations; the risk of death or morbidity was not increased among elderly patients compared with younger patients in the three groups examined in their retrospective cohort. Thus, their study showed robot-assisted surgery to be a safe and effective technique for the aging patient population, especially for major abdominal cancer surgery.[26]

Early Disease

Endoscopic resection may be suitable for well differentiated, early-stage gastric cancer that is smaller than 2 cm, confined to the mucosa, and is not ulcerated. Intestinal Lauren histology and no evidence of lymphovascular invasion also indicate mucosectomy in the following tumors: intramucosal cancers without ulceration, irrespective of tumor size; ulcerated intramucosal cancers less than 3 cm; or cancers with early invasion into the submucosa measuring less than 3 cm. Endoscopic submucosal dissection has proven more effective than endoscopic mucosal resection but requires greater skill and instrumentation and entails a significant risk for complications, including perforation.[23,27]

For locally advanced disease, complete resection with adequate margins remains the cornerstone of curative treatment. In gastric cancer, the type of resection, subtotal compared with total gastrectomy, depends on the anatomic location of the primary tumor. A total esophagectomy with a partial gastrectomy or an extended gastrectomy is generally performed for esophagogastric junction cancers, but the extent of lymph node dissection remains a subject of controversy. Nevertheless, consensus exists regarding lymphadenectomy: it must include at least 15 lymph nodes, and gastrectomy with D2 lymph node dissection is a recommended procedure.[27]

Neoadjuvant Chemotherapy

The indication for neoadjuvant chemotherapy is also a subject of great interest. According to the European Organisation for Research and Treatment of Cancer trial, which examined 40,954 inpatients with locally advanced gastric cancer, neoadjuvant chemotherapy did not provide a

survival benefit.[28] However, a meta-analysis by Sjoquist and colleagues showed that neoadjuvant chemotherapy provided a significant survival benefit to patients with gastroesophageal cancer (p = .005).[29] Thus, the Spanish Society of Medical Oncology recommends neoadjuvant chemotherapy for patients with stage IB disease.

The POET[30] and CROSS[31] studies assessed the role of neoadjuvant CRT for locally advanced gastric and gastroesophageal carcinoma. The pathologic complete response was significantly higher for patients in the CRT group, but OS did not significantly differ between groups.[30,31] However, the meta-analysis by Sjoquist and colleagues supports an increase in OS for patients who have undergone CRT.[29]

Perioperative Chemotherapy

At many centers in Portugal, Spain, and most European countries, perioperative chemotherapy has been adopted as an interesting option for medically fit patients with resectable locally advanced (cT2 or higher, any N) distal esophageal, esophagogastric junction, or gastric tumors. The British MAGIC trial,[32] the French FNLCC/FFCD 9703 study,[33] and a meta-analysis[34] have shown that perioperative chemotherapy significantly increases R0 rates and survival outcomes without significantly increasing perioperative complications or mortality. Moreover, the approach based on 3-cytotoxic agent combination also exhibits a quite tolerable grade 3 to 4 toxicity rate, however it is not normally used.[34]

Adjuvant Chemoradiotherapy/Chemotherapy

Based on the evidence of the INT-0116 trial and CALGB 80101 study, adjuvant CRT is indicated in patients with stage IB–IV (M0) resected gastric or gastroesophageal junction adenocarcinoma.[35,36] The MacDonald regimen (CRT based on fluorouracil [5-FU]/leucovorin [LV]) improved progression-free survival (PFS; hazard ratio [HR], 1.52; p < .001) and OS (HR, 1.35; p = .005) compared with surgery alone. Furthermore, the CALGB study compared the INT-0116 regimen with epirubicin, cisplatin, and 5-FU (or ECF) before and after 5-FU/radiotherapy in resected gastroesophageal junction or gastric cancer without observing differences in the 3-year OS (52% and 50% for ECF and 5-FU/LV, respectively). The role of adjuvant trastuzumab for patients with HER2-positive disease is still being assessed in the phase II TOXAG trial. Nevertheless, patients with stage II or III gastric cancer submitted to D2-resection significantly benefited from S-1 at 1 year in the ACTS-GC randomized phase III trial (HR, 0.708; 95% CI, 0.510–0.983).[37,38] However, the CLASSIC phase III trial[39] also demonstrated that XELOX (capecitabine, oxaliplatin) significantly (p = .0015) benefited patients with stage II and III disease: the median 5-year PFS was 68% compared with 53%, and the estimated 5-year OS was 78% compared with 69% in the XELOX and the surgery-only groups, respectively.[37-39]

Currently, adjuvant approaches (chemotherapy vs. CRT) are controversial for patients with stage II-III D2 disease after resection. The ARTIST trial is an important study that compared CRT (cisplatin and capecitabine, or XP) with concurrent radiotherapy) with chemotherapy alone (XP every 3 weeks for 6 cycles) in patients with at least D2 lymphadenectomy and R0 resection. The long-term follow-up analysis showed no differences in the outcomes (PFS and OS; p = .527). However, a subgroup analysis showed that CRT significantly improved PFS (p = .04) in patients with node-positive, intestinal-type gastric cancer.[40] Furthermore, the ARTIST II trial is expected to demonstrate the role of S-1 with or without oxaliplatin and radiotherapy. Currently, CRT has a limit role when surgery is D2 quality; and it is commonly reserved for patients with node-positive disease, insufficient lymphadenectomy, or questionable surgery precedence[41].

Metastatic Disease

Advanced gastric cancer is a challenge for oncologists, especially because the clinical status of some patients is too poor to begin chemotherapy. However, chemotherapy is mandatory for patients with a good performance status to improve OS. Specifically, the combination of cisplatin and fluoropyrimidine is the treatment cornerstone for patients with HER2-negative disease. Both CF (cisplatin and 5-FU) and ECF can be considered standard combinations that extend OS in Southern Europe.[16] However, head-to-head studies comparing the efficacy of these treatment modalities are not available. Furthermore, docetaxel, cisplatin, and 5-FU–based chemotherapy is considered a more effective option than CF, but it exhibits a worse toxicity profile.[42] Regarding platinum toxicity and efficacy, some studies demonstrated that oxaliplatin can replace cisplatin because of its improved tolerability.[3,43] Furthermore, trastuzumab in combination with chemotherapy significantly improved OS according to the ToGA trial (p = .0046), and this drug is also being used in Southern Europe in a metastatic setting for patients with HER2-positive disease.[3,44] Conversely, irinotecan combined with 5-FU (FOLFIRI or IF) is an option for patients with chemotherapy-naive disease.[23,45,46] However, less than 60% of patients receive second or later lines of therapy for gastric cancer in clinical practice.[44,47] Therefore, first-line treatment should be maximized for these patients to attain clinical outcomes and quality of life.

Nevertheless, several efforts are being made to develop tolerable drugs for patients with advanced, previously treated gastric cancer, such as antiangiogenic drugs. For example, ramucirumab showed significant efficacy as a monotherapy (REGARD) or in combination with paclitaxel (RAINBOW). Specifically, the REGARD trial randomly assigned 445 patients to ramucirumab or placebo, and ramucirumab produced a significant OS benefit (5.2 vs. 3.8 months; HR, 0.77) over placebo.[48] In addition, the RAINBOW trial randomly assigned 665 patients to ramucirumab plus paclitaxel or paclitaxel plus placebo, and the ramucirumab plus paclitaxel arm showed a significantly superior OS (9.6 vs. 7.3 months; HR, 0.80, p = 0.017) over paclitaxel monotherapy.[49] More recently, apatinib was also shown to be superior to best supportive care in previously treated patients,[47] and an Italian study[50] showed that the combination of irinotecan and 5-FU is a manageable and acceptable regimen. Moreover, third-line

FOLFIRI has been shown to benefit patients with heavily pretreated disease without excessive toxicity. In particular, almost half of patients experienced disease control in their study.[50] Furthermore, immunotherapy acquired an important role in gastric cancer. In January 2017, a randomised phase III study, NCT02267343, indicated that nivolumab (a human monoclonal IgG4 antibody which blocks the human PD-1 receptor) has superior survival ($p < .0001$) when compared to placebo in pretreated patients with advanced gastric cancer.[51] Thus, it also could be considered a promising option for treat these patients in later lines.

FUTURE DIRECTIONS

Gastric cancer is a challenge to health care professionals worldwide, especially in high-risk areas. Moreover, the landscape of gastric cancer is different in Southern Europe and Mediterranean countries than in other Central and Northern European countries. Environmental and genetic factors constitute an important background to understand the disease trajectory, mainly in the diagnosis and screening phases. However, well-implemented screening programs are lacking in these high-risk countries, and most patients consequently present with late-stage gastric cancer at diagnosis. Moreover, the eradication of *H. pylori* infection is important to decrease this manageable risk factor. Currently, novel target drugs and immune-checkpoints inhibitors could be promising options to prolong the outcomes of advanced patients with good quality of life. Further epidemiologic studies are warranted to improve the disease outcomes and implement preventive strategies.

Deploying Immunotherapy in Pancreatic Cancer: Defining Mechanisms of Response and Resistance

Gregory L. Beatty, MD, PhD, Shabnam Eghbali, and Rebecca Kim

OVERVIEW

The immune reaction to pancreatic ductal adenocarcinoma (PDAC) is a strong prognostic determinant of clinical outcomes and may be a promising therapeutic target. We use multiplex immunohistochemistry to illustrate distinct patterns of T-cell and myeloid cell infiltration seen in PDAC that have therapeutic implications and discuss the current state of immunotherapy in this disease. Based on collective findings from clinical and preclinical studies, two conceptual models have emerged for applying immunotherapy in PDAC that involve (1) restoring elements of T-cell immunosurveillance and (2) redirecting myeloid cells to condition tumors with increased sensitivity to cytotoxic therapies. Overall, the success of immunotherapy in PDAC will most likely rely on strategic combinations of therapies that are informed by well-designed correlative analyses that consider the spatial heterogeneity of immune responses detected in malignant tissues.

Therapeutic resistance to standard cytotoxic therapies (e.g., radiation and chemotherapy) is a hallmark of PDAC, a disease for which the 5-year overall survival rate has remained below 10% for the past two decades despite considerable efforts to improve clinical outcomes.[1] The recent advent of immunotherapy has brought new hope to this disease with the possibility of redirecting the immune system to recognize and eliminate malignant cells. However, PDAC is capable of orchestrating several mechanisms of immune escape that can thwart the therapeutic potential of immunotherapy.[2] Thus, unlike many solid malignancies for which a sizable subset of patients have demonstrated remarkable responsiveness to immunotherapy, PDAC has shown striking resistance. Nonetheless, lessons learned from preclinical models and several clinical trials investigating immunotherapy in PDAC have provided critical insight into strategies to circumvent immune resistance in this disease. This knowledge is now guiding the next generation of immunotherapy in PDAC with an emphasis on rationally designed and novel treatment combinations.

THE IMMUNE REACTION TO PDAC

The tumor microenvironment is a critical determinant of treatment resistance. In PDAC, this microenvironment is commonly marked by a dense fibrotic reaction with recruitment of fibroblasts and leukocytes, which together can impede the efficacy of therapeutics.[3] The leukocyte infiltrate seen in PDAC is complex and heterogeneous. Myeloid cells are the most prominent component of this infiltrate and are associated with a worse prognosis in patients with surgically resected PDAC.[4,5] In contrast, $CD3^+$ T-cell infiltration has been found in some studies to correlate with improved overall survival for at least a subset of patients with resected PDAC.[4,6] Other reports, though, have failed to demonstrate a correlation between T-cell density and overall survival, suggesting that for many patients, the mere presence of T cells may have little clinical significance.[7,8] This is consistent with the notion that the type and location of T cells within tumors is equally as important as their density.[9]

The location of T cells in PDAC may inform resistance mechanisms to productive T-cell immunosurveillance. For example, $CD3^+$ T-cell infiltrates are more prominent in regions of chronic pancreatitis than in PDAC.[7] In addition, $CD3^+$ T cells have been identified more commonly at the invasive front of PDAC with fewer cells detected in the center, suggesting mechanisms of T-cell exclusion orchestrated by malignant cells.[4] Within primary resected PDAC tumors, $CD3^+$ T-cell infiltrates have been found associated with tertiary lymphoid structures which include B cells, dendritic cells, and other immune cell populations.[10,11] Tumor-infiltrating $CD3^+$ T cells also cluster adjacent to nests of malignant cells (Fig. 1A) and are commonly found diffusely scattered and trapped within stromal tissue (Fig. 1B). In contrast, direct interaction between $CD3^+$ T cells and malignant cells is infrequent (Fig. 1C and D). Thus, although $CD3^+$ T-cell infiltrates can be found in the majority (approximately 75%) of resected primary PDAC tumors, they appear to be trapped within the stroma.[10,12]

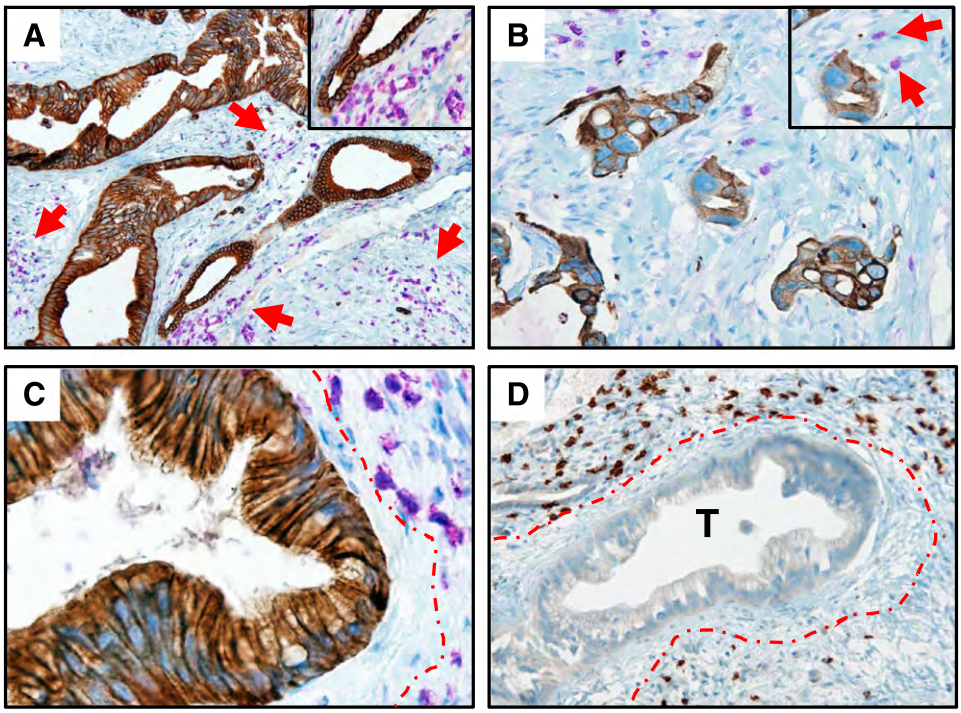
FIGURE 1. Patterns of T-Cell Infiltration in Human PDAC



Shown are representative images of $CD3^+$ T cells (purple) seen clustering (A, red arrows) adjacent to $CK19^+$ tumor cells (shown in brown) and trapped (B, red arrows) in stromal tissue adjacent to $CK19^+$ tumor cells. Insets show higher magnification. $CD3^+$ (C, purple) and $CD8^+$ (D, brown) T cells are seen adjacent to but excluded from interacting with tumor cells. Dotted red line illustrates stromal barrier between T-cell infiltrates and malignant cells. Nuclear staining (light blue) is illustrated by hematoxylin counterstain. Immunohistochemical staining was performed on surgically resected human PDAC specimens using the Ventana Discovery Ultra automated staining system. T, tumor.

The presence of tertiary lymphoid structures in surgically resected PDAC has led to the suggestion that this disease may be more immunogenic than previously appreciated.[10]

KEY POINTS

- **$CD3^+$ T-cell infiltrates are associated with favorable clinical outcomes in pancreatic ductal adenocarcinoma (PDAC), whereas myeloid cell recruitment to tumors portends a poor prognosis.**
- **Multiplex immunohistochemistry can be used to define the quality and quantity of distinct patterns of $CD3^+$ T cell infiltration in PDAC including formation of tertiary lymphoid aggregates, clustering adjacent to tumor cell nests, trapping within stromal tissue, and interaction with malignant cells.**
- **Strategies designed to harness the potential of T cells for the treatment of PDAC may need to address a state of functional paralysis associated with tumor-infiltrating $CD3^+$ T cells.**
- **Clinical experience with immunotherapy and preclinical modeling suggests a need for rationally designed combination treatment strategies that consider elements of immunosuppression imparted by the tumor microenvironment.**
- **Two conceptual models for applying immunotherapy to PDAC have emerged: restoring elements of T-cell immunosurveillance and redirecting the myeloid reaction to PDAC for enhancing the efficacy of cytotoxic therapies.**

These lymphoid structures are detected by immunohistochemistry in most samples analyzed via serial tissue sectioning.[10] Moreover, characterization of the T-cell receptor repertoire in primary PDAC by deep sequencing analysis has found that the majority of the T-cell infiltrate is represented by only a few T-cell clones.[10] However, it is unknown whether these clones are confined to tertiary lymphoid structures or represent true tumor-infiltrating T cells. As T-cell entry into tumors is via the bloodstream and not lymphatics, the antitumor potential of T cells found in tertiary lymphoid structures is uncertain. Indeed, the clonal repertoire of T cells detected in tertiary lymphoid structures, as defined by Vβ T-cell receptor expression, appears to be distinct from T cells detected infiltrating the tumor stroma.[10] As a result, analysis of the immune microenvironment of PDAC using techniques (e.g., RNA and flow cytometry) that do not consider the spatial location of T cells within tumor tissue may overestimate the quality and quantity of the lymphocyte infiltrate in PDAC.[13-15] Nonetheless, despite their unclear role in regulating PDAC biology, tertiary lymphoid structures are associated with a more favorable prognosis in surgically resected PDAC.[16,17]

Expansion of tumor-infiltrating $CD3^+$ T cells isolated from surgically resected PDAC tumors has showed that at least a subset of T cells in PDAC has tumor reactivity.[10,18] However, the frequency of the expanded T cells displaying tumor reactivity is usually low (less than 1%).[10] In addition, within the majority of PDAC specimens (more than 80%), $CD3^+$ T cells show a considerable decrease or loss of CD3zeta chain

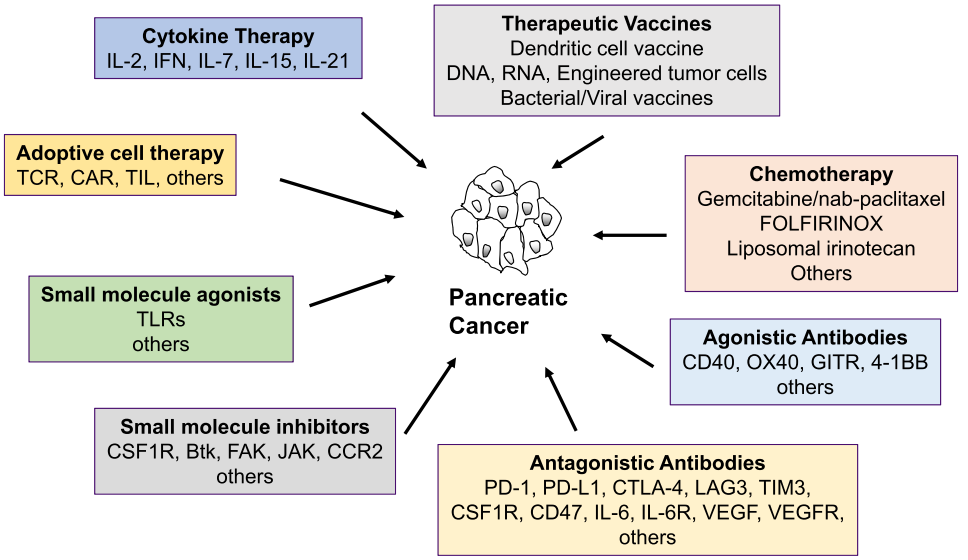
expression, which is required for T-cell receptor signaling and activation.[12] A notable decrease in CD3ζ expression on T cells has also be detected in nearly half (9 of 19) of peritumoral lymph nodes analyzed and is seen in the peripheral blood of patients with metastatic PDAC compared with healthy control subjects.[12,19] Decreased CD3zeta expression correlates with limited T-cell capacity to secrete cytokines, in particular interferon (IFN)-gamma.[19] Moreover, consistent with the notion of poor T-cell activation in PDAC, genomic profiling of human PDAC tumors suggests that despite potentially targetable neoantigens being present in nearly all PDAC samples, albeit at much lower levels than seen in other tumors such as melanoma, T cells detected in tumor tissue lack an activation gene signature.[13] Thus, strategies designed to harness the potential of T cells for the treatment of PDAC must address a state of functional paralysis associated with tumor-infiltrating and circulating $CD3^+$ T cells in this disease.

CLINICAL EXPERIENCE WITH IMMUNOTHERAPY IN PANCREATIC CANCER

The success of immunotherapy is reliant on activating potent and durable T-cell immunity against PDAC. T-cell immunosurveillance is dependent on elements of the cancer immunity cycle that proposes that tumors harbor unique antigens capable of being recognized by T cells and that these antigens, when appropriately presented by antigen-presenting cells, can prime and activate T cells to infiltrate tumors, where they then recognize and eliminate malignant cells.[2,20] Multiple clinical-grade therapeutics are available for bolstering elements of the cancer immunity cycle (Fig. 2). The most extensively evaluated approach in PDAC has involved the use of vaccines (Table 1).

Vaccines can induce T-cell responses against PDAC. In a phase I study, vaccination with GVAX, an irradiated allogeneic whole tumor cell vaccine expressing granulocyte-macrophage colony-stimulating factor (GM-CSF), stimulated delayed-type hypersensitivity responses to autologous tumor cells in a subset of patients and induced the development of mesothelin-specific $CD8^+$ T cells that correlated with improved disease-free survival.[21,44] Based on this finding, GVAX combined with low-dose cyclophosphamide (Cy), as a strategy to deplete regulatory T (Treg) cells, was subsequently tested with or without an attenuated *Listeria*-based mesothelin vaccine (CRS-207) in a prime/boost strategy intended to stimulate and maintain tumor-specific immunity.[24] In this phase II study, Cy plus GVAX followed by CRS-207 compared with GVAX alone was associated with improved overall survival (6.1 vs. 3.9 months) in patients with previously treated metastatic PDAC. Moreover, the development of mesothelin-specific $CD8^+$ T cells in response to treatment was associated with longer overall survival. These promising results led to a phase IIB study comparing Cy/GVAX plus CRS-207 with CRS-207 alone or chemotherapy alone in patients with previously treated PDAC. However, the combination of Cy/GVAX plus CRS-207 produced no survival benefit over chemotherapy alone. Similarly, algenpantucel-L, an irradiated allogeneic tumor cell vaccine expressing murine alpha-1,3-galactosyltransferase, was recently found in a phase III study of patients with resected PDAC to not significantly impact overall survival when combined with standard of care versus standard of care only.[23] A large phase III study evaluating sequential or simultaneous telomerase peptide vaccination in combination with chemotherapy in patients with locally advanced or metastatic PDAC also demonstrated no notable improvement in overall survival with chemoimmunotherapy with a potential trend toward worse outcomes in the sequentially treated group.[35] Limited-efficacy data have also been observed for a range of other tumor-specific peptide-based vaccines despite their capacity to stimulate tumor-specific T-cell immune responses

FIGURE 2. Immunotherapeutic Strategies for the Treatment of PDAC



Multiple therapeutic options with clinical-grade agents capable of restoring distinct elements of the cancer immunity cycle exist for the treatment of PDAC.

TABLE 1. Completed Phase II/III Clinical Trials of Immunotherapy in PDAC

Treatment	Trial Phase	Setting	No. of Patients	ORR, *N* (%)	Median PFS (Months)	Median OS (Months)	Reference

(Table 1). Together, these data collectively demonstrate the capacity of vaccines to elicit tumor-specific T-cell responses in patients that are in some cases associated with improved clinical outcomes, but suggest the importance of immune resistance mechanisms that regulate the efficacy of T-cell immunosurveillance in this disease.

T-cell effector activity is an exquisitely regulated process that is controlled by a balance of positive and negative signaling pathways. In this regard, immune checkpoint molecules (e.g., CTLA-4 and PD-1/PD-L1) provide negative signals to T cells to limit their expansion and effector activity in tissues.[45] Disruption of these signals using blocking antibodies has demonstrated remarkable success in stimulating antitumor T-cell immunity in a subset of patients across a wide range of malignancies.[46] However, for patients with PDAC, treatment with checkpoint inhibitors against CTLA-4, PD-L1, and Lag-3 has not produced considerable clinical activity.[36,47] Interestingly, *PD-L1* transcriptional expression in PDAC,

unlike other solid malignancies, is correlated with worse disease outcomes in patients with surgically resected PDAC.[48] Nonetheless, emerging evidence suggests that a subset of patients with cancer with mismatch repair (MMR) deficiency may be particularly sensitive to PD-1/PD-L1 blockade.[49] However, while this population may represent as much as 15–20% of PDAC patients,[50-52] it is noteworthy that the predictive value of MMR deficiency, as seen in colorectal cancer, is correlated with an enhanced quality and density of tumor-infiltrating T cells.[49,53] It is currently unclear, though, whether a similar correlation will be observed in PDAC. Thus, ongoing studies are investigating the prospect of PD-1–blocking antibodies for this population. Nonetheless, for the majority of patients with PDAC, exceptional resistance to checkpoint immunotherapy has emerged as a common theme.

The ability of vaccines to modulate the immune microenvironment in PDAC by stimulating the formation and activation of tertiary lymphoid aggregates in tumor tissue has suggested that immune checkpoint inhibitors may enhance the efficacy of vaccines.[11] Combining CTLA-4–blocking antibodies with chemotherapy and vaccines, though, has been largely ineffective in PDAC.[54-56] However, multiple studies are underway that seek to provide further insight into the capacity of vaccines and chemotherapy to combine with immune checkpoint inhibitors as a strategy to convert PDAC from immunoresistant to immunosensitive (Table 2). The ultimate goal is to sequentially restore major elements of the cancer immunity cycle by layering in therapies that can stimulate tumor-specific T-cell expansion, activation, trafficking, and effector activity.

An alternative approach to stimulating tumor-specific T-cell activity in patients is to adoptively transfer tumor-reactive T cells. This approach bypasses the need for in vivo T-cell priming and allows for assessment of downstream mechanisms that may regulate T-cell infiltration and effector activity within tumors.[57] For example, engineering T cells with a chimeric antigen receptor (CAR) that recognizes mesothelin, which is expressed on the surface of malignant cells, can yield potent major histocompatibility complex (MHC)–independent cytolytic activity in vitro against autologous PDAC tumor cells.[58] In PDAC, expression of MHC class I molecules is frequently altered in primary and metastatic lesions with poor infiltration by T cells seen in MHC class I–negative tumors.[8] Thus, CARs offer a unique strategy for overcoming elements of immune escape mediated by downregulation or loss of antigen processing and presentation machinery in tumor cells. CARs combine the protein recognition capacity of antibodies with intracellular stimulatory components of the T-cell receptor to redirect T cells against a tumor-specific target protein.[57] However, clinical benefit with CAR T cells in PDAC has thus far been limited, despite evidence for potential clinical activity.[59] For instance, one patient with metastatic PDAC responded to CAR T-cell therapy with a complete metabolic response in the liver detected on fluorodeoxyglucose-PET/CT imaging, but ultimately succumbed to disease because of progression of their primary pancreatic lesion. Similar mixed clinical responses have been seen in patients with advanced-stage PDAC treated with intravenous infusions of MUC1-specific lymphocytes in combination with intradermal vaccination using MUC1-expressing dendritic cells.[60] The finding of mixed tumor responses seen in these studies implies tumor lesion heterogeneity but also suggests that T cells may be capable of producing, in some cases, remarkable clinical activity.

Chemotherapy alone may also alter the immune microenvironment in PDAC. In patients with surgically resectable disease, preoperative therapy with chemoradiotherapy or chemotherapy has shown the capacity to decrease myeloid cell and Treg infiltrates, leading to an increase in the ratio of CD8 T cells to Treg cells.[15] Similarly, a separate study showed that neoadjuvant chemoradiotherapy can increase T-cell infiltrates, which is a stronger predictor of long-term outcomes than pathologic response to treatment.[61] To enhance the immunostimulatory capacity of chemotherapy, cytokines such as IFN-alpha-2b have been investigated in the adjuvant setting but have not been found to produce noteworthy improvement in clinical outcomes.[39]

The use of molecularly targeted therapies to disrupt signaling pathways may enhance cancer immunogenicity. For example, an early-phase clinical trial has suggested the capacity of MEK inhibitors to uncover therapeutic benefit with PD-L1 checkpoint blockade in patients with MMR-proficient colorectal cancer.[62] The potential immune-enhancing effects of inhibiting the MEK pathway is suggested by preclinical studies showing enhanced expression of cancer differentiation antigens and MHC expression in the setting of MEK inhibition.[63,64] Similarly, in preclinical models of PDAC, MAPK has been found to regulate PD-L1 expression on malignant cells which can inhibit CD8 T cell antitumor activity.[65] In this model system, combining MAPK inhibition with PD-1 blockade produced T-cell–dependent antitumor immunity. Epigenetic modulation may also have a significant role in defining the immunogenicity of cancer cells.[66] To this end, epigenetic modifiers, such as inhibitors of DNA methyltransferase (DNMT) or histone deacetylase (HDAC), have been found to enhance cancer cell immunogenicity through increased MHC expression and in preclinical models, combine with checkpoint immunotherapy to produce increased T cell–dependent antitumor activity.[67] Thus, incorporating molecular targeted therapies to improve cancer cell immunogenicity may be a promising therapeutic avenue for shifting PDAC from immune-resistant to immune-sensitive. Overall, findings from clinical trials investigating immunotherapy in PDAC suggest that many patients, although not all, respond to vaccines by eliciting tumor-specific T-cell responses. However, the productivity of vaccine-induced T cells as well as adoptively transferred T cells has been marginal, and based on histologic analyses of tissues showing discreet patterns of infiltration and activation, attention has turned to the tumor microenvironment as a major determinant and barrier to the efficacy of T-cell immunotherapy in PDAC.

TABLE 2. Immune Targets Under Active Clinical Investigation in Pancreatic Cancer

Target Category	Target	Target Agent (Active Clinical Trials)
Checkpoint molecules	CTLA-4	Tremelimumab (NCT02311361, NCT02639026)

Other	Young TIL	NCT01174121

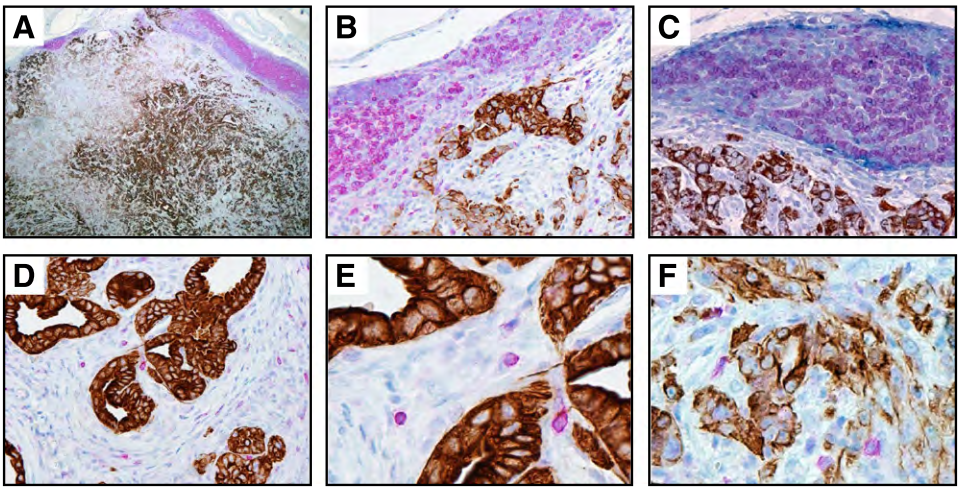
Abbreviations: hTERT, human catalytic reverse transcription subunit of telomerase; IDO, indoleamine 2,3-dioxygenase; LOAd703, oncolytic adenovirus; P53MVA, modified vaccinia virus Ankara vaccine expressing p53; PI3K, phosphatidylinositide 3-kinase; TIL, tumor-infiltrating lymphocyte.

PRECLINICAL MODELING TO GUIDE THE APPLICATION OF IMMUNOTHERAPY IN PDAC

The development of genetic mouse models that recapitulate salient features of human PDAC, including the immune reaction, offer an opportunity to rapidly study the tumor microenvironment, novel therapeutic targets, and combination treatment regimens.[68,69] In these genetic mouse models, similar to human disease, $CD3^+$ T-cell infiltrates can be detected in lymphoid aggregates adjacent to tumors (Fig. 3A) and are sometimes found diffusely scattered within tumor tissue (Fig. 3B), but infrequently seen to interact directly with malignant cells (Fig. 3C). In contrast, myeloid cells are a common component of the immune reaction to both mouse and human PDAC and can be found in close contact with malignant cells (Fig. 4). Moreover, inducing pancreatic inflammation pharmacologically[70-72] or with radiotherapy[73] has been shown to drive pancreatic cancer development and accelerate tumor progression, implying that the myeloid reaction to PDAC can have a protumor role.

Depletion of myeloid cell subsets in genetic mouse models of PDAC has been shown to alter the immune dynamics in tumors with increased $CD3^+$ T-cell infiltration.[74] In addition, pharmacologic inhibition of macrophages has been suggested as a strategy to inhibit metastasis formation.[75] Disrupting myeloid cell recruitment to tumors can also alter tumor sensitivity to cytotoxic therapies. For example, inhibiting

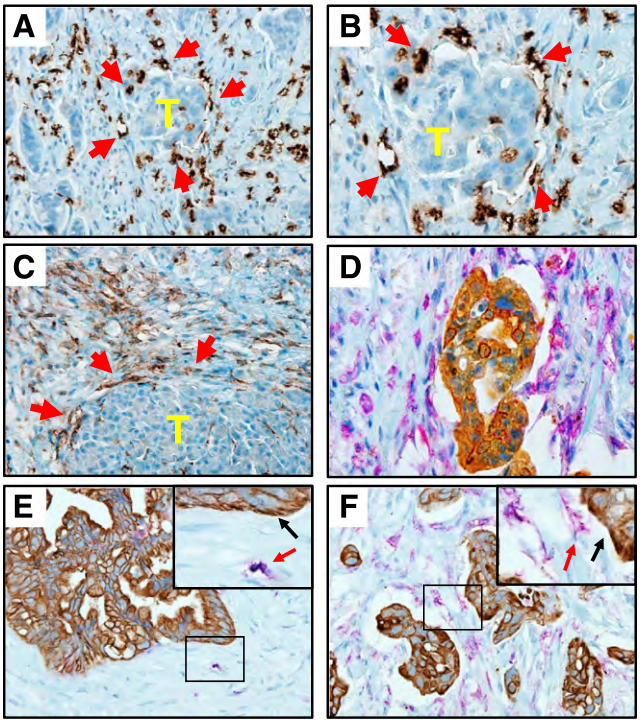
FIGURE 3. Patterns of T-Cell Infiltration in Murine PDAC Tumors



Shown are representative immunohistochemical images showing low-power (A) and high-power (B) magnifications of $CD3^+$ T cells (purple) detected in lymphoid aggregates adjacent to $CK19^+$ PDAC cells (brown). (C) $CD3^+$ T cells (purple) are confined to lymphoid structures demarcated by Lyve-1 (dark blue). Shown are low-power (D) and high-power (E) magnification images of $CD3^+$ T cells (purple) seen trapped in stromal tissue adjacent to $CK19^+$ PDAC cells (brown) and rare direct cell-cell interaction between $CD3^+$ T cells (purple) and malignant $CK19^+$ cells (brown; F). Nuclear staining (light blue) is illustrated by hematoxylin counterstain. Immunohistochemical staining was performed on PDAC specimens obtained from *Kras*$^{G12D/+}$; *Trp53*$^{R172H/+}$; *Pdx-1Cre* mice using the Ventana Discovery Ultra automated staining system.

myeloid cell infiltration by antagonizing the CCL2/CCR2 pathway has been found to increase the efficacy of chemotherapy[76,77] and radiotherapy[78] in mouse models of PDAC. Blockade of macrophage colony-stimulating factor using neutralizing antibodies has also been shown to decrease myeloid accumulation in PDAC and in doing so, enhance the efficacy of radiotherapy.[73] CXC chemokines, involved in the recruitment of neutrophils and immature myeloid cells, are

FIGURE 4. Patterns of Myeloid Cell Infiltration in Human PDAC



Low-power (A) and high-power (B) magnification images showing $CD15^+$ granulocytes (brown) surrounding tumor cells (yellow T). (C) $CD14^+$ macrophages (brown) are seen closely interacting with the periphery of a nest of tumor cells (yellow T). Red arrows indicate cellular localization patterns in A–C. (D) $CD14^+$ macrophages (purple) are seen to encompass $CK19^+$ malignant cells (orange). $CD14^+$ macrophage (purple) recruitment to $CK19^+$ tumor cell structures (brown) is heterogeneous within tumor tissues, with some tumor clusters showing rare single cells excluded from interacting with malignant cells and other tumor clusters (E) showing robust macrophage infiltration and close interaction with PDAC cells (F). The black arrows in E and F mark tumor cells, and the red arrows mark macrophages to illustrate the distance separating macrophages and tumors in each image. Nuclear staining (light blue) was detected by hematoxylin counterstain. Immunohistochemical staining was performed on surgically resected human PDAC specimens using the Ventana Discovery Ultra automated staining system.

also detected at increased levels in both mouse and human PDAC. Chemokine (C-X-C motif) receptor (CXCR) 2–dependent recruitment of neutrophils and myeloid cell progenitors has been found to limit the efficacy of cytotoxic chemotherapy and immune checkpoint inhibition with PD-1–blocking antibodies in mouse models of PDAC.[79] Promising early phase clinical results investigating small-molecule inhibitors of CCR2 in patients with both borderline resectable/locally advanced[80] and unresectable[81] disease support a role for inhibiting myeloid cell recruitment to tumor tissues for improving the efficacy of cytotoxics in PDAC.

Although blocking myeloid recruitment to tumors is one strategy for shifting the immune reaction in PDAC from tumor-promoting to tumor-inhibitory, the biology of myeloid cells is inherently pliable such that under the appropriate conditions, they can also acquire antitumor properties.[82] This biology creates an opportunity to leverage myeloid cell recruitment to tumors for potential therapeutic benefit. For example, CD40 agonists have been found to impart antitumor and antifibrotic properties on tumor-infiltrating myeloid cells in vivo.[83,84] This myeloid-dependent antifibrotic activity induced by CD40 agonists can shift PDAC tumors from resistant to chemotherapy to sensitive to chemotherapy, thereby implying a potential role for immunotherapy in enhancing the efficacy of cytotoxic therapies.

CD40 agonists are best appreciated for their capacity to license antigen-presenting cells with T-cell stimulatory properties.[85] In mouse models of spontaneously arising PDAC, CD40 agonists can reverse functional T-cell paralysis detected in lymphoid structures adjacent to tumor tissue.[83] However, the capacity of CD40 agonists to restore productive T-cell immunosurveillance is exquisitely regulated by macrophages residing outside of the tumor microenvironment.[86] This finding implies that strategies to reverse elements of immune suppression imposed by myeloid cells may be critical to the success of T-cell immunotherapy.

Inhibition of myeloid cell activation through targeting of Bruton's tyrosine kinase (BTK) has been found to inhibit tumor progression.[87] Moreover, combining BTK inhibition with chemotherapy produces T-cell–dependent tumor regressions in an orthotopic model of PDAC.[87] T-cell–dependent antitumor activity can also be induced in orthotopic models when chemotherapy is combined with inhibitors of CCR2, CSF1R, and CXCR2, which all limit myeloid accumulation in tumors.[73,77,79] These findings suggest that redirecting or disrupting the myeloid reaction in tumors may be a cardinal feature for the success of T-cell immunotherapy in PDAC.

The inflammatory reaction that surrounds PDAC is likely directed, at least in part, by tumor cell-intrinsic signaling pathways. For example, Kras activation can drive the release of factors (e.g., interleukin [IL]-8 and GM-CSF) that induce the recruitment and accumulation of myeloid cells in tumor tissue.[88,89] In addition, hyperactivation of focal adhesion kinase (FAK) activity in malignant cells has been found to stimulate the release of chemoattractants involved in myeloid cell recruitment.[90] Disruption of FAK signaling genetically or pharmacologically delays tumor progression, reduces fibrosis, and decreases myeloid cell accumulation in mouse models of PDAC. In patients with resected PDAC, FAK activity has been associated with decreased $CD8^+$ T-cell infiltration.[90] Moreover, FAK inhibition can enhance the efficacy of both chemotherapy and PD-1 antagonists in mice with spontaneously arising PDAC tumors.[90]

Overall, genetic mouse models have suggested that the tumor microenvironment is a key determinant of T-cell efficacy in PDAC. However, whether the microenvironment acts as a physical barrier to T-cell infiltration is less clear. Adoptive transfer studies in a genetic mouse model of PDAC has shown that tumor-reactive T cells can effectively penetrate the fibrotic matrix that surrounds malignant cells.[91] However, the functional capacity of tumor-infiltrating T cells is fleeting and associated with upregulation of multiple negative regulatory molecules.[91] In essence, tumor-infiltrating T cells may ultimately become trapped in the stromal compartment, as is also seen in human disease.[12] Elements of the stroma, including fibroblasts, have been implicated in this active sequestration of T cells away from malignant cells through secretion of chemokines including CXCL12.[92,93] Inhibiting the interaction of CXCL12 with its receptor, CXCR4, which can be found on T cells among many other cell types including myeloid cells, has shown potential to restore T-cell infiltration and, in doing so, uncover therapeutic activity with immune checkpoint inhibitors including CTLA-4 and PD-L1–blocking antibodies.[92] Thus, elements of the tumor microenvironment including fibroblasts and myeloid cells possess properties capable of inhibiting the efficacy of immunotherapy in PDAC.

STRATEGICALLY APPLYING IMMUNOTHERAPY TO PDAC

Unlike other malignancies in which monotherapy with immune checkpoint inhibitors can produce extraordinary activity in some patients, PDAC is a disease that has demonstrated remarkable immunologic resistance. Applying immunotherapy to PDAC will undoubtedly require strategically designed combinations of therapies. Genetic mouse models of PDAC have been strongly predictive of immunotherapy outcomes and thus can offer a high-throughput platform for the study of treatment combinations.[69] From clinical and preclinical studies, two conceptual models for applying immunotherapy in PDAC have emerged: (1) restoring elements of the cancer immunity cycle to stimulate productive T-cell immunosurveillance and (2) redirecting the immune reaction to PDAC for enhancing the efficacy of cytotoxic therapies. Although strategies capable of invoking T-cell immunity are critical for treatment response durability, leveraging the immune microenvironment in PDAC to improve outcomes with cytotoxic chemotherapy and radiotherapy may be particularly relevant for tumor debulking.[85]

Effective T-cell immunity in PDAC will likely require a multipronged approach that involves (1) conditioning the tumor microenvironment by reversing elements of immunosuppression and therapeutic resistance, (2) activation of tumor-specific T-cell responses using vaccines, targeted

therapy, chemotherapy, radiotherapy, or transfer of T-cell immunity, and (3) maintenance therapy to sustain T-cell effector activity and counteract negative regulatory signals encountered within tumors. Well-designed correlative analyses applied to early phase clinical trials that incorporate tissue analysis using genomic and proteomic assays (e.g., multiplex immunohistochemistry) that consider the spatial heterogeneity of tumors will be fundamental to rapidly learning from each patient treated and interpreting treatment responses and failures based on expected biologic activity.

Given considerable heterogeneity seen in the immune microenvironment in PDAC, it is also likely that immunotherapy must ultimately be personalized. One approach to this is actively being explored and involves applying genetic determinants (e.g., MMR deficiency and BRCA1/2 mutations) to identifying patient subgroups that may be more likely to respond to a particular immunotherapeutic strategy. For example, MMR deficiency has been suggested from clinical studies to be a potential biomarker for clinical activity with PD-1 antagonists.[49] Similarly, in mouse models of BRCA mutant PDAC, IL-6–neutralizing antibodies enhance the efficacy of PD-L1 antagonists.[94]

The application of immunotherapy to PDAC has been associated with mixed clinical responses. This has been seen with adoptive cell therapy using CAR T cells as well as MUC-1–specific lymphocytes.[59,60] In addition, CD40 agonists administered in combination with chemotherapy have produced heterogeneous treatment responses in individual lesions detected within the same patient.[95] Together, these findings suggest that tumor heterogeneity could emerge as a major challenge to the success of immunotherapy in PDAC.

In conclusion, immunotherapy is a novel treatment approach to PDAC that leverages the specificity and diversity of the immune system for cancer therapy. Multiple clinical trials evaluating immunotherapy in PDAC are ongoing (Table 2). However, PDAC has repeatedly triumphed over novel therapeutic strategies in the past. Thus, for immunotherapy to be different and successful in this disease, it must be applied strategically and guided by rigorous "bedside-to-bench and back" research.

Gastric Cancer in Asia: Unique Features and Management

Tomoyuki Irino, MD, PhD, Hiroya Takeuchi, MD, PhD, Masanori Terashima, MD, PhD, Toshifumi Wakai, MD, PhD, and Yuko Kitagawa, MD, PhD

OVERVIEW

Gastric cancer (GC) poses a burden to patients across the globe as the third leading cause of cancer deaths worldwide. Incidence of GC is particularly high in Asian countries, which is attributed to the prevalence of *Helicobacter pylori* (*H. pylori*) infection and has prompted the establishment of unique treatment strategies. D2 gastrectomy, which was established in the 1950s in Japan, has served as a gold standard for locally advanced GC for over half a century. Since the beginning of the 21st century, endoscopic resection (ER) techniques and minimally invasive laparoscopic surgery have greatly changed the treatment of patients with early GC. S-1, which showed a striking survival benefit in a large randomized trial in Japan, has been used as adjuvant therapy for the last decade. Likewise, S-1–based chemotherapy regimens are currently the standard of care for the treatment of unresectable/metastatic GC in Asia. Along with the development of standardized therapy, novel techniques and new drugs have been rapidly brought into clinical practice. State-of-the-art sentinel node (SN) navigation surgery enables clinicians to perform truly minimally invasive surgery for early GC, and appropriate chemotherapy regimens are now determined by a tumor's molecular expression. New classifications based on gene signatures are proposed and may replace conventional clinical classifications. Such highly individualized treatment has the potential to alter our clinical practice in GC in the near future. The best practice in each geographic region should be shared and integrated, resulting in the best practice without borders.

GC is the fifth most common cancer worldwide with 952,000 new patients diagnosed in 2012, and the third leading cause of cancer deaths in both men and women.[1] Geographic distribution of incidence and mortality of GC is known to be disproportionate, namely it is particularly high in Asian countries and low in the Western hemisphere. This uneven distribution has been closely correlated with the prevalence of *H. pylori* infection, which is undoubtedly the primary cause of noncardia GC (Fig. 1).[2-4] GC has therefore been one of the leading causes of cancer mortality in Asia.

In Japan, as well as other high-risk areas, the infection rate of *H. pylori* was very high a hundred years ago with an estimated prevalence of 80% in people born in the 1900s; however, the prevalence has gradually declined and no more than 10% of people born in the 2000s harbor *H. pylori*.[5] This fact is well associated with the trend of incidence and mortality of GC in Japan. At that time, because surgical resection of the stomach was the only treatment of GC, Japanese surgeons struggled to determine how to manage this intractable cancer that presented with extensive lymph node metastasis and systemic dissemination. They finally devised two approaches: one approach was the elucidation of lymphatics around the stomach followed by the establishment of classification of GC, and the other approach was implementation of a screening program for GC.

Meticulous analysis of gastric lymphatics was initially studied by Inoue et al in 1936. Based on the study, Tamaki Kajitani and other Japanese gastric surgeons established systematic lymph node dissection of the stomach in the 1950s, namely today's D2 lymphadenectomy. The fundamental concept of D2 gastrectomy was resection of the primary tumor with whole dissection of the lymphatic system around the stomach, which was most likely to involve not only macroscopic (visible) but also microscopic (invisible) nodal metastases. Gastrectomy with adequate lymphadenectomy was reasonable in light of cancer surgery and thus has been widely accepted by Japanese surgeons. Careful, organized findings about GC was exhaustively collected and finally published in the first edition of the *Japanese Classification of Gastric Carcinoma* in 1964. Surgical resection has been the predominant treatment of GC thereafter.

In contrast, a major problem was that the cancer was already advanced and metastatic when many patients presented with their symptoms. Thus, it was crucial to find cancer at an early stage to achieve cure. Toshio Kurokawa et al first performed a mass screening program for GC in

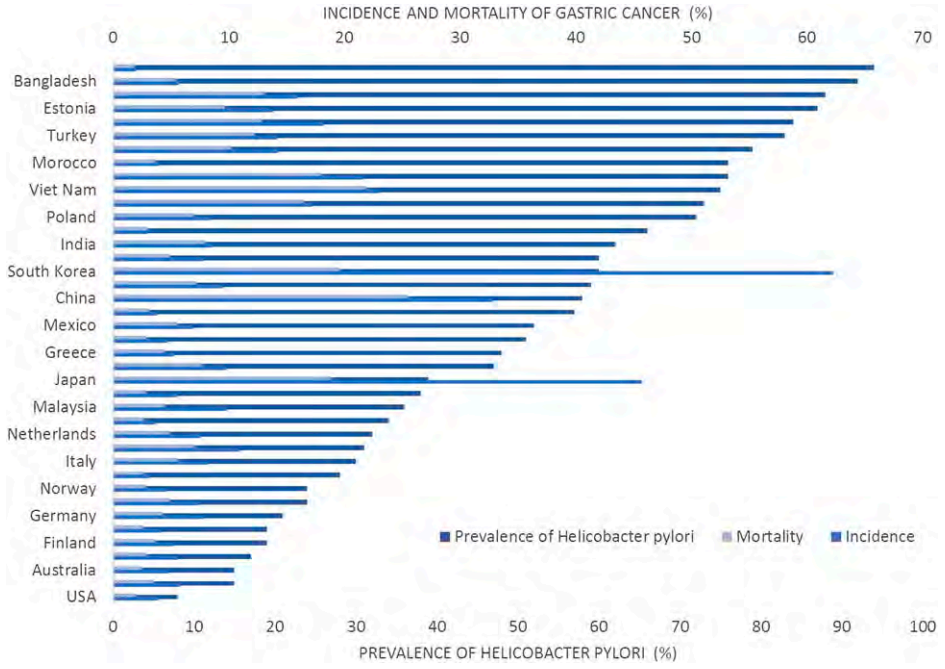
FIGURE 1. Prevalence of *Helicobacter pylori* Infection by Country Along With the Incidence and Mortality of Gastric Cancer



the 1950s "with the intention of early discovery and prevention of cancer through the diagnosis of people who felt they were perfectly healthy."[6] His tremendous effort also led to the development of diagnostic tools and techniques used today, represented by endoscopy and double-contrast barium radiography. Owing to the screening program, over half of GCs were detected at an early stage in the early 1980s, whereas less than 5% were detected before 1955. Although the question whether mass screening programs for GC can ultimately reduce mortality of GC is still open to debate,[7] it is no longer in doubt that such a program detects a large number of early GCs that are curable.

These unique features have greatly influenced the management of GC in Asian countries, particularly in Japan. Nowadays, much evidence comes from Western countries where evidence-based medicine has been widely accepted for many years. Guidelines and clinical practices in Asian countries, for example in breast cancer and colorectal cancer, depend much on external evidence from the West. In contrast, by taking advantage of the large numbers of patients with GC, we have developed best practices not by extrapolating external evidence, but by establishing our own evidence. In this review, we outline how the management of GC has been established, by tracing back the history of GC treatment in Japan and then discuss whether in future we should follow our own path as done so far, or should collaborate with other countries in the West to establish common evidence.

KEY POINTS

- **As a result of the large numbers of patients with GC in Asia, we have established our own evidence-based best practices.**
- **The sentinel node concept was demonstrated to be applicable in certain early GCs, enabling highly individualized sentinel node navigation surgery.**
- **Conventional D2 gastrectomy followed by adjuvant chemotherapy using S-1 or capecitabin plus oxaliplatin serves as a gold standard for locally advanced GC in Asia.**
- **S-1 is one of the key drugs used in the Asian population and S-1–based chemotherapy regimens currently achieve the best survival in unresectable/metastatic GC.**
- **In the new era of precision medicine, the best treatment strategy is determined by a tumor's molecular expression and gene signatures including Epstein-Barr virus status, microsatellite and/or chromosomal instability, genomic stability, epithelial mesenchymal transition, p53 activity, cytokine signaling, cell proliferation, and DNA methylation.**

SURGICAL MANAGEMENT OF EARLY GC: TRULY MINIMALLY INVASIVE SURGICAL THERAPY

The high incidence of early-stage GC in Japan has had considerable influence on its surgical management, and has resulted in the development of endoscopic treatment and minimally invasive surgery. ER was first reported by Tsuneoka et al in 1969, which has since become the standard of care for early GCs in which the risk of lymph node involvement is most likely to be zero.[8,9]

Early cancers that are not eligible for endoscopic therapy are primarily treated by surgical resection of the stomach with D1+/D2 lymphadenectomy, as is performed for

patients with locally-advanced GC, because there is a high risk (approximately 15%) of lymph node metastasis.[10,11] Open gastrectomy was the standard of care until a decade ago; however, since 1991, when laparoscopic gastrectomy as minimally-invasive surgery for patients with gastric cancer was first performed by Seigo Kitano et al, laparoscopic surgery has become popular worldwide. The Japan Clinical Oncology Group (JCOG) is now conducting a large, randomized phase III trial comparing laparoscopic gastrectomy with conventional open gastrectomy in patients with early GC (JCOG0912), and short-term outcomes showed the safety of the procedure in line with the result from a large phase III trial in Korea (KLASS-01).[10,11] Although many randomized, controlled trials of laparoscopic gastrectomy for early GC have demonstrated surgical and oncologic noninferiority, only a limited study provided evidence of its superiority over conventional surgery. This is in part because the procedure in the abdomen is more or less the same between open and laparoscopic surgery (i.e., gastrectomy with lymphadenectomy).[12] Therefore, how to avoid gastrectomy without compromising radicality, which is truly minimally invasive, is one of the long-standing issues surgeons have attempted to solve for decades.

SN biopsy was first introduced by Cabanas et al in penile carcinoma in 1977, and also dramatically altered the surgical and oncologic management of breast cancer.[13] If nodal status can be pathologically confirmed prior to gastrectomy, radical lymphadenectomy would not be necessary for patients without lymph node involvement, which accounts for up to 90% of all early GCs. Hence, if the SN concept can be applied to the gastric lymphatic drainage, which is relatively complicated, it would be possible to mitigate the burden of gastrectomy.[14] To evaluate whether the SN theory can be applied to GC, a large, prospective, multicenter phase II study was implemented by the Japan Society of SN navigation surgery, in which a standardized protocol and technique with an endoscopic dual tracer injection method were used.[15] A total of 397 patients with cT1/T2 gastric adenocarcinoma smaller than 4 cm were analyzed, and the SN detection rate was 97.5% and the overall accuracy of nodal evaluation for metastasis was 99.0% with only four false-negative cases (1.0%). The study confirmed that the SN theory can be applied to the complicated gastric lymphatic drainage and a large phase III study is currently being conducted in which long-term oncologic safety and quality of life will be evaluated.

D2 gastrectomy alone has been the standard of care for early GCs as well as locally advanced cancers. According to the SN study, 96% of metastatic nodes reside within the D2 area, which indicates the need for the radical and complete technique of D2 gastrectomy. However, D2 gastrectomy might be overtreatment for patients who are at very low risk of lymph node metastasis. Gastric surgeons have long confronted this dilemma, that it is hard to please everybody. Hence, SN navigation surgery can help individualize surgical treatment, thereby appropriately providing radical and less-invasive procedures for patients with early GC.

On the basis of the SN theory, a new rendezvous-style surgical procedure using endoscopy and laparoscopy was developed for early GC. The concept of the procedure, which is called laparoscopy-endoscopy cooperative surgery (LECS), was originally developed for submucosal tumors of the gastrointestinal tract and various modified methods have been currently proposed.[16] Nonexposed endoscopic wall–inversion surgery is one of the modified procedures, in which a full-thickness gastric wall resection can be achieved in a closed manner.[17] By combining nonexposed endoscopic wall–inversion surgery with SN navigation, Goto et al reported the first case of stomach-preserving surgery in a 55-year-old female patient with 2-cm diffuse-type early GC that was not eligible for ER.[18] (Fig. 2)

Although this minimally invasive technique is just being developed and thus needs to be carefully evaluated, it has great potential to change the role of gastrectomy for early GC, which has served as a gold standard for decades.

TREATMENT STRATEGY FOR LOCALLY ADVANCED GC: PERIOPERATIVE TREATMENT

Since Kajitani et al established D2 gastrectomy alone as the standard of care for locally advanced GC for many years until S-1 (an orally-administered combination drug of tegafur and gimeracil plus oteracil) was introduced as adjuvant therapy in 2006. In the late 1990s, results from two randomized trials from Holland (Dutch trial) and the United Kingdom (MRC trial) comparing D2 with D1 were published, in which D2 gastrectomy yielded no survival benefit and showed more postoperative complications and high mortality.[19,20] However, Japanese surgeons did not accept high morbidity and in-hospital death rates in the D2 group as sufficient reason to change their management practices, and D2 gastrectomy remained the standard of care in Japan. Results of a 15-year follow-up analysis of the Dutch trial were published in 2010, which demonstrated advantages of D2 gastrectomy in terms of locoregional recurrence (22% in D1 vs. 12% in D2) and GC-related death (48% in D1 vs. 37% in D2; hazard ratio [HR] 0.74; 95% CI, 0.59–0.93; p = .01), although there were no significant differences in disease-free survival (p = .31) or risk of recurrence (p = .10).[21] Based on these results, and that it is currently performed safely in Western high-volume centers, D2 gastrectomy is currently recommended for medically-fit patients in the guideline of the National Comprehensive Cancer Network and European Society of Medical Oncology.[22,23]

Five large, randomized, controlled trials were conducted in Japan by JCOG to evaluate the survival benefit of extended lymphadenectomy and surgical procedure because there had been much discussion among Japanese surgeons about the optimal extent of lymphadenectomy (Table 1).[24-27] JCOG9501, the first big surgical randomized trial that evaluated survival benefit of prophylactic paraaortic lymph node dissection, demonstrated a negative result. The results between the two groups were strikingly similar for 5-year overall survival (OS; 69.2% for D2 and 70.3% for extended D2; HR 1.03; 95% CI, 0.77–1.37) and other relevant outcomes.[24] The

(A) Fluorescence image after indocyanine green was injected around the primary tumor. (B) Visualization of indocyanine green through infrared camera. (C) Circumferential seromuscular incision followed by linear suturing. (D) Endoscopic removal of the primary lesion.

second trial tested noninferiority of spleen-preservation during gastrectomy in patients with locally-advanced cancer that was not located in the greater curvature (JCOG0110).[26] Because standard D2 total gastrectomy had included the nodal station 10 (splenic hilar nodes), splenectomy was necessary to complete D2 dissection. The study demonstrated noninferiority of spleen preservation in regards to 5-year OS (75.1% for splenectomy and 76.4% for spleen preservation; HR 1.21; 90.7% CI, 0.67–1.16 with noninferiority margin 1.21; p = .025), having altered the definition of D2 since January 2017. The third study, JCOG1001, started in 2010 and compared bursectomy with nonbursectomy in patients with cT3/T4 GC. As a result, pancreatic fistula was twofold more likely to occur in the bursectomy group, whereas bursectomy failed to provide significant 5-year OS benefit (HR 1.07; 95% CI, 0.81–1.42; one-sided p = .68), and the data monitoring committee recommended early publication after all patients completed recruitment as planned.[27] None of the trials showed a benefit of extended surgery, and conventional D2 gastrectomy without splenectomy and bursectomy is currently recognized as the standard procedure for locally-advanced cancer. Therefore, perioperative treatments should have promising potential to improve survival in patients with locally advanced GC.

Although surgery was regarded as the most effective treatment, the importance of perioperative therapy was also recognized; however, there was no evidence to support this. The first large, randomized phase III trial by JCOG commenced in 1988 in which surgery plus adjuvant mitomycin C (MMC) and 5-fluorouracil (5-FU) followed by tegafur demonstrated no survival benefit compared with surgery alone in patients with serosa-negative GC (Table 2).[29] Importantly, T1 cancer accounted for 32.8% of all tumors in this study, suggesting that surgery alone for T1 cancer yielded good survival without need for any adjuvant therapy. Other JCOG studies compared curative surgery alone with MMC, 5-FU, cytosine arabinoside followed by oral 5-FU in serosa-negative GC (JCOG9206-1),[30] and intraperitoneal and intravenous cisplatin followed by oral 5-FU in serosa-positive GC (JCOG9206-2).[31] However, both trials yielded negative results, failing to show the advantage of adjuvant chemotherapy.

In 1984, an oral tegafur/uracil drug named UFT was developed in Japan and has become commercially available. Taking advantage of this "homemade" drug, a national randomized trial comparing surgery alone with surgery plus adjuvant UFT was conducted (*N*-SAS-GC).[32] The patient accrual was slow and only 190 patients (38% of initially-planned) were finally included in the study. The result was favorable for the adjuvant therapy group; however, the 5-year recurrence-free survival rate was relatively poor, calling for a replication of the study to validate the result.

Meanwhile, another homemade agent named S-1 was developed and launched in 1999. S-1, commercially available as TS-1 in Asia and Teysuno in Europe, is an orally bioavailable fluoropyrimidine antagonist consisting of tegafur

TABLE 1. Practice-Changing Randomized Phase III Trials in Gastric Cancer Surgery in Asia

with two modulators of 5-FU activity, 5-chloro-2,4-dihydroxypyridine and potassium oxonate in a molar ratio of 1:0.4:1.[36] The landmark phase III ACTS-GC trial was initiated in 2002, comparing D2 gastrectomy alone with surgery plus S-1 for 1 year in patients with pathologic stage II/III GC.[33] The result was remarkable; adjuvant S-1 yielded a 32% reduction of risk for 3-year OS (80.1% for S-1 vs. 70.1% for surgery alone; HR 0.68; 95% CI, 0.52–0.87; p = .003). These results dramatically changed clinical practice in Japan, where surgery had been believed to be the only effective treatment of locally advanced GC. After these findings, the majority of chemotherapy regimens have been developed in combination with S-1.

Another adjuvant study was started in 2006 in three Asian countries, South Korea, China, and Taiwan, which aimed to seek an optimal adjuvant regimen after curative D2 gastrectomy. This study was abbreviated as the CLASSIC trial, and compared surgery alone with capecitabine plus oxaliplatin (CapeOX) as adjuvant therapy.[35,37] This study was stopped in accordance with the recommendation by the data monitoring committee for reasons of benefit, unveiling the efficacy of CapeOX with a 3-year disease-free survival HR of 0.56 (95% CI, 0.44–0.72; p < .0001).

Efficacy of adjuvant chemoradiation therapy was first demonstrated by the INT0116 study in the United States.[38] However, because surgery alone has been deemed to offer good local control, radiation therapy, which also provides local control, has not become common in Japan. Most clinical trials from Japan comprise of chemotherapy alone without radiation. For that reason, adjuvant chemoradiation therapy in an Asian population was first evaluated in South Korea. This randomized phase III trial (ARTIST trial) compared adjuvant capecitabine and cisplatin (XP) with XP plus concurrent capecitabine radiotherapy (XRT) after curative D2 gastrectomy.[34,39] No additional benefit with radiation was observed in both 5-year OS (HR 1.130; 95% CI, 0.775–1.647; p = .527) and disease-free survival (HR 0.710; 95% CI, 0.520–1.050; p = .922), although the XP group showed significantly more local recurrence (XP 13% vs. XRT 7%; p = .033). However, subgroup analyses suggested some benefit for patients with positive lymph node involvement (HR 0.700; 95% CI, 0.493–0.994), motivating them to start another study (ARTIST-2 trial) in which three arms of chemotherapy or chemoradiation regimens will be compared: adjuvant S-1 and oxaliplatin (SOX) plus radiation (45 Gy) and two chemotherapy regimens (S-1 alone for 1 year and SOX for 6 months) for patients with node-positive disease after curative D2 gastrectomy.

Adjuvant S-1 has become the standard of care since 2006 when the results of the ACTS-GC trial was unveiled. The final result was published in 2011, showing a 5-year OS of 71.7% with S-1 compared with 61.1% with surgery alone (HR 0.669; 95% CI, 0.540–0.828). In contrast, patients diagnosed with a more advanced stage (stage IIIB) demonstrated unsatisfactory survival outcomes, with no significant difference in 5-year OS (50.2% for S-1 vs. 44.1% for surgery alone; HR 0.791; 95% CI, 0.520–1.205).[40] These data have provoked a discussion for another strategy to improve survival among patients with high-risk of relapse, which includes the possibility of neoadjuvant treatment and/or regimens with multiple agents.

Several clinical trials are currently being conducted in Asia. A randomized phase III trial by JCOG was initiated in 2016 comparing surgery plus adjuvant S-1 compared with preop-

erative SOX and surgery plus adjuvant S-1 in patients with cT3-4 node-positive disease (JCOG1509). Another group in Japan is evaluating the superiority of S-1 plus docetaxel compared with S-1 alone for patients with stage III disease after curative D2 gastrectomy (START-2 trial). Nivolumab, an anti–PD-1 monoclonal antibody, demonstrated a survival benefit in patients with unresectable advanced or recurrent gastric or gastroesophageal junction (GEJ) cancer refractory

to or intolerant of standard therapy.[41] Based on the result, an international phase III trial will begin in 2017 in which the efficacy of nivolumab as adjuvant therapy will be investigated in patients with pathologic stage III disease who will undergo curative D2 gastrectomy.

D2 gastrectomy has long been the gold standard for locally advanced GC, which will remain unchanged in gastric cancer surgery for the time being. However, not only in Asia but also worldwide, questions of what practice is the best and which chemotherapy regimen is optimal will continue to be debated. Even though numerous chemotherapy drugs have become available worldwide during the last decade, the majority of trials in Asia are planned in combination with S-1. Hence, at least in Asian populations, S-1 will continue to be a key agent in the perioperative treatment of locally advanced GC.

MULTIDISCIPLINARY APPROACHES IN RECURRENT OR METASTATIC GC: PARADIGM SHIFT FROM CYTOTOXIC TO MOLECULARLY TARGETED THERAPY

The effect of surgical therapy for unresectable and metastatic GC has long been controversial, because it is unknown whether resection of the primary tumor provides a survival benefit. For this reason, a phase III randomized trial was conducted in Japan, Korea, and Singapore in which palliative gastrectomy plus chemotherapy was compared with chemotherapy alone for advanced GC with a single noncurable factor (JCOG0705/KGCA01, REGATTA trial).[28] OS between the two groups showed no significant difference (HR 1.09; 95% CI, 0.78–1.52; p = .70), concluding that palliative resection offered no survival benefit. However, patients with a tumor in the lower gastric body, namely who were likely to undergo distal gastrectomy, showed relatively favorable outcomes; further subgroup analyses are currently underway.

Because superiority of chemotherapy over best supportive care was demonstrated in patients with advanced GC, several phase II trials were conducted in Japan to determine the optimal regimen. However, no standard regimen for advanced GC was proposed worldwide at that time. Therefore, the 2004 Guidelines for Diagnosis and Treatment of Carcinoma of the Stomach by the Japanese Gastric Cancer Society recommended chemotherapy with a fluorinated pyrimidine (e.g., 5-FU) combined with cisplatin as a standard regimen for the treatment of GC, but a specific regimen could not be recommended based on results from clinical trials inside and outside of Japan.[42] In a randomized phase III trial by JCOG (JCOG9205), three regimens of 5-FU alone, cisplatin plus 5-FU, and UFT plus MMC were compared, and demonstrated median OS of 7.1, 7.3, and 6 months, respectively, although cisplatin plus 5-FU yielded the best response rate of 34%.[43] This study suggested that the response rate was not always correlated with survival outcomes, which also provided evidence to a growing consensus that efficacy of chemotherapy should be evaluated by survival in a phase III trial (Table 3).

In 1999, when S-1 was first launched in Japan, a large, randomized phase III noninferiority/superiority trial commenced that compared the noninferiority of S-1 alone and superiority of irinotecan plus cisplatin compared with infusion 5-FU alone for the first-line treatment of advanced GC (JCOG9912).[44] Another phase III trial was also conducted to compare S-1 alone with S-1 plus cisplatin for the same patient population in 2002 (SPIRITS trial).[45] The result from JCOG9912 was presented at the American Society of Clinical Oncology Annual Meeting in 2007, showing noninferiority of S-1 compared with 5-FU (median OS, 11.4 vs. 10.8 months, respectively; HR 0.83; 95% CI, 0.68–1.01; p = .0005). As a result, oral S-1 replaced infusion 5-FU as standard of care. Results from the SPIRITS trial were also presented, revealing superiority of S-1 plus cisplatin compared with S-1 alone with a median OS of 13.0 months and 11.0 months, respectively (HR 0.77; 95% CI, 0.61–0.98; p = .04). Since this meeting, the first-line treatment of advanced GC has been S-1 plus cisplatin until today.

A recent phase III study comparing SOX with cisplatin plus S-1 in patients with advanced GC (G-SOX trial) demonstrated noninferiority of S-1 plus oxaliplatin compared with S-1 plus cisplatin with a median progression-free survival of 5.5 months and 5.4 months, respectively (HR 1.004; 95% CI, 0.840–1.19 with a noninferiority margin of 1.30; p = .0044). As a result, SOX has become a major option as first-line chemotherapy.[46] In addition, an advantage of SOX is that it can be safely administered on an outpatient basis without any hydration, which is used for cisplatin. For such a reason, SOX has rapidly gained popularity among expert communities of GC.

Since the mid-2000s, molecular-targeted agents have become popular in the management of gastrointestinal solid tumors as well as breast cancer, exemplified by monoclonal antibodies like trastuzumab, bevacizumab, cetuximab, and so forth. An international, large phase III trial (ToGA trial) was started in 2005, in which chemotherapy (5-FU plus cisplatin or capecitabin plus cisplatin) plus trastuzumab was compared with chemotherapy alone.[47] A total of 584 patients with HER2 expression were included from 122 centers in 24 countries including Japan, South Korea, China, Taiwan, and India. The HER2-positive rate was 22.1%, which was consistent to that in breast cancer. The result demonstrated additional benefit of trastuzumab compared with chemotherapy alone (median OS, 13.8 vs. 11.1 months, respectively; HR 0.74; 95% CI, 0.60–0.91; p = .0046) with acceptable tolerance, offering a new treatment option for advanced GC. The Japanese and Korean guidelines thus recommend that trastuzumab should be added to the first-line chemotherapy regimen for HER2-positive disease.[50,51]

In contrast, the AVAGAST trial did not demonstrate a survival advantage with the addition of bevacizumab to capecitabine and cisplatin compared with placebo (median OS, 12.1 vs. 10.1 months, respectively; HR 0.87, 95% CI, 0.73–1.03; p = .1002) in patients with unresectable and/or metastatic GC.[52] One big difference between the two studies was that the ToGA trial included only patients with positive HER2

status, whereas the AVAGAST included all eligible patients without any molecular selection. A biomarker study from AVAGAST suggested that baseline plasma VEGF-A levels and tumor neuropilin-1 expression were potential predictors of bevacizumab efficacy.[53] Therefore, patient selection was unlikely to be a reason for the negative result of AVAGAST, implying that targeted molecular expression or serum levels as predictive biomarkers for efficacy must be examined before use to exploit molecularly-targeted agents.

With regard to second-line chemotherapy, there are two randomized phase III studies from Japan (WJOG4007) and Korea.[54,55] The former trial, WJOG4007, evaluated superiority of irinotecan alone compared with paclitaxel alone as a consensus regimen, resulting in a median OS of 9.5 months with paclitaxel and 8.4 months with irinotecan (HR 1.13; 95% CI, 0.86–1.49; p = .33). Although the result was negative, this study provided evidence and further treatment options for the second-line treatment of advanced GC. The latter trial compared docetaxel or irinotecan alone with best supportive care. Patients who received chemotherapy demonstrated a median OS of 5.1 months (95% CI, 4.0–6.2) compared with 3.8 months with best supportive care (95% CI, 3.0–4.6; p = .009). Based on the results of these two studies, the Japanese guideline recommends monotherapy with either docetaxel, paclitaxel, or irinotecan, whereas the Korean guideline recommends combination therapy including docetaxel, paclitaxel, platinum, and fluoropyrimidine.

Recent key global studies for the second-line treatment were the REGARD and RAINBOW trials, in which the efficacy of ramucirumab plus paclitaxel was evaluated compared with placebo plus paclitaxel in patients with previously treated advanced gastric or GEJ adenocarcinoma.[48,56] The result of the RAINBOW trial was positive (HR 0.807; 95% CI, 0.678–0.962; p = .017), providing a new option for second-line treatment. Another landmark was the ONO-4538 (nivolumab) trial conducted in Japan, South Korea, and Taiwan. The result was presented at the 2017 ASCO Gastrointestinal Cancers Symposium, which showed an OS benefit in patients with unresectable advanced or recurrent gastric or GEJ cancer refractory to or intolerant of standard therapy.[41] This is the first immunotherapy with demonstrated efficacy in terms of OS in GC. The median OS was 5.3 months with nivolumab and 4.1 months with placebo (HR 0.63; 95% CI, 0.50–0.78; p < .0001) and a 1-year OS of 26.6% and 10.9%, respectively. All patients accrued had received at least two prior treatment regimens; therefore, nivolumab will be used in the third- or subsequent-line in clinical practice. In China, a randomized phase III trial using apatinib, a tyrosine kinase inhibitor that selectively inhibits VEGFR2/KDR, was conducted among patients with chemotherapy-refractory advanced or metastatic gastric or GEJ adenocarcinomas. In this trial, apatinib alone showed a survival benefit and is thus regarded as another promising targeted agents for the third or subsequent line.[49]

Numerous potential molecularly targeted antitumor agents have been developed and tested, which are likely to alter the standard of care after completion of their phase III controlled trials. Many promising agents are currently being investigated in collaboration with Asian and Western countries. The RAINFALL trial, which is being conducted in the Americas, Europe, and Japan, is evaluating the efficacy of ramucirumab, a human IgG1 monoclonal antibody directed to the ectodomain of VEGFR2. In this global phase III trial, patients with HER2-negative, metastatic gastric or GEJ adenocarcinoma will receive ramucirumab plus cisplatin and capecitabine with placebo plus cisplatin and capecitabine as first-line treatment. Another study, named the JACOB trial, is a parallel-arm study that is evaluating the efficacy of pertuzumab in combination with trastuzumab, fluoropyrimidine, and cisplatin as first-line treatment in patients with HER2-positive metastatic gastric or GEJ adenocarcinoma. These two studies have the potential to establish combination therapy with ramucirumab or pertuzumab as an option for the first-line treatment of advanced GC.

Two studies are investigating drug candidates for second-line treatment: the ENRICH and BRIGHTER trials. The ENRICH study is a collaborative trial between Japan and Korea that is comparing nimotuzumab plus irinotecan with irinotecan monotherapy in patients with EGFR-overexpressed advanced gastric and GEJ cancer who have received previous treatment. The BRIGHTER trial will evaluate the efficacy of paclitaxel plus BBI608, an orally administered first-in-class cancer stemness inhibitor, compared with paclitaxel plus placebo in patients with pretreated, advanced gastric and GEJ cancer. Other molecularly- argeted agents, avelumab and pembrolizumab, are also being investigated in Asian and Western countries (JAVELIN-100, -300 trials and KEYNOTE-059, -061, -062 trials).

BEST PRACTICE IN A NEW ERA OF PRECISION MEDICINE: SO FAR AND HEREAFTER

We are currently at a major turning point in medical history. Until very recently, only a single landmark trial established the optimal regimen, in which most patients receive "one-size-fits-all" chemotherapy. Since the beginning of the 21st century, however, numerous molecular candidates for targeted agents have been discovered, and subsequently, a tremendous number of molecularly targeted agents are currently being tested in clinical trials. In the future, it may be almost impossible to compare the exponentially increasing combinations that will be available in the next decades. Therefore, it naturally follows that patients will receive a "bespoke" regimen based on their own gene signatures and molecular expression, which is called precision medicine.[57,58] To achieve this, new biomarkers that can predict a patient's disease status and treatment outcomes are urgently needed.[59-61]

The Cancer Genome Atlas Research Network performed comprehensive molecular characterization of gastric adenocarcinoma by analyzing 295 primary gastric adenocarcinomas. The study proposes a new classification of GC that falls into four genomic subtypes according to the following tumor profiles: positive for Epstein-Barr virus, microsatellite unstable, genomically stable, and chromosomal instability.[62]

The Asian Cancer Research Group proposed another classification based on gene expression profiles with distinct clinical outcomes: microsatellite unstable type, mesenchymal-like type, and p53-active or -inactive types.[63] Each subtype demonstrate noticeable genomic features, which can help develop molecularly-targeted drugs. Patient eligibility in future clinical trials may include such gene profiles to select for distinct populations.

In Asia, during a long period of time, we have established our own evidence that established the best practice and management strategies to treat patients with GC. In a new era of precision medicine, even though differences in history, culture, race, religion, and way of thinking continue to exist, differences in the best practice are soon disappearing, as similarly seen in the globalization of the economy. The new era has just begun. However, there remains a paucity of data. In the future, we should accumulate individual information to be analyzed, share the data, collaborate, and then establish global and comprehensive evidence for the sake of our patients with GC.

Immunotherapy for Esophageal and Gastric Cancer

Ronan J. Kelly, MD, MBA

OVERVIEW

PD-L1 upregulation occurs in approximately 40% of gastroesophageal cancers. However, unlike other solid tumors, there is minimal PD-L1 expressed on the cancer cells; rather, expression occurs predominantly on infiltrating myeloid cells. Preliminary clinical data involving single-agent PD-1/PD-L1 inhibitors in metastatic gastroesophageal cancer have reported response rates of 22%–27% for patients with PD-L1$^+$ tumors and 10%–17% for unselected patients. The phase III ONO-4538-12 (ATTRACTION 2) trial has demonstrated an improved overall survival for nivolumab compared with placebo for patients with heavily pretreated gastric cancer. In the future, we will need better biomarkers to select those most likely to respond and/or identify patients who may need combination immunotherapeutics or alternate strategies. A number of subsets of gastric cancer with different immune signatures, most notably tumors positive for Epstein-Barr virus and microsatellite instability, have been identified, with approximately 50% and 94% PD-L1$^+$ staining seen on tumor cells and immune cells in the EBV subtype and approximately 33% and 45% PD-L1$^+$ staining seen on tumor cells and immune cells in MSI high tumors. Both subtypes demonstrate PD-L1$^+$ immune cells with tumor-infiltrating patterns, unlike the more commonly seen PD-L1$^+$ immune cells at the invasive margin. PD-L2 expression has been reported in 52% of esophageal adenocarcinomas but little is known about the expression of other immune checkpoints. Additional factors that suggest gastroesophageal cancers may respond to checkpoint inhibition include the high somatic mutation burden and the link with chronic inflammation. Here we provide a comprehensive review of the checkpoint inhibitor data published to date in advanced esophagogastric cancers and rationalize how the immune microenvironment in these diverse tumors can explain response or resistance to immunotherapeutics.

Esophageal and gastric cancers have limited treatment options in the locally advanced and metastatic setting, with chemotherapy resistance limiting efficacy beyond the first- or second-line setting. With the exception of trastuzumab and ramucirumab, results of clinical trials utilizing targeted agents have been disappointing.[1-3] The Cancer Genome Atlas (TCGA) recently published comprehensive molecular characterizations of gastric and, more recently, esophageal cancer.[4,5] It was hoped that with a more complete biologic understanding of the mutational landscape underpinning upper gastrointestinal tumors, newer targeted therapeutic options would emerge. Unfortunately, this does not seem to be the case, and although basket trials investigating novel targeted agents may be useful for a small select patient population with a targetable oncogenic mutation, the majority of patients will not derive substantial therapeutic benefits.

The link between infection, chronic inflammation, and malignancy has long been recognized in esophagogastric cancer and suggests that targeting the immune system may lead to improved outcomes in tumors that are inherently resistant to systemic treatments as a result of histologic, molecular, and etiological heterogeneity.[6-8] TCGA investigators identified that the Epstein-Barr virus (EBV) subtype in gastric cancer displays recurrent PIK3CA mutations, extreme DNA hypermethylation, and amplification of JAK2, PD-L1, and PD-L2, and the microsatellite instability (MSI) subtype shows elevated mutation rates.[4] It is likely that the majority of patients who respond to single-agent checkpoint inhibition may have these subtypes, although this remains to be determined. Alternatively, patients with the genomically stable subtype (mutations of RhoA or fusions involving Rho-family guanosine 5′-triphosphatase–activating proteins) and the chromosomal unstable subtype (marked aneuploidy and focal amplification of receptor tyrosine kinases) may need novel combination immunotherapeutics. Recently published TCGA esophageal data also highlighted that squamous cell esophageal carcinomas show frequent genomic amplifications of *CCND1* and *SOX2* and/or *TP63*, whereas *ERBB2*, *VEGFA*, *GATA4*, and *GATA6* were more commonly amplified in adenocarcinomas. In fact, esophageal adenocarcinomas strongly resembled the chromosomally unstable variant of gastric adenocarcinoma.[5] These data, although interesting, do not help us with preselecting patients for immunotherapeutic strategies. Emerging data in other tumor types suggest that negative immune checkpoint

proteins are usually upregulated in tumor tissues with a T cell–inflamed phenotype and that infiltration of tumors by effector T cells is necessary to drive upregulation of immune checkpoints.[9] This finding suggests that targeting the PD-1/PD-L1 axis in esophagogastric cancer may only be clinically effective in the subgroup of tumors (excluding MSI^+ or EBV^+) that contain tumor-infiltrating immune cells. The clinical relevance of other factors such as the potential contributions of myeloid-derived suppressor cells, $CD4^+CD25^+FoxP3^+$ regulatory T cells, and indoleamine 2,3-dioxygenase (IDO) must be elucidated. Given the considerable number of trials that are currently ongoing, it is hoped that improved characterization of the tumor immune microenvironment in upper gastrointestinal tumors may yield a more nuanced understanding of the interactions between $CD8^+$ T cells and immunosuppression and provide further targets for immune-based therapy.

THE IMMUNE MICROENVIRONMENT IN ESOPHAGEAL AND GASTRIC CANCER

Tumors escape immune surveillance by a number of mechanisms, but, simplistically, four groups have been proposed utilizing PD-L1 status and the presence or absence of tumor-infiltrating lymphocytes (TILs). These include type I ($PD\text{-}L1^+$ with TILs driving adaptive immune resistance), type II ($PD\text{-}L1^-$ with no TIL indicating immune ignorance), type III ($PD\text{-}L1^+$ with no TIL indicating intrinsic induction), and type IV ($PD\text{-}L1^-$ with TILs indicating the role of other suppressors in promoting immune tolerance).[10] Malignant melanoma has been extensively studied and a high proportion of type I and type II microenvironments are seen,[11] whereas this information is yet to be defined in gastric and esophageal cancers. It is clear, however, in two of the four proposed immune resistance mechanisms that PD-L1 expression appears to play a key role. The early events that lead to enhanced expression of PD-1/PD-L1 by tumor cells and/or host immune cells in esophageal and gastric cancer are not yet known. Genomic aberrations leading to enhanced PD-L1 expression have been demonstrated in both the MSI and EBV subtypes of gastric cancer.[4,12]

We currently know that there are a number of factors in the immune microenvironment that can predict whether a patient is likely to respond to single-agent PD-1 inhibition. These factors include a high tumor antigen load, loss of help by $CD4^+$ helper cells, and immune-regulatory cytokines and ligands for coinhibitory proteins expressed by tumor and stromal cells, leading to a progressive loss of the ability of effector $CD8^+$ T cells to produce proinflammatory cytokines (e.g., interleukin-2, interferon [IFN]-γ, tumor necrosis factor-α, and β-chemokines) and ultimately their ability to kill cancer cells, a state termed T-cell exhaustion. We previously demonstrated in esophagogastric cancers that more $CD8^+$ T-cell infiltration occurs in tumors and at the peritumoral interfaces of tumors that were also $PD\text{-}L1^+$ compared with those that were $PD\text{-}L1^-$. When $CD8^+$ T-cell densities were divided into low, mid-, and high categories, we found that 89% of stroma $PD\text{-}L1^+$ tumors had high $CD8^+$ densities. This highlights the linkage between $CD8^+$ T cells, mechanistically thought to be a source of cytokines such as IFN-γ, and expression of PD-L1 in esophagogastric cancer.[11,13]

PD-L1 upregulation occurs in approximately 40% of gastroesophageal cancers; however, key differences are emerging in that unlike lung cancer or melanoma, there is little PD-L1 expressed on the cancer cells of upper gastrointestinal tumors, but rather expression occurs predominantly on infiltrating myeloid cells at the invasive margin.[13-15] There are exceptions, however. In the 10% of gastric cancers that are EBV^+, approximately 50% and 94% $PD\text{-}L1^+$ staining is seen on tumor cells and immune cells, respectively.[16] MSI also affects $PD\text{-}L1^+$ status, with tumor and immune cells staining positive in 33% and 45% of cases, respectively, with both subtypes having $PD\text{-}L1^+$ immune cells with tumor-infiltrating patterns.[16] The localization of PD-L1 expression within the tumor microenvironment (infiltrating immune cells, at invasive margin or tumor core) may affect its use as a biomarker and the stromal expression rather than membranous expression may be responsible for the somewhat lower responses to single-agent PD-1 inhibitors in gastroesophageal cancer compared with other tumor types but more knowledge is needed. PD-L2 expression has been reported in 51.7% of esophageal adenocarcinomas,[14] but little is known about the expression of other checkpoints and what the impact is on the response to PD-1 inhibitors. Additional factors that warrant investigation in esophagogastric cancers and may predict response include the association with chronic inflammation and high somatic mutation burden.

KEY POINTS

- **PD-L1 is expressed in approximately 40% of esophagogastric cancers.**
- **Unlike melanoma or lung cancer, membranous PD-L1 expression is rare in esophageal and gastric cancers and occurs predominantly on infiltrating myeloid cells at the invasive margin.**
- **The EBV and MSI subtypes of gastric cancer are unique, with approximately 50% and 94% $PD\text{-}L1^+$ staining seen on tumor cells and immune cells in EBV positive tumors and approximately 33% and 45% $PD\text{-}L1^+$ staining seen on tumors cells and immune cells in MSI high tumors. Both subtypes demonstrate $PD\text{-}L1^+$ immune cells with tumor-infiltrating patterns, and preliminary data show higher response rates to PD-1 inhibitors.**
- **Phase II and phase III data show that unselected patients with metastatic esophagogastric cancer have response rates of approximately 10%-17%, whereas patients who have $PD\text{-}L1^+$ tumors (> 1% of cells) have response rates of 22%–27%. Novel combination trials are ongoing with improved efficacy but with more toxicity.**
- **The ONO-4538-12 (ATTRACTION 2) is the first phase III immunotherapy trial to date to show an improved overall survival benefit for patients with heavily pretreated metastatic gastric and esophageal cancer (5.32 months with nivolumab vs. 4.14 months with placebo; hazard ratio, 0.63; $p < .0001$).**

CHRONIC INFLAMMATORY CHANGES, HIGH SOMATIC MUTATION BURDEN, AND EBV

Esophagogastric tumors develop in part as a result of prolonged chronic gastric reflux–induced inflammation. In response to gastric reflux, the occurrence of Barrett metaplasia in the esophagus is accompanied by a change from an acute (TH1-type) immune response associated with IFN-γ expression to a TH2-type chronic inflammation with production of interleukin-4/interleukin-13, which is reported to result in an immunosuppressive, tumor-promoting microenvironment.[17,18] In addition, it is thought that high somatic mutational burden may be important in predicting response to PD-1 inhibitors and only melanoma, lung, and bladder cancers display a more mutated profile than gastroesophageal cancers.[19] Continued research on the link between mutation burden and the T cell-inflamed phenotype may be more predictive of response than the number of mutations alone.

Defective mismatch repair (MMR) genes have also been identified as being predictive of response to PD-1 inhibition, because somatic mutations have the potential to encode non-self immunogenic neoantigens.[12] Whole-exome sequencing has demonstrated a mean of 1,782 somatic mutations in MMR-deficient tumors compared with approximately 73 in MMR-proficient tumors.[12] In addition, immunologic assessment of the immune microenvironment in MMR-deficient tumors demonstrated strong expression of several immune checkpoint ligands, most notably, PD-1/PD-L1, LAG-3, IDO, and CTLA-4, which help confer resistance to immunologic attack.[20] MMR deficiency has been identified in approximately 17%–21% of gastric cancers, and very preliminary data indicate a higher response rate among these patients (on the order of approximately 50%).[15,21] Ongoing and future studies of gastroesophageal cancer are stratifying patients according to their MSI status.

EBV^+ gastric cancers occur predominantly in the gastric fundus or body and are more common among men. Gastric TCGA investigators describe a recurrent amplification at 9p24.1; this is the locus containing *JAK2* but also *CD274* and *PDCD1LG2*, which encode PD-L1 and PD-L2, respectively. These 9p amplifications occurred in 15% of EBV-driven gastric tumors and result in enhanced neoepitope

TABLE 1. Selected Ongoing Clinical Trials Involving PD-1 Targeting Therapies for Esophageal and Gastric Cancer

Clinical Trial Identifier	Phase	Study Design	Study Population	Primary Endpoints
Pembrolizumab				
NCT02443324	I	Pembrolizumab plus ramucirumab	Gastric/GEJ plus other tumor types	Safety
NCT02346955	I	Pembrolizumab plus CM-24 (anti-CEACAM1)	Gastric/GEJ plus other tumor types	RP2D, safety
NCT02268825	I	Pembrolizumab plus FOLFOX chemotherapy	Metastatic gastric/esophageal	Safety
NCT02563548	IB	Pembrolizumab plus PEGPH20	Gastric/GEJ plus other tumor types, second line	ORR, safety
NCT02689284	IB/II	Pembrolizumab plus margetuximab (anti-HER2)	Metastatic, $HER2^+$, second line	MTD, antitumor activity
NCT02730546	I/II	Pembrolizumab plus chemotherapy plus RT	Resectable GEJ/cardia	Pathologic response, PFS
NCT02452424	I/II	Pembrolizumab plus PLX3397 (CSF1R inhibitor)	Gastric plus other tumor types	Safety

presentation.[4] Ongoing studies are evaluating checkpoint inhibitors in EBV+ gastric cancer (NCT02488759).

PD-L1 EXPRESSION IN ESOPHAGEAL AND GASTRIC CANCER

PD-L1 expression occurs in approximately 40% of gastric and gastroesophageal junction (GEJ) cancers.[22-24] The KEYNOTE-012 trial assessed single-agent pembrolizumab administration for patients with PD-L1+ advanced gastric or GEJ adenocarcinomas (with Dako 22C3 antibody staining both tumor cells and mononuclear inflammatory cells). Of the 162 patients screened, 65 (40%) were considered PD-L1+. PD-L1 positivity was defined as membrane staining in at least 1% of scorable cells or the presence of a distinctive interface pattern. The trial investigators commented that it was necessary for them to assess PD-L1 expression in the immune cells as opposed to tumor cell expression exclusively.[15] We previously reported that of 34 resected gastric or GEJ tumors stained by immunohistochemistry using the 5H1 clone, only 12% of tumors demonstrated cell membranous PD-L1 expression, whereas 44% showed expression within the immune stroma.[13] We do not yet know whether stromal versus membranous expression affects response in esophagogastric cancer; however, in a recently published first-line metastatic lung cancer study comparing pembrolizumab to chemotherapy, membranous PD-L1 expression of more than 50% was needed to demonstrate superiority of immunotherapy over cytotoxic therapy.[25]

MOVING BEYOND PD-L1: OTHER POTENTIAL BIOMARKERS IN ESOPHAGOGASTRIC CANCER

In addition to PD-L1 staining, a mononuclear inflammatory cell density score of 0–4 was assessed in the KEYNOTE-012 trial.[15] Four of 9 patients (44%) with a score of 3 or more had a partial response, compared with only four of 26 patients (15%) with a score of 2 or less. Unfortunately, these numbers are too small to make definitive conclusions, but the data are intriguing. Ongoing larger phase III studies are assessing a number of immune correlates and gene signatures, which should provide more clarity. The KEYNOTE-012 trial also investigated the use of a six-gene IFN-γ signature that was previously identified to predict response in melanoma.[26] The six genes included *CXCL9*, *CXCL10*, *IDO1*, *IFNG*, *HLA-DRA*, and *STAT-1* and were used to calculate an IFN-γ composite score. Unfortunately, the numbers of enrolled patients were small and the prespecified gene signature did not meet significance at .05, but there is a signal and the ongoing KEYNOTE studies will continue this line of investigation.

CLINICAL TRIAL DATA INVOLVING PD-1/PD-L1 INHIBITORS IN ESOPHAGOGASTRIC CANCER

Nivolumab (PD-1 Inhibitor)

ONO-12 (ATTRACTION 2) was a multicenter, double-blind, randomized phase III study of nivolumab for patients with unresectable advanced or recurrent gastric or GEJ cancer refractory to or intolerant of two or more prior chemotherapy regimens (NCT02267343; Table 1). The results were presented at the 2017 ASCO Gastrointestinal Cancers Symposium and showed for the first time that PD-1 inhibition could lead to an improvement in overall survival for patients with heavily pretreated gastric or gastroesophageal cancer.[27] Median overall survival was 5.32 months (95% CI, 4.63–6.41) with nivolumab versus 4.14 months (95% CI, 3.42–4.86) with placebo, and the 12-month overall survival rate was 26.6% (95% CI, 21.1%–32.4%) versus 10.9% (hazard ratio, 0.63; 95% CI, 6.2%–17%; $p < .0001$). In addition, median progression-free survival was 1.61 months with nivolumab versus 1.45

Abbreviations: RT, radiation therapy; IO, novel immune-oncology drug; SCC, squamous cell cancer; EBV, Epstein-Barr virus; GEJ, gastroesophageal junction; ORR, objective response rate; PFS, progression-free survival; DoR, duration of response.

months with placebo (hazard ratio, 0.60; p < .0001). The overall response rate was 11.2% with nivolumab versus 0% with placebo, and the median duration of response to nivolumab was 9.53 months (95% CI, 6.14–9.82 months).

CheckMate-032 was a phase I/II open-label study of the safety and activity of nivolumab alone or with ipilimumab in advanced and metastatic solid tumors (NCT01928394). This study enrolled 160 patients with advanced/metastatic gastric or gastroesophageal cancer who had progressed while receiving standard chemotherapy, most of whom received two or more prior regimens.[28] Patients were randomized to receive 3 mg/kg of nivolumab every 2 weeks (N3), 1 mg/kg of nivolumab plus 3 mg/kg of ipilimumab (N1 plus I3) or 3 mg/kg of nivolumab plus 1 mg/kg of ipilimumab (N3 plus I1) every 3 weeks for four cycles, followed by 3 mg/kg of nivolumab every 2 weeks until disease progression or treatment was no longer tolerable. Treatment toxicities (any grade) were more common in the N1 plus I3 arm (84%) than in the N3 (70%) or N3 plus I1 (75%) arms. From the preliminary data presented to date, 96% of patients (154) were evaluable for efficacy outcome reporting and the objective response rates for unselected patients were 14% (nivolumab alone), 26% (N1 plus I3), and 10% (N3 plus I1). The median overall survival was highest in the N1 plus I3 group (6.9 months; 95% CI, 3.6 or not achieved), followed by N3 (5.0 months; 95% CI, 3.4–12.4), and N3 plus I1 (4.8 months; 95% CI, 3.0–9.1). For patients with PD-L1$^+$ tumors (defined as greater than 1% of cells staining positive), the response rate for single-agent nivolumab was 27% (four of 15 patients); the response rate for the combination of the more active N1/I3 was an impressive 44%, albeit the numbers reported to date are small and we await updated information (four of nine patients). For patients with PD-L1$^-$ tumors (< 1% of cells staining positive), the response rates were 12% (three of 25 patients) for nivolumab and 21% (six of 29 patients) for N1/I3. These data highlight important points for future investigation. As with other solid tumors, we know that PD-L1 is not a perfect biomarker; however, given the relatively low response rate among patients with esophagogastric cancer whose tumors are PD-L1$^-$, it may be more appropriate to investigate combination strategies in this population.

Many of the studies performed to date have included only the adenocarcinoma histology in esophagogastric cancer. We do, however, have some data investigating nivolumab for patients with advanced esophageal squamous cell cancer. In the ONO-4538-12 study, nivolumab (3 mg/kg every 2 weeks) was administered to 65 patients in a phase II, single-arm, multicenter study in Japan, and the investigators found that 17.2% of patients achieved an objective response.[29] The median overall survival was 12.1 months and 14% of patients had serious adverse events, but no treatment-related deaths occurred. This study supports further phase III testing of nivolumab for patients with esophageal squamous cell cancer. The ongoing adjuvant study CheckMate-577 investigating nivolumab in resected stage II/III esophageal cancer is enrolling both patients with adenocarcinoma and squamous cell carcinomas.

Pembrolizumab (PD-1 Inhibitor)

In addition to nivolumab, there are a number of ongoing trials investigating the efficacy of the PD-1 inhibitor pembrolizumab in esophagogastric cancer. The KEYNOTE-012 study was a multicenter, nonrandomized, open-label, multicohort phase Ib trial evaluating single-agent pembrolizumab (10 mg/kg every 2 weeks or a 200-mg fixed dose every 3 weeks) for patients with PD-L1$^+$ recurrent or metastatic gastric/GEJ adenocarcinoma.[15] From the data published to date, 39 patients were enrolled at 13 centers based in the United States, Israel, Japan, South Korea, and Taiwan and 36 were considered evaluable. A partial response rate of 22% (8 of 36 patients; 95% CI, 10–39) was observed for this group of heavily pretreated patients, more than 75% of which had received two or more prior therapies in the metastatic setting. The regimen was well tolerated overall, with 13% of patients experiencing grade 3–4 toxicity; no patients discontinued the study because of a treatment-related adverse

TABLE 4. Summary of Selected Published and Ongoing Phase III Trials or Completed Phase I/II Trials in the Refractory Setting in Gastroesophageal Cancer

Anti–PD-1, Anti–PD-L1, or Anti–CTLA-4	Adjuvant or Neoadjuvant	First-Line Metastatic Cancer	Second-Line Metastatic Cancer	Refractory Disease	Refractory Disease (Phase I/II Trials)
Nivolumab (PD-1)	CheckMate-577 (phase III): nivolumab vs. placebo in resected stage II/III esophageal/GEJ cancer			ONO-4538-12 (ATTRACTION 2; phase III): nivolumab vs. placebo; OS, 5.32 months vs. 4.14 months; 12-month OS, 26.6% vs. 10.9%	CheckMate-032 (phase I/II): ORR, 14% PD-L1 unselected; ORR, 27% PD-L1$^+$ (> 1%)
					ONO-4538 (phase II): ORR, 17.2% (Asian patients, squamous cell esophageal)
Pembrolizumab (PD-1)		KEYNOTE-059 (phase II): pembrolizumab plus cisplatin/5-FU (cohort B) or pembrolizumab alone (cohort C)	KEYNOTE-061 (phase III): pembrolizumab vs. paclitaxel		KEYNOTE-012 (phase I): ORR, 22%
		KEYNOTE-062 (phase III): pembrolizumab vs. pembrolizumab + cisplatin/5-FU vs. placebo + cisplatin/5-FU	KEYNOTE-181 (phase III): pembrolizumab vs. paclitaxel, docetaxel, or irinotecan		KEYNOTE-028 (phase I): ORR, 30%
					KEYNOTE-180 (phase II): third-line study of single-agent pembrolizumab
Avelumab (PD-L1)		JAVELIN Gastric 100 (phase III): maintenance avelumab after FOLFOX			JAVELIN (phase I): ORR, 9.7% PD-L1 unselected; ORR, 18.2% PD-L1$^+$ (> 1%)
Nivolumab/ipilimumab		CheckMate-649 (phase III): nivolumab + ipilimumab vs. FOLFOX/XELOX			CheckMate-032 (phase I/phase II): ORR, 26% PD-L1 unselected; ORR, 44% PD-L1$^+$ (> 1%)
Durvalumab/tremelimumab					NCT02340975 (phase I/phase II) durvalumab vs. tremelimumab vs. combination

Abbreviations: GEJ, gastroesophageal junction; 5-FU, fluorouracil; FOLFOX, leucovorin calcium (folinic acid)/fluorouracil/oxaliplatin; XELOX, capecitabine (Xeloda)/oxaliplatin; OS, overall survival; ORR, objective response rate.

event. PD-L1 positivity was reported in 40% of gastric/GEJ tumors, and the authors defined positivity as membranous staining on more than 1% of scorable cells or the presence of a distinctive interface pattern using immunohistochemistry clone 22C3.[22]

The KEYNOTE-028 study evaluated the role of pembrolizumab (10 mg/kg every 2 weeks up to 2 years or until progression) in PD-L1$^+$ advanced solid tumors including esophageal/GEJ cancers (adenocarcinoma and squamous cell cancer).[30] From the data presented to date, 23 patients were enrolled, with a median follow-up duration of 31 weeks (range, 5.7–71), and 87% had received two or more prior therapies. The objective response rate was 30% (95% CI, 13.2–52.9) with 6- and 12-month progression-free survival rates of 30.4% and 21.7%, respectively. In this trial, 74% of patients had squamous histology.

Per ongoing efforts in other solid tumors, PD-1 inhibitors are being combined with cytotoxic chemotherapy in an attempt to improve response rates. The KEYNOTE-059 study is a first-line HER2$^-$ phase II study of patients with advanced

gastric/GEJ adenocarcinoma. Patients receive 200 mg of pembrolizumab plus 800 mg/m^2 of fluorouracil (5-FU; or 1,000 mg/m^2 of capecitabine in Japan) plus 80 mg/m^2 of cisplatin every 3 weeks for six cycles, followed by pembrolizumab plus 5-FU/capecitabine maintenance for up to 2 years or until progression.[31] After a median follow-up of 5.5 months (range, 4.0–7.3), 17 patients (94%) had experienced a treatment-related adverse event (any grade), including anorexia, nausea, and neutropenia; of these patients, 12 (67%) experienced grade 3–4 toxicities. These preliminary data suggest that combinatorial PD-1/chemotherapy therapy has manageable toxicity profiles for patients with advanced gastric cancer. We await the efficacy data from this study; given the positive results from a lung cancer trial of pembrolizumab plus chemotherapy, it is hoped that they will be similar in esophagogastric cancer.[32]

Important ongoing phase III studies are the KEYNOTE-061 and the KEYNOTE-062 trials. KEYNOTE-061 is an open-label trial evaluating pembrolizumab versus paclitaxel for patients with advanced gastric or GEJ cancer whose tumors have progressed after first-line therapy with a platinum/fluoropyrimidine combination.[33] Patients are randomly assigned to receive 200 mg of pembrolizumab every 3 weeks or 80 mg/m^2 of paclitaxel on days 1, 8, and 15 of a 28-day cycle. Treatment will continue until the disease progresses or the drug is no longer tolerated; the primary efficacy endpoints are progression-free survival and overall survival for patients with PD-L1$^+$ tumors. The KEYNOTE-062 trial is designed to compare the efficacy and safety of pembrolizumab alone (200 mg every 3 weeks) or in combination with cisplatin plus 5-FU (cisplatin 80 mg/m^2 every 3 weeks and 5-FU 800 mg/m^2 on days 1–5 of each 3-week cycle) with chemotherapy alone (cisplatin + 5-FU) as first-line therapy for PD-L1$^+$/HER2$^-$ advanced gastric or GEJ adenocarcinoma. Primary endpoints are overall survival and progression-free survival.

Avelumab (PD-L1 Inhibitor)

Avelumab, an anti–PD-L1 IgG1 antibody, is currently being assessed in the JAVELIN program (NCT01772004) with expansion cohorts for selected tumor types, including gastric/GEJ tumors (Table 2).[34] Patients received 10 mg/kg of avelumab every 2 weeks, and preliminary data show a 9.7% response rate in the second-line setting. For Japanese patients who had progressed while receiving prior chemotherapy, the reported overall response rate was 15% (three of 20 patients), with the proportion of patients' progression-free survival at 12 weeks being 43.3%.[35] The JAVELIN Gastric 300 trial is currently recruiting patients with recurrent, locally advanced, or metastatic gastric/GEJ tumors in an open-label study comparing avelumab to best supportive care in the third-line setting (NCT02625623). Maintenance immunotherapy is being assessed in the JAVELIN Gastric 100 study, which compares single-agent avelumab (10 mg/kg every 2 weeks) to continuation of first-line chemotherapy (5-FU/leucovorin or capecitabine plus oxaliplatin; NCT02625610).[36]

Durvalumab (PD-L1 Inhibitor)

Durvalumab is a selective, high-affinity, human IgG1κ monoclonal antibody that blocks PD-L1 binding to CD80 and PD-1. Investigators reported that 10 mg/kg of single-agent durvalumab given intravenously every 2 weeks for 12 months showed potential clinical activity in gastroesophageal cancers.[37] A small 26-patient phase II open-label study is currently investigating treatment with 1,500 mg of maintenance durvalumab given intravenously every 4 weeks to patients with persistent residual esophageal cancer after definitive surgery following concurrent chemoradiation (NCT02639065). A phase IB/II study is currently enrolling patients with GEJ or gastric adenocarcinomas in the second- and third-line metastatic settings for treatment with single-agent durvalumab, single-agent tremelimumab, or combination durvalumab and tremelimumab (anti–CTLA-4).[38]

ADJUVANT AND NEOADJUVANT STUDIES IN STAGE II/III ESOPHAGOGASTRIC CANCER

Alternative approaches to improve patient outcomes with acceptable toxicity might include substitution of immunotherapy into the adjuvant or indeed neoadjuvant setting in stage II or stage III disease (Table 3). Given the potentially harmful effects of multiple chemotherapy treatment regimens on the immune system, it is possible that application of PD-1 pathway blockade earlier in a disease course before a tumor metastasizes may significantly enhance a drug's ability to induce immune-mediated cancer regression. In addition, it is postulated that PD-L1 and other immune biomarkers may actually be induced by prior anticancer therapy including chemoradiation.[39] We have shown that after neoadjuvant therapy, there is a consistent trend for chemoradiation to induce more TILs (tumor lymphocytes), clustering of lymphocytes around tumor-associated blood vessels (perivascular lymphocytes), and clusters of lymphocytes (tertiary lymphoid structures).[13] The appearance of these microenvironment features after induction therapy suggests that a tumor will respond favorably to immune-based therapy and, in particular, to PD-1–based checkpoint blockade. This provides an intriguing possibility to study the efficacy of neoadjuvant and adjuvant PD-1 inhibition.

CheckMate-577 is a randomized phase III study of adjuvant nivolumab for patients with resected lower esophageal/gastroesophageal cancer (Table 4). Approximately 760 patients will be randomly selected in a 2:1 fashion to receive either 240 mg of nivolumab intravenously once every 2 weeks for 16 weeks and then 480 mg once every 4 weeks for a maximum of 12 months or to the current standard of care (placebo). To date, this is the largest adjuvant study of a checkpoint inhibitor performed in esophageal cancer. Primary endpoints are overall and disease-free survival. Results of this study are eagerly anticipated, as the lack of data for adjuvant chemotherapy after trimodality therapy in resected stage II/III esophageal cancer has led to confusion about the optimal treatment strategy for patients who do not achieve a pathologic complete response to neoadjuvant chemoradiation. Smaller phase I/II studies with differing

designs are currently assessing the safety and efficacy of nivolumab, pembrolizumab, and durvalumab in the neoadjuvant setting, given either concurrently or sequentially with neoadjuvant chemoradiation.

CONCLUSION

Preliminary data from clinical trials involving single-agent checkpoint inhibitors in metastatic gastroesophageal cancer have demonstrated response rates of approximately 22%–27% for the subset of patients with PD-L1$^+$ tumors (40%) and response rates of approximately 10%–17% for unselected patients. In addition, as with other solid tumors, it is likely that viral infection, mutational burden, and MSI status will be predictive of response to checkpoint inhibitors, driven in part by differences in the density of TILs and PD-L1 expression. We do, however, need a much greater understanding as to how immunosuppressive factors such as myeloid-derived suppressor cells, CD4$^+$CD25$^+$FoxP3$^+$ regulatory T cells, and IDO interact in the immune microenvironment in esophagogastric cancer. We must also determine whether tumor location plays a role, with distinctive biology emerging between esophageal, GEJ, and gastric cardia tumors. A recent TCGA publication on esophageal cancer showed that no esophageal adenocarcinomas were positive for MSI or EBV.[5] However, among GEJ adenocarcinomas that were not clearly of esophageal origin, the authors did identify MSI$^+$ and EBV$^+$ tumors.

It is also hoped that we can determine whether specific mutational changes akin to the recently described *JAK1/2* mutations leading to loss of IFN-γ signaling are present in esophageal and gastric cancer.[40] These immunotherapy-resistant mutations represent an immune-editing process that defines patients with cancer who would not be good candidates for PD-1 blockade therapy. We must ensure that the genomic data obtained from the esophageal and gastric TCGA are used in future immunotherapy trials as we look for signals for responsive or resistant disease. The efforts to identify predictive signatures to guide our treatment decisions are of crucial importance, and we must refine PD-L1 assessment so that it becomes easier to interpret. In 2017, we know that the higher the PD-L1 expression, the higher the response rate; this seems to be similar for combination strategies involving PD-1/CTLA-4 inhibitors. However, there is a substantial subset of patients with PD-L1$^-$ tumors that respond to combination strategies, with 21% of heavily pretreated patients responding to nivolumab/ipilimumab combinations. In the coming years, it is hoped that as the larger phase II/III esophagogastric immunotherapy studies mature, we will gain a more nuanced understanding of the interactions that are occurring in the immune microenvironment so that individualized tailored treatment can be prescribed for patients so that the true promise of immunotherapy can be realized in these diverse tumors.

Pancreatic Adenocarcinoma: Improving Prevention and Survivorship

Davendra P. S. Sohal, MD, MPH, Field F. Willingham, MD, MPH, Massimo Falconi, MD, Kara L. Raphael, MD, and Stefano Crippa, MD, PHD

OVERVIEW

Pancreatic cancer is a growing problem in oncology, given slowly rising incidence and continued suboptimal outcomes. A concerted effort to reverse this tide will require prevention, early diagnosis, and improved systemic therapy for curable disease. We focus on these aspects in detail in this study. Hereditary pancreatic cancer is an underappreciated area. With the growing use of genomics (both somatic and germline) in cancer care, there is increasing recognition of hereditary pancreatic cancer cases: around 10% of all pancreatic cancer may be related to familial syndromes, such as familial atypical multiple mole and melanoma (FAMMM) syndrome, hereditary breast and ovarian cancer, Lynch syndrome, and Peutz-Jeghers syndrome. Screening and surveillance guidelines by various expert groups are discussed. Management of resectable pancreatic cancer is evolving; the use of multiagent systemic therapies, in the adjuvant and neoadjuvant settings, is discussed. Current and emerging data, along with ongoing clinical trials addressing important questions in this area, are described. Surveillance recommendations based on latest ASCO guidelines are also discussed. Finally, the multimodality management of borderline resectable pancreatic cancer is discussed. The various clinicoanatomic definitions of this entity, followed by consensus definitions, are described. Then, we focus on current opinions and practices around neoadjuvant therapy, discussing chemotherapy and radiation aspects, and the role of surgical resection.

Pancreatic adenocarcinoma remains a vexing cancer. Incidence is increasing slowly, but clinical outcomes have not improved remarkably. There are 53,670 new cases expected in the United States in 2017,[1] and it is expected to be the second leading cause of cancer-related deaths by 2030.[2] Important reasons for these statistics are late diagnosis—only about 20% of cases present as resectable disease—and suboptimal efficacy of systemic therapies. Therefore, prevention, early diagnosis, and improved therapeutic approaches and agents are components of a broad strategy aimed at reducing morbidity and mortality from this cancer. Our focus is to discuss these components, highlighting state-of-the-art evidence and future directions.

BEST PRACTICES IN MANAGEMENT OF RESECTABLE PANCREATIC CANCER: EMERGING STANDARDS FOR ADJUVANT THERAPY AND SURVEILLANCE

Definition of Resectability

The terms resectable, borderline resectable, and unresectable tumor are emerging as consensus terminology to describe the feasibility of surgical resection. These are based largely on the relationship of the tumor to surrounding blood vessels. Borderline resectable cancer is discussed in detail in the final section. For resectable cancers, we focus on tumor-vessel wall interface, describing the extent of the interface in terms of geometry (degrees of circumference), instead of subjective terms such as abutment, involvement, impingement, encasement, etc. The working definition of resectable cancers is derived from the Intergroup approach[3]:

- Absence of tumor-artery (celiac artery, common hepatic artery, superior mesenteric artery, and, if present, replaced right hepatic artery) interface;
- No involvement, or < 180° tumor-vein (portal vein, superior mesenteric vein) interface, and patent portal vein/splenic vein confluence; and
- Absence of metastatic disease (including lymphadenopathy outside the surgical basin).

Based on this definition, about 15%–20% of cases of pancreatic cancer are resectable at presentation.

Standard of Care for Resectable Disease

The standard of care is upfront resection followed by adjuvant therapy (Table 1). The goal of resection is to remove all macroscopic disease; all attempts should be made

TABLE 1. Key Published Adjuvant Therapy Trials in Pancreatic Adenocarcinoma

Study, Year First Published	Total Patients	Treatment Arms	Primary Outcome	Result*
GITSG, 1985	43	5-FU/RT × 2 years, Sx	OS	20 vs. 11 (p = .03)
EORTC, 1999	218	5-FU/RT, Sx	OS	24.5 vs. 19 (HR 0.8; p = .21)
ESPAC-1, 2004	289	4 arms, 2 × 2 design: 5-FU vs. no comparison	OS	20.1 vs. 15.5 (HR 0.71; p = .009)
ESPAC-1, 2004	289	4 arms, 2 × 2 design: RT vs. no comparison	OS	15.9 vs. 17.9 (HR 1.28; p = .05)
CONKO-001, 2007	368	Gem, Sx	DFS	13.4 vs. 6.7 (HR 0.55; p < .001)
RTOG 9704, 2008	451	5-FU with 5-FU/RT, Gem with 5-FU/RT	OS	NA (HR 0.93; p = .51)
ESPAC-4, 2017	730	Gem with capecitabine, Gem	OS	28 vs. 25.5 (HR 0.82; p = .032)

*All outcomes are shown in months.

Abbreviations: RT, radiation; Sx, surgery; Gem, gemcitabine; DFS, disease-free survival; NA, not available.

to obtain negative surgical margins. A common adjuvant approach consists of gemcitabine for 6 months, based on improved disease-free survival (primary outcome) seen in the CONKO-001 study.[4] Overall survival (OS) was marginally improved with gemcitabine in this trial. The ESPAC-1 study also suggested an improvement in OS with the addition of adjuvant 5-fluorouracil (5-FU).[5] The ESPAC-3 and RTOG-9704 trials showed no difference between gemcitabine and 5-FU, making either approach reasonable.[6,7] The role of adjuvant radiation remains controversial: there are no data clearly showing improvement in OS with the addition of radiation, other than the original GITSG study, albeit a small trial with older treatment methods.[8] In fact, later studies such as ESPAC-1 and EORTC 40891 showed no improvement in OS with adjuvant chemoradiation.[5,9] A meta-analysis of these trials of adjuvant therapy showed that 5-FU is associated with the most benefit, gemcitabine with modest benefit, and chemoradiation with no benefit.[10] Although the nuances of each study and differences between the various trials are debatable, it is clear that even with the best care standard today, surgery followed by adjuvant therapy, the median OS remains less than 2 years (Table 1).

KEY POINTS

- **Around 10% of pancreatic cancer cases may be familial.**
- **Increased genetic testing may allow early identification of persons at risk of developing pancreatic cancer, and surveillance recommendations are available to guide follow-up.**
- **For resected pancreatic cancer, adjuvant therapy standards are evolving toward multiagent chemotherapy regimens; the role of radiation is being tested.**
- **Borderline resectable pancreatic cancer is now well-recognized as an important clinical entity, and a consensus definition and management paradigms are evolving.**
- **Neoadjuvant chemotherapy is being tested for resectable tumors and chemotherapy and chemoradiation strategies for borderline resectable tumors. Results from these trials in the coming years will help refine standards of care.**

Emerging Standards for Resectable Disease

The ESPAC-4 trial results were published recently.[11] It was shown that adjuvant gemcitabine plus capecitabine, compared with gemcitabine alone, improved OS (28 vs. 25.5 months; hazard ratio [HR], 0.82; 95% CI, 0.68–0.98; p = .032). Therefore, the addition of capecitabine to adjuvant gemcitabine may become the new standard of care for adjuvant therapy. In addition, this is the first large study to report median OS of more than 2 years in this setting; it is unclear if this is the result of better patient selection with improved imaging techniques, better overall management, or both.

The growing realization, however, is that pancreatic cancer is a systemic disease from the outset.[12] The ideal approach, therefore, is to treat with systemic therapy upfront. We now have FOLFIRINOX (5-FU, irinotecan, and oxaliplatin) and gemcitabine/nab-paclitaxel as effective regimens in the metastatic setting.[13,14] It is only logical that these should be tested in the curative setting as well. The perioperative/neoadjuvant setting allows for early delivery of aggressive systemic therapy (which may not be feasible after major surgery), evaluation of chemosensitivity of cancer in vivo (potentially sparing those with chemotherapy-resistant disease major surgery), and tolerance of chemotherapy. This approach is being studied in various clinical trials (Table 2) for which results will guide future management strategies.

Role of Surveillance

After completion of adjuvant therapy, surveillance for recurrence remains undefined. The Clinical Practice Guidelines from ASCO recommend clinical evaluation every 3 to 6 months.[15,16] The use of routine imaging or serial tumor markers such as carbohydrate antigen (CA) 19.9 is not

TABLE 2. Key Ongoing Trials in Resectable Pancreatic Adenocarcinoma

Study, Clinical Trial Registry Number	Planned Duration	Planned Sample Size	Treatment Arms	Primary Outcome

recommended because of lack of data showing clinical benefit of these interventions; limited data suggest that they may simply be contributing to lead-time bias, and they come at the cost of financial burden and emotional distress. Early detection of asymptomatic pancreatic cancer recurrence, unfortunately, does not translate into improved outcomes, unlike, for example, colorectal cancer, because of limited therapeutic options for pancreatic cancer.

MULTIMODALITY MANAGEMENT OF BORDERLINE RESECTABLE PANCREATIC CANCER: WHEN IS AN OPERATION APPROPRIATE?

Definition of Borderline Resectable Pancreatic Cancer

The definition of borderline resectable pancreatic cancer (BRPC) is evolving.[3,17] One approach is to evaluate this entity from three different perspectives[18]: (1) anatomic BRPC, defined based on tumor and vessel wall interface; (2) biologic BRPC, characterized by indeterminate or questionable metastatic disease; and (3) BRPC for comorbidities, including patients with poor performance status and/or major medical comorbidities.

Anatomic BRPC. Numerous definitions of anatomic BRPC have been proposed, with the greatest point of contention being related to the involvement of the superior mesenteric vein-portal vein (SMV-PV).[3,19,20] Some heterogeneity also depends on the experience of the physicians involved in the care of these patients, as the evaluation in experienced centers leads to a change in the staging and management of 20%–30% of cases.[21,22] The most common definitions are listed in Table 3. The definition of anatomic BRPC used in the Intergroup Trial A021101 relies on objective radiographic criteria to increase uniformity,[3] and it has been likewise adopted by the 2016 National Comprehensive Cancer Network (NCCN) guidelines. Anatomic BRPC often requires a vascular resection associated with pancreatectomy. A recent meta-analysis showed that, compared with patients undergoing standard pancreatectomy, those undergoing upfront surgery with SMV-PV resection had an increased risk of postoperative mortality (risk difference, 0.01) and R1/R2 resection (risk difference, 0.09) and poorer 5-year OS rates (hazard ratio, 3.18).[23] Similar results are reported for pancreatectomy with resection of superior mesenteric artery/common hepatic artery/celiac trunk. In a meta-analysis, arterial resections were associated with a significantly increased risk of perioperative mortality (odds ratio, 5.04) and of poor 3-year OS (odds ratio, 0.39) compared with patients without arterial resection.[24] In keeping with these data, involvement of the splenic artery has recently emerged as a new prognostic factor. This was not included in the formal definition of anatomic BRPC (Table 3) because pancreatic cancer involving splenic artery alone is usually technically resectable. Three studies indicate that 5-year OS was 0% for all patients with pathologic infiltration of the splenic artery, compared with 8%–32% when the splenic artery was uninvolved.[25-27] It can be postulated that the morphologic evidence of vascular infiltration represents the stigmata of more advanced disease, leading to a higher risk of incomplete (R1/R2) resection and distant metastases. Of note, R0 resections are associated with improved OS rates (18–41.6 months) when compared with R1 (14–23.4 months) or R2 resections (10–11 months).[28-30]

Biologic BRPC. In the setting of biologic BRPC, the disease is technically resectable, but there is a high likelihood of occult metastases. The proportion of patients who develop tumor recurrence and die within 1 year from surgery can be as high as 37%.[31,32] Factors associated with early recurrence after surgery include elevated CA 19.9, presence of back pain as presenting symptom, and duration of symptoms more than 40 days.[32-35] Particularly, high preoperative CA 19.9, with a cutoff ranging between 100 and 200 U/mL, has been correlated with the presence of micrometastatic disease.[32,35-38] A recent study analyzing 10,806 patients with early-stage pancreatic cancer from the National Cancer Database (NCDB) showed that those with CA 19.9 greater than 37 U/mL had significantly decreased survival at 1 and 3 years (56% vs. 68% and 15% vs. 25%, respectively) compared with patients with normal levels (< 37 U/mL).[37]

BRPC for comorbidities. Finally, some patients can be considered "borderline resectable" because of their poor performance status and/or associated comorbidities. Pancreatic resections are recognized as highly invasive procedures, with a considerable postoperative morbidity,[39] which may

preclude delivery of adjuvant therapy. As a matter of fact, only 62% of patients in the CONKO-001 trial received the planned full dose of adjuvant gemcitabine.[40] Only 54.3% of 1,144 patients who underwent pancreatectomy at Johns Hopkins University received adjuvant therapy, and these data are in keeping with adjuvant chemotherapy rates from national databases (51%–54%).[41-43] Postoperative complications and lower preoperative prognostic nutritional index were associated with failure to complete adjuvant chemotherapy in different studies.[41-44]

Management of BRPC: Neoadjuvant Treatment Strategy

Currently, there is no established standard of care for managing BRPC. Enrollment in a clinical trial is preferred. The neoadjuvant approach is widely considered as the step forward—we review extant literature and discuss possible strategies moving forward. It is worth nothing that the 2016 NCCN guidelines do not recommend upfront surgery for BRPC and suggest an initial approach involving neoadjuvant therapy, preferably at a high-volume center.

A note on semantics: Neoadjuvant treatment usually implies that resection is feasible and planned, whereas in many BRPC cases, that may not be true. In anatomic BRPC, especially, resection may not be feasible even after chemotherapy with/without radiation. The approach to allow resection in such cases may be better termed "conversion" therapy. However, as discussed further below, radiologic assessment after chemotherapy—and, especially, radiation—may not be entirely reliable, and surgical exploration may indeed be recommended. Given these uncertainties, unless unresectable, the term "neoadjuvant" continues to be in favor when applied to systemic therapy for pancreatic cancer where resection is being considered.

Several retrospective or population-based studies have been published to analyze the role of neoadjuvant treatment. The interpretation and comparison of these studies is difficult because they have used various definitions of borderline resectable, they sometimes include a combination of resectable, borderline resectable, and locally advanced tumors, and they used different neoadjuvant chemotherapy/chemoradiation regimens, with or without adjuvant treatment.[3,17] Considering these limitations, recent and growing data support the advantages of the neoadjuvant approach, with resectability rates of 60%–80% for patients with BRPC, R0 resection rate of 80%–90%, and median OS of 20–30 months in an intention-to-treat analysis for those resected, similar to survival rates of patients with up-front resectable disease.[45-49] Importantly, neoadjuvant chemotherapy/chemoradiation was not associated with increased postoperative morbidity and mortality.[45,49,50] Two recent studies analyzed a large cohort of resected patients with stage I to II pancreatic cancer from the NCDB and showed that neoadjuvant chemotherapy was associated with improved OS, lower pathologic T- and N-stage, and lower rates of positive resection margins.[45,46] Perioperative (neoadjuvant plus adjuvant) chemotherapy demonstrated a considerable OS advantage compared with adjuvant chemotherapy alone.[45] Another study identified 593 patients with stage III pancreatic cancer from the NCDB.[48] Of these, 377 (63.6%) underwent neoadjuvant treatment, and 273 (46%) had subsequent resection, in which 216 (36.4%) were in the surgery-first cohort. Intention-to-treat Kaplan-Meier analysis demonstrated superior survival for neoadjuvant compared with surgery-first strategy (median OS, 20.7 vs. 13.7 months).

Neoadjuvant Chemotherapy/Chemoradiation Regimens

Currently, given the lack of prospective randomized studies, no particular preoperative regimen can be recommended over others. Emerging clinical trials support the use of regimens most active in the treatment of systemic disease (FOLFIRINOX: gemcitabine/nab-paclitaxel).[50] There is also considerable debate regarding the role of neoadjuvant radiation in addition to chemotherapy. Chemoradiation has been considered to be particularly important to facilitate a margin-negative resection for those patients with anatomic BRPC, especially if there is an involvement of the superior mesenteric artery.[51] A recent analysis of the NCDB data failed to show a survival advantage for neoadjuvant chemoradiation over chemotherapy alone.[45] However, the quality of this analysis is limited by the lack of data on duration and intensity of radiation treatment. The choice to perform chemoradiation instead of chemotherapy alone was likely influenced by the extent of tumor and may reflect more advanced disease. Further studies are needed to clarify the role and timing of radiation therapy in the neoadjuvant setting, especially in patients with biologic BRPC without vascular involvement.

TABLE 3. Comparison of Borderline Resectable Pancreatic Cancer Definitions[3]

CA	Clear	Abutment	Clear	Interface < 180°

Abbreviations: AHPBA, American Hepato-Pancreato-Biliary Association; SSAT, Society for Surgery of the Alimentary Tract; SSO, Society of Surgical Oncology; MDACC, The University of Texas MD Anderson Cancer Center; NCCN, National Comprehensive Cancer Network; SMV-PV, superior mesenteric vein-portal vein; SMA, superior mesenteric artery; CHA, common hepatic artery; CA, celiac artery.

When Is an Operation Appropriate After Neoadjuvant Treatment?

The assessment of treatment response is critically important in patients with BRPC. In these patients, defining an appropriate treatment response can be challenging. Particularly, radiographic imaging can be inadequate to detect tumor response, as in most cases, considerable downsizing is not evident. The difficulty is likely because of the dense stromal component of pancreatic cancer, which may remain radiographically unchanged even in the presence of a noteworthy pathologic response, and the development of treatment-related fibrosis after treatment, especially chemoradiation.[52,53] Two recent studies reported a high number of pancreatic resections following neoadjuvant treatment in BRPC with a sizable proportion of R0 resection (> 60%) despite no considerable anatomic tumor downstaging.[54,55] The lack of a demonstrable radiologic response should not be considered a contraindication for surgical exploration in the absence of frank local or systemic progression. In view of these limitations, it would be useful to evaluate other (biologic) factors; currently, however, a reliable biomarker of response is lacking. Furthermore, the role of adjuvant therapy after resection of BRPC treated with neoadjuvant therapy remains to be defined.

In conclusion, in BRPC, enrollment in a clinical trial focusing on a neoadjuvant strategy should be considered strongly instead of upfront surgery. The recommended regimens of chemotherapy/chemoradiation remain to be determined. Surgical exploration after neoadjuvant therapy should be reserved for patients who have good performance status (ECOG score ≤ 1) and in whom there is absence of local and/or distant radiologic progression, even in the absence of a radiologic response.

HEREDITARY PANCREATIC CANCER: SURVEILLANCE AND MANAGEMENT

Genetic Basis

Approximately 10% of cases of pancreatic cancer are thought to have a familial basis.[56,57] Multiple studies have demonstrated that a family history of pancreatic cancer in a first-degree relative confers a significantly elevated risk,[58-63] and that risk increases with the number of first degree relatives affected. A large prospective study found that patients with one first-degree relative with pancreatic cancer had a standardized incidence ratio of 4.6, whereas those patients with three or more affected first-degree relatives had a standardized incidence ratio of 32.[64] These patients are considered to compose one broad group of hereditary pancreatic cancer, defined as familial pancreatic cancer.

Multiple hereditary syndromes also confer an elevated risk for developing pancreatic cancer. Patients with familial cancer syndromes, such as FAMMM syndrome (*p16*/*CDKN2A*), hereditary breast and ovarian cancer (*BRCA1*, *BRCA2*, and *PALB2*), Lynch syndrome (DNA-mismatch repair genes *hMSH2*, *hMLH1*, *hPMS1*, *hPMS2*, and *hMSH6*/*GTBP*), and Peutz-Jeghers syndrome (*STK11*), have a significantly increased risk of developing pancreatic cancer.[65-67] Approximately 5%–10% of cases of hereditary pancreatic cancer are attributable to this group, broadly defined as those with pancreatic cancer–associated hereditary syndromes.[68] Next-generation sequencing and genome-wide association studies have identified additional potential susceptibility genes that may be implicated in familial pancreatic cancer.[69,70] Patients with a family history of prostate cancer, without a hereditary cancer syndrome, have an elevated risk (1.45-fold) of developing pancreatic cancer.[60] The novel capability to examine detailed gene associations will likely lead to better risk stratification and hopefully provide new opportunities for therapeutic interventions.

Hereditary Pancreatitis

In addition to familial pancreatic cancer and pancreatic cancer–associated hereditary syndromes, hereditary pancreatitis is a major risk factor for the development of pancreatic cancer.[67,71-73] Studies suggest that the standardized incidence ratio of patients with hereditary pancreatitis and pancreatic cancer may be as high as 87.[71,72,74] Hereditary pancreatitis is a rare cause of recurrent acute and chronic pancreatitis, often identified in patients in the first 2 decades of life, and frequently manifesting with parenchymal fibrosis and calcification, ductal distortions, and strictures (Fig. 1). Hereditary pancreatitis is attributed to defects in multiple genes, including *PRSS1*, *CFTR*, *CTRC*, and *SPINK1*.[67] One study suggested that patients with a history of both hereditary pancreatitis and cigarette smoking may develop pancreatic cancer approximately 20 years earlier than patients whose sole risk factor was cigarette smoking.[75] Given the predilection for progression to pancreatic cancer in patients with hereditary pancreatitis, screening should be considered, as described further in review of guidelines.

Clinical Features and Diagnosis

Hereditary and sporadic forms of pancreatic cancer present with similar clinical manifestations. Late presentation

FIGURE 1. Fluoroscopic Image From an ERCP in a Patient With Hereditary Pancreatitis

The patient was a 24-year-old woman with four hereditary pancreatitis mutations (one *CTRC*, one *SPINK1*, and two *CFTR* mutations) who presented with recurrent acute pancreatitis. Her pancreatogram revealed a severely dilated and ectatic pancreatic duct with side branch dilatation and stricturing in the pancreatic head and neck region.

is common.[76] The most common presenting symptoms include abdominal pain, asthenia, weight loss, and jaundice. Symptoms may vary depending on the location of the tumor; for instance, pancreatic head tumors more often present with jaundice and steatorrhea than tumors in the body or tail.[77] The initial work-up typically involves a laboratory evaluation and cross-sectional imaging. Abdominal CT has been shown to be more sensitive and specific than ultrasound for detecting pancreatic cancer.[78,79] MRI with magnetic resonance cholangiopancreatography is another option to delineate ductal anatomy and may help discriminate solid from cystic mass lesions. Endoscopic ultrasound (EUS) is the most sensitive modality for diagnosing pancreatic mass lesions, and EUS with fine needle aspiration can establish a tissue diagnosis in the vast majority of cases.[80,81] Endoscopic retrograde cholangiopancreatography (ERCP) is frequently indicated in patients with ductal obstruction, jaundice, and or ascending cholangitis. Although hereditary pancreatic cancer may present earlier than sporadic, it is still rare for hereditary pancreatic cancer to develop prior to the age of 45.[82] Hereditary pancreatic cancer is slightly more common in men than in women. A history of pancreatic cancer (especially in first-degree relatives), familial cancer syndromes, or a personal or family history of hereditary pancreatitis increases the probability of a hereditary predisposition.

Screening and Surveillance

Family members of patients with hereditary pancreatic cancer, familial cancer syndromes, or hereditary pancreatitis have a greatly increased risk of developing hereditary pancreatic cancer. The risks, benefits, and data on outcomes can allow patients and providers to make individualized decisions regarding strategies for screening and monitoring. Ideally, screening should be performed in patients who would be candidates for pancreatic surgery at an experienced center with a multidisciplinary team available to participate in their care. A validated risk-assessment model has been developed for hereditary pancreatic cancer (PancPRO), which can predict risk for the development of pancreatic cancer, based on age and mutation carrier probability.[83]

There have been several guidelines published for screening high-risk individuals for hereditary pancreatic cancer (Table 4). In 2007, the Fourth International Symposium of Inherited Diseases of the Pancreas updated recommendations for counseling people at risk for the development of pancreatic cancer. This panel recommended screening patients with a more than 10-fold increased risk for pancreatic cancer. This high risk group was defined as follows: (1) patients with three or more first-, second-, or third-degree relatives with pancreatic cancer, (2) patients who are known carriers of *BRCA1*, *BRCA2*, or *p16* with at least one first- or second-degree relative with pancreatic cancer, (3) patients who are known to be germline carriers of Peutz-Jeghers syndrome, (4) patients with two relatives in the same lineage (and one of those who is a first-degree relative) with pancreatic cancer, and (5) patients who have a diagnosis of hereditary pancreatitis. However, this group was unable to form a consensus on how or when to perform screening.[84]

In 2013, screening guidelines by the International Cancer of the Pancreas Consortium were published. Their suggested high-risk screening population was similar, but added patients who carried the hereditary breast cancer gene *PALB2* as well as patients who were known carriers of DNA-mismatch repair genes (Lynch syndrome). For the initial screening modality and subsequent surveillance, this group recommended EUS as the primary and MRI/magnetic resonance cholangiopancreatography as the secondary modality. Abdominal CT was not favored because of the use of ionizing radiation, and ERCP was not favored because of the lack of additional diagnostic yield and the risk of post-ERCP pancreatitis. The recommended screening interval was 6–12 months for a nonsuspicious cyst and 3 months for an indeterminate solid lesion or indeterminate main pancreatic duct stricture. They were unable to form a consensus on which patients should undergo surgery, recommending individualized decision making.[85]

TABLE 4. Summary of Published Guidelines for Screening for Pancreatic Cancer

		Published Guidelines		
Criterion	**Relative Risk for PC**	**4th International Symposium**	**CAPS Consortium**	**ACG 2015**
More than 3 relatives with PC	Up to 32	✔	✔	✔
Two relatives with PC, one an FDR	Up to 6	✔	✔	✔
Known carrier of PJS (*STK11* gene)	132	✔	✔	✔
Known carrier of HBOC (*BRCA1*, *BRCA2*, and *PALB2* genes)	3–10	✔	✔	✔
Known carrier of FAMMM (*p16* gene)	13–36	✔	✔	✔
Known carrier of Lynch syndrome (DNA-mismatch repair genes)	8.6		✔	✔
Known diagnosis of hereditary pancreatitis (*PRSS1*, *SPINK1*, and other genes)	50–82	✔		✔

Abbreviations: PC, pancreatic cancer; CAPS, Cancer of the Pancreas Screening; ACG, American College of Gastroenterology; FDR, first-degree relative; PJS, Peutz-Jeghers syndrome; HBOC, hereditary breast and ovarian cancer; FAMMM, familial atypical multiple mole melanoma.

The American College of Gastroenterology published their screening guidelines in 2015. They defined high-risk individuals who should be screened for pancreatic cancer similarly, but expanded their recommended screening to individuals with fivefold or higher relative risk for pancreatic cancer and added additional familial cancer syndromes (Table 4). They recommended surveillance be performed at experienced centers under research conditions and using a multidisciplinary approach. They recommended surveillance with EUS or MRI and specified that surveillance be annual, starting at age 50, or 10 years younger than the earliest age of pancreatic cancer in the family, or at age 35 in individuals with Peutz-Jeghers syndrome. No guidelines could be issued as to when surgery would be indicated and noted that this decision is best individualized after multidisciplinary assessment.[86]

Management

There are no established guidelines on the management of pancreatic lesions found during screening, which occurs up to 42% of the time during screening of individuals at risk for hereditary pancreatic cancer.[87] A conservative, individualized, stepwise approach to management, based on the type of lesion identified, and performed at an experienced center with input from a multidisciplinary team is recommended. Rarely, solid pancreatic lesions are detected during screening with EUS or MRI. These lesions can be true cancers, pancreatic neuroendocrine tumors, or low-grade pancreatic intraepithelial neoplasia.[87,88] For solid or concerning lesions, EUS-guided fine needle aspiration with on-site cytology may often be helpful in the evaluation. For suspicious solid lesions (≥ 1 cm, visualized on multiple imaging modalities) or with positive cytology, surgical resection may be indicated. For indeterminate solid lesions (subcentimeter, seen on only one imaging modality, or with negative cytology), close interval surveillance may be considered. Each case should be individualized and presentation at a multidisciplinary tumor board for a consensus recommendation is frequently beneficial.

Cystic lesions are found in approximately 60% of those screened, and the prevalence increases with increasing age.[87] The majority of these cysts are low-risk, small side-branch intraductal papillary mucinous neoplasms that remain stable throughout the surveillance period.[89,90] EUS-guided fine needle aspiration is not recommended for very small cystic lesions because of the low cytologic yield[91]; however, EUS may be indicated with larger cysts or for cysts with worrisome features (pancreatic ductal dilatation > 5 mm, lymphadenopathy, thickened or enhancing cyst walls, solid component or mural nodule, or growth on surveillance imaging).[92] Benign-appearing cystic lesions may be monitored with repeat annual imaging. Main pancreatic duct strictures should be evaluated with EUS with or without fine needle aspiration and followed with surveillance imaging to exclude an occult neoplasm.

In conclusion, genetics play an increasingly recognized role in the development of pancreatic cancer. Hereditary pancreatic cancer predisposition may be considered in three groups: familial pancreatic cancer (individuals with multiple family members with pancreatic cancer), hereditary syndromes with pancreatic cancer associations (FAMMM, hereditary breast and ovarian cancer, Lynch, and Peutz-Jeghers syndrome), and hereditary pancreatitis. With the development of next-generation genome sequencing, additional, novel mutations are being associated with pancreatic cancer. Guidelines can steer providers to screening modalities and frequency; however, there is no clear consensus, and surveillance is individualized based on the patient's wishes, risk, and suitability for surgical management if a lesion is detected. For patients who wish to be proactive and have risk factors for the development of pancreatic cancer, we may offer alternating EUS and MRI on a yearly basis. Given the poor prognosis, it is hoped that more refined genetic data combined with more powerful screening and surveillance tools may lead to early detection that can translate to improved OS.

CONCLUSION

Pancreatic cancer remains a difficult, and growing, problem in oncology. We are now better understanding the biology, especially with respect to genomic (both somatic and germline) alterations as pathogenic, predictive, and prognostic factors. Better interventional and surgical approaches are minimizing procedural morbidity and mortality. We have some improvement in overall outcomes with aggressive systemic regimens. However, the ultimate goal of considerable improvement in clinical outcomes will require continued scientific and clinical investigations, multidisciplinary care of patients, and focus on collaborative research across various institutions. We have highlighted the emerging trends in early diagnosis, especially in known or suspected cases of familial origins of pancreatic cancer, neoadjuvant and perioperative approaches for resectable and borderline resectable cases, and key ongoing clinical trials that can help us better understand the nuances of multimodality management of these cases.

The Promise of Immunotherapy in the Treatment of Hepatocellular Carcinoma

Anthony El-Khoueiry, MD

OVERVIEW

Advanced hepatocellular carcinoma (HCC) has presented a therapeutic challenge. Despite its heterogeneity, which is partially related to its various etiologies, it frequently arises in a background of chronic inflammation, which makes it a potentially excellent candidate for immunotherapeutic approaches. There is evidence of antitumor immunity in HCC as manifested by the cell infiltrate and its association with prognosis, the presence of tumor-associated antigens, and the reports of immune-mediated spontaneous regressions. However, both the liver itself and the tumor environment possess a diverse armamentarium of mechanisms that suppress antitumor immunity. Here, we describe the rationale for immunotherapy in HCC and discuss the emerging clinical data from various immunotherapeutic approaches including checkpoint inhibition, cell therapy, oncolytic viral therapy, and various combinatorial approaches. We also highlight the potential for various modalities to be adapted across different stages of the disease.

HCC has an incidence of over 500,000 new cases globally and is the second most frequent cause of cancer-related deaths worldwide.[1] In the United States, the incidence of HCC has increased from 4.4 per 100,000 (95% CI, 4.3–4.5) in 2000 to 6.7 per 100,000 (95% CI, 6.6–6.8) in 2012.[2] The curative treatment options of liver transplantation or liver resection are limited to patients who present with early-stage disease, typically defined as Barcelona Clinic Liver Cancer (BCLC) stage A. The treatment of more advanced disease, defined as BCLC stages B and C, has been a challenge; locoregional modalities such as transarterial chemoembolization or radioembolization for patients with BCLC stage B disease result in a median survival of about 20 months[3]; sorafenib, the multitargeted kinase inhibitor, is the only approved systemic therapy for advanced HCC (BCLC stage C) with a median survival of 10.5 months reported in the SHARP trials and 6.5 months in the Asia Pacific study.[4,5] Needless to say, there is a pressing need for more effective treatment options that would result in longer survival and expand the chance of cure to more patients.

BRIEF OVERVIEW OF THE CURRENT STATUS OF TREATMENT OF ADVANCED HCC

As noted earlier, sorafenib continues to be the only standard therapeutic option for patients with advanced HCC, commonly defined as those with extrahepatic metastases, vascular invasion, or multifocal liver-limited disease that has failed locoregional therapy. Since the approval of sorafenib, there were multiple randomized phase III trials that compared other targeted agents or a combination of targeted agents to sorafenib, all of which failed to reach their primary endpoint (Table 1).[6-10] At the time of this review's publication, a press release had recently reported that a randomized phase III study of lenvatinib versus sorafenib in patients with HCC who had not previously received systemic treatment reached its primary endpoint of noninferiority for overall survival (OS), but with superior response rates and progression-free survival compared with sorafenib. In the setting of second-line treatment (after sorafenib failure), prior to the results of the RESORCE trial, several phase III trials comparing agents such as brivanib,[7] ramucirumab,[11] and everolimus[12] to placebo had failed to show an improvement in OS. In the RESORCE study,[13] patients with documented radiologic progression on sorafenib who had tolerated a dose of 400 mg or higher of sorafenib daily for 20 of the last 28 days, were randomly selected in a 2:1 fashion to receive regorafenib versus placebo. Regorafenib resulted in superior OS (10.6 vs. 7.8 months; HR 0.62, 95% CI, 0.50–0.78) and became the first agent to show a clinically and statistically meaningful benefit after sorafenib failure.

THE RATIONALE FOR IMMUNOTHERAPY IN HCC

Evidence of Antitumor Immunity in Patients With HCC

Despite being rare, there are scattered reports in the literature of spontaneous HCC regression, which has been

TABLE 1. The Challenge: First-Line Randomized Phase III Trials

Phase III	Target(s)	Time to Progression (Months)	Overall Survival (Months)
Sunitinib vs. sorafemb (Cheng et al[6])	VEGFRs, PDGFRs, c-kit, (Flt)3, RET	3.8 vs. 4.1; HR 1.13, 95% CI, 0.98–1.31; p = 0.16	7.9 vs. 10.2; two-sided p < .0014
Brivanib vs. sorafenib (Llovet et al[7])	VEGFR2, FGFR	4.2 vs. 4.1; HR 1.01, 95% CI, 0.88–1.16	9.5 vs. 9.9; HR. 1.06, 95% CI, 0.93–1.22; p < .373
Linifanib vs. sorafenib (Cainap et al[8])	VEGFR and PDGFR	5.4 vs. 4; HR 0.76, 95% CI, 0.64–0.89; p < .001	9.1 vs. 9.8; HR 1.04, 95% CI, 0.89–1.22; p = NS
Sorafenib + erlotinib vs. sorafenib + placebo (Zhu et al[9])	VEGFR1/2/3, Ras, Raf, EGFR	3.2 vs. 4; HR 1.13, 95% CI, 0.94–1.36; p = 0.91	9.5 vs. 8.5; 0.92, 95% CI, 0.78–1.1; p = 0.2
Doxorubicin + sorafenib vs. sorarfenib CALGB 80802 (Abou Alfa et al[10])	VEGFR1/2, PDFG, Ras, Raf	3.6 vs. 3.2; HR 0.90, 95% CI, 0.72–1.2	9.3 vs. 10.5; HR 1.06, 95% CI, 0.8–1.4

attributed to the host antitumor immune response as well as vascular events.[14,15] Patients with HCC tumors who have a marked proinflammatory T-cell infiltrate with a high CD4:CD8 ratio have a reduced risk of tumor recurrence following liver transplantation; the hypothesis behind the CD4:CD8 ratio impact is that CD8+ cytotoxic T cells rely on CD4+ helper lymphocytes for maximal effect.[16] Similarly, patients with resected HCC whose tumors contained a low intratumoral T-regulatory lymphocytes (Tregs) level in combination with high intratumoral activated CD8+ cytotoxic T cells (CTLs) had improved disease-free survival and OS.[17] The other evidence of immunogenicity in HCC comes from the presence of tumor-associated antigens recognized by CTLs in 50%–70% of patients with HCC[18,19]; the tumor-associated antigens recognized by CTLs included cyclophilin B, squamous cell carcinoma antigen recognized by T cells (SART) 2, SART3, p53, multidrug resistance-associated protein (MRP) 3, alpha-fetoprotein (AFP), and human telomerase reverse transcription (hTERT). Unfortunately, the presence of intratumoral T-cell infiltration that could inhibit tumor growth and the detectable adaptive immune responses against tumor antigens are counteracted by tolerance-inducing mechanisms that prevent a consistent effective antitumor response.[20]

KEY POINTS

- **HCC continues to represent a major therapeutic challenge.**
- **HCC is an immunogenic disease.**
- **Antitumor immunity is suppressed by various mechanisms in HCC.**
- **Checkpoint inhibition has shown consistent and promising early signals of efficacy.**
- **Combinatorial approaches of various immunotherapies or of immunotherapy with standard modalities hold great promise.**

The Immunosuppressive Environment of HCC

Both the liver itself and the tumor environment possess a diverse armamentarium of mechanisms that suppress antitumor immunity. These mechanisms of immune tolerance have been described in several elegant reviews,[21,22] and a detailed discussion of these mechanisms is beyond the scope of this article. However, we will highlight a few examples of immunosuppressive processes that represent opportunities for potentially effective immunotherapeutic interventions.

Upregulation of inhibitory molecules. CTLA-4, PD-1, TIM-3, LAG-3 (lymphocyte activation gene 3 protein), and BTLA (B and T lymphocyte attenuator) are coinhibitory molecules known as immune checkpoints that regulate the activation of T cells to prevent unchecked immune activation and collateral tissue damage.[23,24] Lower expression of levels of the PD-1 ligands, PD-L1 and PD-L2 in HCC tumor cells, is associated with superior disease-free survival and OS.[25] CD4 and CD8 lymphocytes infiltrating the tumor in hepatitis B–related HCC show expression of TIM-3 and are replicative senescent.[26] In the setting of hepatitis C infection, there is evidence of apoptosis in immune cells and spontaneous T-cell exhaustion, which are at least partially driven by upregulation of TRAIL, LAG-3, TIM-3, PD-1, and CTLA-4 in hepatitis C–primed peripheral blood mononuclear cells.[27]

Production of immunosuppressive cytokines. Interleukin-10 (IL-10), TGF-β, IDO, and arginase are among a long list of immunosuppressive molecules that HCC cells can produce to escape innate and adaptive immunity.[22] Tumor-associated macrophages in HCC produce IL-6, which in turn enhances IL-10 production by myeloid-derived suppressor cells (MDSCs); high IL-10 levels downregulate HLA class II expression by macrophages, which impairs antigen presentation, stimulates Treg cell expansion, and blocks natural killer cell activation.[28] IDO inhibits T-cell activation and proliferation, and promotes Treg cell function.[29,30] In the setting of HCC, IFN-γ production suppresses T-cell proliferation and functionality by a mechanism that is blocked upon addition of the IDO inhibitor 1-methyl-tryptophan.[31]

Shift toward an immunosuppressive environment driven by immune cell subtypes. MDSCs represent a diverse group of myeloid cells that suppress antitumor immunity and produce protumoral effects. Patients with HCC have been shown to have increased levels of CD14+ HLA-DR−/low MDSCs in the peripheral blood and in tumors. These MDSCs are unable to stimulate an allogeneic T-cell response, suppress T-cell proliferation, and induce CD4+ CD25+ Foxp3+ Treg expansion.[32] MDSCs contribute to the immunosuppressive milieu of HCC through a variety of other mechanisms that are detailed in a review by Wan et al.[33] One notable example is

the inhibition of natural killer cell cytotoxicity and cytokine release by MDSCs (CD14+ HLA-DR−/low).[34] Tumor-associated macrophages constitute another cell type with protumor effects by inducing angiogenesis and promoting tumor cell invasion and metastasis.[35] There is evidence of active dynamic interaction and communication between MDSCs, Tregs, and tumor-associated macrophages, which creates a network of immunosuppression. On one hand, tumor-associated macrophages produce chemokines such as CCL17, CCL18, and CCL22, which preferentially attract Treg and Th2 cells to the tumor and, in turn, impair CTL activation.[36] On the other hand, Treg production of IL-10, IL-4, and IL-13 can promote differentiation of monocytes into immunosuppressive tumor-associated macrophages.[37]

Impact of Tumor Immune Milieu on Patient Outcomes in HCC

There is an emerging body of literature linking the status of antitumor immunity to outcomes of patients with HCC treated with various modalities. The prognostic association of various components of the antitumor immunity with survival provides another justification for immunotherapy in this disease. In a study of 36 patients with HCC treated with hepatic intra-arterial infusion, the frequency of MDSCs was significantly lower in the group with complete or partial response to therapy compared with the group with stable disease or progressive disease ($p = .006$); furthermore, the OS of patients with a high frequency of MDSCs before treatment was significantly shorter ($p = .003$). The frequency of MDSCs remained as a prognostic marker on multivariate analysis.[38] Gao and colleagues evaluated the impact PD-L1 and PD-L2 expression in tumors in patients with resected HCC; the median disease-free survival and OS were 14.9 and 29.6 months, respectively, for PD-L1–positive patients compared with not reached and 59.4 months for PD-L–1 negative patients, respectively ($p = .047$ and $p = .029$, respectively). Similarly, there was a significant association between PD-L2 expression and OS ($p = .041$).[39] In another study, CD3+, CD4+, CD8+, Foxp3+, and granzyme B+ tumor-infiltrating lymphocytes were assessed by immunohistochemistry in tissue microarrays containing HCC from 302 patients. The presence of low intratumoral Tregs in combination with high intratumoral activated CD8+ CTLs, a balance toward CTLs, was an independent prognostic factor for both improved disease-free survival ($p = .001$) and OS ($p < .0001$). Five-year OS and disease-free survival rates were only 24.1% and 19.8%, respectively, for the group with intratumoral high Tregs and low activated CTLs, compared with 64.0% and 59.4%, respectively, for the group with intratumoral low Tregs and high activated CTLs, respectively.[17]

CHECKPOINTS AS A THERAPEUTIC TARGET IN THE CLINIC

Targeting CTLA-4

As discussed previously, the upregulation of inhibitory immune checkpoints including CTLA-4 and PD-1 has been reported in the setting of HCC and has been associated with outcome. Given the success of targeting CTLA-4 and PD-1/PD-L1 in multiple solid tumors, it became important to evaluate the efficacy of checkpoint inhibitors in HCC. Tremelimumab, an IgG2 anti–CTLA-4 monoclonal antibody, was the first checkpoint inhibitor to be evaluated in HCC by Sangro and colleagues.[40] Patients with hepatitis C–related HCC, Child-Pugh A or B, and whose disease was not amenable to curative therapy, percutaneous ablation, or locoregional therapy were enrolled. Notable baseline characteristics included a Child-Pugh B status in 43% of patients, presence of portal vein thrombosis in 29%, and extrahepatic metastases in 10%. Twenty-four percent had received prior sorafenib treatment. In the 20 patients evaluable for safety, the most common treatment-related grade 3 or higher adverse events included AST and ALT elevation in 45% and 25%, respectively, total bilirubin elevation in 10%, neutropenia in 5%, and diarrhea and rash in 5% each. Seventeen patients were evaluable for treatment response; three patients (17.6%) had a confirmed partial response lasting 3.6, 9.2, and 15.8 months. Ten patients (58.8%) had stable disease. Intent-to-treat median time to progression was 6.48 months (95% CI, 3.95–9.14) and median OS was 8.2 months (95% CI, 4.64–21.34). One of the important conclusions of this small study was the feasibility of administration of an anti–CLTA-4 antibody to patients with HCC in the setting of liver cirrhosis and hepatitis C; the adverse events appeared to be manageable and the elevation of AST and ALT were transient and not associated with overall deterioration of liver function. Another important finding of the study is the documentation of antiviral and antitumor immune responses in patients; there was a statistically significant decrease in hepatitis C viral load in 11 patients at day 120 ($p = .011$) and in six patients at day 210 ($p = .017$) along with a general trend to increased number of virus-specific IFN-c–producing lymphocytes.[40]

Targeting PD-1/PD-L1

Nivolumab, a fully human IgG4 monoclonal antibody against PD-1, has been undergoing evaluation in CheckMate 040, a phase I/II study for patients with advanced HCC. Given hypothetical concerns about the risk of inducing immune-mediated fulminant hepatitis and the overall safety of checkpoint inhibition in the setting of viral hepatitis, the phase I part of the study included a classic 3 + 3 dose escalation in parallel separate cohorts of patients with hepatitis B, hepatitis C, and noninfected patients. There was no maximum tolerated dose despite escalation up to 10 mg/Kg every 2 weeks. One dose-limiting toxicity of grade 2 hepatic decompensation was noted at 10 mg/Kg in the uninfected cohort. The adverse events were consistent with the toxicity profile of nivolumab in other tumor types. During the phase I dose escalation part of the study, grade 3 and 4 treatment-related adverse events occurred in 25% of patients (12 of 48); the most common grade 3 and 4 adverse events were asymptomatic laboratory abnormalities including lipase increase in 13%, AST and ALT increase in 10% and 6%, respectively, and amylase increase in 4%. During the phase II expansion,

214 patients were recruited into one of four parallel cohorts: (1) noninfected sorafenib naive or intolerant, (2) noninfected sorafenib progressors, (3) hepatitis C–infected, and (4) hepatitis B–infected. The safety profile for the phase II expansion was similar to the dose escalation. Baseline characteristics for the overall patient population (dose escalation and expansion combined) were notable for 67% of patients who had prior treatment with sorafenib, 76% with extrahepatic metastases, and 8% with vascular invasion. All patients (except two) had Child-Pugh scores of 5 or 6. In terms of efficacy, the objective response rate based on RECIST 1.1 was 15% (including three complete responses) during dose escalation and 20% during dose expansion. Responses were seen across all cohorts independent of etiology. During dose escalation, for which there was adequate follow-up, the median duration of response was 17 months (95% CI, 6–24) and the median OS was 15 months (95% CI, 9.6–20.2). Median OS in the uninfected sorafenib progressor cohort was 13.2 months (95% CI, 8.6–NE [not estimable]); medians were not reached in the other dose-expansion cohorts. There was no clear association between PD-L1 expression on tumor cells (< 1% vs. ≥ 1%) and the likelihood of radiologic response. Other biomarkers are being evaluated in tumor samples and peripheral blood.[41-43]

In addition to nivolumab, other studies evaluating pembrolizumab, durvalumab and other PD-1– or PD-L1–targeting agents have been ongoing for hepatocellular carcinoma. Ongoing phase III studies are critical to validate the promising signal seen in early-phase trials; such phase III studies include Keynote-240, comparing pembrolizumab to placebo in patients who had documented disease progression on sorafenib or intolerance to sorafenib (NCT02702401), and CheckMate 459, comparing nivolumab with sorafenib in patients with advanced HCC who had not received other prior systemic therapy (NCT02576509).

Other checkpoints and costimulatory receptors. As is the case with other tumors, there is a rationale to block other immune checkpoints (such as Lag-3, TIM-3, etc.) and to evaluate antibodies that agonistically bind costimulatory receptors on immune cells (OX40, GITR, CD137). Early-phase studies evaluating such agents are ongoing, and some of them allow patients with HCC. There are also emerging efforts to combine agents that targets immune checkpoints such as PD-1 and CTLA-4 as well as other combinations involving costimulatory receptors.

Other combinations involving immune checkpoint antibodies. There is a large number of preclinical and clinical studies that are evaluating multiple modalities in combination with immune checkpoint inhibitors; the unifying concept is to harness various components of the immune system or to circumvent potential resistance mechanisms. An extensive review of this field is beyond the scope of this article. However, we will highlight a few approaches that highlight the potential of such combinations. Stereotactic radiation, in which a high dose of radiation is delivered to a limited area, can induce cell death and release of tumor antigens that can be recognized by the immune system to generate a tumor-specific T-cell immune response. In a preclinical model, the administration of an anti–PD-1 antibody concurrently with SBRT resulted in superior survival and was associated with increased CD8+ CTLs in the tumor and increased expression of PD-L1 on tumor-infiltrating macrophages.[44] Studies evaluating the combination of PD-1 or PD-L1 inhibitors with SBRT are recruiting patients with a variety of solid tumors. Embolization and ablative techniques have also been shown to release tumor antigen and stimulate antitumor immunity, which may be further enhanced with the simultaneous administration of checkpoint inhibitors. The combination of the anti–CTLA-4 antibody, tremelimumab, with subtotal radiofrequency ablation or chemoablation was evaluated in 32 patients with HCC; the majority of the patients' disease had progressed on or had been intolerant to sorafenib. This pilot study established the feasibility of the combination, as there were no dose-limiting toxicities and the side effect profile was consistent with that of tremelimumab. Nineteen patients had lesions that were evaluable for response outside of the areas treated with ablation or transarterial chemoembolization; five patients (26%; 95% CI, 9.1%–51.2%) achieved confirmed partial responses. The frequency of activated CD8+ T cells in the peripheral blood was increased by twofold over baseline and was sustained for at least 12 weeks. Tumor biopsies at the time of ablation revealed an increase in tumor-infiltrating lymphocytes compared with baseline.[45] The intriguing clinical and biologic activity noted in this pilot study should be further evaluated in subsequent larger but carefully designed trials.

LEVERAGING THE IMMUNE SYSTEM BEYOND CHECKPOINT INHIBITION

Immunotherapeutic approaches beyond checkpoint inhibition have been evaluated for hepatocellular carcinoma. These include adoptive cellular therapy, vaccines, and oncolytic viruses. Below we will highlight various examples of such approaches in HCC.

Cell Therapy

There are various forms of cell therapy including cytokine-induced killer cells (CIKs), tumor-infiltrating lymphocytes, and genetically modified T cells. Adoptive cell therapy using CIKs has been evaluated in the clinic for HCC. The promise of CIKs is highlighted in the results of a multicenter, open-label, randomized phase III study that evaluated their safety and efficacy as adjuvant therapy after curative therapy for HCC; 230 patients treated by surgical resection, radiofrequency ablation, or percutaneous ethanol injection were randomly assigned to receive immunotherapy (injection of 6.4 109 autologous CIKs, 16 times over 60 weeks) or no adjuvant therapy (control). The autologous CIKs consisted of CD3+/CD56+ T cells, CD3+/CD56– T cells, and CD3–/CD56+ natural killer cells. The median recurrence-free survival (primary endpoint) was 14.0 months longer in the immunotherapy group (44.0 months) than in the control group (30.0 months). The frequency of grade 3 and 4 adverse events and of serious adverse events was comparable between the two groups.[46]

The majority of the patients in this study had hepatitis B, tumors that measured less than 3 cm, and were treated with RFA most commonly; the positive results need to be further evaluated in various populations to validate the benefit, which could offer a highly impactful option in an area of unmet need. This study also serves as a good example of the potential role of immunotherapeutic approaches in early stages of HCC, in contrast to the checkpoint inhibitors, which are now being evaluated largely in advanced disease. Another example of the emerging role of cellular therapy in various stages of HCC is highlighted in a meta-analysis of studies that evaluated transarterial chemoembolization with any form of cell therapy including CIKs, tumor-infiltrating lymphocytes, natural killer cells, and dendritic cells. Patients who underwent cell therapy had higher 6-month PFS (OR, 2.78; p = .05), 12-month PFS (OR, 3.56; p < .00001), 6-month OS (OR, 2.81; p = .0009), 12-month OS (OR, 3.05; p < .00001), and 24-month OS (OR, 3.52; p < .0001).[47]

Oncolytic Virus Therapy

Various viral constructs have been evaluated in HCC preclinical models including adenoviruses, vaccinia viruses, and listeria monocytogenes. The general idea is to use viruses to deliver specific molecules into the liver tumor.[21] JX-594 is an oncolytic and immunotherapeutic vaccinia virus expressing granulocyte-macrophage colony-stimulating factor that has cytoreductive effects and activates both innate and adaptive immune responses.[48,49] Intratumoral injections of JX-594 were shown to be safe with an early signal of efficacy[50]; however, a randomized phase IIB study failed to demonstrate improved OS in patients with advanced HCC whose disease had failed prior first-line chemotherapy, as reported by the company, and did not reach its primary endpoint improvement of OS.[51] An ongoing phase III study is comparing the combination of JX-594 (Pexa-Vec) with sorafenib versus sorafenib alone in first-line treatment of HCC (NCT02562755). In addition, a trial combining JX-594 (Pexa-vec) with anti–PD-1 therapy is pending activation.

THE FUTURE: CHALLENGES AND OPPORTUNITIES

As the body of preclinical and clinical data for immunotherapy in HCC continues to grow, it is critical to focus efforts on identifying biomarkers that would enhance patient selection for the various immune therapeutic modalities and that would allow for smarter combinations based on potential escape pathways and mechanisms of resistance. Another challenge would be to expand the clinical benefit to various patient subgroups, including those with compromised liver function (beyond Child-Pugh A) as well as patients with early- and intermediate-stage disease. Additional investigations in the area of adjuvant therapy and in combination with standard effective locoregional modalities are needed. Lastly, it is critical to account for the biologic heterogeneity of HCC and carefully evaluate the potential interplay between etiology and the oncogenic pathways in the tumor and the tumor microenvironment. The efficacy of certain immunotherapeutic interventions may vary based on such interplay and should be accounted for. In conclusion, the emerging body of evidence suggests that immunotherapeutic modalities have a real potential of bringing new hope to patients with HCC across all stages and etiologies.

GENITOURINARY (NONPROSTATE) CANCER

Evolving Treatment Paradigm in Metastatic Renal Cell Carcinoma

David M. Gill, MD, Neeraj Agarwal, MD, and Ulka Vaishampayan, MD

OVERVIEW

The treatment paradigm for advanced and metastatic renal cell carcinoma (mRCC) has evolved rapidly since the arrival of targeted therapies and novel immunotherapies. mRCC was previously treated only with cytokines. However, discoveries of mutations affecting the von Hippel–Lindau tumor suppressor gene (leading to increased expression of VEGF and hypoxia inducible factor/HIF-1) and of deregulations in the phosphatidylinositol-3 kinase/AKT/mTOR pathway (resulting in tumor angiogenesis, cell proliferation, and tumor growth) have led to the development of numerous targeted therapies. The U.S. Food and Drug Administration (FDA) has thus approved a total of nine targeted therapies since 2005, including VEGF tyrosine kinase inhibitors (sunitinib, pazopanib, axitinib, sorafenib, and lenvatinib), a monoclonal antibody targeting VEGF (bevacizumab), mTOR inhibitors (temsirolimus and everolimus), and a multityrosine kinase inhibitor (cabozantinib). Furthermore, the development of immune checkpoint inhibitors has again shifted the mRCC therapeutic landscape with the FDA's approval of nivolumab. Herein, we discuss the unprecedented changes in the field of clear cell histology mRCC in both the first-line and salvage settings, and we also discuss future therapies and recommend a treatment paradigm on sequencing of these agents.

Prior to 2005 when the FDA approved the first antiangiogenic agent in RCC, treatment of mRCC consisted solely of cytokines. The FDA approved high-dose interleukin-2 (HDIL-2) in 1992 for first-line treatment of mRCC, after preliminary data showed an overall response rate (ORR) of 15% as well as a 5% complete response (CR).[1] A follow-up study reported a 7% CR, with a median duration of response of at least 80 months.[2] However, given acute dose-limiting toxicities, inclusion criteria require excellent performance status and adequate organ function.[1] In an attempt to decrease toxicity, Yang et al[3] compared high- and low-dose interleukin-2 but, unfortunately, ORR was greater in the high-dose arm (21% vs. 13%, p = .048). In addition, analysis from a 2017 prospective cohort (352 patients)[4] and a 2016 retrospective cohort (391 patients)[5] suggests that the survival benefit with HDIL-2 may extend to many more patients. In addition to those with partial response and CR, stable disease (SD) as the best response to therapy was present for 39% and 32% of patients, respectively. Although SD is not historically categorized in HDIL-2 trials, the presence of SD was associated with a survival benefit in these two independent cohorts.[4,5] Interferon-α (hereafter referred to as interferon) had more modest outcomes (overall survival [OS] 2.5 months greater than placebo) without the durable responses of HDIL-2; however, interferon was better tolerated with broader eligibility criteria and therefore was the mainstay of treatment of most patients with mRCC prior to the advent of antiangiogenic therapy.[6]

FIRST-LINE THERAPY SETTING

VEGF-Targeted Therapies

VEGF-targeted therapies with tyrosine kinase inhibitors (TKIs) were developed as a result of improved understanding of von Hippel–Lindau gene mutations leading to the induction of angiogenic protein.[7] VEGF-TKIs currently approved for mRCC include sunitinib, sorafenib, pazopanib, axitinib, cabozantinib, and lenvatinib (Fig. 1). Similarly, bevacizumab is a monoclonal antibody directed against the VEGF receptor (VEGFR). For over a decade, cytokines were the only approved treatment for mRCC. In 2005, sorafenib changed this paradigm, with the TARGET study showing improvement in progression-free survival (PFS) versus placebo in the second-line setting after cytokine therapy (5.5 vs. 2.8 months; p < .01).[8] Shortly thereafter, a landmark 2007 study by Motzer et al[9] showed improved PFS with sunitinib compared with interferon in the first-line setting (11.0 vs. 5.0 months; p < .001). In 2007, AVOREN trial investigators published a comparison of bevacizumab and interferon in combination versus interferon monotherapy. Again, the results nearly doubled the PFS of the comparator arm (10.2 vs. 5.4

months, p = .0001).[10] In a phase III study published in 2010 (VEG105192), pazopanib was used for previously untreated patients and those who had progressed after cytokines. Compared with placebo, there was a 5-month improvement in PFS (9.2 vs. 4.2 months; p < .0001).[11] In 2009, the FDA approved both pazopanib and bevacizumab in combination with interferon (Table 1).

Since that time, no other agent has been approved for the first-line therapy setting. However, a recently published study[24] may change this. Cabozantinib is a small molecule inhibitor targeting multiple tyrosine kinases, including VEGFR-2, hepatocyte growth factor (MET), and AXL. The Alliance A031203 CABOSUN trial compared cabozantinib to sunitinib for patients with previously untreated mRCC with poor and intermediate prognosis per International Metastatic Renal Cell Carcinoma Database Consortium (IMDC) criteria. Results showed improvement in PFS (8.2 vs. 5.6 months) and ORR (46% vs. 18%) and a 34% reduction in the rate of progression or death (adjusted hazard ratio [HR], 0.66; 95% CI, 0.46–0.95; one-sided p = .012) in the cabozantinib arm, with a similar incidence of grade 3 or 4 adverse events (AEs; 67% vs. 68%).[24] Preliminary data on OS, a secondary endpoint, revealed a 20% decrease in the rate of death with cabozantinib, although the study was not designed to show a difference in OS. An independent review for the primary endpoint of PFS is ongoing and if this confirms the findings then cabozantinib will be submitted to the FDA for consideration of approval as front-line therapy.

KEY POINTS

- **New discoveries and advances with antiangiogenic agents have changed the treatment paradigm for clear cell advanced and metastatic renal cell carcinoma.**
- **Based on improved outcomes, axitinib, nivolumab, cabozantinib, and combination lenvatinib plus everolimus are considered standard of care in the post-VEGF/TKI salvage therapy setting, with no clear consensus on how to optimally sequence these agents in the absence of head-to-head comparisons of these agents. Until validated molecular biomarkers predictive for the efficacy of specific agents are discovered, clinical decision making would be key to optimizing sequencing of these agents.**
- **Novel targeted therapies, immune checkpoint inhibitors, and immune-modulating drugs are currently under investigation, many in combination with VEGF pathway inhibitors, in the first-line setting and may replace sunitinib, pazopanib, and HDIL-2 as preferred first-line agents in the near future.**
- **Multidisciplinary input is important when considering the role of cytoreductive nephrectomies and metastatectomies in selected cases depending on overall prognosis and organ of involvement with metastatic disease.**
- **No efforts should be spared in providing access to clinical trials, facilitating approval of novel agents and combinations, and expediting validation of therapeutic biomarkers as well as exploring the optimal sequencing of the therapies.**

mTOR Inhibitors in Front-Line Therapy

Other discoveries showed that mutations in phosphatidylinositol-3 kinase, a kinase upstream of mTOR, were both common in mRCC and amenable to targeted therapy.[25] In 2007, the FDA approved an mTOR inhibitor (temsirolimus) for patients with previously untreated mRCC who were in the poor prognosis category, based on a study showing improvement in OS compared with interferon (10.9 vs. 7.3 months; p = .008) in the Global ARCC trial. Notably, although it was not the primary endpoint, there was only a modest improvement in PFS over interferon by independent radiographic assessment (5.5 vs. 3.1 months). The combination of interferon with temsirolimus was also evaluated but did not improve PFS or OS.[12] With low response rates and modest clinical benefit, temsirolimus is not a widely used therapy in front-line mRCC management.

Notable First-Line Studies Not Resulting in Changes in Regulatory Approval

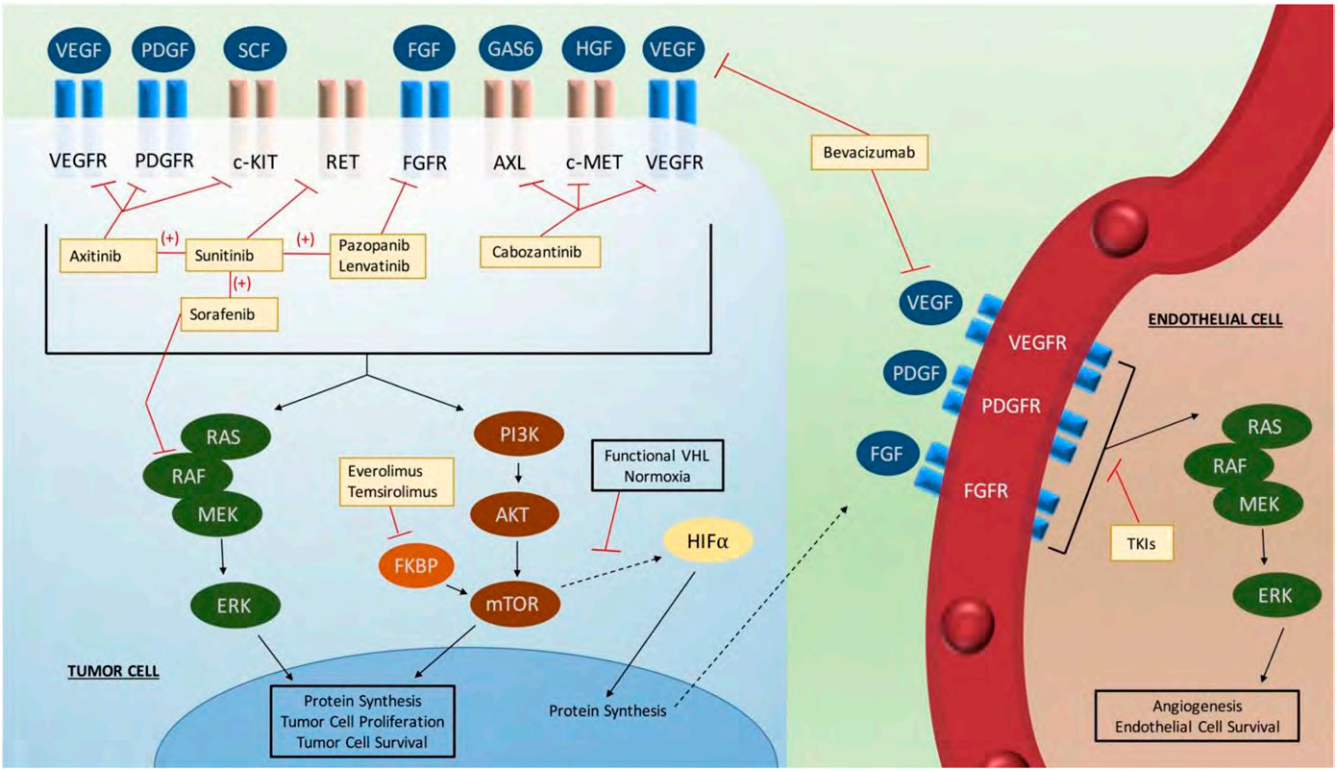
In a randomized study of sorafenib compared with interferon for previously untreated patients, there was no improvement in PFS (5.7 vs. 5.6 months).[26] Another study investigated axitinib versus sorafenib for 288 previously untreated patients. There was an improvement in ORR (32% vs. 15%) and a nonsignificant trend toward improved PFS (median 10.0 vs. 6.5 months) favoring the axitinib arm.[27] The TIVO-1 trial investigated VEGF-TKI tivozanib with sorafenib for 517 previously untreated patients. Although there was an improvement in PFS in the tivozanib arm (11.9 vs. 9.1 months; p = .042), there was a trend toward longer OS in the sorafenib arm (29.3 vs. 28.8 months; p = .105). However, this may have been complicated by notable cross-over differences in the two arms. Of 189 patients who discontinued tivozanib, only 36% received a second therapy and only 10% received another VEGF-directed therapy. Of 226 patients who discontinued sorafenib, 74% received a second-line treatment and nearly 70% received tivozanib.[28] Everolimus, an mTOR inhibitor, was compared with sunitinib for 471 previously untreated patients in the RECORD-3 study using a cross-over treatment design following disease progression. The primary endpoint was noninferiority of everolimus compared with sunitinib in the first-line therapy setting. In addition to inferior PFS in the everolimus arm (7.9 vs. 10.7 months), the combined PFS was inferior with everolimus followed by sunitinib versus sunitinib followed by everolimus (21.1 vs. 25.8 months).[29] The median OS also favored sunitinib followed by everolimus, rather than the reverse (32 vs. 22.4 months). In a 2015 trial, investigators evaluated bevacizumab in a four-arm first-line study with bevacizumab monotherapy versus bevacizumab, temsirolimus versus bevacizumab, and sorafenib versus sorafenib and temsirolimus. There was no notable improvement in the primary endpoint of PFS, but toxicity was significantly greater in the combination arms. Forty-four percent

of patients in the bevacizumab monotherapy arm had grade 3–5 AEs compared with 77%–84% of those in the combination arms.[30] After encouraging phase II results, a phase III trial studied IMA901, a vaccine of 10 tumor-associated peptides, in combination with sunitinib in previously untreated mRCC. Although the peptide vaccine was well tolerated, there was no improvement in clinical outcomes compared with sunitinib monotherapy.[31]

Preferred First-Line Agent

HDIL-2, sorafenib, sunitinib, pazopanib, and bevacizumab with interferon are currently approved agents for previously untreated mRCC. Temsirolimus is approved for patients with mRCC with three or more poor prognosis criteria. To help elucidate the preferred agent, Motzer et al[32] compared pazopanib to sunitinib in the first-line setting in the randomized COMPARZ trial. Although there was a greater ORR with pazopanib (31% vs. 25%), there was no difference in PFS (8.4 vs. 9.5 months) or OS (28.3 vs. 29.1 months). Although the rates of dose reduction and drug discontinuation because of AEs were similar in both arms, health-related quality-of-life scores were worse in the sunitinib arm and were mainly driven by fatigue, mouth and throat soreness, and hand–foot syndrome.[32] The PISCES study, an innovative double-blind randomized controlled cross-over trial assessing treatment preference for pazopanib versus sunitinib, was undertaken with the primary endpoint being patient preference for a specific treatment as determined by a questionnaire developed by mRCC clinicians administered at the end of the treatment period. Utilizing 10-week treatment courses with a 2-week washout, the study showed improvement in patient preference (70% vs. 22%) as well as clinician preference, a secondary endpoint, (61% vs. 22%) favoring pazopanib.[33] Importantly, this is a relatively small study with a high attrition rate and has been criticized for administering the questionnaire immediately prior to the sunitinib rest period.[34] Notably, there have not been any other trials comparing agents currently approved in the first-line therapy setting. Results from the CABOSUN trial may add another layer of complex decision making if they lead to the approval of cabozantinib for the first-line setting. Furthermore, the treatment landscape in the first-line therapy setting is expected to undergo major shifts with expected approval of multiple agents, based on results of numerous ongoing first-line clinical trials (Table 2).

FIGURE 1. Mechanisms of Action of Targeted Therapies in Metastatic Renal Cell Carcinoma



Ligand binding of RTKs leads to many downstream effects. Proangiogenic RTKs (VEGFR, PDGFR, and FGFR) are labeled in blue, whereas growth factor ligand binding to RTKs is colored orange. Simplified mechanisms of the MAPK pathway (left) and mTOR pathway (right) are labeled in the tumor cell. Activation of HIF-α occurs in states of hypoxia and through lack of inhibition from a nonfunctional VHL gene. It leads to synthesis of VEGF, PDGF, and FGF. This can lead to MAPK activation in endothelial cells, depicted on the left side of the diagram. Through FKBP is the site of action of mTOR inhibitors everolimus and temsirolimus and is labeled in orange. Bevacizumab is a monoclonal antibody directed against VEGF. TKIs include sorafenib, sunitinib, axitinib, pazopanib, cabozantinib, and lenvatinib. The aforementioned TKIs inhibit multiple RTKs. RTKs of importance are inhibited by the following TKIs: axitinib (VEGFR, PDGFR, c-KIT), sunitinib (VEGFR, PDGFR, RET, c-KIT), sorafenib (VEGFR, PDGFR, RET, c-KIT, Raf kinases), pazopanib (VEGFR, PDGFR, FGFR, c-KIT, RET), lenvatinib (VEGFR, PDGFR, FGFR, c-KIT, RET), and cabozantinib (VEGFR, c-MET, AXL, c-KIT, RET).

Abbreviations: ERK, extracellular signal–regulated kinase; FGF, fibroblast growth factor; FGFR, fibroblast growth factor receptor; FKBP, FK506-binding protein; GAS6, growth arrest-specific 6; HGF, hepatocyte growth factor; MAPK, mitogen-activated protein kinase; MEK, mitogen-activated protein kinase kinase; PDGF, platelet-derived growth factor; PDGFR, platelet-derived growth factor receptor; PI3K, phosphatidylinositol-3 kinase; RTK, receptor tyrosine kinase; SCF, stem cell factor; TKI, tyrosine kinase inhibitor; VEGFR, VEGF receptor; VHL, von Hippel–Lindau.

TABLE 1. Trials Leading to FDA Approval for Agents in mRCC

Drug	Line of Therapy (Previous Treatment)	FDA Approval	No. of Patients	Control Arm	PFS (Months) vs. Control	OS (Months) vs. Control
Interleukin-2[1]	First	1992	255	None	15% ORR	
Temsirolimus[12]	First (at least 3 poor prognostic factors)	2007	626	Interferon	5.5 vs. 3.1	10.9 vs. 7.3*
Sunitinib[9,13]	First	2006	750	Interferon	11.0 vs. 5.0	26.4 vs. 21.8
Bevacizumab plus interferon[10,14]	First	2009	649	Interferon	10.2 vs. 5.4	23.3 vs. 21.3**
Pazopanib[11]	First/second (cytokines)	2009	435	Placebo	9.2 vs. 4.2	22.9 vs. 20.5**
Sorafenib[8]	Second (cytokines)	2005	903	Placebo	5.5 vs. 2.8	19.3 vs. 15.9*,**
Everolimus[15,16]	Second (sorafenib or sunitinib)	2009	410	Placebo	4.9 vs. 1.9	14.8 vs. 14.4**
Axitinib[17,18]	Second (systemic)	2012	723	Sorafenib	6.7 vs. 4.7	20.1 vs. 19.2**
Nivolumab[19]	Second (antiangiogenic)	2015	821	Everolimus	4.6 vs. 4.4**	25.0 vs. 19.6*
Cabozantinib[20,21]	Second (antiangiogenic)	2016	658	Everolimus	7.4 vs. 3.8	21.4 vs. 16.5
Lenvatinib plus everolimus[22,23]	Second (antiangiogenic)	2016	153	Everolimus	14.6 vs. 5.5	25.5 vs. 15.4

*OS primary outcome.

**Did not reach statistical significance.

Abbreviations: FDA, U.S. Food and Drug Administration; mRCC, advanced or metastatic renal cell carcinoma; ORR, overall response rate; OS, overall survival; PFS, progression-free survival.

As we await the data from these ongoing trials, we suggest HDIL-2 as the preferred agent for patients with excellent performance status, clear cell histology, and intact organ function (regardless of prognostic risk categorization), because HDIL-2 is currently the only agent shown to be associated with durable responses for approximately 10% of patients. We prefer sunitinib or pazopanib for patients in the good and intermediate risk categories who are not candidates for HDIL-2, based on equivalent survival outcomes in a randomized controlled trial comparing these agents. Although there is no randomized trial comparing the combination of bevacizumab and interferon to pazopanib or sunitinib, this remains a reasonable regimen to consider in front-line mRCC. For patients in the poor prognosis category, temsirolimus is approved but is associated with modest survival benefits and requires weekly intravenous administration, which may not be desirable or feasible for many patients. For these patients, sunitinib or pazopanib are the preferred options, based on the results of the COMPARZ trial in which clinical outcomes were similar with both agents.[32]

SECOND-LINE THERAPY AND BEYOND

Headlined by the 2005 FDA approval of sorafenib for patients previously treated with cytokine therapy, antiangiogenic

TABLE 2. Selected Interventional Trials Investigating First-Line Therapy of Novel Agents in mRCC

Identifier	Phase	Arms	Primary Outcome	No. of Patients	Completion Date
NCT02982954	IIIB/IV	Nivolumab plus ipilimumab vs. sunitinib	irAEs	200	January 2023

NCT02959554	II	Nivolumab vs. sunitinib or pazopanib after 3 months TKI	OS	244	November 2022

*OS only calculated for those with detectable PD-L1 tumor expression.

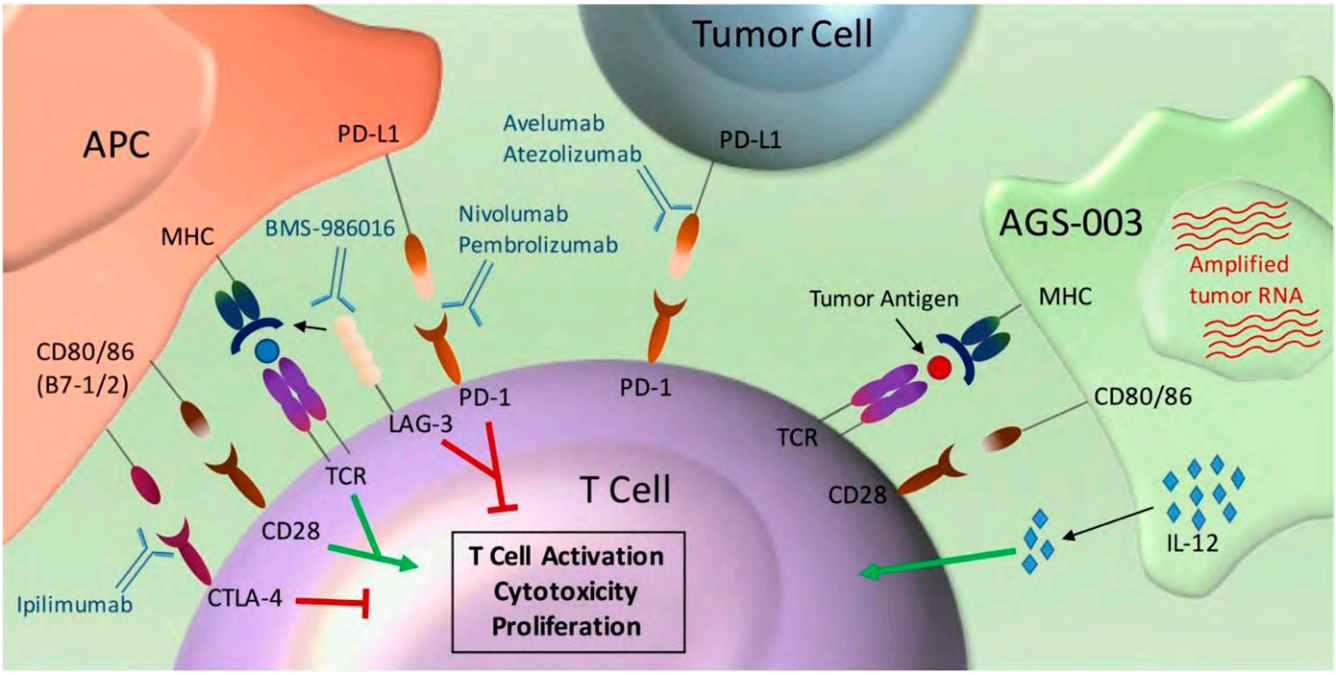
Abbreviations: DOR, duration of response; irAE, immune-related adverse event; mRCC, advanced or metastatic renal cell carcinoma; ORR, objective response rate; OS, overall survival; PFS, progression-free survival; PFSR, progression-free survival rate; TKI, tyrosine kinase inhibitor.

agents have transformed treatment of mRCC salvage therapy over the past decade. After the TARGET study showed improvement in PFS over placebo (5.5 vs. 2.8 months; p < .001), sorafenib became the first VEGF-TKI approved for mRCC.[8] This was followed by the RECORD-1 trial, which investigated everolimus versus placebo for patients who progressed after treatment with sunitinib or sorafenib. Patients in the everolimus-treated arm showed improved PFS (4.9 vs. 1.9 months; p < .001), but everolimus was also associated with increased rates of stomatitis, rash, and fatigue. Similar to temsirolimus studies, there was also an increase in pneumonitis.[15] In the aforementioned phase III VEG105192 study, pazopanib was also compared with placebo for patients in the first-line setting and for those who had progressed while receiving cytokine treatment and improved PFS in both subsets (9.2 vs. 4.2 months; p < .001).[11]

In 2012, the AXIS investigators published results from a study comparing axitinib to sorafenib for 723 patients with mRCC who had progressed with previous systemic therapy (35% of whom were treated with cytokines; the rest received prior treatment with sunitinib, bevacizumab plus interferon, or temsirolimus). Initial results showed that the axitinib arm had improved PFS of 2 months compared with the sorafenib arm (6.7 vs. 4.7 months; one-sided p < .0001), which improved in the updated results (8.3 vs. 5.7 months; one-sided p < .0001). There was a notable improvement in PFS among subsets of patients previously treated with cytokines (12.2 vs. 8.2 months) or those treated previously with sunitinib (6.5 vs. 4.4 months), but not among those who had prior treatment with bevacizumab and interferon or temsirolimus. Overall, ORR was also improved in the axitinib arm (23% vs. 12%), but OS was similar in both arms. AEs were also similar in both arms.[17,18] Temsirolimus was also compared with sorafenib in a study of 512 patients who had previously progressed while taking sunitinib. There was no difference in PFS, but median OS favored the sorafenib arm (16.6 vs. 12.3 months).[35]

The next paradigm shift occurred in 2015, when three novel agents showed improved outcomes in the salvage setting. Nivolumab, a monoclonal antibody directed against the PD-1 receptor, is an immune checkpoint inhibitor that works to reverse tumor-induced immune suppression and stimulate antitumor immunity. Nivolumab was first approved for use in metastatic melanoma followed by non–small cell lung cancer, when a landmark Checkmate025 study compared nivolumab to everolimus in the second-line setting for 821 patients after progression on one or two previous antiangiogenic agents. Although PFS was similar in both arms (4.6 vs. 4.4 months), the primary endpoint OS was superior in the nivolumab arm (25.0 vs. 19.6 months; HR for death, 0.73; p = .002). ORR was also greater in the nivolumab arm (25% vs. 5%) and there were significantly fewer grade 3–4 AEs (19% vs. 37%).[19] Another landmark study, the METEOR trial, investigated cabozantinib versus everolimus for 658 patients who had progressed after antiangiogenic therapy directed against VEGF. Sixty-nine percent of patients had only received one prior treatment, whereas the remaining patients had received at least two prior therapies. Cabozantinib resulted in

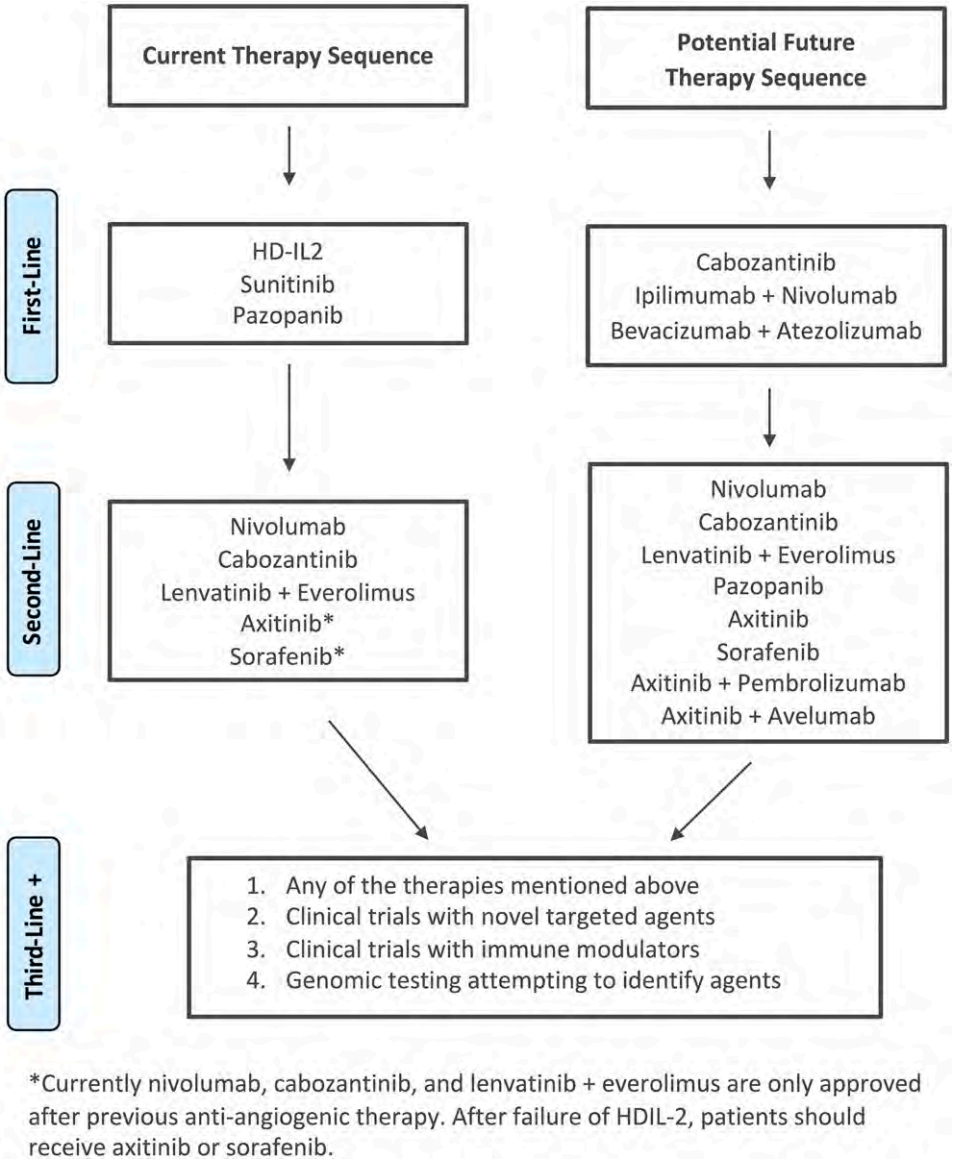
FIGURE 2. Mechanisms of Action of Immunotherapies for Metastatic Renal Cell Carcinoma



Immune checkpoint inhibitors and AGS-003 are featured. Ipilimumab is a monoclonal antibody directed against CTLA-4 on T cells. Nivolumab and pembrolizumab inhibit PD-1 on both tumor and T cells, whereas avelumab and atezolizumab inhibit its ligand, PD-L1. BMS-986016 is a novel immune agent that targets LAG-3, preventing immune inhibition by preventing LAG-3 binding to its ligand, MHC class II receptor. AGS-003 is a mature dendritic cell that has been coelectroporated with tumor DNA and human CD40 ligand. By processing and then presenting tumor antigen, it binds both the TCR and CD28. A third signal leads to with IL-12 promotes memory T-cell development.

Abbreviations: IL, interleukin; MHC, major histocompatibility complex; TCR, T-cell receptor.

FIGURE 3. Sequencing Paradigm of Metastatic Renal Cell Carcinoma



Asterisks indicate that nivolumab, cabozantinib, and lenvatinib plus everolimus are currently approved for use only after previous antiangiogenic therapy. After failure of HDIL-2, patients could receive axitinib or sorafenib.

Abbreviations: HDIL-2, high-dose interleukin-2.

improved in PFS (7.4 vs. 3.8 months; p < .001), ORR (17% vs. 3%; p < .001), and OS (21.4 vs. 16.5 months; HR, 0.66; p = .00026). Remarkably, treatment with cabozantinib resulted in the longest PFS in the post-VEGF/TKI salvage monotherapy setting reported to date. More than 99% of patients in both arms reported an AE of any grade, but there was a greater incidence of grade 3–4 AEs in the cabozantinib arm (68% vs. 58%). More frequent grade 3–4 AEs with cabozantinib included hand–foot syndrome, hypertension, diarrhea, nausea, and thromboembolic events.[20] Also reported in 2015, a phase II study investigated treatment with lenvatinib (a TKI of VEGFR1–VEGFR3, fibroblast growth factor receptors 1–4, platelet-derived growth factor receptor α, RET and KIT) for 153 patients with mRCC who had progressed after VEGF-targeted therapy. Patients were randomized into three arms: combination lenvatinib and everolimus versus lenvatinib monotherapy versus everolimus monotherapy. Respectively, PFS (14.6 vs. 7.4 vs. 5.5 months) and OS (25.5 vs. 18.4 vs. 15.4 months) were greater in the combination arm but only met statistical significance for the primary endpoint, which was PFS for patients who received lenvatinib plus everolimus versus everolimus monotherapy. Combination therapy was more toxic than everolimus monotherapy (grade 3–4 AEs, 71% vs. 50%) with significantly greater diarrhea in the combination arm.[22] These three studies led to FDA approvals for nivolumab, cabozantinib, and lenvatinib in combination with everolimus for patients with mRCC for which an antiangiogenic agent failed previously. Notably, these agents are only approved after VEGF-directed treatment failure and are not approved

for those patients with mRCC for which immune therapy failed.

ONGOING CLINICAL TRIALS FOR UNTREATED MRCC

Although the landscape of second-line and salvage therapy is rapidly evolving, there are many clinical trials at various stages investigating first-line therapy for mRCC (Table 2).

Immunotherapy: Checkpoint Inhibitors

Numerous immunotherapy agents are under active investigation in the first-line setting for mRCC, including seven trials investigating immune checkpoint inhibitors (Fig. 2). In a phase IIIB/IV trial (NCT02982954), nivolumab is being studied in combination with ipilimumab, a checkpoint inhibitor directed against CTLA-4. Nivolumab is also being studied in two phase II trials (NCT02996110 and NCT02959554). The aforementioned trial plans to enroll 650 patients and is comparing nivolumab with ipilimumab versus nivolumab with BMS-986016, a monoclonal antibody checkpoint inhibitor directed against lymphocyte activation gene-3 (LAG-3). The latter trial is enrolling 244 patients and comparing nivolumab to sunitinib or pazopanib after treating patients for 10–12 weeks with a TKI. Pembrolizumab, another PD-1 monoclonal antibody, is currently being studied in combination with axitinib compared with sunitinib in a phase III trial of 840 patients and completion is expected in 2019 (NCT02853331). Another phase III trial of 735 patients (NCT02811861) is comparing the combination of pembrolizumab and lenvatinib against combination lenvatinib and everolimus as well as sunitinib monotherapy. Investigators are also enrolling patients for first-line studies of checkpoint inhibitors targeting PD-L1 (avelumab and atezolizumab). In a phase III trial with 583 patients (NCT02684006), avelumab is being studied in combination with axitinib versus the comparator sunitinib.

Selected Novel Agents in Development

AGS-003 is a personalized immunotherapy of mature autologous dendritic cells that are coelectroporated with both synthetic RNA and the patient's tumor RNA. AGS-003 was designed to achieve the immunomodulatory effects of HDIL-2 with a more favorable toxicity profile, and AGS-003 was studied in combination with sunitinib in a phase II study of 22 patients with low- or intermediate-risk mRCC. There were no CRs, but nine patients had a partial response and the median PFS and OS were encouraging (11.2 and 30.2 months, respectively). Notably, OS exceeded 5 years for five patients (24%), with two patients (approximately 10%) achieving durable responses for more than 5 years.[36] The phase III ADAPT trial (NCT01582672) has completed accrual and results are currently awaited. LY2510924 (X4P-001) is a novel cyclic peptide that inhibits CXCR-4, a chemokine receptor shown to be important in tumorgenesis.[37] A phase II trial (NCT01391130) comparing monotherapy with sunitinib versus sunitinib with LY2510924 is enrolling 108 patients, with completion anticipated in 2017. In a small phase I trial (NCT02035358) with 18 patients, researchers are also investigating a polyvalent immune vaccine called HyperAcute-Renal, which is composed of an allogenic renal cell carcinoma (RCC) cell that has been genetically modified to express 1,3-galactosyltransferase with the intention to augment cellular immune responses. Hypoxia-inducible factors (HIFs) are transcription factors activated in hypoxic states and by loss of von Hippel–Lindau function. HIF-1α and HIF-2α overexpression has long been known to be associated with malignant disease.[38,39] In particular, HIF has been implicated in both tumorigenesis and angiogenesis in mRCC (Fig. 1).[40] In another trial (NCT02293980), PT2385, a recently developed direct antagonist of HIF-2α, is being investigated as a monotherapy and in combination with either cabozantinib or nivolumab for patients with mRCC who have progressed while taking previous therapy. A very similar agent, PT2399, has shown antitumor activity in a mouse model.[40]

Dalantercept, an activin receptor-like kinase 1 inhibitor that targets angiogenesis, is being tested in combination with axitinib for patients who progressed despite previous VEGF/TKI treatment. Phase II results of the DART study reported no dose-limiting toxicities among the 29 patients treated, with an ORR of 25% and PFS of 8.3 months.[41] Part II of the study is a randomized trial (NCT01727336) in which this combination is being compared with axitinib alone; the study is currently enrolling 174 patients, with completion estimated in 2018. Another trial (NCT01806064) is combining a monoclonal antibody against endoglin, TRC105, with axitinib compared with axitinib monotherapy for 168 patients with mRCC. Endoglin is a glycoprotein expressed on endothelial cells and plays an important role in angiogenesis and tumorgenesis.[42]

ROLE OF SURGERY IN THE METASTATIC SETTING

Cytoreductive Nephrectomy

Most patients with mRCC who have been enrolled in systemic therapy clinical trials on mRCC have had cytoreductive nephrectomy (CN) performed. In addition to palliation of pain, hematuria, and paraneoplastic syndromes, CN, if clinically feasible, is likely to improve outcomes for carefully selected patients. CN has been a standard of care since two landmark trials showed an improvement in OS (17 vs. 7 months; HR, 0.54) for patients who underwent CN prior to therapy.[43,44] Although both studies used interferon as the systemic therapy, an updated retrospective cohort of 15,390 patients treated with antiangiogenic targeted therapies reported similar survival data for those who underwent a CN (median OS of 17.1 vs. 7.7 months; $p < .001$).[45] In a different retrospective cohort from the Surveillance, Epidemiology, and End Results database, investigators found that of 7,143 patients with reported mRCC treated with antiangiogenic targeted therapy, 37% underwent CN. Those who underwent a CN had improved 1-year OS (61% vs. 22%; HR, 0.40), which was influenced by many factors, including a greater likelihood of having localized disease and younger age.[46] In a retrospective IMDC cohort in the targeted therapy era,

investigators performed a multivariate analysis of 314 patients, 201 of whom underwent CN. Again, the IMDC investigators noted improvement in OS with CN (19.8 vs. 9.4 months; p < .01), but this benefit was greatest for those with a favorable and intermediate prognosis.[47] Given the inherent biases of these retrospective studies, a prospective study (CARMENA, NCT00930033) is investigating CN by comparing sunitinib with or without CN in previously untreated patients with mRCC. CARMENA has a planned sample size of 700 participants with eligibility including biopsy proven mRCC and an ECOG 0-1. The primary endpoint is OS.

Although prospective results are pending, it is paramount that the treatment decision for CN be based on an individual patient's performance and prognostic status and made in conjunction with multidisciplinary input. Although no specific guidelines yet exist, a reasonable approach may be to exclude those who did not benefit from CN in the IMDC study. These included those with at least four poor IMDC prognostic factors: time from diagnosis to treatment less than 1 year, Karnofsky performance score less than 80, anemia, neutrophilia, and thrombocytosis. In addition, those with anticipated OS shorter than 1 year may not benefit from CN.[47,48] It is also important to consider the probability of successfully debulking of adequate portion of the tumor.

Metastasectomy

Similar to CN, the role of metastasectomy for patients with mRCC is nuanced based on underlying patient characteristics. In a 1998 study of 278 patients with recurrent RCC, investigators found that 44% of patients were able to have long-term remission with oligometastasectomy (based on 5-year OS). Favorable features for response included a solitary metastatic organ site, the lung as the metastatic site, and age younger than 60. Those with the brain as a solitary metastatic site had inferior outcomes to oligometastasectomy than those with lung (5-year OS, 18% vs. 54%; p < .05).[49] A 2011 study of 887 patients who underwent nephrectomy for RCC who later developed lung-confined metastatic lesions also showed impressive 5-year OS with complete versus incomplete resection (73.6% vs. 19.0%; p < .001).[50] The same study also showed a survival advantage, although less robust, favoring complete over incomplete resection for patients with extrapulmonary metastatic lesions (5-year OS, 32.5% vs. 12.4%; p < .001).[50] Other studies have shown improvement for resection of symptomatic bone lesions as well as complete resection of visceral metastases to the liver, thyroid, and pancreas.[51-54] A randomized, double-blind placebo-controlled study, E2810 (NCT01575548), is currently enrolling patients to study whether pazopanib improves outcomes for individuals who successfully undergo complete resection of metastatic lesions.

Adjuvant Therapy

Thus far, adjuvant therapy results have been disappointing in RCC. A 2003 study of 69 patients with locally advanced or metastatic RCC treated with adjuvant HDIL-2 showed no benefit in disease-free survival (DFS) compared with a similar cohort of patients followed with observation.[55] Recently, the Eastern Cooperative Oncology Group (ECOG) 2805 trial investigated sunitinib or sorafenib or placebo as adjuvant therapy for 1,943 patients with resected nonmetastatic RCC. Unfortunately, results revealed that neither sorafenib or sunitinib improved DFS compared with placebo.[56] In the S-TRAC adjuvant study of 615 patients with resected nonmetastatic RCC, sunitinib significantly improved DFS compared with placebo (6.8 vs. 5.6 years; HR, 0.76); however, the duration of improvement in median DFS was similar to the duration of adjuvant therapy with sunitinib.[57] Notably, per independent central review, the magnitude of benefit was higher with adjuvant sunitinib for patients with a higher risk of recurrence, defined as those with T3 tumors, without or with undetermined nodal involvement, with Fuhrman grade 2 or higher tumors, and with a ECOG performance score of 1 or higher; or those with a T4 tumor, local nodal involvement, or both. For these patients, DFS was significantly improved with sunitinib versus placebo (6.2 vs. 4.0 years; HR, 0.74; 95% CI, 0.55–0.99; p = .04). The OS results need to mature on further follow-up to see whether systemic anti-VEGF therapy actually effects a cure for any patient with mRCC. Recently reported preliminary results of the PROTECT study (NCT01235962) with adjuvant pazopanib also failed to reveal a DFS benefit over placebo. A phase III trial through the National Clinical Trials Network, PROSPER RCC, was activated in 2017 and is comparing neoadjuvant and adjuvant nivolumab versus observation in localized RCC, with the hypothesis that prenephrectomy administration may improve T-cell response. In addition, phase III adjuvant therapy trials with atezolizumab and pembrolizumab are ongoing and continue to use placebo as the control arm.

SEQUENCING PARADIGM

To date, no randomized trials have yet established the optimal sequence of therapy in renal cancer. Most of the targeted therapies have been established in phase III trials that were conducted within the same timeframe, so very few were done with comparisons to another agent. The COMPARZ trial showed that pazopanib was noninferior to sunitinib, so either could be considered as a front-line therapy option.[32] Randomized front-line trials comparing either axitinib or tivozanib to sorafenib did not reveal an advantage in efficacy.[27,28] Of the previous trials, only COMPARZ used sunitinib for the comparator arm and others used sorafenib. Contemporary ongoing first-line studies of nivolumab and ipilimumab, atezolizumab and bevacizumab, pembrolizumab and axitinib, avelumab and axitinib, and lenvatinib and pembrolizumab are all using sunitinib as the control (Table 2). As discussed above, the CABOSUN trial also used sunitinib as the comparator against cabozantinib in the first-line setting. As the only therapy with decades of follow-up, HDIL-2 is associated with durable responses for 10% of patients and remains a treatment consideration; however, HDIL-2 requires carefully selecting patients with robust performance status and organ function, which limits its use.

Second-line therapies were also established in clinical trials that were conducted in parallel. Axitinib showed

improved PFS compared with sorafenib, and everolimus showed better efficacy than placebo for patients previously treated with VEGF-directed therapies. All recent studies for the pretreated mRCC population have used everolimus as the comparator arm. Nivolumab, cabozantinib, and lenvatinib plus everolimus each revealed superior efficacy in response rates and OS. Hence, a contemporary therapy sequence pattern has emerged of sunitinib or pazopanib followed by nivolumab or cabozantinib or axitinib. Generally, if nivolumab is used in the second line, cabozantinib or axitinib is used in the third line or later and vice versa. Given higher toxicities but relatively higher response rates and PFS of the lenvatinib plus everolimus combination, this may be reserved for patients with rapidly progressive high-volume disease in the second-line therapy setting, or after disease progression following other monotherapies. It is postulated that the therapeutic sequence will undergo a dramatic change based on the results of first-line therapy trials (Table 2). Figure 3 provides an overview of current and potential future therapeutic sequencing in mRCC.

A biomarker selection process would be a helpful tool; however, no predictive markers have been validated to date. Recent reports on BAP-1, SETD2, and PBRM-1 as potential prognostic and predictive biomarkers may foster the possibility of impacting risk profiling.[58] Even PD-L1 expression, a useful marker in other malignancies, has failed to predict the efficacy of immune therapy in mRCC. Mutation load and the neutrophil-to-lymphocyte ratio are promising biomarkers to predict response to immune therapy within mRCC.[59-61] Novel targets involving resistance pathways such as CXCR-4 (X4P-001) and HIF-2 (PT2385) and immune modulators such as LAG-3 inhibitors (BMS-986016) are under clinical investigation and therapeutic development.

CONCLUSION

The field of kidney cancer has surprisingly thrived on targeted therapy, despite the disease being notorious for its heterogeneity. New advances have improved response rates, OS, and treatment-related toxicities for patients with mRCC. Although new discoveries in targeted therapies are paralleled by those in immunotherapy, the treatment paradigm continues to evolve. Despite the FDA's approval of multiple agents, clinical trials should continue to be the mainstay of treatment in mRCC, because every advance to date can be attributed to patient participation in therapeutic studies.

New Developments and Challenges in Rare Genitourinary Tumors: Non-Urothelial Bladder Cancers and Squamous Cell Cancers of the Penis

Jeanny B. Aragon-Ching, MD, FACP, and Lance C. Pagliaro, MD

OVERVIEW

The diagnosis and treatment of rare genitourinary tumors is inherently challenging. The Rare Diseases Act of 2002 initially defined a rare disorder as one that affects fewer than 200,000 Americans. The lack of widely available clinical guidelines, limited research funding, and inaccessible clinical trials often lead to difficulty with treatment decisions to guide practitioners in rendering effective care for patients with rare genitourinary cancers. This article will discuss basic tenets of diagnosis and treatment as well as recent developments and clinical trials in rare non-urothelial bladder cancers and penile squamous cell cancers.

NON-UROTHELIAL BLADDER CANCER

In 2016 alone, there were 76,960 new cases of bladder cancer, with a higher incidence among men compared with women (58,950 vs. 18,010) and 16,390 deaths (11,820 men and 4,570 women).[1] Although the majority of bladder cancers (over 90%) are urothelial in histology, variants or divergent differentiations exist, which poses a unique challenge in the diagnosis and treatment of bladder cancers. Non-urothelial bladder cancer and variants of urothelial carcinoma comprise up to 25% of all bladder cancers.[2] Pure non-urothelial bladder cancers in the aggregate comprise only 5% or fewer of all bladder neoplasms.[3] The majority (close to 90%) of non-urothelial cancers are also epithelial in nature, such as squamous cell carcinoma (SCC), adenocarcinoma, and small cell carcinoma, whereas non-epithelial tumors include extremely rare histologies in the bladder such as sarcoma, lymphoma, and melanoma. However, these rare histologies pose a substantial barrier to effective management not only because of their generally perceived aggressive nature but also because of a lack of adequately powered studies to define standards of care for treatment. This article describes the unique challenges and pitfalls in the diagnosis and treatment of and recent developments in non-urothelial bladder cancers.

2016 World Health Organization Classification of Urothelial Tumors

The 2016 World Health Organization (WHO) classification for bladder tumors mainly kept the recommendation of the 1997 International Society of Urological Pathology classification and placed strong emphasis on better defining the noninvasive entities of urothelial dysplasia and urothelial proliferation of uncertain malignant potential. A distinction was made to compare the third and fourth editions of the WHO classification, especially with regard to invasive urothelial carcinoma with divergent differentiation. The difference between the 4th and the 3rd edition of the WHO classification are as follows: the nested (including large nested) variants, microcystic, micropapillary, lymphoepithelioma-like, plasmacytoid/signet ring cell/diffuse, the sarcomatoid, giant cell, poorly differentiated, lipid-rich, and clear cell.[4] Although it is still unclear whether treatment or outcomes may differ from these divergent differentiations, pathologists are also encouraged to quantify the amount of morphologic variants seen, because as many as 33% of variants are encountered with invasive urothelial carcinoma.[5]

In addition, apart from urothelial tumors or those with divergent differentiation, non-urothelial cancers consist of the following subclassification: squamous cell neoplasms, glandular neoplasms, urachal carcinoma, tumors of Mullerian type, neuroendocrine tumors, melanocytic tumors, mesenchymal tumors, urothelial tract hematopoietic and lymphoid tumors, and miscellaneous tumors (which includes tumors arising in a bladder diverticulum; Sidebar 1).

Guidelines on Diagnosis and Management of Invasive Non-Urothelial Cancers

Bladder squamous cell carcinoma. Although SCCs account for only 3%–5% of all bladder carcinomas in the United States, SCC confers a fairly dismal prognosis.[6] In areas endemic

SIDEBAR 1. Non-Urothelial Bladder Neoplasms

Squamous Cell Neoplasm
- Pure squamous cell carcinoma
- Verrucous carcinoma
- Squamous cell papilloma

Glandular Neoplasms
- Adenocarcinoma, not otherwise specified
- Enteric
- Mucinous
- Mixed
- Villous adenoma

Urachal Carcinoma

Tumors of Mullerian Type
- Clear cell carcinoma
- Endometrioid carcinoma

Neuroendocrine Tumors
- Small cell neuroendocrine carcinoma
- Large cell neuroendocrine carcinoma
- Well-differentiated neuroendocrine tumor
- Paraganglioma

Melanocytic Tumors
- Malignant melanoma
- Nevus
- Melanosis

Mesenchymal Tumors
- Rhabdomyosarcoma
- Leiomyosarcoma
- Angiosarcoma
- Inflammatory myofibroblastic tumor
- Perivascular epithelioid cell tumor, benign or malignant
- Solitary fibrous tumor
- Leiomyoma
- Hemangioma
- Granular cell tumor
- Neurofibroma

Urothelial Tract Hematopoietic and Lymphoid Tumors

Miscellaneous
- Tumors arising in bladder diverticulum

Adapted from the World Health Organization.

KEY POINTS

- **The most common non-urothelial bladder cancers consist of adenocarcinoma, squamous carcinoma, and neuroendocrine tumors potentially with a more aggressive course and poor response to traditional treatments.**
- **Localized penile cancers are amenable to local therapies with topical chemotherapy, surgery, or radiation, with penis-sparing options, whereas multimodal therapy incorporates chemotherapy for advanced stages.**
- **Studies show that genetic aberrations, amplifications, and protein expression may herald potential drug targets in non-urothelial bladder cancers and penile cancers.**

for schistosomiasis (the second most frequent parasitic infection next to malaria), SCCs comprise the majority of bladder cancers (upward of 75%), which are also termed bilharzial squamous bladder cancers.[7] However, in the United States and other Western countries, triggers that include chronic irritation and inflammation, such as those seen among patients with indwelling catheters, are known to be additional risk factors for nonbilharzial squamous carcinoma.[8,9] Other histopathologic features such as keratinizing squamous metaplasia or other noninvasive histologies like verrucous squamous hyperplasia are known to increase the risk of subsequent development of invasive SCCs,[10,11] although the exact mechanism and fate of these is not quite clear, precluding definitive recommendations for aggressive surgical extirpation in all cases. SCC occurs in men and women about equally. Clinicopathologic behavior is different between bilharzial versus nonbilharzial bladder cancers, with the former presenting with lower-grade or better-differentiated, high-stage, and non-papillary disease,[12] whereas both present in usually more advanced or muscle-invasive stages compared with their urothelial counterparts[13] but with lower rates of lymph node metastases or lymphovascular invasion.

Given the rarity of these cancers, no standard consensus regarding treatment has been advocated.[14] However, studies show that radical cystectomy, with the possibility of preoperative radiation in bilharzial SCC,[8,15] may improve outcomes. Although chemotherapy using cisplatin as the backbone has had relative success in treating urothelial carcinoma, this is less so with SCC. TIP (Taxol or paclitaxel, ifosfamide, and platinum or cisplatin)[16] was used in a prospective trial of patients with non-urothelial variants, which revealed a dismal median survival of 8.9 months but conversely showed complete remission in two out of eight patients with SCC. One large retrospective trial reported on 27 patients with resectable T2–T4 disease; eight patients underwent neoadjuvant therapy, although only three were able to successfully proceed with radical cystectomy.[17] Therefore, it is best to offer patients who are deemed candidates for radical cystectomy the option to undergo surgery upfront, because the therapeutic benefit of neoadjuvant chemotherapy is unclear.

Bladder adenocarcinoma. Adenocarcinomas of the bladder comprise < 2% of all bladder carcinomas. Similar to SCC, infection with schistosomiasis may be a risk factor in up to 10% of bladder cancers that occur in the form of non-urachal adenocarcinomas. Other risk factors such as bladder exstrophy and bladder augmentation can be seen. The distinction between urachal and non-urachal adenocarcinoma is important because their clinicopathologic behavior and treatment are vastly different. Primary adenocarcinomas are therefore typically subdivided into urachal carcinomas, which comprise up to 30% of all primary adenocarcinomas,[18] or non-urachal carcinomas, which comprise 70%. The urachus is a remnant of the umbilical ligament, which is typically obliterated at birth and can be a site of future adenocarcinoma. Patients with urachal carcinoma typically have adenocarcinoma features, their disease is usually advanced when they present with hematuria, and they may

TABLE 1. Differences Between the Mayo Clinic and Sheldon Staging Systems for Urachal Carcinoma

Stage	Mayo Clinic System	Sheldon Staging System
I	Tumors confined to the urachus and/or bladder	No invasion beyond the urachal mucosa
II	Tumors extending beyond the muscular layer of the urachus or the bladder	Invasion confined to the urachus
III	Tumors infiltrating the regional lymph nodes	Local extension into the:
		Bladder (IIIA)
		Abdominal wall (IIIB)
		Peritoneum (IIIC)
		Viscera other than bladder (IIID)
IV	Tumors infiltrating nonregional lymph nodes or other distant sites	Metastases to the: regional lymph nodes (IVA) and distant sites (IVB)

have a palpable mass.[19] There are different staging schema, and it should be noted that the usual TNM staging that is applicable to other primary urothelial bladder carcinomas is not applicable to urachal cancers because the tumor grows from outside of the bladder inward and, depending on the staging, may not even manifest with involvement within the bladder that can be visible via cystoscopy. The Sheldon staging system is commonly used,[20] although a more simplified staging system has also been proposed and used[21] (Table 1). Urachal carcinomas are unique in their presentation, such that presentation in the midline or dome of the bladder should raise suspicion of urachal carcinoma, given direct extension of the umbilical ligament. Urachal carcinomas are almost universally adenocarcinomas in histology, which can have mucinous differentiation. Enteric-type histology, absence of accompanying urothelial cancer or cystitis cystica or dysplasia, and lack of objective findings of involvement of another organ would support the diagnosis. Treatment of urachal carcinomas is also unique, in that they are considered invasive but do not require radical cystectomy and treatment with a partial cystectomy with en bloc resection of the urachal ligament is possible.[22,23] Similarly, given the lack of consensus regarding objective responses to chemotherapy, neoadjuvant chemotherapy is not uniformly recommended. On the other hand, non-urachal adenocarcinomas typically present in more advanced stages with high propensity for metastasis. However, it is of paramount importance to rule out other primary adenocarcinomas, particularly of the colon, gastrointestinal tract, or lung. Radical surgery has historically been the treatment of choice, which results in long-term survival in up to 40% of patients in 5 years.[24] However, few options exist for patients with advanced or unresectable cancer. Early investigations, mostly at The University of Texas MD Anderson Cancer Center, used a regimen that utilizes 5-fluorouracil (5-FU) similar to that for a colon cancer regimen[25] and yielded some promising responses as well as a 5-FU/cisplatin combination with about a 33% response rate. This led to a trial at MD Anderson utilizing gemcitabine, 5-FU, leucovorin, and cisplatin for patients with locally advanced or metastatic urachal carcinoma, suggesting a reasonable objective response rate in about one-third of patients.[26,27] Other regimens reported mostly in case reports or small series include 5-FU and oxaliplatin with leucovorin for colon cancer, single-agent chemotherapy with irinotecan,[28] cisplatin/S-1,[29] or TIP,[16] similar to the SCC bladder histology.

Neuroendocrine/small cell carcinoma. Neuroendocrine cancers or small cell cancers of the bladder are rare, making up only < 1% of all bladder tumors.[30,31] However, they represent aggressive histologic subtypes that mimic the course of other extravesical neuroendocrine tumors and usually present with locally advanced stages.[32] Neuroendocrine cancers typically consist of either small cell cancer, large cell cancer, well-differentiated neuroendocrine tumors, and paragangliomas. Given the uniformly poor prognosis, many advocate for upfront radical cystectomy, which still has dismal outcomes, especially in those with nonconfined bladder tumors.[33] Given the potential benefit of the use of preoperative chemotherapy regimens typically used for extravesical neuroendocrine tumors such as platinum with etoposide regimens,[34,35] multimodality therapy with combined preoperative chemotherapy followed by consolidative radiation,[36] or surgery for those with confined disease, yields the most reasonable response rates.[37]

Role of Genomics for Diagnosis

Bladder cancer is a neoplasm with high mutational burden and is considered the fourth highestnext to melanoma, squamous cell lung cancer, and adenocarcinomas.[38] However, although The Cancer Genome Atlas presented comprehensive analyses of muscle-invasive urothelial cancers and showcased the most common genetic mutations, pure non-urothelial cancers or urothelial carcinomas with divergent differentiation were not represented. However, several small reports show that molecular data may complement the diagnosis and prognostication of non-urothelial cancers or divergent differentiations/variants.[39] One study of sequencing showed high rates of aberrations in TP53, BRCA2, SMAD4, PTEN, KRAS, NRAS, and KIT for bladder adenocarcinoma, with amplifications in EGFR occurring in 27.3% of adenocarcinomas and ERBB2/HER2 in 16.7%.[40] PIK3CA mutations were seen, along with HRAS, BRCA1, and BRCA2, and FBXW7 in SCC with amplifications only in ERBB2 was seen. Interestingly, PD-1 in tumor infiltrating cells were seen in about 44% for both adenocarcinomas and SCCs while PD-L1 was seen in 11.1% and 22% in adenocarcinomas and SCCs, respectively, suggesting the potential utility of immune checkpoint inhibitors in this population of patients. Another study that evaluated the comprehensive genomic profiling of predominantly stage IV small cell bladder cancers found that there was genomic differences compared to urothelial bladder cancers, with higher frequencies of TP53 and RB1 genomic aberrations in small cell compared to urothelial cancers, and with very low FGFR3 and ERBB2 alterations in small cell bladder cancers.[41]

Role of Traditional Chemotherapy for Non-Urothelial Bladder Cancers

Cisplatin-based chemotherapy in the form of dose-dense or accelerated MVAC (methotrexate, vinblastine, adriamycin, and cisplatin) or gemcitabine/cisplatin has been the cornerstone of chemotherapy use in patients with locally advanced bladder cancer.[42] However, patients with pure non-urothelial variants have varying, although usually suboptimal, responses to traditional chemotherapy and these novel entities deserve particular mention in their management. In general, if the histology is predominantly urothelial but the presence of divergent differentiation is documented, treatment still follows that of typical urothelial bladder carcinoma, understanding that the behavior may be more aggressive and warrants a careful approach.

Role of Immunotherapy and/or Targeted Therapy

Immunotherapy has played a major role in the treatment of urothelial cancers, both in noninvasive cancers (e.g., the use of the vaccine Bacille-Calmette Guerin) and in metastatic urothelial cancer; atezolizumab (an antibody against protein PD-L1) was recently approved for treatment of metastatic bladder cancer after failure of first-line platinum.[43] However, its role in non-urothelial bladder cancer or with divergent differentiation is not well defined, because most of the studies using PD-1 and PD-L1 inhibitors either excluded the non-urothelial bladder cancers or did not definitively capture the percentage of urothelial variants or divergent differentiation. Regardless, several small studies with the use of VEGF inhibitors or checkpoint inhibitors are showing promise. A small phase II trial utilizing cabozantinib, a vascular endothelial growth factor (VEGFR-2) and MET pathway inhibitor, included three cohorts of metastatic urothelial cancers, a bone-only cohort, and a third cohort with rare genitourinary tumors.[44] Responses were seen for two of six patients with small cell carcinoma, for three patients with adenocarcinoma, and for one patient with SCC. In a phase I trial utilizing cabozantinib combined with nivolumab, a PD-1 pathway inhibitor, 24 patients in cohort 1 were enrolled, with an intriguing overall response rate of 43% for the whole cohort; four patients with urachal adenocarcinoma and three with SCC exhibited a response.[45] The combination was deemed safe, with fatigue noted in 13% of patients, thromboembolic events in 13%, and decreased neutrophil count in 17%. The recommended phase II dose was 40 mg of cabozantinib with 3 mg/kg of nivolumab with part II of this expansion cohort that includes ipilimumab. In the updated reporting of this trial, four patients with urachal carcinoma and two patients with squamous cell carcinoma were enrolled, with complete response seen in one patient with squamous cell and partial response in the other patient with squamous cell carcinoma and the urachal carcinoma.[46] SWOG Trial S1609 (NCT02834013) is currently accruing patients with rare tumors and is utilizing nivolumab plus ipilimumab with the primary objective of overall response rates.

In summary, diagnosis and treatment of non-urothelial cancers, whether in pure form or with mixed histologies or divergent differentiation, poses a major diagnostic and treatment challenge for the practicing clinician. Efforts to refine molecular targets for both diagnosis and treatment may pave the way for improved outcomes in this very difficult disease state.

SQUAMOUS CELL CARCINOMA OF THE PENIS

SCC is the most common malignant primary tumor of the penis. In the United States, there are an estimated 2,000 new cases of penile cancer per year.[1] The risk of these rare tumors has been linked to lack of circumcision and exposure to human papillomavirus (HPV).[47] Incidence increases with age and peaks among men age 50–70. Despite a lack of randomized controlled trials, several treatment strategies have emerged consisting of surgery or radiotherapy for localized penile cancer, multimodal therapy for locally advanced disease, and systemic therapies for palliation of patients with distant metastasis.

Histologic Classification and Role of HPV

Histologic variants of penile SCC include the basaloid, warty, and verrucous subtypes, which are collectively termed "unusual" variants, and the remaining histology is the majority of penile cancer, which is termed "usual" type, or keratinizing SCC.[48] There may be more than one histologic pattern within a tumor. Evidence of HPV infection has been found in both the usual-type and unusual histologic variants. An estimated 31%–66% of all penile cancers are HPV related, with type 16 virus being most prevalent. The basaloid and warty subtypes are associated with HPV in 80%–100% of cases, whereas the usual type is less commonly associated and the verrucous subtype is least associated.

The viral genes E6 and E7 are expressed in HPV-transformed cells and are known to interact with the RB1 and TP53 tumor suppressor pathways.[49] These pathways are therefore implicated in penile cancer. Mutations of TP53 are found in a subset of penile cancers and are associated with a higher incidence of lymph node metastasis and lower overall survival.[50,51] It is likely that somatic mutations in the RB1 and TP53 pathway genes are more common in HPV-unrelated tumors where those pathways are not already inactivated by viral proteins. Thus, there are possibly distinct molecular mechanisms underlying HPV-related and unrelated penile cancer. HPV-related penile cancers appear to have better prognosis than those that are unrelated.

Treatment Strategies for SCC of the Penis

For patients with localized penile cancer, factors affecting the choice of treatment include tumor size, proximal or distal location, histologic grade, confinement to the foreskin, and patient preference. Topical chemotherapy such as imiquimod or 5-FU is first-line treatment in cases of carcinoma in situ.[52] Other options are laser ablation or total or partial glans resurfacing.[53,54] For Ta/T1a lesions, a glansectomy or circumcision with intraoperative assessment of surgical margins may be sufficient. Penis-sparing techniques allow better quality of life than with partial penectomy. Local

recurrence rates are generally higher with organ-sparing surgery compared with partial penectomy (5%–12% vs. 5%), but with good salvage results and a minimal effect on survival.[55] Radiotherapy is another penis-sparing option for tumors that are less than 4 cm and stage T2 or lower.[56] Higher clinical stage (T3–T4) or more proximal tumors may require total penectomy with perineal urethrostomy for adequate local control.

Patients with regional lymph node metastases are potentially curable. Lymphatic spread occurs first to unilateral or bilateral superficial and deep inguinal lymph nodes.[57] Pelvic lymph nodes are the second regional group to be involved. Radical inguinal lymphadenectomy is the mainstay of treatment. Patients with pelvic lymph node metastases are rarely cured with surgery alone, so the role of pelvic lymph node dissection remains controversial. Some authors recommend neoadjuvant chemotherapy followed by unilateral or bilateral pelvic lymph node dissections in patients with stable or responding disease.[58-60] Spread to lymph nodes above the aortic bifurcation is classified as distant metastasis and such patients are not thought to be curable with current treatment methods.

Chemoradiotherapy to the pelvis has been suggested as an alternative to pelvic lymph node dissection in patients with metastatic penile cancer.[61] There is a lack of positive evidence for this approach in penile cancer specifically. By way of extrapolation, however, successful use of radiotherapy instead of pelvic lymph node dissection for women with metastatic SCC of the vulva has generated interest in this approach for penile cancer.[62] Currently, chemoradiotherapy to the pelvis remains a valuable option for men who have metastatic penile cancer that is inoperable, refuse surgery, or do not respond to neoadjuvant chemotherapy. An upcoming international, multicenter randomized clinical trial (NCT02305654) proposes to randomize patients between upfront surgery, neoadjuvant chemotherapy, and neoadjuvant chemoradiotherapy, with a second randomization between pelvic lymph node dissection and after adjuvant radiotherapy. This will be the first randomized controlled clinical trial for this disease, using overall survival as the endpoint.

Role of Targeted Therapy

Studies of EGFR by immunohistochemistry reveal high levels of expression in the majority of penile cancers.[63] EGFR gene amplification has been identified as a potential mechanism of protein overexpression in penile cancer, although estimates vary on how commonly this occurs.[64] Activating mutations of EGFR are notably rare. Clinical experience with EGFR-targeted therapy for metastatic penile cancer has been largely anecdotal. There are case reports of chemotherapy-refractory penile cancer subsequently responding to cetuximab or pembrolizumab alone and in combinations with chemotherapy.[65-70] For example, in a retrospective series from MD Anderson,[69] 17 patients received cetuximab with or without cisplatin; there were four partial responses (24%). Patients with only lymph node involvement had significantly better overall survival than patients with visceral or bone metastases (median 49.9 weeks and 24.7 weeks, respectively). In a separate multicenter retrospective analysis of second-line systemic therapy for metastatic penile cancer, 17 of 65 men received cetuximab or a cetuximab-including regimen, with a trend for an improved overall response rate compared with other agents (odds ratio, 5.05; 95% CI, 0.84–30.37; p = .077).[71] These results suggest a palliative benefit for some patients treated with EGFR-targeted therapies owing to tumor response, but without evidence of any improvement in progression-free and overall survival. Continuing this line of investigation, a prospective study of afatinib for advanced penile SCC following systemic therapy is currently in progress (NCT02541903).

Role of Checkpoint Inhibitors

PD-1 is a coinhibitory receptor found on B cells, T cells, and natural killer cells. Interaction of PD-1 with its ligand PD-L1 results in inhibition of T-cell proliferation and cytokine production. Immunohistochemistry revealed that a subpopulation of tumor cells express PD-L1 in penile cancer, which was seen in both HPV-related and unrelated penile cancers.[72-74] A multicenter phase II trial of pembrolizumab for advanced penile SCC (T4, N3, or M1) following chemotherapy (one or more regimens) is currently in progress (NCT02837042).

In summary, penile cancer exemplifies a rare disease in which progress has been hampered by the limited ability to conduct randomized trials. Conventional treatment methods that integrate surgery, radiotherapy, and chemotherapy have been largely successful, and a new international randomized trial is aimed at defining the optimal sequence of such treatments. Recent insights regarding the biology of penile cancer have led to opportunities for prevention (HPV), immunotherapy (PD-L1), and targeted therapy (EGFR).[75] Ongoing multicenter clinical trials are essential for development of more effective treatment options.

Systemic Therapy for Non–Clear Cell Renal Cell Carcinoma

Tian Zhang, MD, Jun Gong, MD, Manuel Caitano Maia, MD, and Sumanta K. Pal, MD

OVERVIEW

Treatment options for metastatic clear cell renal cell carcinoma (ccRCC) have evolved markedly over the past decade, with multiple targeted therapies approved for the disease. In contrast, little improvement has been made in the management of metastatic non–clear cell RCC (nccRCC). Non–clear cell disease is an umbrella term that encompasses multiple biologically distinct entities, including but not limited to papillary, chromophobe, and sarcomatoid RCC. To date, prospective studies have largely explored treatments for ccRCC (e.g., VEGF- and mTOR-directed therapies) in trials that aggregate non–clear cell histologies. However, the studies do not acknowledge the varying biology of each non–clear cell subtype. Emerging studies in nccRCC should examine individual histologies and apply biologically relevant therapies. An example of this is SWOG 1500, a randomized phase II study that will compare a VEGF-inhibitor to one of three MET-directed therapies in patients with metastatic papillary RCC. Until the biologic diversity of nccRCC is appreciated, outcomes are likely to remain dismal.

The treatment landscape for metastatic RCC has evolved substantially since the cytokine era, when the mainstay of therapy encompassed agents such as interleukin-2 and interferon alpha (IFN-α).[1] These agents yielded clinical benefit in a small minority of patients and came at the expense of substantial toxicities. A steady stream of targeted therapies have been approved from 2005 onward, beginning with the VEGF-directed therapies followed by inhibitors of mTOR.[2] Over the past 2 years, three new treatments have been introduced for metastatic RCC—the multikinase inhibitors lenvatinib and cabozantinib were approved, as well as the immune checkpoint inhibitor nivolumab.[3-5]

With the notable exception of temsirolimus (an mTOR inhibitor), the phase III trials culminating in the approval of the aforementioned novel therapies have primarily included patients with ccRCC. Clear–cell RCC comprises roughly 80% of all diagnoses, and it has long been known that the disease is driven by alterations in the von Hippel Lindau (*VHL*) gene.[6] Disruption of *VHL* leads to increased levels of hypoxia inducible factor-a (HIF-α) and subsequent upregulation of VEGF, thus explaining the activity of most targeted therapies for this disease. The remaining 20% of RCC has been characterized collectively as non–clear cell. This umbrella term encompasses a multitude of distinct histologies, each of which appears to have unique biology. In contrast to ccRCC, for which dramatic advances have been made in clinical outcomes for metastatic disease, relatively little is known about the optimal management for non–clear cell disease. Herein, we summarize the available literature and highlight potential future directions for the investigative community.

PAPILLARY RCC

Papillary RCC represents 10% to 15% of RCC cases. The Cancer Genome Atlas investigators recently reported genomic analyses from 161 primary papillary RCC specimens.[7] Ultimately, three subsets were characterized. Type I disease was noted to bear a higher frequency of alterations in the *MET* proto-oncogene, whereas type II tumors had *TFE3* fusions, *CDKN2A* silencing, and *SETD2* mutations. Increased expression of *NRF2-ARE* pathway elements was also noted in type II disease. A particularly aggressive subset of type II disease was discerned, bearing mutations in the fumarate hydratase (*FH*) gene.

The activity of sunitinib and sorafenib, both VEGF receptor (VEGFR) tyrosine kinase inhibitors, in papillary RCC was examined in a retrospective study by Choueiri and colleagues. The study included a total of 41 patients with metastatic papillary RCC, among whom only two patients (4.8%) achieved a partial response.[8] There have been several attempts to prospectively characterize the activity of sunitinib in patients with papillary RCC. Tannir and colleagues performed a phase II study including 57 patients with nccRCC, of whom 27 had papillary histology. No responses were observed in this experience, and median progression-free survival (PFS) among patients with papillary RCC was a meager 1.6 months. Better results with sunitinib were achieved in the phase II SUPAP trial reported by Ravaud and colleagues.[9] A total of 61 patients were enrolled, with 15 and 46 patients characterized as type I and type II, respectively. Among type I patients, two patients (13%) were noted to have a partial response and median PFS was 6.6 months. In patients with

type II disease, five responses (11%) were observed and median PFS was 5.5 months.

As alluded to previously, the phase III evaluation of temsirolimus in metastatic RCC did include patients with non–clear cell histology.[10] In this comparison of temsirolimus compared with temsirolimus/IFN-α or IFN-α alone, temsirolimus monotherapy was noted to improve survival compared with IFN-α monotherapy (10.9 months vs. 7.3 months, p = .008). Although the benefit of temsirolimus was noted to extend across both clear and non–clear cell subsets, no distinction was made in the available data for papillary patients. Current clinical guidelines reflect this dataset and suggest mTOR inhibition as a possible first-line approach in patients with nccRCC.

Several attempts have been made to reconcile whether VEGF or mTOR inhibition should be the mainstay of treatment of patients with nccRCC. The randomized, phase II ESPN trial included a total of 68 patients with nccRCC. In the overall cohort, no significant difference in PFS was seen between sunitinib and everolimus (median PFS, 6.1 and 4.1 months, respectively; p = .6), but the trend favored sunitinib.[11] No significant difference in overall survival (OS) was observed in either treatment arm. Interpretation of these results is confounded by the multiple histologic subgroups included in this trial; specifically, 27 patients with papillary RCC, 10 patients with unclassified RCC, seven patients with translocation RCC, 12 patients with chromophobe RCC, and 12 patients with sarcomatoid RCC. Among those patients with papillary disease, no clear benefit was seen in either treatment arm. Crossover was allowed at the time of progression, but the high attrition rate observed from first- to second-line therapy makes these results challenging to interpret.

Two other studies have taken the approach of directly comparing sunitinib and everolimus in the context of non–clear cell disease. The randomized, phase II ASPEN study used an identical randomization schema, although eligibility was limited to chromophobe, papillary, and unclassified histologies.[12] With a total of 108 patients enrolled, a numerical advantage in PFS was seen with sunitinib compared with everolimus (8.3 months vs. 5.6 months; p = .16), mirroring results from ESPN. Again, with a limited number of patients with papillary histology, drawing firm conclusions from this subset is difficult. The RECORD-3 clinical trial is the third study to compare sunitinib with everolimus.[13] The study differs from ESPN and ASPEN in its inclusion of clear cell histology. Akin to ESPN, crossover was allowed at the time of progression. In the cohort of patients with nccRCC (totaling 66 patients), a trend was once again seen toward benefit with sunitinib compared with everolimus (median PFS, 7.23 vs. 5.09 months).[12] No information is available from this trial pertaining to the breakdown of clinical benefit by individual histologies.

From ESPN, ASPEN, and RECORD-3, several common themes emerge (Table 1). First, sunitinib appears to have greater activity than everolimus in non–clear cell disease. Second, each study has a diverse mix of histologies, making it challenging to infer the specific benefit of VEGF-inhibition in metastatic papillary RCC. Third, each study suggests that the benefit of sunitinib is more modest than anticipated in the context of clear cell disease. In RECORD-3, for instance, median PFS with sunitinib in the clear cell cohort was 10.84 months compared with 7.23 months in non–clear cell disease. These collective results have informed the design of an international randomized, phase II study led by the Southwest Oncology Group (SWOG; Fig. 1). In SWOG 1500, patients with metastatic papillary RCC with zero to one prior therapies (excluding VEGF-inhibitors) will be randomly assigned to receive either sunitinib (the control arm) or one of three MET-directed therapies. As noted previously, The Cancer Genome Atlas data indicate a role for *MET* in the context of type I disease. Data from the French RCC network further supports *MET* as an oncogenic driver across papillary RCC subtypes—in this large experience of samples from 220 patients, 81% and 41% of type I and type II cases, respectively, demonstrated copy number alterations in *MET*.[14]

The MET-directed therapies comprising the experimental arms are each associated with varying levels of evidence in metastatic RCC. Cabozantinib, a dual VEGFR2/MET inhibitor, has been assessed in a phase III clinical trial in metastatic ccRCC.[4] Compared with everolimus, cabozantinib was associated with improved PFS and OS in patients who had previously received first-line VEGF-directed therapy.[4] Surprisingly, little data are available pertaining to the activity of cabozantinib in non–clear cell subtypes, although an antitumor effect with cabozantinib has been observed in the ACHN cell line, derived from a patient with papillary RCC (personal communication, Jeremy Jones, PhD). Savolitinib is a distinct and more specific MET inhibitor that will be examined in SWOG 1500. This agent has been shown to have activity in multiple papillary RCC xenograft models, and results from an ongoing phase II study that included patients with papillary RCC are anticipated in the near future.[15] Crizotinib will be evaluated in the third experimental arm in SWOG 1500. Crizotinib is approved in *ALK*-rearranged non–small cell lung cancer, but the agent also appears to have affinity for MET kinase. Patients with type I metastatic

KEY POINTS

- **Non–clear cell renal cell carcinoma is an umbrella term that encompasses an array of biologically diverse diseases.**
- **Published clinical trials to date (e.g., ESPN, ASPEN) have largely taken the approach of aggregating multiple non–clear cell subtypes.**
- **Interpreting results from these studies can be challenging given the inclusion of small numbers of each subtype.**
- **Future studies should take the approach of treating a single histology using agents with biologically relevant mechanisms of action.**
- **As one example, SWOG 1500 will explore MET-directed therapies in the context of papillary renal cell carcinoma.**

TABLE 1. Selected Prospective Trials in Non–Clear Cell RCC

Trial	Treatment	Randomized?	Number Enrolled	Histology Type	Overall Response Rate	Progression-Free Survival	Overall Survival
ESPN	Sunitinib vs. everolimus	Yes	68 patients	All non-clear cell	9% vs. 3%	6.1 vs. 4.1 months	16.2 vs. 14.9 months
ASPEN	Sunitinib vs. everolimus	Yes	108 patients	All non-clear cell	18% vs. 9%	8.3 vs. 5.6 months	31.5 vs. 13.2 months
RECORD-3	Sunitinib vs. everolimus	Yes	66 patients	All non-clear cell	N/A	7.2 vs 5.1 months	N/A
SUPAP	Sunitinib	No	61 patients	Papillary	13% (type I) and 11% (type II)	6.6 months (type I) and 5.5 months (type II)	17.8 months (type I) and 12.4 months (type II)

papillary RCC were included in the CREATE trial, a basket study led by the European Organisation for Research and Treatment of Cancer in which multiple tumor types were treated with crizotinib.[16] Among a total of 23 patients enrolled, responses were observed in two of four patients bearing *MET* alteration. No responses were observed among 16 patients lacking this alteration. With the caveat of a relatively small sample size, mean treatment duration was also noted to be longer in the *MET* altered cohort (11.9 vs. 5.3 months).

This is not the first time a correlation between response and *MET* status has been observed in the context of MET-directed therapies for metastatic papillary RCC. In a phase II study examining foretinib, a dual VEGFR2/MET inhibitor, in patients with metastatic papillary RCC, responses were observed in five of 10 patients (50%) bearing germline alterations in the *MET* oncogene.[17] In the remaining 57 patients, only five responses were observed (9%). These datasets have informed the translational aims of SWOG 1500, which will perform a detailed exploration of *MET* status, including assessment of *MET* mutation and copy number alteration, as well as MET protein expression.

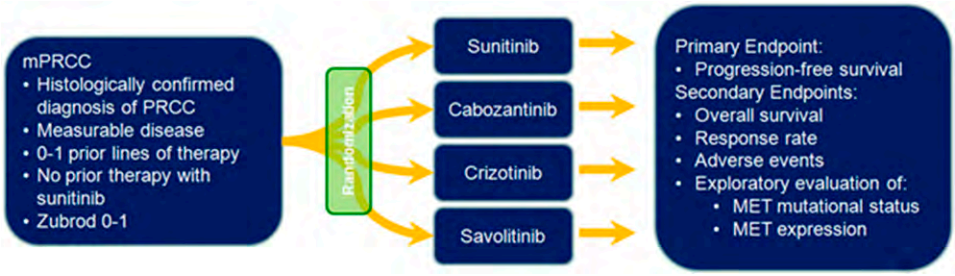
CHROMOPHOBE RCC

As with papillary RCC, the biology of chromophobe RCC, which comprises roughly 5% of RCC cases, has been characterized by The Cancer Genome Atlas investigators.[18,19] In a series of 66 cases, the major observations were alterations in mitochondrial DNA (mtDNA), underscoring the importance of oxidative phosphorylation in the pathogenesis of chromophobe RCC. Increases in TERT expression were also observed, derived through rearrangements in the *TERT* promoter region. From the standpoint of systemic management, there are scant data to address the role of targeted agents in chromophobe disease. Keizman and colleagues reported a retrospective experience including 36 patients with metastatic chromophobe RCC who received first-line sunitinib therapy.[20] Median PFS was 10 months and median OS was 26 months. When matched to similar patients with metastatic clear cell disease, no significant difference in clinical outcome was observed. Data for mTOR inhibitors in the context of chromophobe disease are more scant; several case reports suggest potential activity, though no large case series exist.[21-23]

SARCOMATOID RCC

Sarcomatoid histology rarely exists as an independent entity; rather, sarcomatoid elements are typically admixed with other RCC histologies. It is estimated that 15% to 20% of patients with RCC harbor sarcomatoid elements. Patients with RCC with sarcomatoid features often have an aggressive clinical course and poor prognosis. Recent genomic assessments of sarcomatoid RCC (sRCC) have produced varying results. Through comparison of sarcomatoid and nonsarcomatoid components in individual patients using RNA-sequencing, our group has shown increased expression of aurora kinase pathway elements and increased mTOR pathway activity in sarcomatoid disease. Karam and colleagues assessed a larger series of patients with dominant sarcomatoid histology using comprehensive genomic profiling.[24]

FIGURE 1. Schema for SWOG 1500: A Randomized, Phase II Study Comparing Sunitinib, Cabozantinib, Crizotinib, and Savolitinib in Patients With Metastatic Papillary Renal Cell Carcinoma



In 26 patients, the most frequent alterations were in *TP53* (42.3%), *VHL* (34.6%), *CDKN2A* (26.9%), and *NF2* (19.2%).

Although these studies appear to suggest that sarcomatoid histology may have a biology unique to ccRCC, the current treatment paradigms for metastatic sRCC do not reflect this. Initial approaches to sRCC centered on use of cytotoxic chemotherapy. In ECOG 8802, the regimen of doxorubicin plus gemcitabine was assessed in a series of 38 patients.[25] The degree of the sarcomatoid involvement varied: 18 patients (47%) were noted to have pure sarcomatoid disease. The response rate in this cohort was 16%, with a modest PFS of 3.5 months. A separate study assessed a regimen of doxorubicin and ifosfamide in 25 patients with metastatic sRCC.[26] No responses were observed, and PFS was a meager 2.2 months. Other studies have attempted to study the combination of cytotoxic therapy with VEGF inhibition in sRCC. One phase II study evaluated gemcitabine and sunitinib in 39 patients with sRCC. Patients with sRCC had an overall response rate of 26%.[27] Median time to progression was 5 months, and median OS was 10 months. Patients developed grade 3 or higher adverse events of neutropenia, anemia, and fatigue. There is an ongoing randomized phase II trial of sunitinib alone compared with sunitinib and gemcitabine in patients with advanced RCC with sarcomatoid features (NCT01164228).

Given the low response rates to cytotoxic therapy, additional efforts have been made to characterize the activity of VEGF- and mTOR-directed therapies in sRCC. A retrospective experience including 43 patients with metastatic sRCC treated with VEGF-directed agents showed a response rate of 19%, with a median PFS of 5.3 months.[28] The activity of everolimus has similarly been characterized in patients with sarcomatoid disease. Bastos and colleagues retrospectively assessed the activity of temsirolimus and everolimus in 29 patients; a median PFS of 3.4 months was observed with three responses (10%).[29]

With the approval of the immune checkpoint inhibitor nivolumab for metastatic ccRCC, there has been renewed interest in the activity of checkpoint inhibitors in non–clear cell histologies as well. The PD-L1 inhibitor atezolizumab was evaluated in a mixed cohort of pretreated patients with both clear cell and sarcomatoid disease.[30] Among 18 patients who demonstrated either Furhman grade 4 or sarcomatoid histology, an encouraging response rate of 22% was observed. A randomized phase III study comparing the combination of bevacizumab with atezolizumab to sunitinib in the first-line metastatic setting will include patients with sarcomatoid elements (NCT02420821). Furthermore, an ongoing adjuvant clinical trial comparing atezolizumab with placebo in patients with high-risk localized RCC will similarly allow for patients with sarcomatoid elements (NCT03024996).

RARE NON–CLEAR CELL RCC SUBTYPES

Several rare non–clear cell subtypes comprise less than a percentage point of all RCC diagnoses. These tumor types are both diagnostic and therapeutic conundrums. Collecting duct carcinoma is a particularly aggressive disease affecting a younger patient population.[31] We recently reported a genomic assessment of 17 cases of collecting duct RCC, identifying occasional alterations in *NF2, SETD2*, *SMARCB1*, and *CDKN2A*.[32] At present, these data have not been used in a prospective study to inform therapy. The one prospective study that has been conducted to date explores a combination of gemcitabine with either cisplatin or carboplatin.[33] Median PFS and OS were 7.1 and 10.5 months, respectively, with a response rate of 26%. Anecdotal reports exist documenting responses to sunitinib and sorafenib therapy.[34-36] No consensus exists regarding optimal treatment of this entity, although platinum-based chemotherapy is still frequently used in clinical practice.

Renal medullary carcinoma carries a similarly aggressive phenotype, and affects younger patients with sickle-cell trait. Loss of the tumor suppressor *SMARCB1/INI1* is the most common genetic alteration.[37-39] Shah and colleagues recently reported an experience including 52 patients with renal medullary carcinoma, the majority of whom had stage III or IV disease.[40] Of 45 patients who received chemotherapy, 13 patients (29%) had an objective response. Interestingly, among 28 patients who received targeted agents, no responses were observed. Of note, there was a recent case report of a young man with sickle-cell trait and renal medullary carcinoma who had a total nephrectomy and adjuvant chemotherapy (carboplatin, gemcitabine, paclitaxel, and bevacizumab). He then developed disease recurrence in the lymph nodes and was subsequently treated with nivolumab. Interestingly, he had a complete response that lasted more than 9 months and was ongoing at the time of publication.[41] Upon retrospective analysis of the patient's lymph node biopsy, 23% of the tumor cells had PD-L1 expression. Two percent and 5% of stromal cells expressed PD-1 and PD-L1, respectively. Tumor-infiltrating T cells accounted for 21% of the cells (10% CD8-positive and 41% CD4-positive). This case is tantalizing and suggests a potential role for immune checkpoint inhibition in patients with renal medullary carcinoma.

Xp11.2 translocation RCC is another distinct entity comprising a small fraction of all RCC cases. The translocation entails fusion of the *TFE3* gene with the alveolar soft part sarcoma locus (*ASPL*) or *PRCC,* and the fusion product appears to regulate cell cycle.[42] Two separate reports document the activity of VEGF-directed agents in Xp11.2 translocation RCC. The Juvenile RCC network reported a series of 11 patients who received sunitinib in the first-line setting with a median PFS of 8.2 months.[43] Choueiri and colleagues assessed a separate series of 15 patients with Xp11.2 RCC. In this series, three patients (20%) achieved a partial response, and median PFS was 7.1 months.[44]

Notably, the rare histologic subtypes of RCC presented herein are not intended to represent a comprehensive list. Multiple other subtypes exist, including unclassified, mucinous tubular, and spindle cell, and so on. However, the body of evidence behind specific systemic therapy regimens is scant. At present (mirroring other more common subtypes),

practitioners often extrapolate from treatment algorithms for clear cell disease.

As more interest has developed in immune checkpoint blockade, PD-L1 status has also been evaluated in several studies. In one series of 101 archival specimens of nccRCC, PD-L1 expression by tumor cells was demonstrated in only 11% of specimens and associated with poor prognosis (higher grade and stage, as well as shorter OS).[45] In contrast, 56% of samples demonstrated PD-L1 expression on tumor-infiltrating mononuclear cells. However, others have shown that PD-L1 expression by tumor cells from archival specimens is not correlated with prognosis.[46] These early correlative studies are, at best, hypothesis generating. Performed carefully in a rare disease population, though, they can be quite helpful in designing future studies. In general, clinicians need better biomarkers for response to immune checkpoint blockade.

CONCLUSION

The approach to systemic management of nccRCC has been relatively straightforward over the past several decades. Simply put, approved treatments for ccRCC have been transposed to non–clear cell histologies. In the era of VEGF- and mTOR-directed therapies, this approach has produced modest results at best, as illustrated by the numerous examples cited herein. Investigators have also made the mistake of lumping together multiple non–clear cell histologies in prospective trial designs. As seen in the ASPEN and ESPN trials, blending a heterogeneous array of histologic subtypes within a single study can confound interpretation of results.

Progress in treating nccRCC will likely be contingent upon acknowledging the unique biology of individual histologies. Trials such as SWOG 1500, which test a potentially relevant pathway in a single disease (e.g., MET inhibition in papillary RCC), are more apt to improve the current standard of care. These trials do not come without substantial challenge—randomly assigning hundreds of patients with these rare tumor types requires national, if not international, cooperation in trial conduct. It is challenging to envision any definitive studies taking place at single institutions; rather, cooperative group mechanisms must be used to band together a sufficient number of tertiary centers with experience in these rare diseases. Patient advocacy groups are also key to disseminating information pertaining to these trials. With a unified approach, the investigative community can gradually shift the treatment paradigm for nccRCC.

Diagnosis and Treatment of Prostate Cancer: What Americans Can Learn From International Oncologists

Nicholas James, BSc, MBBS, PhD, John Graham, MB ChB, FRCR, FRCP, Tobias Maurer, MD, Matthias Eiber, MD, and Jürgen E. Gschwend, MD

OVERVIEW

The three main sections in this article illustrate a number of facets of European health care. The first section looks at the influence of NICE on treatment of metastatic castration-resistant prostate cancer. The second section explores the impact of molecular imaging on diagnosis and treatment, in particular the development and clinical implementation of ^{68}Ga PET imaging in prostate cancer. The final section of the session looks at the STAMPEDE trial and how running a trial on this scale has impacted care of prostate cancer in the United Kingdom and also at the uptake of docetaxel chemotherapy in hormone-sensitive advanced disease.

European health care systems vary enormously from country to country in terms of structure and funding models. They broadly operate, however, on the principle that the state has a duty to ensure health care is available to all members of the population. This contrasts with the situation in the United States, starkly illustrated by the recent U.S. presidential elections, with huge controversy over the Patient Protection and Affordable Care Act (also known as "Obamacare") and the idea that health care may be an individual's rather than the state's responsibility—an alien concept to most Europeans. This leads to the situation where U.S. citizens with adequate insurance enjoy some of the most technologically advanced health care in the world, while some of their fellow citizens struggle with huge financial burdens associated with uninsured health care costs. In contrast, implicit in social insurance or taxpayer-based systems is some form of centralized decision making. This may lead to restricted access to "cutting-edge" medicines but, at the same time, facilitates access for all affected to an accepted standard of care.

Within Europe, two broad subdivisions may be identified in how health care advances are funded. With new drugs, there are two levels of decision to be made: Should a drug be approved for patients—marketing authorization—and secondly, should the public health care system fund the use of the drug? In many countries (e.g., France, Germany, Italy), no distinction is made and a marketing authorization makes the drug available via the public health care system. In a second group, notably in the United Kingdom and Scandinavia, these decisions are separated so that a marketing authorization may or may not lead to broad public access. In the United Kingdom, these decisions are made by the National Institute for Health and Care Excellence (NICE), and NICE decisions are often then used as templates by other countries and hence are very influential. NICE attempts to judge the cost effectiveness as well as the clinical effectiveness of new agents. It is the former that drives the controversy often associated with some NICE decisions. However, the need to meet NICE cost-effectiveness requirements is undoubtedly a factor in driving down the costs of new medicines within the United Kingdom in particular, as compared with countries where marketing authorization and access are simultaneous.

A further feature of the U.K. system is the state supports entry into academic trials via the National Health Service (NHS). This means the public hospital system is directly financially incentivized to support trials badged as suitable by the U.K. National Cancer Research Institute. This has led to the United Kingdom having one of the highest rates in the world of cancer trial participation. This is well illustrated by the STAMPEDE trial, which has to date recruited more than 8,000 men to a trial now encompassing 10 research arms, with two further in setup, across more than 100 hospitals. With such a broad base of participation, questions are asked and answered in a very "real-world" setting, ensuring broad applicability. It also ensures relatively easy rollout of positive results (such as the docetaxel data), as centers and clinicians are familiar with the rationale and administration of the trial therapies and have also personally invested their own time and energy into the trial data set.

The three main sections in this article illustrate a number of facets of European health care. The first section looks at the influence of NICE on treatment of metastatic castration-resistant prostate cancer (mCRPC). The second section explores the impact of molecular imaging on diagnosis and treatment, in particular the development and clinical implementation

of ^{68}Ga PET imaging in prostate cancer (PCa). The final section of the session looks at the STAMPEDE trial and how running a trial on this scale has impacted care of PCa in the United Kingdom and also at the uptake of docetaxel chemotherapy in hormone-sensitive advanced disease.

HOW RANDOMIZED TRIALS OF STAMPEDE HAVE INFLUENCED TREATMENT DECISIONS IN THE UNITED KINGDOM

Background

The STAMPEDE trial was set up in 2004 and 2005 and commenced recruitment in 2005. The basic principle of the trial was to assess the addition of new treatment modalities to standard of care with the aim of improving overall survival. At the time of setup, zoledronic acid had recently been approved for mCRPC affecting bone, and docetaxel was in the final stages of phase III evaluation. Both agents seemed to be worth evaluating in the newly diagnosed, as opposed to the relapse setting. Given the large numbers of patients diagnosed with PCa, the Trial Management Group decided to seek a third agent to evaluate and eventually selected celecoxib as an agent with possible metastasis and invasion-preventing properties. The Trial Management Group also decided to look at agents both alone and in combination, giving a total of five experimental arms in original design. A second novel feature of the trial was the integration of a feasibility stage, interim efficacy stages, and a final overall survival stage to give a multiarm, multistage design. Table 1 shows the primary and secondary endpoints for the various stages. Figure 1 shows the original trial design in terms of agents being evaluated.

KEY POINTS

- **The PSMA represents a promising molecular target in PCa useful for PET imaging.**
- **In patients with relapsed PCa, PSMA PET imaging improves detection of metastatic lesions even at low PSA values.**
- **In patients with primary intermediate to high-risk PCa, PSMA PET imaging showed increased specificity and sensitivity compared with current standard imaging for detection of lymph node and bone metastases.**
- **In combination with multiparametric MRI, PSMA PET imaging might provide additional molecular information useful for intraprostatic PCa localization.**
- **Although current knowledge is still limited and derived mostly from retrospective series, PSMA-based imaging might enable improved patient-tailored PCa management in the future.**

TABLE 1. Trial Endpoints

Comparison Stage	Primary Outcome Measure	Secondary Outcome Measures
Pilot phase	Safety*	Feasibility
Activity stages	Failure-free survival**	Overall survival

		Skeletal-related events
Efficacy stage	Overall survival	Quality of life
		Cost effectiveness
		Failure-free survival**
		Toxicity
		Skeletal-related events

*Based on toxicity.

**Including biochemical failure.

Setting Up and Running the STAMPEDE Trial

The aim of running what is effectively a suite of phase II and III trials is to reduce the bureaucracy associated with the opening and closing of multiple studies and linked inherent delays in the analysis, close down and set up when the traditional phase II and separate phase III model is used. We estimate that around 30% of phase III trials produce a positive result in the sense that the experimental arm is better than the control arm. By having multiple arms, we, simply put, had more chances to win and hence to change practice. Secondly, the fact that all patients contribute to all analyses overall means that fewer total patients are needed compared with separate phase II and III studies. In particular, separate phase III studies for each agent would each need a control arm, which is hence duplicated if multiple trials are recruiting in the same disease "space." This again means that, overall, fewer patients are needed to answer questions about different agents compared with multiple simultaneous trials. In addition, multiple trials would be competing with each other for resources and, very importantly, for patients, leading to likely slower overall aggregate recruitment. The effects on numbers of patients and time are illustrated in Fig. 2.

A second consequence of the multiarm, multistage model is that new arms can be added at a later stage, with the staged analyses for the new arm being frame shifted to the timetable for that arm. We first tested this approach in 2011 with the addition of arm G evaluating the upfront use of abiraterone. We have subsequently added three further arms: radiotherapy (RT) in M1 patients, combination abiraterone/enzalutamide, and metformin, with two additional new arms in setup.

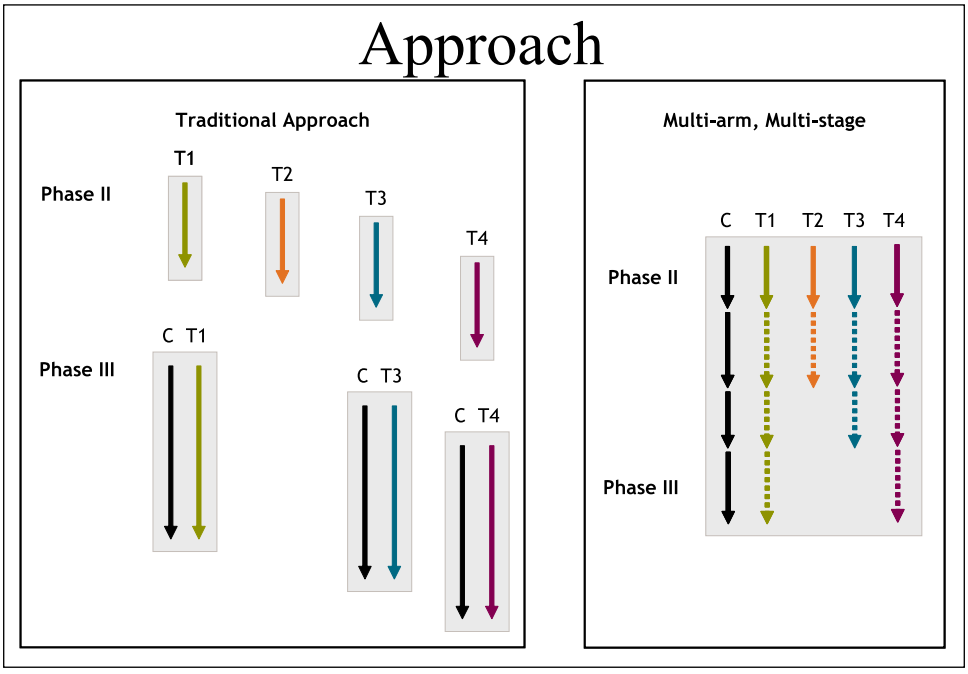
Adding an arm is extremely efficient compared with setting up a new trial, which would compete for patients with the original trial. All setup costs have to be reincurred for the new arm, and investigators' time and energy are diverted. In contrast, adding an arm by protocol amendment is simple from the administration point of view in centers and avoids competition between trials for scarce resources and patients. Figure 3 shows the time to set up the original comparisons as compared with the first three arms added.

The faster setup is also translated into faster recruitment, as, once open, the new arm benefits from the established ongoing recruitment for the parent trial. Figure 4 shows the recruitment to arm G (abiraterone) was originally projected to run from Q4 2011 to Q4 2014 with 1,500 patients. Due to very rapid recruitment, the target was expanded to 1,800, which was completed a year ahead of schedule in late 2013. Arms H (RT:M1) and J (abiraterone/enzalutamide) have similarly recruited well ahead of time and target again with expanded numbers to increase power and accelerate reporting.

To recruit patients to a trial with oncology-based therapies such as docetaxel, we needed to change referral pathways. This required buy-in from urologists and a willingness to refer patients from urology to oncology much earlier than was previously the norm. We have involved urologists in the design, setup, and implementation of the trial, and support among urologists throughout has been huge.

The U.K. system facilitates the shared financing of trials. The core resource has been funded via Cancer Research UK, with additional resources from the Medical Research Council Clinical Trials Unit. We had financial assistance from the manufacturers of the three drugs initially chosen for evaluation in terms of free or subsidized drugs and additional grant support over and above the core academic funding.

FIGURE 2. Multiarm, Multistage Trials Versus Multiple Phase II and III Trials



In addition, a key feature of the U.K. NHS is that NHS hospitals receive additional funding in return for putting patients in suitably badged studies via the National Cancer Research Institute and linked National Cancer Research Network.

In conclusion, the structure of clinical trial funding within the U.K. NHS greatly facilitates large-scale trials. The STAMPEDE multiarm, multistage model works well within this system, and the flexible approach to adding arms to an existing trial results in extremely rapid uptake and recruitment compared with starting multiple new trials.

Control Arm Data: Radiotherapy in Node-Positive Disease

With a trial as large as STAMPEDE recruiting in every major oncology center in the United Kingdom, data emerging from the control arm has immense value in telling us about patterns of care and the impact of different care patterns on outcomes. The best example to date is the impact of radiotherapy in locally advanced or node-positive, nonmetastatic disease. Radiotherapy was recommended but not mandatory from 2005 to 2011 when two randomized trials demonstrated the impact of radiotherapy in locally advanced disease. Within the trial, many patients up to 2011 did not receive RT for locally advanced disease due to differences in unit policies. The impact of RT in this group was to increase failure-free survival at three years from 62% to 87%, validating the SPCG7[1] and PR07[2] results in a real-world, high-risk setting. Additionally, and very importantly, we were able to look at the impact in TxN+M0 disease and saw an increase in three-year failure-free survival from 47% to 71%. There are no randomized trials in this setting; multivariate analysis suggested a hazard ratio for the improvement of 0.5 in favor of pelvic and prostate radiotherapy.[3]

Docetaxel Data

The first survival data from the trial were published in 2016[4] and showed an increase in survival from six cycles of docetaxel but no significant impact from zoledronic acid given at inception of hormone therapy.[4] The docetaxel results confirmed data from the U.S. CHAARTED trial in M1 disease[5] and cemented the role of upfront chemotherapy in newly diagnosed metastatic disease (Fig. 5). This was confirmed by a meta-analysis copublished with the STAMPEDE results.[6] The broad base of recruitment to STAMPEDE means that these results can be seen as broadly applicable within the NHS.

Implementing STAMPEDE Trial Results

In order for results to have impact, they must be implemented in the health care system. The NHS in the United Kingdom is actually four devolved services: England, Wales, Scotland, and Northern Ireland, with around 80% of the population living in England. Within NHS England, NICE considers medical treatments and makes guidelines to NHS hospitals. This is two edged, as it can either facilitate or block implementation. After some initial delay, NHS England and NICE decided to run a rapid evidence review and issued guidance via NICE[7] and commissioning guidance[8] supporting the use of docetaxel in this setting. This was published January 2016, the same month as *The Lancet* results publication, thus ensuring broad availability from date of publication.

The STAMPEDE trial illustrates a number of positive features of the "socialized" health care model: the ability to centrally support trials and the flexibility in trial legislation that has allowed the trial to evolve into a platform for serially evaluating many different interventions. Finally, the central control, although sometimes a tool for rationing,

FIGURE 3. Time to First Patient Into Trial Across STAMPEDE Centers by Trial Arm

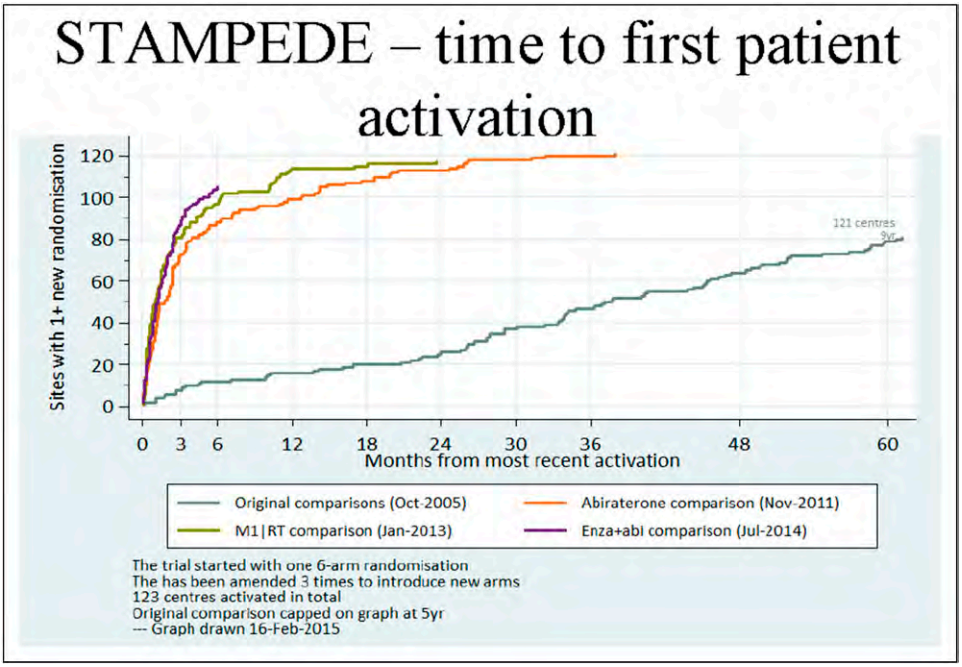


FIGURE 4. Recruitment in Arms Added After Trial Inception

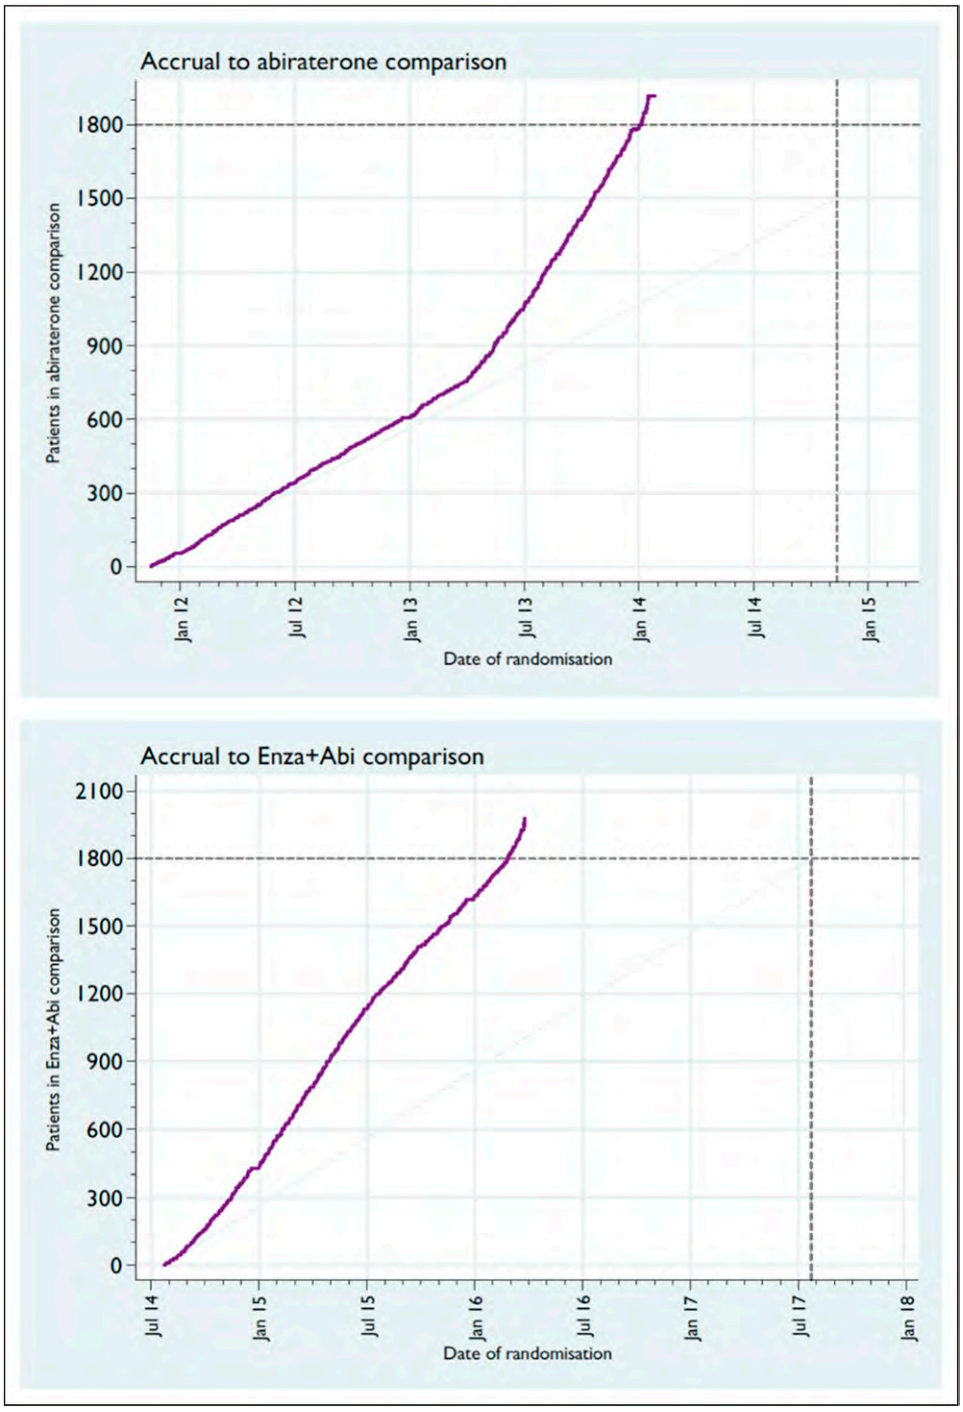
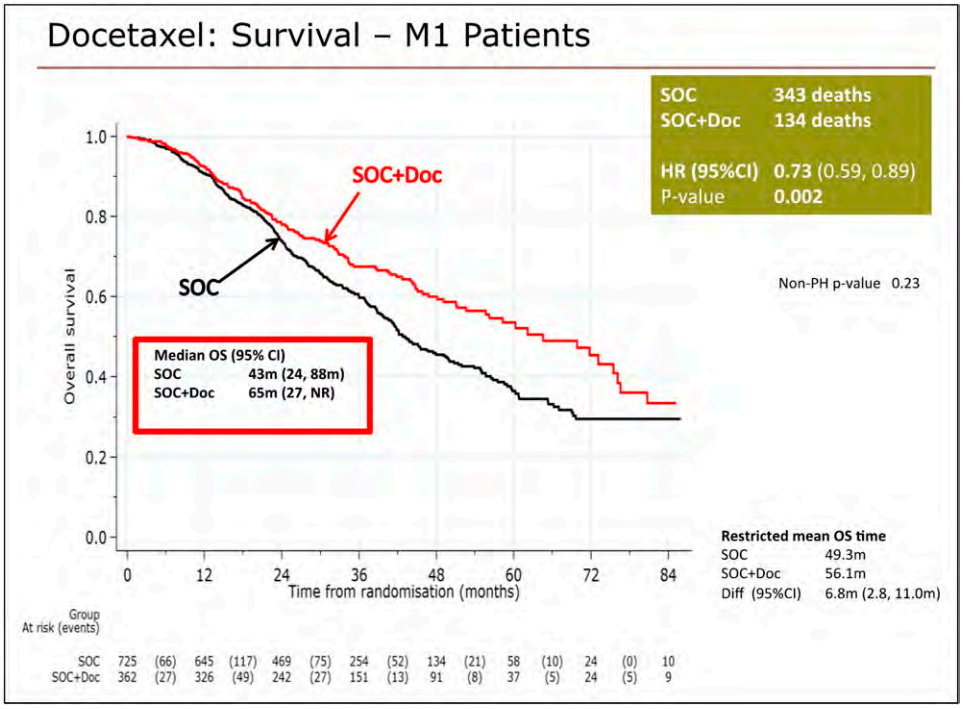


can also be a tool for enabling the rapid implementation of clinically important results.

HAVE DECISIONS BY NICE AFFECTED OUTCOMES OF BRITISH PATIENTS WITH METASTATIC CASTRATION-RESISTANT PROSTATE CANCER?

Government-funded health care systems must ensure that taxpayers' money is being well spent. The NHS Constitution states that "it is committed to providing the most effective, fair, and sustainable use of finite resources."[9] It is generally agreed that evidence-based medical practice improves outcomes and reduces variations in care. The Cochrane ladder of evidence (efficacy, effectiveness, and cost effectiveness) puts the assessment of cost effectiveness as the optimum goal for evidence-based practice.[10] The quality-adjusted life year (QALY) is the most widely adopted method and allows cancer treatments to be compared with, for example, treatments for

FIGURE 5. Impact of Docetaxel on Overall Survival in Men With Metastatic Disease Starting Long-term Hormone Therapy for the First Time



mental illness. Inevitably, there are compromises. In the United Kingdom, NICE uses the EuroQoL EQ-5D system to measure quality-of-life benefits.[11] Compared with cancer-specific measures such as the EORTC QLQC33 or FACT-P for PCa, EQ-5D is less detailed, but it offers two key advantages. EQ-5D can be applied to different medical conditions, and it can be weighted to reflect the values that different societies place on health states. Estimated total costs and QALYs are collected over the modeled time horizon for each treatment. The total costs will include all costs associated with the treatment, follow-up, further treatment, and management. QALYs are calculated by multiplying the life years that patients spend in each health state by the associated quality-of-life weighting, which represents the patient's and society's valuation of their health state.[12] Cost effectiveness is calculated by assessing the incremental change in health utility measured by QALYs. The incremental cost-effectiveness ratio (ICER) can then be calculated using the formula shown in Figure 6.

NICE was set up in 1999 by Tony Blair's Labor Government as the National Institute for Clinical Excellence to reduce variations in availability and quality of care in the NHS in England.[13] Initially, it was run as a special health authority within the NHS, but from April 2013, it has been a nondepartmental public body outside the NHS, accountable to the Department of Health, and with a broader remit for social care as well as health care. Its name was changed to the National Institute for Health and Care Excellence, but the acronym NICE was retained.

NICE is an English body but provides some services for Scotland, Wales, and Northern Ireland. Its appraisal system for new drugs applies only to NHS England. Drugs approved through the Technology Appraisal (TA) system[14-25] have a guaranteed funding stream for the duration of the guidance. This distinguishes TAs from all other NICE guidance (clinical guidelines, diagnostic assessments), which are advisory to the various bodies that commission health and social care. The privileged financial position of NICE TAs means that they sit separately from NICE's clinical guidelines and are excluded from them. The two NICE guidelines on the management of PCa published in 2008 and 2014 have no guidance

FIGURE 6. Formula 1

$$\text{Incremental cost effectiveness ratio (ICER)} = \frac{\text{Mean cost with B} - \text{Mean cost with A}}{\text{Mean effect with B} - \text{Mean effect with A}}$$

Sipuleucel-T	TA332[18]	January 2015	Not recommended
Radium-223	TA376[19]	January 2016	Approved
Enzalutamide prechemotherapy	TA377[20]	January 2016	Approved
Abiraterone prechemotherapy	TA387[21]	April 2016	Approved
Cabazitaxel	TA391[22]	May 2016	Approved

on the use of chemotherapy or radium-223 in mCRPC, other than the incorporated recommendations from the appraisal of docetaxel in 2005 (TA101).[26]

So this discussion of NICE's decisions on treatments for mCRPC will focus on the TA process for men treated by NHS England. It will also cover treatments provided by the CDF and issues relating to NICE's clinical guidelines on the management of PCa. NICE has appraised the following drugs for mCRPC: docetaxel, cabazitaxel, abiraterone, enzalutamide, sipuleucel-T, and radium-223. Table 2 shows the dates and outcomes of the appraisals.

There are two types of appraisals for new drugs, single technology assessments (STAs)[23] and multiple technology assessments.[24] Most appraisals are STAs, as was the case for all the drugs for mCRPC. The advantage of an STA is that it is generally a quicker process. The manufacturer submits a case for the clinical and cost effectiveness of their product, and this is sent to an independent academic group, the evidence review group (ERG), commissioned by NICE to review the submitted evidence. Then the manufacturer and the ERG present their findings to the TA committee that makes a decision.

In a multiple technology assessment, an independent group is commissioned to produce a health technology assessment of a product or multiple products with one or more indications. This assessment is presented to the TA committee along with evidence from selected stakeholders such as health care professionals, patients, and commissioners. The process is more complex than an STA and usually takes longer, but it can result in multiple recommendations on several products and their relationship to each other.

In its early days, NICE was criticized for the slowness of its appraisal process, resulting in a move toward more STAs. An appraisal cannot start until a drug receives U.K. marketing authorization, but NICE works closely with the licensing authorities and tries to issue a scope for the appraisal within a few months of authorization. There are problems with the STA process:

- It is restricted to a single drug for a single indication, so if several drugs are licensed for the same indication over a relatively short time, the recommendations may not reflect the way that the drugs are being used in clinical practice.
- It relies on evidence provided principally by the manufacturer (albeit with an independent review).
- Early assessment of cost effectiveness can be difficult due to a lack of evidence, particularly of downstream consequences.
- It has become less transparent as more confidential drug discounts, called patient access schemes, are being negotiated.
- It relies on the cooperation of the manufacturer.

Although an STA is an accelerated approval process, it is not exactly quick, as the timeline for the approval of enzalutamide prechemotherapy, TA377, shows (Table 3). The entire process from scoping to publication of the final decision took 2 years and 3 months. However, NICE did start the TA a year before marketing authorization for the change in license for this indication. A detailed look at this TA highlights some of the complexities in approving new drugs.

A draft scope for TA377 was developed in October 2013 by NICE. This was exactly one year ahead of the decision of the European Medicines Agency on Oct. 23, 2014, that approved a variation to the EU marketing authorization for enzalutamide for "the treatment of adult men with meta-

TABLE 3. Timeline for the Appraisal of Enzalutamide Prechemotherapy

Step	Date

European Medicines Agency approval for EU marketing authorization	October 2014
Final scope for the appraisal	November 2014
U.K. marketing authorization	November 2014
First TA committee meeting	May 2015
Appraisal consultation document	June 2015
Second TA committee meeting	July 2015
ERG critique of Astellas' revised patient access scheme submission	November 2015
Final appraisal determination	December 2015
TA377 published	January 2016

Abbreviations: TA, technology appraisal; ERG, evidence review group.

static castration-resistant PCa who are asymptomatic or mildly symptomatic after failure of androgen deprivation therapy in whom chemotherapy is not yet clinically indicated." The draft scope used a PICO format (P: Patient, Population, Problem; I: Intervention, prognostic factor, or exposure; C: Comparison or intervention; O: Outcome) to outline the population, comparators, and outcomes. It also posed several questions to stakeholders who were invited to comment, as were a number of invited topic experts. The final scope was published in November 2014, and an ERG at the University of Aberdeen was commissioned by NICE to appraise the manufacturers' submission.

NICE's TA Committee B met in public in May 2015 to discuss the evidence with the manufacturer, the ERG, and invited experts, including patient representatives. The committee then moved to a closed session to agree on the appraisal consultation document (ACD), which was published in June 2015. The initial recommendation was not to recommend the drug as not cost effective. There is a very detailed summary of the committee discussions in the ACD relating to the interpretation of the data from the PREVAIL trial,[27] the appropriate comparator, and other issues affecting the health economic calculations.

After public consultation on the ACD and a resubmission of evidence by the manufacturer Astellas, which included a revised patient access scheme (discounted price), the ERG produced a critique in November 2015. This resulted in a final appraisal determination that reversed the previous decision and, in January 2016, recommended approval of enzalutamide. What changed between the ACD and final appraisal determination? A decision was made to use only the comparator of enzalutamide versus best supportive care, changes were made to the downstream modeling to reflect the type of treatments NHS patients would receive after progression on enzalutamide, and Astellas offered a discount on the list price of enzalutamide. Due to the confidential nature of the patient access schemes, NICE does not publish detailed cost calculations. However, we know from the ACD[25] that the incremental cost-effectiveness ratio for enzalutamide compared with best supportive care was between £40,000 and £50,000 in the ERG's base case. In the final appraisal determination, this had fallen to below £30,000, and enzalutamide was considered a cost-effective treatment.

Cancer Drug Fund

From October 2010, patients in England have had access via the Cancer Drug Fund (CDF) to many drugs not approved by NICE. The fund was set up by the coalition government (Conservative and Liberal Democratic coalition in power from May 2010 to May 2015) "to enable patients to access the cancer drugs their doctors think will help them."[28] Initial implementation was variable because the fund was managed separately by 10 regions in NHS England, each of whom had different drugs available. From April 2013, the fund has been centrally administered with a single list for all of England. The annual budget of £200 million was exceeded in 2013 and, by 2014/2015, was overspent by 48%. A National Audit Office report in 2015 noted that it was "difficult to evaluate in a meaningful way the £733 million spent through the Cancer Drugs Fund since October 2010."[29] The fund was substantially restructured in July 2016. It is now managed by NICE, whose TA committees can recommend adding a drug to the CDF list if there is insufficient evidence to either approve or reject the treatment. Drugs will be provided via the CDF for up to two years, and NICE will reassess the drug based on data collected centrally by the systemic anticancer therapy (SACT) database (www.chemodataset.nhs.uk). The SACT data set is a mandatory collection of chemotherapy data from cancer centers in England who upload the information monthly.[30]

Have the decisions by NICE affected outcomes for men with metastatic PCa? There is no doubt that approval by NICE following market authorization takes many months, sometimes several years. However, the introduction of the CDF has significantly reduced the period between market authorization and the drug becoming available to patients in NHS England. In fact, enzalutamide prechemotherapy, the subject of the TA discussed previously, was available via the CDF before it received market authorization. Figure 7 shows the timelines of the treatments that have received marketing authorization for mCRPC since 2005: when they were licensed, when they were assessed by NICE, and when they were made available via the CDF. The only treatment not available in the United Kingdom was sipuleucel-T, which received marketing authorization in September 2013 but had it withdrawn in May 2015.

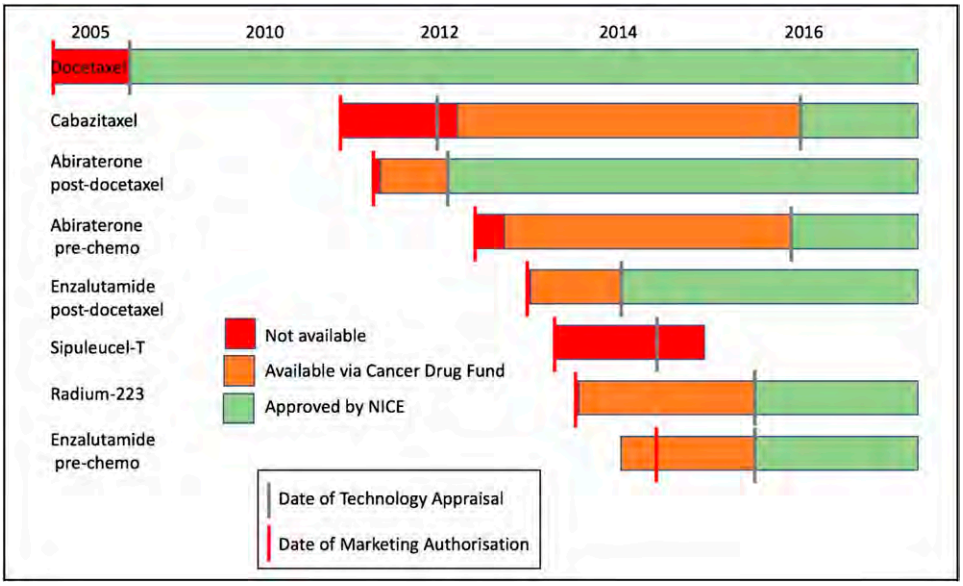
Latest cancer statistics show the mortality from PCa in England falling between 2005 and 2014, the last year for which figures are available. In 2005, the age-standardized mortality rate per 100,000 men in England was 53.92, and in 2014, it was 48.15.[31] A similar fall in PCa mortality has been seen in many developed countries over this period. To date, in the United Kingdom, we have not had enough information to determine whether treatment availability has affected outcomes. The restructuring of the CDF and the collection of chemotherapy prescribing information via SACT, which has only been available for a few years, should allow us to establish the efficacy and cost effectiveness of new anticancer treatments when used in routine clinical practice.

Approvals of treatments for men in England with mCRPC have not substantially delayed availability and are unlikely to have substantially affected outcomes. All treatments that have been licensed for mCRPC since 2005 (bar sipuleucel-T) are currently available in NHS England, most at a substantial discount to the list price.

HOW ADVANCES IN MOLECULAR IMAGING HAVE CHANGED OUR UNDERSTANDING OF STATE AND STAGE OF THE DISEASE

Currently, CT, MRI, and bone scintigraphy represent standard imaging procedures in PCa. Over the last two decades, PET evolved as novel imaging technology for detection or staging in PCa patients. For PET imaging, several tracers

FIGURE 7. Dates of Marketing Authorization, Cancer Drug Fund Approval, and NICE Technology Assessment



have been used in the past, but recently with the introduction of small molecular tracers targeting the prostate-specific membrane antigen (PSMA), PET imaging has gained increasing interest. PSMA is a transmembrane protein that shows overexpression on most PCa cells and thus represents an ideal molecular target. In biochemical recurrent PCa, PET imaging using ^{68}Ga-labeled PSMA inhibitors has been shown to increase detection of metastatic sites even at low PSA (prostate-specific antigen) values in comparison with conventional imaging or PET studies with different tracers. In primary intermediate to high-risk PCa, PSMA-based PET imaging has been reported to improve detection of metastatic disease as compared with CT or MRI, possibly rendering additional cross-sectional imaging or bone scintigraphy unnecessary. Furthermore, ^{68}Ga-PSMA PET imaging in combination with multiparametric MRI might provide additional molecular information useful for intraprostatic PCa localization. Thus, although current knowledge is still limited and derived mostly from retrospective series, PSMA-based PET imaging holds great promise to substantially influence PCa management in the future.

Until recently, imaging procedures for detection or staging of PCa depend mainly on morphology or bone metabolism and cannot always meet the diagnostic needs for clinical decision making. Consequently, imaging specialists have tried to identify specific molecular targets on PCa cells that can be used for molecular-based PET imaging.[32] Several radiotracers have been proposed, including choline, as a marker of membrane cell proliferation. For recurrent PCa, choline-based (i.e., ^{18}F-choline or ^{11}C-choline) PET/CT is currently widely used in clinical routine in Europe and is beginning to be adopted in the United States. Numerous studies reported an increased sensitivity and specificity compared with standard cross-sectional imaging; however, the diagnostic potential especially in early biochemical recurrence is still limited.[33,34] Other radiotracers evaluated for PET imaging of PCa include ^{11}C-acetate, bombesin analogs, and ^{18}F-FACBC (^{18}F-fluciclovine, a radiolabeled leucine analog).[32,35-38]

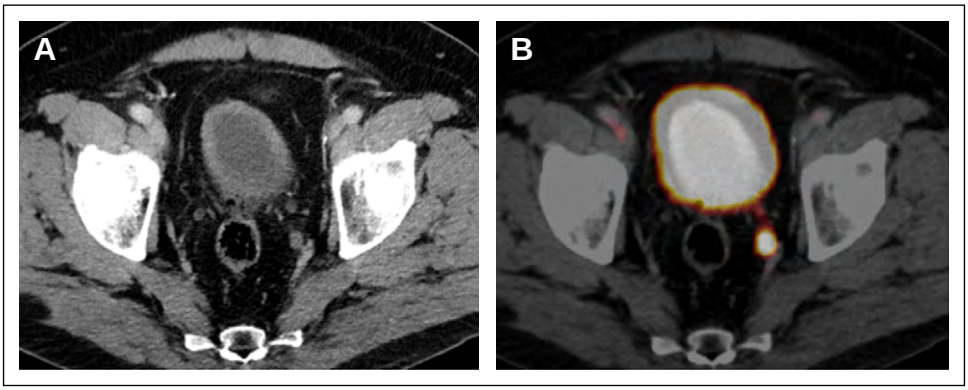
PSMA as Molecular Target in PCa

In recent years, the PSMA, a transmembrane protein that shows overexpression on most PCa cells, has gained increasing interest as a molecular target for PCa PET imaging.[39] Instead of targeting metabolism, PSMA tracers directly target PCa cells based on PSMA expression, independently of their metabolic state. So far, several small compounds directed against PSMA (also known as PSMA ligands) have been developed and are currently being investigated. The majority of data available report experience using the ^{68}Ga-labeled PSMA inhibitor Glu-NH-CO-NH-Lys(Ahx)-HBED-CC (also termed: ^{68}Ga-PSMA, ^{68}Ga-PSMA HBED-CC, ^{68}Ga-PSMA-11).[40-44] Compared with previously used PSMA antibodies for imaging, PSMA ligands seem to provide superior contrast images due to extracellular binding followed by internalization into PCa cells and fast blood clearance reducing background activity.[45-47]

PSMA PET for Staging of Recurrent PCa

A major challenge for imaging is localization of PCa lesions in patients with biochemical relapse. The differentiation between localized disease and metastatic spread is of great importance, especially at low PSA values, as it might influence further disease management (targeted radiotherapy, salvage surgery vs. systemic treatment). As mentioned above, choline-based PET examinations improve staging and show enhanced detection rates in recurrent PCa compared with conventional cross-sectional imaging.[36] However, they still lack the ability to identify smaller or less metabolic lesions, especially at low PSA velocity or PSA values below 2 ng/mL.[33,48]

FIGURE 8. Patient With PCa Relapse (PSA of 1.26 ng/mL) and Histologically Proven Lymph Node Metastasis Corresponding to ^{68}Ga-PSMA PET Imaging



(A) CT. (B) Fused ^{68}Ga-PSMA PET/CT.

In 2015, two large patient cohorts on ^{68}Ga-PSMA PET have been published evaluating the staging of recurrent PCa.[49,50] In the study by Afshar-Oromieh et al, 319 patients with recurrent PCa (226 after radical prostatectomy; median PSA value, 4.6 ng/mL) were examined.[49] The authors reported detection rates of 50% and 58% for PSA values below 0.5 ng/mL and between 0.5 and 1 ng/mL, respectively. In a subset of 42 patients, histologic confirmation of suspicious lesions could be obtained. In these patients, all ^{68}Ga-PSMA PET–positive lesions could also be histologically confirmed to contain metastatic PCa. In this study, Gleason scores as well as antiandrogen deprivation therapy did not significantly influence detection rates. Our group confirmed those results in a homogeneous consecutive cohort of 248 patients with biochemical recurrence after radical prostatectomy (mean PSA value, 1.99 ng/mL).[50] Here, ^{68}Ga-PSMA PET revealed suspicious lesions in 89.5% of the patients. Similarly, detection rates increased from 57.9%, 72.7%, 93.0%, to 96.8% for PSA values of 0.2 to less than 0.5, 0.5 to less than 1, 1 to less than 2, and above 2 ng/mL, respectively. Compared with contrast-enhanced CT, ^{68}Ga-PSMA-11 PET exclusively showed suspicious findings in 32.7% of patients and provided information about additional involved anatomic regions in 24.6%. Compared with absolute PSA value, the effects of PSA velocity and PSA doubling time were less pronounced, although they also influenced detection rates.

Most recently, Perera et al summarized data from literature for ^{68}Ga-PSMA, including 16 studies with over 1,300 patients. The predicted positivity rates in a meta-regression analysis were 58%, 76%, and 95% for PSA values of 0.2 to 1.0, 1.0 to 2.0, and over 2.0 ng/mL, respectively.[51] These values are considerably higher than reported for choline-based PET tracers.[33,48,52-54] Furthermore, two studies comparing ^{18}F-choline and ^{68}Ga-PSMA in a head-to-head analysis both show higher detection rates for PSMA-based PET imaging.[45,46]

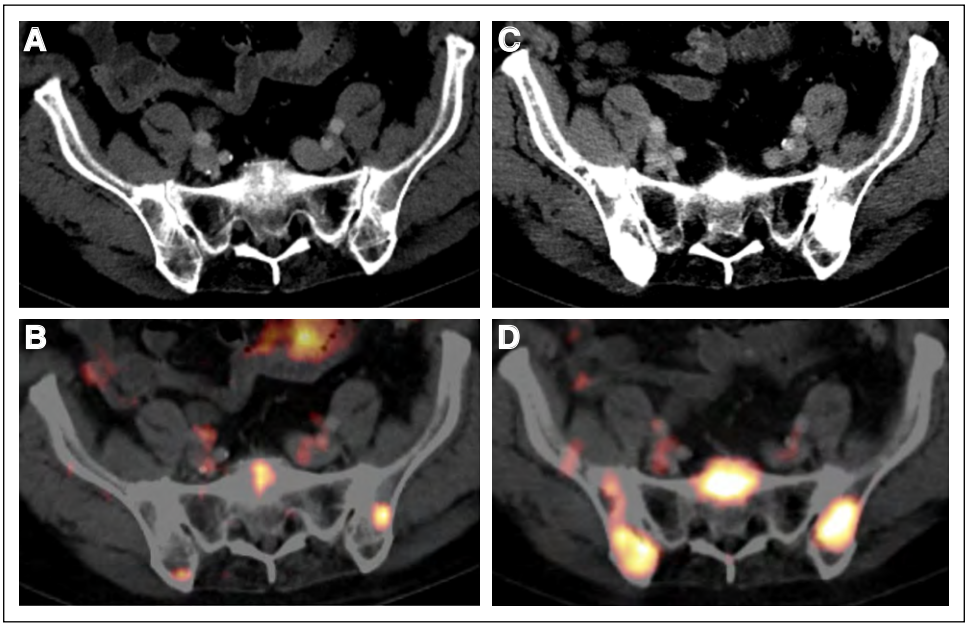
A major limitation of all the above-mentioned PET studies in patients with recurrent PCa is the lack of systematic histologic confirmation. Thus, in general, results of those imaging studies still have to be considered with caution. However, due to their high sensitivity and specificity, PSMA ligands have also been successfully applied in intraoperative tracking of metastatic PCa lesions during radioguided surgical procedures.[55,56] With the technology of PSMA-radioguided surgery, even small metastatic soft-tissue PCa deposits could be localized and successfully removed during salvage surgery procedures (Fig. 8).

PSMA PET for Primary Staging

For primary staging of PCa, evidence for ^{68}Ga-PSMA PET is still limited. The goal of primary staging is to detect metastatic spread to lymph nodes, bone, or other visceral organs. In low-risk PCa, metastatic spread is very unlikely and consequently current guidelines suggest staging examinations only for intermediate to high-risk PCa. In these patients, exact staging can have great impact on further treatment (e.g., radical prostatectomy vs. radiation therapy vs. palliative systemic treatment; extent of lymph node dissection during surgery, planning of radiation field; multimodal therapy concepts).

Conventional cross-sectional imaging almost exclusively depends on morphologic information, and metastatic lymph nodes are mainly detected by size. However, almost 80% of metastatic lymph nodes in PCa are smaller than the threshold size of 8 mm and therefore cannot be detected by anatomic imaging.[57,58] In the currently largest series of 130 patients with intermediate to high-risk PCa undergoing radical prostatectomy and template lymph node dissection, ^{68}Ga-PSMA PET imaging significantly improved lymph node metastases prediction compared with standard imaging.[59] On a patient-based analysis, the sensitivity, specificity, and accuracy of ^{68}Ga-PSMA PET were 65.9%, 98.9%, and 88.5%, respectively, compared with anatomic standard imaging with 43.9%, 85.4%, and 72.3%, respectively ($p = .002$). However, data from this study and others also showed that lymph node metastases smaller than 3 to 4 mm are also regularly missed by ^{68}Ga-PSMA.[59-61] Thus, especially in patients with high-risk disease, a negative ^{68}Ga-PSMA PET examination should not preclude a proper treatment of local lymph node drainage fields.

FIGURE 9. Patient With PCa With Metastatic Bone Lesions



Although bone lesions were hardly detectable on initial CT (A), fused ^{68}Ga-PSMA PET/CT (B) showed lesions already highly suggestive for bone metastases. Follow-up imaging clearly revealed bone metastases on CT (C) and fused ^{68}Ga-PSMA PET/CT (D).

Furthermore, bony and visceral lesions of PCa that might not be detectable by standard imaging can be visualized by ^{68}Ga-PSMA PET (Fig. 9). However, data are even more limited. In a comparative study of 126 PCa patients, ^{68}Ga-PSMA PET significantly outperformed planar bone scintigraphy for the detection of affected bone regions as well as determination of overall bone involvement.[62] Especially for identification of small metastatic bone lesions, ^{68}Ga-PSMA PET performed superior.

PSMA PET for Local Detection

In recent years, multiparametric MRI evolved as imaging of choice for local detection of PCa as well as evaluation of capsule penetration or seminal vesicle involvement.[63,64] The introduction of whole-body hybrid PET/MRI scanners with simultaneous acquisition and anatomic coregistration of PET imaging and multiparametric MRI opened the window to combine these functional MRI-derived sequences with molecular information from PET.[65,66] Although the spatial resolution of PET imaging is clearly inferior to MRI, ^{68}Ga-PSMA PET could still be of value to localized PCa by adding molecular information from PET. In a recent retrospective study on 53 patients who underwent radical prostatectomy after imaging, ^{68}Ga-PSMA PET/MRI improved the diagnostic accuracy for PCa localization both compared with multiparametric MRI as well as PET imaging alone.[67] On a sextant-based analysis, simultaneous ^{68}Ga-PSMA PET/MRI statistically outperformed multiparametric MRI (area under the curve: 0.88 vs. 0.73; $p < .001$) and sole ^{68}Ga-PSMA PET (area under the curve: 0.88 vs. 0.83; $p = .002$) for localization of PCa. Furthermore, compared with multiparametric MRI, ^{68}Ga-PSMA PET imaging was more accurate (area under the curve: 0.83 vs. 0.73; $p = .003$). It could be observed that PSMA-based PET provided a high uptake ratio between malignant versus nonmalignant tissue. However, although simultaneous ^{68}Ga-PSMA PET/MRI might improve the diagnostic accuracy for PCa localization and thus might be useful for example biopsy targeting or boost irradiation, availability of this technology as well as cost-efficiency issues might preclude ^{68}Ga-PSMA PET/MRI from widespread use (Fig. 10).

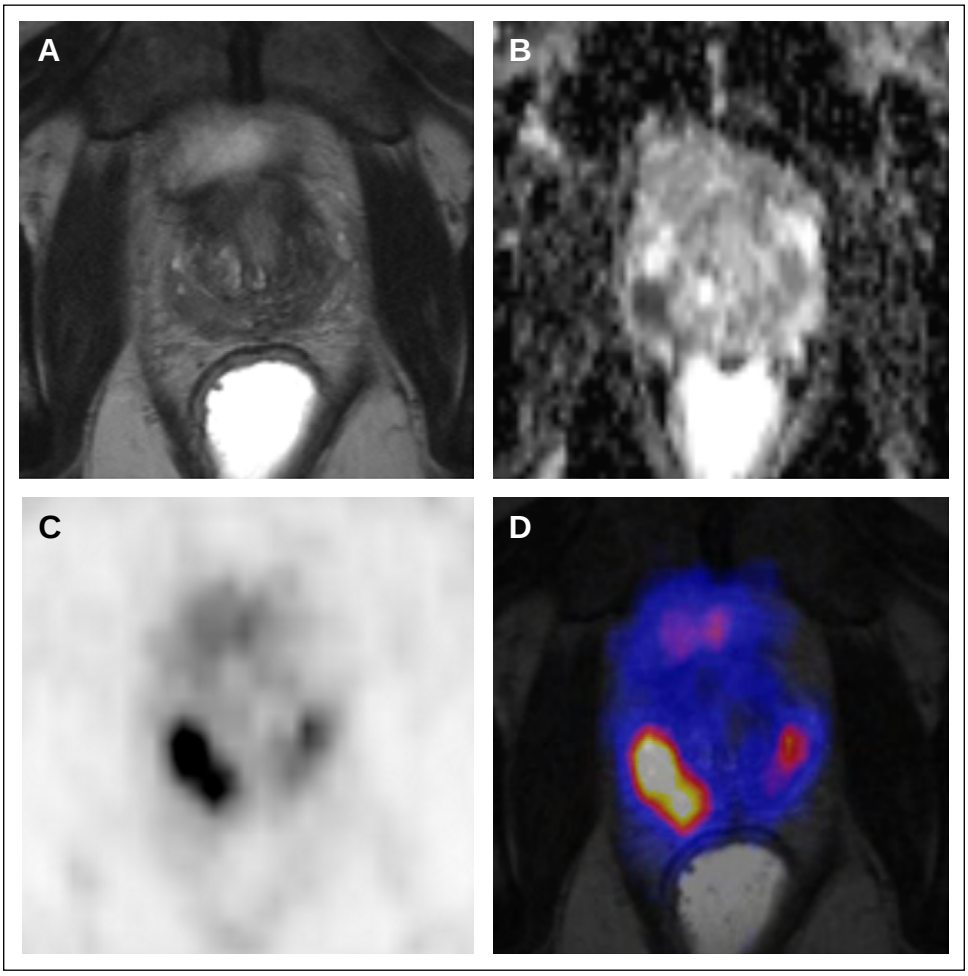
Limitations of PSMA-Based PET Imaging of PCa

Although PSMA-based PET imaging might be on its way to revolutionize PCa imaging, several limitations have to be addressed. It has to be noted that not all PCa exhibits a significant PSMA overexpression. Up to 10% of primary PCa can be negative on PSMA PET.[59,67] Thus, not only the local tumor, but also metastases might not be detectable. In addition, a variety of reports describe positive PSMA PET in several benign and malignant conditions.[47] Thus, accurate analysis of PSMA PET studies by experienced imaging specialists is mandatory.

CONCLUSION

Imaging with ^{68}Ga-PSMA PET has already achieved high potential to influence PCa management.[46] In biochemical recurrent PCa, ^{68}Ga-PSMA PET imaging has been shown to increase detection of metastatic sites even at low PSA values in comparison with conventional imaging or PET examination with different tracers. Furthermore, especially in high-risk PCa patients, ^{68}Ga-PSMA PET could enable a complete and more accurate staging of local tumors, lymph node involvement, and bone and organ metastases within

FIGURE 10. 65-Year-Old Patient With Histologic Proven Intraprostatic PCa Within the Right Basal Peripheral Zone



T2 sequence of multiparametric MRI (A) shows a hypointense area in the right prostate base with corresponding diffusion restriction (B). ^{68}Ga-PSMA PET (C) and fused ^{68}Ga-PSMA PET/MRI (D) reveal an area with increased tracer accumulation. Gleason score, 3 + 4; PSA, 10.3 ng/mL.

a single examination, thus outperforming current standard imaging. Thus, although current knowledge is still limited and derived mostly from retrospective series, PSMA-based imaging holds great promise to advance PCa management.

Personalizing Therapy for Metastatic Prostate Cancer: The Role of Solid and Liquid Tumor Biopsies

Terence W. Friedlander, MD, Colin C. Pritchard, MD, PhD, and Himisha Beltran, MD

OVERVIEW

Although biopsies of metastatic prostate cancer are rarely undertaken in the clinical setting, there is increasing interest in developing personalized approaches to therapy by taking into account the genetic and phenotypic changes in an individual tumor. Indeed, analysis of metastatic prostate tumors can predict sensitivity to agents that inhibit DNA repair and resistance to novel hormonal agents, such as abiraterone and enzalutamide, and identify phenotypic changes, such as neuroendocrine differentiation, that have important clinical implications. Although obtaining metastatic tumor tissue is necessary for this genomic and molecular profiling, knowing when to biopsy, selecting the appropriate metastatic lesion, and interpreting the results are major challenges facing clinicians today. In this article, we discuss the rationale for obtaining metastatic tumor tissue, review the bioinformatic approach to analyzing these specimens, discuss the timing and approach to solid and liquid tumor biopsies, review the challenges associated with obtaining and acting on clinically relevant results, and discuss opportunities for the future.

Prostate cancer is characterized by a long natural history, with 10 years or longer often elapsing between the time of diagnosis and time of death in many patients. Further, prostate tumors typically acquire molecular alterations with disease progression and treatment resistance. Therefore, evaluation of the primary tumor is not often representative of what is going on when trying to make a treatment decision for a patient with metastatic castration-resistant prostate cancer (mCRPC). Hence in recent years, metastatic biopsies have become increasingly considered in clinical practice for patients for whom guidance for trial participation or next-line therapy is needed.

CHALLENGES IN TRANSLATING MOLECULAR RESULTS INTO MEANINGFUL CLINICAL USE

Genomic evaluation of cancers to guide treatment decisions is conceptually within the realm of precision oncology, an approach to match the right patient with the best systemic therapy on the basis of the underlying molecular alterations of that patient's tumor. However, in prostate cancer, precision oncology is challenged by a predominance of sclerotic bone metastases making biopsies technically challenging, few therapeutically actionable mutations, and limited guidelines to inform when and how to perform metastatic biopsies in patients and what to do with the results.

Clinical Indications

Although there are no formal guidelines outlining evidence-based indications for performing metastatic biopsies in patients with advanced prostate cancer, recent research studies have pointed to potential scenarios in which a biopsy may be considered.

Clinical trial participation. Metastatic biopsy programs, including the International Stand Up To Cancer-Prostate Cancer Foundation Dream Team, have elucidated the genomic landscape of mCRPC and have identified mutations that are enriched in advanced disease.[1-3] In addition to well-understood perturbations of androgen receptor (AR) signaling, potentially actionable and/or prognostic alterations include *TP53*, WNT pathway (e.g., *R*-spondin rearrangements and *CTNNB1* mutations), PI3K pathway (e.g., *PTEN* copy loss and *PIK3CA* and *PIK3CB* mutations), and cell cycle pathways (e.g., *RB1* and *CCND1*). These data combined with encouraging results from early-phase clinical trials have led to the initiation of several ongoing or planned biomarker-driven trials for patients with mCRPC. Therefore, repeat biopsy and genomic assessment may be indicated for patients for whom these trials are being considered.

A finding that is already influencing clinical decisions to pursue tumor genetic testing is that loss-of-function mutations in homologous recombination (HR) and mismatch DNA repair pathway genes are present in approximately 20% of metastatic prostate cancer tumors.[1,3,4] Mutations in

HR DNA repair genes such as *BRCA1* and *BRCA2* are well-established predictors of response to PARP inhibitors and platinum-based chemotherapy in ovarian cancer.[5,6] This has led to the recent U.S. Food and Drug Administration approval of two PARP inhibitors as monotherapy for patients with ovarian cancer who harbor *BRCA1* or *BRCA2* mutations in tumor tissue (olaparib[7] and rucaparib[8]). Results from early-phase clinical trials suggest that *BRCA1*, *BRCA2*, and other HR DNA repair gene mutations will also prove to be highly predictive of PARP inhibitor response in men with metastatic prostate cancer. In the TOPARP-A phase II trial, 14 (88%) of 16 patients with metastatic prostate tumors who had HR DNA repair gene mutations predicted to inactivate both gene copies (biallelic) responded to the PARP inhibitor olaparib, compared with only two (6%) of 33 patients who did not.[9] This finding has led to a biomarker-driven phase III trial and the U.S. Food and Drug Administration granting "breakthrough status" for olaparib in men with metastatic prostate tumors who harbor biallelic *BRCA1*, *BRCA2*, or *ATM* mutations. There is also early data that suggest these mutations predict response to platinum-based chemotherapy in metastatic prostate cancer. One small case series found that three of three patients who had an exceptional response to carboplatin therapy harbored biallelic inactivating *BRCA2* mutations in their tumors.[10]

Remarkably, approximately one-half of the men with metastatic prostate cancers harboring DNA repair gene defects have a germline (inherited) mutation.[1,11] A recent multi-institutional study that evaluated 692 men across eight independent cases series of men with metastatic prostate cancer not selected for age or family history found that nearly 12% had potentially clinically significant high-penetrance germline mutations in 16 different DNA repair genes.[11] This was compared with 4.6% of men in a primary prostate cancer cohort from The Cancer Genome Atlas heavily enriched for high-risk disease (2.7% in the general population). The bulk of the mutations were in *BRCA2* (5.3%), *BRCA1* (0.9%), *ATM* (1.6%), and *CHEK2* (1.9%). Another recent study of 313 men with metastatic prostate cancer revealed similar rates of germline *BRCA2*, *BRCA1*, and *ATM* mutations (6% combined for these three genes) with fewer mutations in men with low-risk localized disease (1.4% combined for these three genes).[12] These findings not only inform treatment considerations, but also have implications for genetic testing and cancer risk for family members (i.e., breast, ovarian, pancreatic, and prostate cancers).

Somatic alterations involving PI3K/AKT pathway genes, most commonly *PTEN* deletion, occur in approximately 40% of patients with mCRPC.[1] In a phase II study by de Bono et al,[13] the combination of the AKT inhibitor ipatasertib with abiraterone improved progression-free survival and overall survival (OS) for patients with mCRPC when compared with placebo, and PTEN loss was associated with response.[13] Based on this work, a phase III trial is planned, including further investigation of PTEN as a predictive biomarker.

Recent trials in mCRPC have found that a subset of patients with mCRPC responded exceptionally well to immunotherapy with checkpoint inhibitors. Graff et al reported data from 20 patients enrolled on an ongoing phase II trial in which pembrolizumab was added at time of progression on enzalutamide.[14] Of the 11 patients who responded, profound and durable responses were observed, and in some cases, prostate-specific antigen (PSA) declined to undetectable levels. Similar to other tumor types, there is early suggestion that defects in mismatch repair and the hypermutated phenotype may predict response to immunotherapy. Although less than 5% of patients with mCRPC demonstrated loss of mismatch repair, this may nonetheless have clinical significance in selecting patients for anti–PD-1 inhibitor therapy.

When is the optimal time to test for genomic alterations involving these and other genes? Although certain alterations tend to be enriched in mCRPC, research into how they evolve during the course of therapy, including studies of matched primary metastatic tumors, has been limited. Therefore, in practice, biopsy evaluation is often recommended at the time of trial consideration.

Small cell/neuroendocrine transformation. Despite primary androgen deprivation therapy and subsequent potent AR-directed therapies, most mCRPC tumors continue to evolve as an androgen-driven disease. Therefore, a major focus of research and drug development has been to identify more effective therapeutic strategies to target the AR more potently. But a subset of tumors become less dependent on the AR and, in some cases, can lose AR expression and/or signaling altogether. This evolution from mCRPC to an AR-indifferent state is often associated with clinical, pathologic, and molecular characteristics of small cell neuroendocrine carcinoma.[15] A similar phenomenon has been observed in EGFR-mutated lung adenocarcinomas in which a subset of patients transform to small cell lung cancer at the time of resistance to EGFR-targeted therapy, with retention of the original EFGR mutation.[16] Conceptually, targeting

KEY POINTS

- **Multiple new therapeutic targets have been identified in metastatic prostate cancer; however, selecting the right therapy for an individual patient is a clinical challenge.**
- **Obtaining metastatic tissue to inform these decisions has historically been hampered by cost, morbidity of the biopsy, and concerns about low tumor yields.**
- **Recent studies show that metastatic solid tissue biopsies, including bone biopsies, are feasible and can provide clinically relevant molecular and phenotypic information.**
- **Different approaches to gene sequencing (hotspot panels, comprehensive gene panels, and whole exome/genome approaches) provide qualitatively different types of information, with important clinical implications.**
- **Additionally, liquid biopsies of circulating tumor cells and circulating tumor DNA can inform a patient's prognosis, predict response to new hormonal therapies, and serve as a discovery platform for precision medicine.**

a key driver in cancer (in prostate cancer, this is the AR) leads to an escape mechanism associated with epithelial plasticity as a way for the cancer cells to evade therapy. Once a predominantly neuroendocrine prostate cancer (NEPC) phenotype is diagnosed, patients may respond better to small cell carcinoma chemotherapy regimens than typical mCRPC therapies. When to evaluate patients with mCRPC for small cell/NEPC transformation is not well defined. Metastatic biopsies may be considered if there is clinical suspicion of NEPC, including rapid progression, often to unusual sites including parenchymal brain metastases, in the setting of a low or modestly rising serum PSA (suggesting less androgen-driven disease). Treatment regimens based on data for aggressive variant prostate cancer and applicable to mixed CRPC-adenocarcinoma tumors may include platinum (carboplatin or cisplatin) plus etoposide (extrapolated from small cell lung cancer data) or platinum plus taxane.[17] Defining the prognostic significance of mixed/hybrid tumors and non–small cell histologic variants in mCRPC is an area of active research.

Biomarker Research

Genomics in combination with clinical data have informed the development of molecular biomarkers. As these data continue to accumulate in the coming years and with prospective clinical follow-up of large patient cohorts, the predictive and/or prognostic value of common molecular alterations in mCRPC and how to test for them will continue to be defined.

The presence of AR alterations, including mutations, amplifications, and overexpression of AR splice variants (most commonly the AR-V7 variant), commonly occur in patients with mCRPC[1] and has been associated with decreased response to subsequent abiraterone or enzalutamide.[18-20] In addition to prognostic value, detection of AR alterations may also improve selection of next-line therapy such as the selection of taxane versus AR-targeted therapy for a patient with mCRPC.[21] Further, patients may be selected for trials investigating AR *N*-terminal domain inhibitors or novel drugs targeting the AR variants.

Loss of *RB1* and *TP53* occurs in 5% of primary prostate cancers and up to 40% of mCRPC and is enriched in patients with the NEPC resistance phenotype (similar to small cell lung cancer, in which losses of *RB1* and *TP53* are universal).[1,15] In preclinical studies, the combination has been associated with lineage plasticity, enzalutamide resistance, and AR independence,[22,23] and current clinical efforts are focused on further defining the prognostic and predictive role of *TP53*/*RB1* in mCRPC.

Another area of active research is understanding the prognostic role of DNA repair alterations and their association with response to other agents such as AR-targeted therapies, taxanes, and immunotherapy. Further understanding of the biologic role of other common genomic alterations such as WNT pathway alterations and other cell cycle alterations[1] and their clinical impact, particularly in the context of other common resistance pathways, may also play an appropriate biomarker role for emerging drugs and the early identification of resistance mechanisms in patients.

What and Where to Biopsy

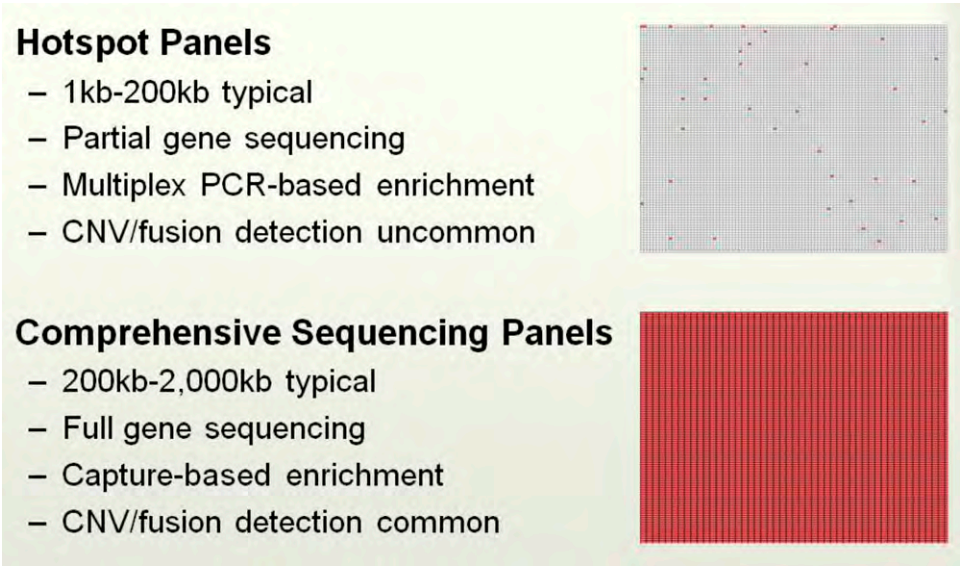
Ninety percent of patients with mCRPC have bone metastases, and up to 50% of patients have bone-only metastases. Visceral metastases develop in up to 20% of patients with mCRPC, typically arising in later stages of disease progression.[24] Nodal, visceral, or other soft tissue (i.e., nonbone) metastases are typically the biopsy lesions of choice because of higher tumor yield and technical feasibility. The location choice in patients with multiple sites is usually based on safety and accessibility for image-guided biopsies. To date, no noteworthy genomic differences have been reported between bone and nonbone lesions, although the transcriptome is likely influenced by the microenvironment.

Bone metastases in prostate cancer are most often sclerotic, rather than lytic, making bone biopsies technically challenging. Although there has been an increased focus on applying newer imaging techniques and novel tracers for patients with mCRPC, the most widely deployed modalities for identifying and monitoring bone metastases are a combination of bone scintigraphy and CT scan. These images provide limited information to guide interventional radiologists toward the most active lesion to biopsy. Recent studies focused on applying clinical and imaging criteria may improve diagnostic yield and acquisition of high-quality tissues and nucleic acids for genomic and other molecular studies.[25] Along with improvements in biopsy tools, tissue processing, and pathology evaluation, bone biopsy success rates have improved in recent years to approximately 60% to 80% at specialized centers.

What to Ask for

In the past, metastatic biopsies in mCRPC were typically performed to confirm a diagnosis of prostate cancer, and therefore limited pathologic evaluation was necessary. Biopsies in mCRPC may demonstrate poorly differentiated carcinoma. Gleason grading is not applicable for treated tumors. In a patient with suspected NEPC transformation, discussion with the pathologist regarding the morphologic characteristics may help distinguish classic adenocarcinoma, adenocarcinoma with neuroendocrine differentiation, small cell or large cell carcinoma, intermediate atypical carcinoma, mixed or hybrid tumors, or other pathologic variants.[26] Immunohistochemistry for AR signaling markers (e.g., PSA, AR, PSMA, and NKX3.1) and classic neuroendocrine markers (e.g., chromogranin, synaptophysin, and CD56) may support a diagnosis. For small cell carcinoma of unknown primary, a positive ERG break-apart fluorescence in situ hybridization test may be clinically useful to confirm prostatic origin. For patients in which immunotherapy trials are to be considered or if a hypermutated phenotype is identified by sequencing, MSI and MMR genes (i.e., MLH1 and MSH2) may be considered. Most commercial and institutional sequencing platforms incorporate a panel of genes to evaluate for copy number and somatic nucleotide variants, and both sample

FIGURE 1. Hotspot Versus Comprehensive Somatic Mutation Panels



quality and tumor content are important. These tests may or may not include germline DNA into the test/filter, which may affect the clinical interpretation (as discussed later).

Genomic Cancer Panels: Methods Matter

Translating these new genetic biomarkers into clinical use requires careful attention to who and when to test, testing methods, and the accurate interpretation of test results. In this section, we cover aspects of genomic cancer panel testing that is already clinically available and increasingly used for men with metastatic prostate cancer. Specifically, we will focus on testing methods, sample considerations related to cancer tissue and plasma circulating DNA, and reporting considerations. These are covered with an emphasis on issues most relevant to metastatic prostate cancer from the perspective of a practicing molecular pathologist.

Next-generation sequencing (NGS) technology is arguably the key driver for the rapid discovery and clinical implementation of new genetic biomarkers in prostate cancer. Compared with the older Sanger sequencing methods, NGS produces about a millionfold more data for the same cost and speed. For discovery, whole-genome and whole-exome sequencing are quite useful. For clinical use, smaller targeted gene panels that encompass only genes of interest are the current standard. Targeted NGS gene panels focus the sequencing power on just the genes of interest, allowing high depth of coverage and better assay performance compared with spreading out the same sequencing power across the whole exome or genome. Targeted panels also facilitate custom design to ensure key, clinically meaningful mutations are detected in regions that can be missed by generic exome and genome sequencing methods.

There are two general types of NGS cancer panels: hotspot panels and comprehensive panels (Fig. 1). Hotspot panels only interrogate specific sites or portions of genes that are known to be hotspots for somatic mutations. They typically sequence less than 200 kb of total DNA and use multiplex polymerase chain reaction as the method for gene enrichment (also known as amplicon-based sequencing). Hotspot panels usually do not accurately detect copy number variation, although this can be achieved with specialized bioinformatics.[27] A commonly used hotspot approach is the "AmpliSeq" panel, which has been applied to prostate cancer.[28] Advantages of hotspot approaches are that they are usually faster and cheaper, use less sample input, require less bioinformatics support for a laboratory to operate, and are easier to interpret. The primary disadvantage is that hotspot approaches may miss many of the mutations, including de novo ones, which are most important for guiding cancer care.

Comprehensive panels typically sequence between 200 to 2,000 kb of DNA, which is more than hotspot approaches but still far less than whole-exome or -genome sequences (compare with approximately 50,000 kb for exome sequencing). Although methods are variable, comprehensive panels typically use a "capture-based" approach to enrich the target genes that relies on solution hybridization with baits that pull down the genes of interest. An advantage of this approach is that it is easier to preserve gene dosage and perform accurate gene copy number assessment. DNA capture-based approaches may also detect gene fusions if the correct regions are captured and appropriate bioinformatics employed. Comprehensive NGS cancer panels have been successfully applied to metastatic prostate cancer to detect relevant events that would not be readily detected by hotspot approaches, such as *TMPRSS2-ERG* fusions, *AR* amplification, complex DNA repair gene rearrangements, and homozygous *BRCA2* copy loss.[4,29,30] Although comprehensive panels have the advantage of greater sensitivity, they are generally more expensive, require greater bioinformatics expertise, and are more challenging to interpret than hotspot approaches. Marketing can be misleading: It is important for the practicing oncologist to understand that

the number of genes sequenced often matters less than the regions of the genes sequenced. In other words, a 200-gene hotspot panel is not the same as a 200-gene comprehensive panel.

Limit of detection can be especially important in tumor panel testing, particularly in the setting of cell-free circulating tumor DNA (ctDNA) testing in which mutations may be present at very low levels. Clinical NGS assays achieve improved limit of detection through multiple means, including higher depth of coverage, specialized genomic library preparation methods that improve signal-to-noise by eliminating most polymerase chain reaction artifacts, and bioinformatics approaches that improve signal-to-noise through error suppression.[31,32] When asking about methods, it is important to understand that higher depth of coverage alone usually cannot improve the overall limit of detection below approximately 1% because of sequence error rates.[33] In other words, "What's your depth of coverage?" is only one part of the question.

Sample Considerations: Tissue or Plasma?

The specifics of the sample tested for tumor profiling are critical to the quality of the study. Metastatic prostate cancer sources used for current clinical testing can be from fresh or fresh frozen tissue, formalin-fixed, paraffin embedded tissue, or ctDNA in plasma, each with unique characteristics in terms of quality, quantity, tumor content, and the possibility of false-positive and false-negative results (Table 1). For each specimen, it is important to ask the following: (1) Is the sample appropriate for the clinical question and representative of the tumor(s) I am trying to treat? (2) What is the prostate cancer content, and is it high enough for the test being performed? (3) Is there enough quantity of sample for testing? (4) Could there be unrelated somatic "interfering" mutations that might be misinterpreted as coming from prostate cancer? It is standard practice for molecular pathology laboratories to assess sample quality and tumor content for cancer tissue–based testing for NGS panels by reviewing the histomorphology in corresponding stained slides. Tumor content can be enriched through dissection of tumor-rich areas. For ctDNA, the tumor content is just as critical to the quality of testing, but it is not possible to review a corresponding slide and not straightforward to do tumor enrichment. There are emerging techniques that can allow assessment of tumor content in plasma cell–free DNA that rely on differences in fragment length in cancer-derived ctDNA, but these techniques are not yet widely used in clinical practice.[34-36]

When testing plasma ctDNA in a patient with metastatic prostate cancer, it is critical to understand that prostate cancer may not be the only source of somatic mutations present in the plasma. Age-related and cytotoxic chemotherapy treatment–related clonal hematopoiesis is well described and quite common in older men.[37-39] Most hematopoietic clones can be subtracted out when matched white blood cell sequencing is done, although this is not always done. Further, there are likely to be additional sources of somatic clones in the plasma that are as yet not well understood. Special caution should be exercised in interpreting mutations detected in ctDNA that are not obviously derived from the prostate cancer, especially those detected at very low variant allele fractions.

TABLE 1. Sample Considerations for Cancer Next-Generation Sequencing Testing

	Fresh Tumor Tissue	Fixed Tumor Tissue	Plasma Circulating Tumor DNA
Quality	High	Moderate	Low
Quantity	High	Moderate	Very low
Tumor Content	High (usually)	High (usually)	Low (usually)
False Negatives	Less common	Less common	More common
False Positives	Less common	Fixation artifact	Somatic clones in blood misinterpreted as cancer derived

Reporting Considerations

Reporting considerations for NGS cancer panels can be divided into two aspects: analytical and clinical (Table 2). Analytical features include the types of mutations that are validated (e.g., whether or not copy number changes are detected), the limits of detection (e.g., whether or not this test has a chance of detecting the resistance mutation you are looking for), and sequencing platform–related issues that may make some types of mutations more prone to false-positive or false-negative results. Clinical features include the context for testing (e.g., post-abiraterone or post-enzalutamide treatment in which AR-V7 and other resistance clones may be present versus treatment-naive presentation of metastatic prostate cancer), the laboratory's strategies for variant classification, and the laboratory's policies on how much to report.

Somatic mutation reporting guidelines have only recently been proposed and are not well established. This year, ASCO, the Association of Molecular Pathologists, and the College of American Pathologists published a framework for somatic mutation interpretation based on four tiers that

TABLE 2. Reporting Considerations

Analytical
1. Types of mutations validated
2. Limits of detection
3. Pseudogenes
4. Platform-specific considerations
Clinical
1. Clinical context
2. Strategy for poorly characterized variants
3. Decision support
4. Incidental findings

depend on the level of evidence of a specific mutation or alteration being associated with a specific therapy.[40] Guidelines for interpretation of germline mutations, such as the joint recommendations by the American College of Medical Genetics and Genomics and the Association of Molecular Pathologists, are better established and typically rely on a five-tier system that classifies variants as either pathogenic, likely pathogenic, uncertain significance, likely benign, or benign.[41] These variant interpretation guidelines are helpful but do not adequately address the complexity of the diagnostic challenge for an individual patient with prostate cancer because the clinical history and other patient- and sample-specific factors must be understood to render an accurate interpretation of the mutation results. The challenge is equal or greater than that of other areas of diagnostic medicine, such as complex imaging studies in radiology and histopathologic diagnosis in surgical pathology. Similar to testing in radiology and surgical pathology, the performance and interpretation of these NGS studies is part of the practice of medicine. These studies require highly trained doctors who specialize in the area of medicine to render an accurate diagnosis and should not be treated simply as routine laboratory tests or medical devices in which an algorithmic approach can be applied to interpretation and reporting.

Reporting on ctDNA sequencing is especially challenging because we do not yet understand all of the factors that influence these results. Recent studies that compared clinical reporting of plasma ctDNA and tumor-based NGS results between two widely used commercial reference laboratories found that less than one-half of the reported mutations overlapped within the same patients.[42,43] More importantly, only about one-quarter of the treatment recommendations on clinical reports overlapped. Some of the discordance could be attributed to the reporting of low-level clones in ctDNA (at variant allele fraction less than 1%), with the key mutations that are most likely to be predictive of treatment more often being shared.[42] This highlights the need for expert interpretation of both tissue and ctDNA results when treatment recommendations are made.

Case Vignette

We end this section with a hypothetical case vignette to highlight the use of clinical NGS panels in metastatic prostate cancer tissue and ctDNA. A 63-year-old man diagnosed with Gleason 5 + 4 prostate cancer underwent a radical prostatectomy followed by salvage radiotherapy. After 2 years, he developed metastatic disease to bone and soft tissue, including the liver. A metastatic biopsy of his liver lesion was performed for NGS panel testing to evaluate for therapeutic options. The tumor slide was reviewed by the molecular pathologist, and tumor content was estimated at 50%. Results from a comprehensive sequencing panel revealed a BRCA2 frameshift loss-of-function mutation (c.5946delT, more commonly known as 6174delT) detected in 49% of sequencing reads and without associated loss of heterozygosity; a second complex BRCA2 frameshift loss-of-function mutation was detected in 25% of sequencing reads. Because of the pattern of the variant allele fractions of the two BRCA2 mutations, and because the 6174delT mutation is a common pathogenic germline mutation, the molecular pathologist reported back to her oncologist colleague that there was a high suspicion the 6174delT mutation was inherited in the germline. This came as a surprise to the oncologist because there was no known family history of cancer. Follow-up targeted germline testing confirmed that the BRCA2 6174delT was present in the germline. Additional at-risk family members were offered genetic counseling and targeted testing. The patient received a regimen including carboplatin chemotherapy with a complete PSA response for 18 months. Following a PSA rise, NGS panel testing of plasma ctDNA was performed to evaluate for possible resistance and showed no evidence of secondary resistance such as BRCA2 reversion mutations.[44] Based on the ctDNA results, the oncologist switched to a PARP inhibitor, which resulted in a sustained PSA response.

Challenges

Pathway crosstalk. Evolution of drug resistance in mCRPC involves a concerted interplay between multiple genes and pathways. For instance, biologic insights into the reciprocal feedback between AR signaling and PI3K/AKT pathways has led to the rational development of cotargeting strategies.[45] How genomic alterations interact and influence treatment response is an area of active research and will be essential for the identification of robust predictive molecular biomarkers and approaches for targeting pathway crosstalk.

Nongenomic pathways. Although most "precision medicine" approaches have focused on genomic alterations, epigenomic assessment, messenger RNA/pathway analysis, immune analyses, and other functional readouts will also be critical in identifying novel resistance pathways that may not be identified by genomics. The use of patient-derived preclinical models including organoids and patient-derived xenografts may accelerate this process.[46,47]

Tumor heterogeneity and evolution. Most studies evaluating tumor metastases in patients with advanced disease have supported a monoclonal origin of mCRPC,[48,49] with all metastatic lesions traceable back to a common early ancestor and mostly shared genomic driver alterations observed across metastases. The differences or heterogeneity that are also observed across metastases that occur through polyclonal subclonal seeding or other means, and the temporal evolution of cancer with disease progression and treatment resistance, are not captured well by single-site biopsies and may be better captured by circulating tumor cell (CTC) or ctDNA approaches (as described later).[50,51] This heterogeneity poses important questions for interpretation of mutation results obtained from a single metastatic site, and for results from ctDNA, which a mixture of shedding from multiple metastatic sites. Fortunately, there is evidence that there is minimal metastasis-to-metastasis heterogeneity of the key driver mutations that constitute the "trunk" of the prostate cancer rather than the "branches" and that NGS testing of a single metastatic site may be sufficient for the clinical

TABLE 3. Comparison of Solid and Liquid Biopsies

Source of Cancer Cells	Advantages	Limitations
Metastatic biopsy	Pathologic gold standard	Cost
	Histology and phenotypic changes easily assessed (pure adenocarcinoma, neuroendocrine differentiation, intermediate atypical phenotypes)	Morbidity
	Ample genomic material (DNA, RNA) and protein for analysis; deep sequencing feasible	Not all lesions amenable to biopsy
		Bone biopsies are technically challenging (approximately 70% success rate)
		Does not account for heterogeneity of different metastatic sites
Circulating tumor cells	Noninvasive	Limited cell recovery (typically < 1,000 cells)
	Serial monitoring feasible	Contamination by leukocytes, endothelial cells
	Cell counts are an established prognostic marker for survival	Inherent selection bias in most platforms, hard to recover all circulating tumor cells shed by a tumor; may not identify cells that have undergone epithelial to mesenchymal transition
	Detection of AR-V7 predictive of resistance to abiraterone/enzalutamide	Unclear origin of circulating tumor cell: primary tumor vs. metastasis
	Estimation of tumor heterogeneity; can identify multiple circulating tumor cell subsets	Genomic analysis may require DNA amplification and introduce bias; rare mutations may be missed
	Immunocytochemistry can shed light on AR localization (nuclear vs. cytoplasmic), presence of AR splice variants, and cell surface markers	Limited ability to profile RNA/gene expression
ctDNA	Noninvasive	Unable to estimate tumor heterogeneity
	Serial monitoring feasible	Most platforms only screen a limited panel of genes
	Highly sensitive detection of specific mutations	Limited ability to screen for novel mutations
	Circulating-tumor DNA burden prognostic for survival	Limited ability to profile RNA/gene expression
	Adrogen-receptor mutations and copy gain may predict resistance to abiraterone/enzalutamide	DNA by definition released from dying cells; may not accurately capture resistance mutations in living tumor cells
	Potential to identify DNA repair mutations and predict response to PARP therapy	

purposes of selecting therapy because therapies are aimed at the key oncogenic drivers.[49]

LIQUID BIOPSIES: CURRENT UTILITY AND FUTURE DIRECTIONS

Isolation and analysis of CTCs and ctDNA from patients with prostate cancer have emerged in recent years as a way to better understand molecular and genomic mechanisms that drive the disease. Although these "liquid biopsies" yield less tumor tissue than a soft tissue or bone biopsy,[1,25,52] they do offer numerous advantages: liquid biopsies are noninvasive, less morbid, faster to perform, and offer the realistic ability to monitor changes serially in the tumor over time (Table 3). Additionally, although PSA is a widely adopted biomarker across all stages of disease, it is a unidimensional measurement of disease burden, with limited prognostic and predictive capabilities, especially in the mCRPC setting.[53] Analysis of liquid biopsies in prostate cancer therefore offers the opportunity to better establish an individual patient's prognosis, to predict response to specific therapy, and to discover specific genomic alterations that may be clinically actionable. Here we will discuss some of the current utility of CTC and ctDNA analysis in men with prostate cancer, focusing on the different context in which they could be useful for the clinician and researcher and some of their potential drawbacks. We will lastly discuss opportunities for the future.

Defining and Detecting ctDNA and CTCs

ctDNA and CTCs are both thought to be shed from cancer cells into circulation, and increasingly sophisticated techniques to identify these cells and genomic fragments are being developed.[54] Broadly, analysis of ctDNA allows for the identification of multiple genomic abnormalities, including point mutations, changes in copy number, translocations, and epigenetic changes. Because these genomic changes are tumor specific, ctDNA analysis can rapidly identify these rare sequences among the large pool of shed-circulating

DNA. Additionally, although initial techniques such as real-time or digital polymerase chain reaction have focused on the identification of predefined, known oncogenic mutations,[55,56] increasingly sophisticated methods of identifying ctDNA are allowing for the detection of whole-exome and whole-genome copy aberrations and translocations.[57-59] Currently, most clinically available ctDNA platforms focus on a panel of specific DNA alterations, providing the clinician with a list of potentially actionable genomic changes present in the cancer.[60-62] Major challenges facing this field are the identification of de novo genomic changes, estimation of tumor heterogeneity, and the inability to detect genomic aberrations that occur at the transcriptional or translation level.

CTCs offer a similar ability to analyze tumor DNA; however, they also offer the ability to quantify RNA expression, fusion transcripts, and splice variants, identify expression of specific proteins, and visualize cellular and subcellular morphology and can allow for an estimation of tumor heterogeneity. Multiple technologies exist to enrich for and identify prostate cancer CTCs; although not completely comprehensive, broadly, CTCs can be identified using antibody capture techniques;[63] high-resolution imaging;[64] separation by physical properties such as size,[65] density,[66] microfluidic properties,[67] and dielectric potential;[68] or separation by specific physical characteristics such as invasive potential[69] or through secretion of known proteins.[70] Each of these techniques has advantages and disadvantages, in that platforms that require expression of a specific antigen, for example, may miss cancer cells that have downregulated the protein, although systems that aim to identify all cancer cells in circulation may suffer specificity issues from the identification of false-positives. Therefore, it should be strongly emphasized that there is no best CTC-capture technology; rather, each of these technologies should be thought of as a specific tool. In this light, an antibody-capture technique, such as the CellSearch platform, may be suitable for reliable enumeration of epithelial cell-adhesion molecules plus CTCs, whereas high-resolution imaging such as the Epic Sciences platform may be more suitable to estimate CTC heterogeneity or to identify nuclear versus cytoplasmic AR localization.

Clinical Applications of CTC and ctDNA in Prostate Cancer

Establishing prognosis. In prostate cancer, enumeration of CTCs has been investigated to establish whether their number can inform clinicians as to whether a patient will have longer or shorter survival. In this regard, the CellSearch (Veridex) platform has been perhaps the best explored. In a study of over 200 patients with mCRPC starting a new line of chemotherapy, the presence of five or more CTCs was associated with shorter overall survival (median 11.5 vs. 21.7 months; $p < .0001$).[63] Change from unfavorable counts to favorable was statistically associated with improved overall survival, and conversely, change from favorable to unfavorable was associated with worse overall survival. This work was validated in the context of a phase III study of docetaxel-based therapy,[71] and findings similar to these have been reported for patients with metastatic breast and colon cancers.[72,73]

For ctDNA, recent work has shown that the ctDNA burden is similarly prognostic for survival in a phase III study of chemotherapy.[74] Perhaps more excitingly, the detection of mutation-specific ctDNA after definitive surgery has been associated with subsequent disease recurrence in patients with colon[75] and breast[76] cancers, although it remains to be seen if this will be the case for patients with prostate cancer, and indeed, the utility of liquid biopsies for men with localized disease is under investigation.[77-79]

These studies of liquid biopsies in mCRPC are important in that they support the notion that the circulating tumor burden reflects the underlying disease burden. The major challenge is that using CTCs and ctDNA to establish prognosis, especially in the metastatic setting, has rather modest clinical utility, in that it does not inform the clinician as to whether switching therapy would be of benefit. Indeed, a randomized study of women with breast cancer failed to show a benefit to a chemotherapy switch for women with unfavorable counts after the initiation of chemotherapy.[80] That said, improving the ability to predict recurrence after definitive treatment of localized disease could prompt studies of adjuvant therapies or enhanced surveillance strategies and may be useful to add to known prognostic scores[81-84] for risk-stratifying patients in clinical trials.

Predicting response to therapy. Understanding some of the limitations of a purely prognostic biomarker, a number of investigators have sought to use liquid biopsies to inform the decision about whether to give a particular therapy. Perhaps the most research to date in prostate cancer has focused on the ability to predict response to next-generation hormonal therapy such as abiraterone acetate and enzalutamide. Although both of these agents target the AR and have impressive clinical activity, approximately 20% of patients did not respond to treatment.[85,86] Preclinical work has shown that alternative splicing of the AR messenger RNA can lead to constitutively active forms of the receptor that are unable to bind ligand and are therefore generally insensitive to AR ligand blockade or other forms of hormonal manipulation.[87,88] The detection of these AR splice variants in CTCs has been investigated in a number of contexts using multiple platforms, and the presence of a specific, relatively abundant form called AR variant 7 (AR-V7) was shown to independently predict resistance to abiraterone and enzalutamide in multiple different cohorts of men with mCRPC.[19,21,51] Importantly, in these studies and others, the presence of AR-V7 did not predict responsiveness to taxane-based chemotherapy, demonstrating its specificity as a marker for AR inhibitor resistance, rather than a marker of overall poor prognosis.[89] Multiple assays to identify AR-V7 in CTCs are currently in commercial development.

Beyond AR-V7, a number of recent efforts have sought to characterize the AR more comprehensively using liquid biopsies. In one study, investigators were able to use NGS to sequence informative regions of the AR using plasma

ctDNA in 97 men with mCRPC.[18] They detected both AR copy gain and point mutations and saw the emergence of nonsynonymous (protein-altering) mutations in 13% of patients whose disease was progressing on abiraterone. The presence of pre-existing AR gain was also associated with resistance to abiraterone and shorter overall survival. A similar study collected plasma ctDNA from 62 patients with mCRPC whose disease was progressing on therapy.[20] These investigators observed that AR amplification was more common in patients with enzalutamide-resistant disease, and detected potentially significant AR mutations in 18% of patients. Patients with these aberrations seemed to have less profound PSA declines and shorter times to radiographic progression. Other studies have described similar findings, including through the analysis of AR transcripts contained in exosomes.[90,91] Taken together, these recent studies highlight the potential for analysis of liquid biopsies to inform specific treatment decisions for patients with mCRPC.

Moving beyond the AR, recent studies have shown that PARP inhibition has activity in men with mCRPC whose tumors harbor mutations in key DNA repair genes such as *BRCA1*, *BRCA2*, *ATM*, and others.[9] Recent studies have also shown that these mutations are detectable in CTCs in men with mCRPC, and their presence appears to correlate with response to PARP inhibition.[92] If confirmed, these findings could offer clinicians a noninvasive means to identify patients for treatment and potentially monitor for the development of resistance. Indeed, serial monitoring of response to therapy using liquid biopsies has shown promise in multiple other malignancies, including in lung cancer, where a liquid biopsy can predict the development of resistance to EGFR- or ALK-targeted therapy,[93,94] and in colorectal cancer, where mutations in KRAS have been documented in the circulation well in advance of clinical resistance to EGFR-targeted therapy.[95]

Discovery of novel targets. Perhaps the most immediate use for liquid biopsies is to personalize therapy by generating an individual tumor profile to identify targets for therapy. Recent transcriptomic analysis of single cell mCRPC CTCs has highlighted the importance of noncanonical WNT signaling in resistance to hormonal therapy[96] and could spur the development of therapeutic strategies aimed at this pathway. Currently, multiple commercial assays are available that profile ctDNA and provide the clinician with list of mutated or aberrant genes.[60,93] This approach parallels what is currently underway with solid tissue biopsies, in which targeted sequencing can identify oncogenic and potentially actionable mutations.

Although generating a personalized genomic profile of a patient's tumor using a liquid biopsy represents a step forward for precision medicine, it should be emphasized that this approach comes with both costs and benefits. The clear benefit is the identification of a therapeutic target that would not otherwise be found and may provide the rationale for using "off-label" treatment for an individual patient, potentially to their benefit. The risk to this approach is that it is still not known if the vast, unbiased genetic information provided is worth the added cost and potentially serious side effects associated with assigning patients to unproven therapy without appropriate study in clinical trials.[97] Additionally, given recent evidence that only about one-half of genetic findings between matched solid and liquid biopsies were concordant, caution should be used to avoid acting on a potentially false-positive call.[42] Given that the trend toward personalized medicine is well underway, future studies must validate this approach to better understand its clinical utility.

DIRECTIONS FOR THE FUTURE

Moving beyond straightforward CTC enumeration, recent work has shown that it is possible to identify tumor heterogeneity,[50] identify a neuroendocrine phenotype,[98] profile transcriptomic changes in tumor-derived exosomes[99] (cell-derived vesicles that contain tumor protein and RNA), and use CTCs as a surrogate for survival in clinical trials.[100] Although still in early stages, these all have potential to improve our ability to better assign therapy but need validation in appropriately designed cohorts with clear clinical endpoints. As the cost of genetic sequencing continues to decline[101] and the number of actionable targets in prostate cancer increase,[102] the ability to rapidly obtain personalized genomic information about an individual patient in a minimally invasive way will be critical to delivering better care.

Screening and Treating Prostate Cancer in the Older Patient: Decision Making Across the Clinical Spectrum

Alicia K. Morgans, MD, MPH, William Dale, MD, PhD, and Alberto Briganti, MD, PhD

OVERVIEW

Treatment of the growing geriatric patient population is increasingly being recognized as a necessary priority of the oncology community. As the most common cancer among men in developed countries, prostate cancer afflicts a sizable portion of elderly men. Caring for this population requires knowledge of aspects of disease presentation, screening strategies, treatment approaches, and survivorship care considerations unique to the geriatric population. In this article, we review characteristics of prostate cancer screening and treatment decision making for localized disease in elderly men, including a discussion of the biology of disease in the elderly population. We also review best practices for providing treatment for localized and recurrent disease in an elderly population, including engaging in a basic geriatric assessment to determine fitness for treatment, eliciting information about patient preferences and support systems, and balancing treatment decisions in the context of these factors using the resources of a multidisciplinary care team. We then consider complications of prostate cancer survivorship related to systemic treatment in the elderly population of men with this disease. Finally, we emphasize the importance of engaging patients in treatment decision making across the spectrum of disease to personalize treatment plans and provide optimal care.

It is expected that between 2012 to 2050 the population older than age 65 in the United States will nearly double, increasing from 43.1 to 83.7 million, making up approximately 20% of the overall population (Fig. 1).[1] Prostate cancer is the most common cancer among men in developed countries, and the incidence of prostate cancer increases with age.[2,3] Given the aging population, the incidence of prostate cancer in the United States alone is expected to climb as high as 382,000 diagnoses annually in 2030—nearly 2.5 times higher than the expected 161,360 diagnoses in 2017.[2,3] Therefore, providing expert screening, treatment, and long-term survivorship care for the aging prostate cancer population is paramount as we move into this era.

Evidence suggests that although technological advances have improved cancer survival outcomes overall, not all populations appear to experience the same degree of improvement.[4] In particular, an analysis of Surveillance, Epidemiology, and End Results (SEER) data for patients with prostate cancer by age found that although younger men had noteworthy improvements in survival during the past decade, survival has not improved significantly in men age 75 and older.[4] It is postulated that the reason for this is multifactorial, including different prescribing patterns by age group. This is compounded by a lack of clinical trial data specific to the older patient population and provider concerns about extrapolating data to elderly patients with a poorer functional status and a greater number of comorbidities. Further, patient preferences to maximize quality of life as they age may lead them to decline more toxic treatments despite a possible survival benefit. Whether because of provider decisions or patient preferences, this disparity in outcomes by age provides an opportunity to improve health outcomes among the elderly prostate cancer population.

In this article, we review aspects of screening, initial treatment, treatment of recurrence, and survivorship care specific to the elderly prostate cancer population, with a focus on risk-adapted decision strategies throughout the spectrum of disease.

PROSTATE CANCER PREVALENCE AND AGGRESSIVENESS IN ELDERLY PATIENTS: THE IMPORTANCE OF PATIENT ASSESSMENT

There is increasing evidence that older patients have a higher risk of being affected not only by prostate cancer but also by more aggressive disease as compared with their younger counterparts. In an autopsy study of men with no previous history of prostate cancer, 45% of men age 70 or older or were affected by prostate cancer, compared with 19% of men younger than age 70.[5] Furthermore, older men were

more likely to have higher stage disease (pT3: 21% vs. 3.8%) and more poorly differentiated tumors (Gleason score ≥ 7: 42% vs. 15% in older vs. younger men, respectively).[5] The association between age and prostate cancer aggressiveness has also been confirmed in several retrospective series that demonstrated higher rates of progression and cancer specific mortality in elderly men when compared with their younger counterparts.

When determining a treatment plan for elderly men with prostate cancer, the higher rates of aggressive prostate cancer at presentation should be considered in the context of the overall patient health and comorbidity status to minimize the risk of under- or overtreatment. There is general consensus that the diagnostic and therapeutic clinical decision-making process should not be based on chronologic age, but on biologic aging and health status. To accomplish this, recently released guidelines have suggested using a stepwise process for treatment decision making that incorporates multiple patient parameters, including age, patient comorbidity profile, cognitive and neurologic function, and nutritional status.[6] Such a comprehensive assessment should be performed to properly classify elderly patients into different prognostic groups, namely healthy or fit, frail, disabled or patients with severe comorbidities, and the terminally ill.[6] This classification is key to properly selecting the most appropriate personalized treatment strategy for an individual patient.

Are Screening and Early Diagnosis Justified?

Currently, screening for prostate cancer is one of the most controversial topics in urologic literature. Based on conflicting results coming from large, randomized controlled trials, many scientific societies and groups have taken different positions.[7-11] Although the U.S. Preventive Services Task Force currently recommends against routine screening for men of any age group,[9] many medical and urologic societies suggest offering individualized risk-adapted strategies to well-informed men.[7,10] Such an approach should be multifactorial, including patient age, family history of prostate cancer, and baseline prostate-specific antigen (PSA) values, to maximize the benefit of screening while limiting the risk of over-detection. All available recommendations underline the importance of correctly informing men of the uncertainties, harms, and potential benefits associated with prostate cancer screening.

With regard to specific recommendations in the elderly population, general consensus exists against routine screening in men with a life expectancy of less than 10 to 15 years because the expected mortality benefit from screening is estimated to occur years after the initial screening.[8,10-13] The decision not to screen men with a shorter life expectancy is primarily a consequence of the long natural history of untreated localized prostate cancer and the impact of competing causes of death.[14,15]

In elderly men with a longer life expectancy, the potential benefit of prostate cancer screening remains unclear. In the recently released European Randomized Study of Screening for Prostate cancer (ERSPC) trial, there was no benefit to screening men age 70 or older, although no screening study has been specifically restricted to elderly patients only.[12] Because subgroup analyses of cohorts included in large trials cannot provide the quality of evidence needed to definitively address clinical questions, the real effect of routine screening in the elderly population remains to be proven. Therefore, although some men older than age 70 have a life expectancy of less than 10 to 15 years and may benefit from PSA screening, the quantitative evidence defining the magnitude of benefit in this age group is limited.

Given the complexity of the decision and the heterogeneity of the patient population, the life expectancy of elderly men should be estimated prior to informing them of the harms and benefits of risk-adjusted PSA screening and early detection. This is of particular importance in the context of a higher incidence of aggressive disease in this patient population. Several validated predictive models developed in community-dwelling elderly patients based on age, gender, body mass index, functional status, and comorbidities can be used to assess patient life expectancy.[16,17]

KEY POINTS

- **Older adults are much more likely to have other comorbidities and chronic conditions, which can impact the biology of their disease and influence decisions about screening and treatment of early prostate cancer.**
- **Older men must have an RLE greater than 10 to 15 years to consider screening for prostate cancer, and those with longer RLE should have an informed, shared discussion about their treatment goals with their physician.**
- **Treatment decisions for elderly patients with prostate cancer should include consideration of a patient's fitness for treatment, an estimate of RLE, a review of cancer aggressiveness, and a discussion of patient preferences and expectations.**
- **Engaging a multidisciplinary team to provide care to the elderly prostate cancer population is an ideal way to provide the medical, physical, and social supports necessary to meet the unique needs of this patient population.**
- **Systemic treatment with androgen-deprivation therapy can result in long-term complications, including osteoporosis and fracture, cardiovascular disease, diabetes, and cognitive impairment, which can increase morbidity and mortality in the elderly patient population.**

Who Are the Optimal Candidates for Treatment of the Primary Tumor?

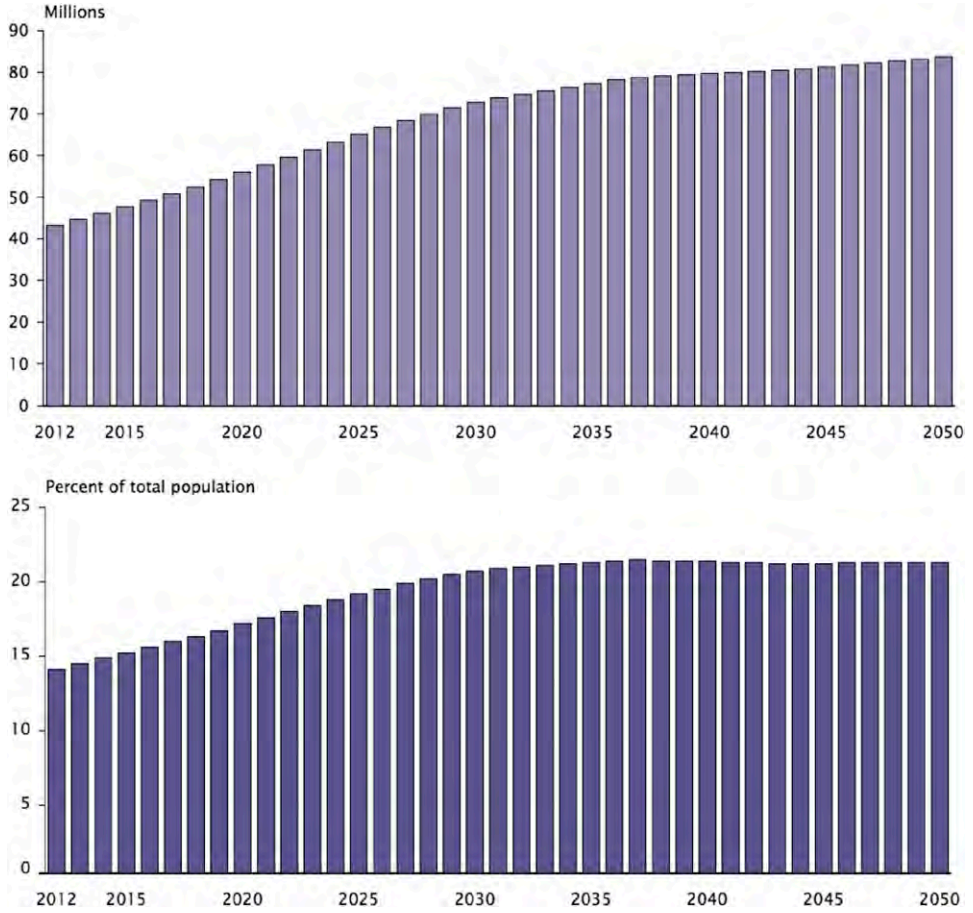
Once elderly patients diagnosed with prostate cancer are thoroughly assessed and deemed fit for treatment with a life expectancy of 10 years or longer, the standard treatment algorithm for younger patients can be followed. Although subanalyses coming from prospective randomized trials should always be interpreted with caution, it seems that the effect of treatment of the primary tumor is not significantly

affected by patient age. In the Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4) study, although the highest benefit of radical prostatectomy was seen in younger men, surgery was associated with reduced risk of metastases in men age 65 or older (p = .04).[18] Similar results were obtained in the subanalysis performed in older men included in the Prostate Cancer Intervention versus Observation Trial (PIVOT) using metastasis-free survival as an endpoint.[19] Furthermore, in the recent Prostate Testing for Cancer and Treatment (ProtecT) trial, the number of deaths from prostate cancer was similarly low across all age groups regardless of treatment arm.[20] Taken together, these results indirectly suggest a role for primary treatment in older men with adequate life expectancy.

In addition to considering life expectancy, the indication for primary treatment in elderly patients should be individualized according to prostate cancer features. The highest benefit of primary treatment seems to be expected in men with more aggressive prostate cancer features, even among elderly patients.[21] Results coming from studies including patients treated with noncurative intent have shown that older men with high-risk prostate cancer (i.e., PSA ≥ 20 ng/mL, biopsy Gleason score of ≥ 8, or a clinical stage ≥ T2c) have a substantial risk of dying from the disease.[7] A nationwide study in Sweden showed that among patients age 75 or older with Gleason scores 7 or higher who are treated conservatively, prostate cancer was the leading cause of death.[22] Similarly, in another population-based cohort study including men with localized prostate cancer diagnosed between 1971 and 1984, men older than age 70 with Gleason scores 8 or higher who were managed conservatively had a 64% chance of dying of their disease.[23]

However, despite these data, too few elderly men with high-risk prostate cancer receive curative treatment. An analysis of different age groups in the United States demonstrated that a minor proportion of men age 75 or older were treated with radical prostatectomy, including those with high-risk disease. Less than half of these men received any form of radical treatment, compared with 90% of patients age 74 or younger.[24] A study of the U.S. Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) database reported that, of the 11,790 men included in the analysis, up to 60% of men older than age 75 were conservatively treated.[25] Regardless of their risk score, older men were more often treated with androgen-deprivation therapy (ADT) compared with their younger counterparts. Interestingly, even after accounting for confounders, older men (> age 70) with high-risk tumors receiving local therapy had

FIGURE 1. U.S. Census Projected Population Age 65 and Older From 2012 to 2050 in Millions and as Percentage of Total Population[1]



a 46% reduction in mortality compared with those treated conservatively. Similar results were reported in Europe.[25]

Taken together, these data suggest possible undertreatment among elderly men, perhaps because of the assumption that they will die of other causes than prostate cancer. This has been disproven in men with high-risk disease. Conversely, older patients with low/very low–risk disease are likely good candidates for active surveillance. Although this occurs because of the natural course of the disease and the impact of competing causes of death, increasing evidence suggests that patient age is a negative prognostic factor for men affected by prostate cancer and initially treated with active surveillance.[26] Older men undergoing active surveillance are indeed at higher risk of disease reclassification and progression over time. These findings were confirmed when a population of patients suitable for active surveillance but treated with radical prostatectomy was analyzed: patient age was a significant predictor ($p < .05$) of unfavorable prostate cancer at final pathology.[27,28] Ultimately, fit elderly men initially treated with active surveillance should be properly counseled from the beginning about their higher risk of disease reclassification and progression over time. Frank conversations about the risks and benefits of active surveillance compared with active treatment should be conducted.

Prostate cancer features in elderly patients: Lead-time bias or biology? Two possible explanations may be used to explain the more aggressive tumor characteristics and higher risk of recurrence in elderly patients. The first is lead-time bias: the onset of prostate cancer in specific categories of elderly patients may be similar to their younger counterparts, but the presence of a greater number of adverse features in the tumor can be simply related to a delayed diagnosis.[29,30]

On the other hand, the intrinsic biology of tumor cells and their relationship with cellular aging process may play a more important role. Indeed, the phenomenon of tumor senescence has been emphasized by several studies.[31] Cellular senescence is essentially an irreversible arrest of cell proliferation and growth that occurs when cells are exposed to potentially oncogenic stress. As an example, cellular senescence can be potentially induced by telomere shortening,[32,33] genomic damage,[34,35] mitogens and proliferation-associated signals,[36,37] epigenomic damage,[38,39] and activation of tumor suppressors.[38,40]

Despite the arrest of cell proliferation, an important feature of many senescent cells is the senescence-associated secretory phenotype (SASP), which includes a large number of cytokines, chemokines, growth factors, and proteases. The SASP is probably the most impressive feature of senescent cells because it has the potential to explain the role of cellular senescence in aging and hyperplastic pathologies.[41,42] Important evidence comes from xenograft studies, where co-injection of senescent, but not nonsenescent, fibroblasts significantly ($p < .05$) stimulated the proliferation of mouse and human epithelial tumor cells in immune-compromised mice. This stimulation is partially because of soluble factors produced by senescent cells.[43,44] Of particular importance are the SASP components stromelysin (MMP3),[44] which also promotes tumor cell invasion, and VEGF,[45] which promotes tumor-driven angiogenesis.

In addition to stimulating tumor growth in mice, SASP factors can stimulate malignant phenotypes in cultures. One such phenotype is the epithelial-to-mesenchymal transition, which enables transformed epithelial cells to invade and migrate through tissues and is critical in the development of metastatic cancer.[46,47] Senescent cells may also promote cancer initiation. Indeed, an important feature of the SASP is the ability to cause inflammation, stimulating the infiltration of leukocytes, which produce reactive toxic moieties that can cause DNA damage.[48,49] The picture that emerges is that senescent cells accumulate with age, creating a microenvironment that is permissive for the development and progression of cancer. This hypothesis represents one of the possible explanations for the adverse characteristics that are usually observed in elderly patients affected by prostate cancer.

CARE CONSIDERATIONS FOR OLDER MEN WITH RECURRENT PROSTATE CANCER

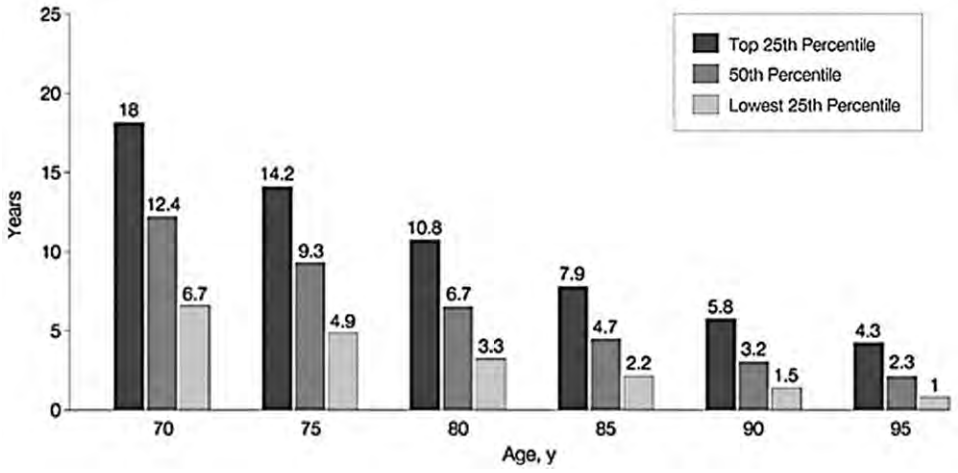
Treating older men with prostate cancer—whether early in the course of disease, after recurrence, or during the later stages—appropriately first requires staging the cancer and then "staging the aging."[50] A clinician must balance the risks from treating the disease with the risks of not treating it, weighing a patient's remaining life expectancy (RLE) against the likely progression of the cancer. This must be done while considering the impact of potential treatment options on the disease and further considering the impact of toxicities on the aging individual.[51] Individualizing care for older adults therefore uses care strategies from both oncology and geriatrics. Systematically using those strategies is the core of an integrated approach to caring for older men with prostate cancer. To illustrate this approach, this section focuses on older men with early disease recurrence.

The first evidence of disease recurrence following initial treatment is a rising PSA on a surveillance blood test in an asymptomatic patient, typically referred to as biochemical recurrence.[52] This occurs in approximately 25% to 40% of men initially treated with surgery or radiation.[53] In such a situation, clinicians often consider initiating ADT. However, there is a paucity of evidence confirming that ADT prolongs life or reduces side effects in this clinical situation.[54] Furthermore, ADT is associated with numerous side effects, including osteoporosis, sarcopenia, falls, fractures, and frailty—complications that can be detrimental both in the short and long term for elderly patients.[55] Current guidelines suggest the use of ADT for biochemical recurrence only in a small proportion of highly selected men with adequate life expectancy.[56] How should a clinician make the decision to pursue immediate treatment or to delay it in the setting of elderly patients?

Use of Geriatric Assessment

From an aging perspective, there are, broadly speaking, two important clinical considerations when making treatment

FIGURE 2. Upper, Middle, and Lower Quartiles of Life Expectancy for Elderly Men at Selected Ages



Adapted from Walter et al.[57]

choices for older patients with cancer: (1) what is the patient's RLE, independent from their cancer-based prognosis? and (2) what resources are needed to maximize functional status and quality of life?[57] (Fig. 2). Fortunately, both of these can be objectively ascertained through the use of a geriatric assessment, which then can be used to make decisions about when to offer cancer-directed therapy, as well as which referrals, interventions, and resources may optimize quality of life.

RLE can be assessed in a number of ways using elements from geriatric assessment. The primary goal is to ascertain in which of three groups a given patient belongs: fit, vulnerable, or frail. If an older patient is found to be fit, with a long RLE, then cancer treatment timing should be indistinguishable from younger adults. If found to be frail, then cancer treatment—especially treatments with high toxicity like ADT—should be started only when absolutely necessary to help improve quality of life. For those found to be vulnerable, with shorter RLE, but not fully frail, more nuanced approaches to choosing treatments are required. Fortunately, the geriatric assessment can also be used to guide this approach.

Broadly speaking, geriatric assessment is grouped into a number of health domains, including physical health (e.g., comorbidities, nutritional status), mental health (e.g., depression, cognitive impairment), functional health (e.g., instrumental activities of daily living), symptoms (e.g., pain, shortness of breath), and social health (e.g., caregiving support, social networks; Table 1).[58] Each of these domains can identify those areas in which patients are in greatest need of support. Resources can be targeted to those domains found to be in need on a geriatric assessment. Geriatric oncology experts in both the United States and Europe have agreed on which of these domains are of greatest importance to be acted on when deficits are identified.[59,60]

Putting It Together

Once an older man with recurrent prostate cancer has undergone a geriatric assessment, a treatment strategy can be devised.[61] Based on the projected risk of disease progression—using a combination of Gleason score, PSA doubling time, and time to relapse—and a geriatric assessment for assessing RLE and areas needing to be addressed, decision making about care plans can be performed. While formulating a treatment plan, it is critical to consider an individual patient's preferences for care. Even after a thorough medical assessment of the patient, shared decision making requires clear communication about the treatment options that may be medically available, as well as the integration of patient values when choosing treatment options.

In summary, a five-step process for making appropriate treatment decisions for older patients is as follows:

1. A cancer-based prognosis with and without treatment (i.e., staging the cancer)
2. An aging-based prognosis separate from cancer-based prognosis (i.e., staging the aging)
3. Identification of resources needed to maintain independence using a geriatric assessment and targeting interventions to match those needs
4. Ascertainment of the patient's preferences and values for care
5. Communication of the available options to the patient

Considering a 75-year-old man with biochemical recurrent prostate cancer, such a decision-making process might go as follows: First, an assessment of the risk of cancer reveals that he has Gleason (3 + 4; 7) disease, no evidence of bone metastases on imaging, a PSA doubling time of 8 months, and a time to recurrence of 3 years. These factors place him in a moderate-risk category when staging the cancer. Second, a geriatric assessment places him in the lowest 25% and gives him a noncancer RLE of about 6 years. Among the deficits identified are weakness based on a low score on physical performance, difficulties in managing his money and cooking, and poor social support since his wife died last year. Throughout the process, the physician investigates the patient's preferences and learns that he wishes to remain living independently at home in his apartment. His geriatric

oncologist chooses to delay the start of ADT out of concern for further loss of strength and loss of independence. She also arranges for the patient to receive physical therapy at a nearby facility and engages with social work to arrange Meals on Wheels and help with his finances. This team then identifies a daughter who lives nearby who can arrange a pillbox every week and help cook some meals. The doctor orders a dual energy x-ray absorptiometry scan to assess for osteoporosis and initiates bisphosphonate therapy in anticipation of starting ADT in the future. Thus, a multidisciplinary, integrated care plan commences that combines appropriate cancer care and a functional-centered approach compatible with the patient's preferences.

PHYSICAL AND COGNITIVE EFFECTS OF SYSTEMIC THERAPY IN ELDERLY MEN WITH PROSTATE CANCER

It is estimated that 40% to 50% of the men living with prostate cancer in the United States will received systemic treatment with ADT during the course of treating their disease.[62] In addition to hot flashes, erectile dysfunction, and loss of libido that noticeably affect patients shortly after starting ADT, this treatment causes numerous other more insidious physical and cognitive complications that negatively impact morbidity and mortality in men with prostate cancer. With an average age of diagnosis of 66 and a 5-year survival of 99% overall, many of the men exposed to ADT and its side effects are elderly. Despite the tendency for older men to have more aggressive disease, they are still more likely to die of comorbid illness rather than prostate cancer itself.[63] Considering the burden of treatment effects on men, the potential increase in mortality from comorbid conditions, such as diabetes, cardiovascular disease, and falls, and the risk of disease progression are critical aspects of treatment decision making for the elderly prostate cancer population.

Osteoporosis and Risk of Fracture

Though osteoporosis is commonly considered a disease of elderly women, one-quarter of all hip fractures occur in elderly men, and the lifetime risk of fracture in men over age 50 is 27%.[64-67] The mortality risk in the year after hip fracture is higher among men than women, ranging from 30% to 35%, compared with 17% to 22% for women.[66,68,69] This increased risk of mortality persists after the first year when individuals are compared with age-matched controls without a fracture, and the risk in men exceeds that of women at any given age.[69,70] In addition to mortality, hip fracture is a major cause of loss of mobility and independence in the elderly, and it comes with a high financial burden.[69,71,72]

ADT causes a decline in bone mineral density (BMD), eventually leading to osteoporosis and increasing the risk of fracture.[73-77] Evidence from prospective studies suggests that within the first year of treatment, BMD typically decreases by approximately 2% at the hip and 3% at the lumbar spine (range 0.7%–3.3% and 1.4%–3.3% at the hip and lumbar spine, respectively).[78-80] This decline in BMD is associated with an increased rate of fracture in several population-based studies.[76,77] In a SEER-Medicare analysis including over 50,000 men, the rate of developing a fracture in the 5 years after diagnosis of prostate cancer was

TABLE 1. Common Geriatric Assessment Tools, Based on Data From Balducci et al[58]

Tool	Description
Mini Nutritional Assessment (MNA)	A validated nutrition screening and assessment tool used to identify geriatric patients age 65 or older who are malnourished or at risk for malnutrition
Mini Mental State Examination (MMSE)	A brief, quantitative measure of cognitive status in adults that serves as a screen for cognitive impairment and to estimate the severity of cognitive impairment at a given point in time; the MMSE can be used to follow cognitive changes over time.
Geriatric Depression Scale (GDS)	A basic screening measure for depression in older adults
Activities of Daily Living (ADLs), Instrumental Activities of Daily Living (IADLs)	ADLs: Measures of a person's daily functioning, reflecting the things we normally do in daily living, including any daily activity we perform for self-care IADLs: Measures of activities that allow an individual to live independently in a community
Barthel Index	Ten items that measure a person's daily functioning, specifically ADLs and mobility; the Barthel Index can determine a baseline level of functioning and monitor improvement in ADLs over time.
Eastern Cooperative Oncology Group (ECOG) Performance Status	Criteria used to quantify how the disease affects the patient's daily living abilities
Cumulative Illness Rating Scale for Geriatrics (CIRS-G)	A tool to measure comorbidity that reflects chronic medical illness burden including the severity of chronic diseases; the CIRS-G is a revised version of the original measure that reflects common problems of elderly people, and it was validated in a geriatric residential population.
Euro-QoL 5D (EQ-5D)	A standardized instrument to measure health outcomes for a wide range of health conditions and treatments; it provides a simple descriptive profile and a single index value for health status.
Pain Visuo-Analogic Scale	An instrument that measures a continuum of pain values
Short Physical Performance Battery (SPPB)	An objective assessment tool for evaluating lower extremity functioning in older persons
Vulnerable Elders Survey (VES 13)	A function-based tool for screening community-dwelling populations to identify older persons at risk for health deterioration
Senior Adult Oncology Program (SAOP2)	A screening tool to identify elderly persons at risk for disabilities

19.4% in men treated with ADT compared with 12.6% in unexposed men.[76] A similar analysis in a random 5% sample of Medicare participants with nonmetastatic prostate cancer found a relative risk of any form of clinical fracture of 1.21 (95% CI, 1.14–1.29; p < .001) for men exposed to ADT compared with unexposed men.[77]

Guidelines suggest that men receiving treatment with ADT should initiate screening with bone density scans and treatment with osteoclast inhibitors to prevent fractures when appropriate.[81] Clinicians should consider using osteoclast-inhibiting therapy to prevent the decline of BMD for men with a 10-year probability of hip fracture 3% or greater or with a 10-year probability of major osteoporosis-related fracture 20% or greater.[81] Although bone density scans are recommended to make this assessment of fracture risk more precise, rates of screening for osteoporosis among men is low overall (14.5% of men initiating ADT in 2007–2009), and it decreases in the elderly (odds ratio [OR] 0.76% in ≥ 85 years vs. 66–69 years).[82] This is particularly concerning in the elderly prostate cancer population, which may be at risk for fracture because of systemic treatment of prostate cancer and higher risk of mechanical falls because of aging. A recent study of 363 men seen at a single academic center found that 3.3% of men age 70 or younger are at high enough risk for fracture to meet criteria for osteoclast-inhibiting treatment, whereas 76.6% of men between ages 70 and 79 and 98.8% of men over age 80 meet the criteria.[83] Though older men are at higher risk of fragility fracture, they are being screened for intervention at a lower rate.[82] Finally, it is also important to recognize that although they do not experience fractures as commonly as white men, black men experience a similar rate of BMD decline with ADT and should take similar precautions to avoid skeletal complications, particularly with long-term exposure to ADT.[84]

Obesity and Sarcopenia

Approximately 41% of American men between ages 65 and 75 meet criteria for obesity—a condition associated with excess mortality in elderly individuals.[85,86] In men with prostate cancer, 1 year of exposure to ADT was associated with increasing rates of obesity, with a 10% increase in fat body mass and a 3% decrease in lean body mass.[87,88] In particular, subcutaneous abdominal adipose tissue increases with ADT exposure, raising the risk of cardiovascular disease, diabetes, and death.[89-92] Specific guidelines describing the optimal strategy to prevent the development of obesity during treatment with ADT have not yet been developed. Despite that, it is important to discuss this complication in conjunction with information on maintaining an active lifestyle and heart-healthy diet when making treatment decisions in the elderly prostate cancer population to prevent obesity and associated diabetic and cardiovascular complications.

Impaired Insulin-Sensitivity and Diabetes

The prevalence of diabetes in the United States is 29.1 million, with 20.1 million diagnosed and 8.1 million undiagnosed.[93] Diabetes is the seventh leading cause of death in the United States, and it is likely that its impact on mortality is underreported.[93] Risk factors for developing diabetes in the general population include obesity and increasing age.[93]

ADT is associated with the development of insulin resistance, a condition that in turn increases the risk of diabetes.[92,94-96] In a small prospective study of 25 men with locally advanced or recurrent prostate cancer without diabetes initiating treatment with ADT, there was a decrease in insulin sensitivity as early as 12 weeks after starting treatment (insulin sensitivity index decreased by 12.9 +/− 7.6%; p = .02).[94] Three population-based analyses demonstrate an association between ADT and an increased rate of developing diabetes.[97-99] A SEER-Medicare analysis of 73,196 men with locoregional prostate cancer found an adjusted hazard ratio (HR) for developing diabetes of 1.44 (p < .001), suggesting that exposure to ADT increased the risk of diabetes by 44%.[97] This association was validated in a Canadian matched cohort study including 38,158 men, 50% of whom were treated with ADT.[99] The HR for men exposed to ADT was 1.16 (95% CI, 1.11–1.21).[99] In a cohort of 37,443 veterans, treatment with ADT was associated with an increased risk of incident diabetes (adjusted HR 1.48; 95% CI, 1.31–1.67).[98]

Importantly for elderly men considering treatment of prostate cancer, the risk of developing diabetes during treatment with ADT appears to increase with age. A recent study of 2,985 men without baseline diabetes enrolled in a prospective clinical trial suggests that there is a synergistic relationship between ADT and increasing age such that the risk of diabetes increases with each year in age after 76 (OR 2.1; 95% CI, 1.0–4.4).[100] The study failed to find an association between diabetes and ADT exposure in men younger than age 76.

Cardiovascular Complications

Cardiovascular disease is the leading cause of death among American men, with 25% of deaths in the United States attributable to heart disease.[101] Both increasing age and male gender increase the risk of cardiovascular complications.[102,103] Treatment with ADT has been associated with the development of cardiovascular disease in multiple studies, though others fail to find a relationship.[97,104-106]

One population-based SEER-Medicare study included 73,196 men older than age 66 with locoregional prostate cancer.[97] Treatment with ADT was associated with an increased risk of sudden cardiac death (HR 1.16; p = .04), myocardial infarction (HR 1.11; p = .03), and new diagnosis of heart disease (HR 1.11; p < .001).[97] A subsequent SEER-Medicare study of 22,816 men age 65 or older with any-stage prostate cancer found a 20% increased risk of cardiovascular morbidity associated with ADT exposure.[104]

In contrast, several other analyses failed to find an association between ADT and cardiovascular disease. A Canadian-linked administrative database compared 19,079 men older than age 66 with prostate cancer who were treated with 6 or more months of continuous ADT with age-matched controls with prostate cancer not treated with ADT.[99] There was no association between ADT and the risk of

cardiovascular disease (HR 0.91; 95% CI, 0.84–1.00). Multiple Radiation Therapy Oncology Group prospective studies have been assessed retrospectively to evaluate cardiovascular morbidity and mortality and failed to find an association between treatment with ADT and cardiovascular disease despite long-term follow-up.[105-108]

The relationship between ADT and cardiovascular disease may affect specific populations more than others, and elderly men may be at higher risk than their younger counterparts.[100,109-111] Several studies suggest that increasing age is associated with an increased risk of cardiovascular disease.[100,110,111] In one prospective study including 3,112 men with localized prostate cancer without baseline cardiovascular disease, there was a synergistic association between increasing age, ADT exposure, and cardiovascular disease, with risk of cardiovascular disease increasing at age 74 (OR 1.9; 95% CI, 1.0–3.5) and with each year of age thereafter.[100] In a population-based study of 3,262 men treated with ADT after prostatectomy, ADT was associated with increased cardiovascular disease only among men older than age 65.[110] A meta-analysis of three studies including men treated with radiation and ADT also found an association between ADT and cardiovascular disease in men older than age 65 but not in younger men.[111] In addition to age, a SEER-Medicare analysis of men with prostate cancer found an increased risk of cardiovascular disease in men treated with ADT with a history of cardiovascular disease at baseline (HR 1.09; 95% CI, 1.02–1.06).[109] This is especially important when treating elderly men with prostate cancer because of the increased risk of cardiovascular disease with increasing age.

Elderly men with pre-existing cardiovascular disease may be at the highest risk of future morbid or fatal cardiac events.[109] In practice, ADT should be avoided when its use is not supported by evidence. Additionally, engaging with other specialties to provide multidisciplinary care is critical. By including primary care physicians and cardiologists to identify and treat patients with risk factors associated with cardiovascular disease, we may reduce the chance of potentially catastrophic cardiovascular complications in the elderly prostate cancer population.[112]

Cognitive Complications

Controversy exists regarding whether ADT is associated with cognitive decline in elderly men with prostate cancer. However, several recent studies suggest that ADT is associated with cognitive decline, Alzheimer disease, and other forms of dementia. In a prospective study of 58 men with locoregional prostate cancer receiving ADT, 84 age-matched controls with prostate cancer not receiving ADT, and 88 men without cancer, ADT was associated with cognitive impairment at 12 months ($p < .001$).[113] A smaller prospective study included 29 men with biochemical recurrent prostate cancer and assessed cognitive function before, during, and after intermittent ADT.[114] Participants experienced a reversible decline in working memory and spatial abilities.[114] A recent claims-based study of men with prostate cancer demonstrated an association between ADT exposure and risk of Alzheimer disease (HR 1.88; $p = .21$).[115] Increasing age was associated with an increased risk of developing Alzheimer disease (HR 1.06; 95% CI, 1.04–1.08, $p < .001$).[115] The same group subsequently found a similar association between duration of ADT exposure and development of an array of types of dementia in a second claims-based analysis (HR 2.17; 95% CI, 1.58–2.99; $p < .001$).[116] A recent meta-analysis of 14 studies demonstrated a consistent decline in visuomotor task scores but failed to find a consistent decline in other cognitive domains across studies.[117]

Data from several other studies failed to find an association between ADT exposure and cognitive decline.[118,119] A Canadian group compared objective and subjective measures of cognitive function among 57 men with nonmetastatic prostate cancer treated with ADT and 51 healthy matched controls.[118] After a median duration of ADT of 1.8 years, there was no significant difference between groups in subjective or objective measures of cognitive function.[118] A second prospective cohort study included 77 men with nonmetastatic prostate cancer treated with ADT, 82 men with prostate cancer not receiving ADT, and 82 healthy controls over 36 months.[119] In this study with long-term follow-up, ADT was not associated with a decline in cognitive function.[119] Finally, a population-based study from the United Kingdom including a cohort of 30,903 men with non-metastatic prostate cancer failed to find an association between ADT exposure and duration of ADT exposure with dementia.[120]

The controversy regarding the association between cognitive decline and ADT is still being settled, and prospective studies that may establish a biologic rationale for cognitive change in the setting of low testosterone in the elderly prostate cancer population are necessary. One prospective study couples imaging with cognitive testing in men with metastatic castration-resistant prostate cancer randomly assigned to treatment with ADT and abiraterone acetate compared with enzalutamide in an effort to clarify a biologic rationale for the development of cognitive dysfunction in the setting of low testosterone signaling (NCT03016741). For the elderly population of men with prostate cancer, developing cognitive complications can limit independence, can lead to falls and functional decline, and may contribute to frailty. Considering whether patients may be at greater risk to experience cognitive decline should be an integral part of treatment decision making, particularly in settings in which ADT use is discretionary.

CONCLUSION

The incidence of diabetes, cardiovascular disease, osteoporosis, and dementia increase with age in the general population, and use of ADT in elderly men with prostate cancer puts them at a much higher risk than untreated men. However, clinicians must be aware of the increased risk of aggressive prostate cancer in this population and consider it in the context of the geriatric assessment or multidisciplinary team-based assessment of the patient's holistic fitness for more toxic treatments. Appropriate prevention,

screening, and referral strategies—particularly multidisciplinary strategies—are a critical part of caring for elderly men with prostate cancer receiving systemic hormonal therapy. In situations in which the use of ADT is discretionary, it is critical to consider the potential consequences of treatment when making treatment decisions. This is particularly important in the elderly population as seemingly trivial complications can be debilitating, permanently life altering, or fatal.
