Control System Advanced Methods

The Electrical Engineering Handbook Series

Series Editor

Richard C. Dorf

University of California, Davis

Titles Included in the Series

The Avionics Handbook, Second Edition, Cary R. Spitzer

The Biomedical Engineering Handbook, Third Edition, Joseph D. Bronzino

The Circuits and Filters Handbook, Third Edition, Wai-Kai Chen

The Communications Handbook, Second Edition, Jerry Gibson

The Computer Engineering Handbook, Vojin G. Oklobdzija

The Control Handbook, Second Edition, William S. Levine

CRC Handbook of Engineering Tables, Richard C. Dorf

Digital Avionics Handbook, Second Edition, Cary R. Spitzer

The Digital Signal Processing Handbook, Vijay K. Madisetti and Douglas Williams

The Electric Power Engineering Handbook, Second Edition, Leonard L. Grigsby

The Electrical Engineering Handbook, Third Edition, Richard C. Dorf

The Electronics Handbook, Second Edition, Jerry C. Whitaker

The Engineering Handbook, Third Edition, Richard C. Dorf

The Handbook of Ad Hoc Wireless Networks, Mohammad Ilyas

The Handbook of Formulas and Tables for Signal Processing, Alexander D. Poularikas

Handbook of Nanoscience, Engineering, and Technology, Second Edition,

William A. Goddard, III, Donald W. Brenner, Sergey E. Lyshevski, and Gerald J. Iafrate

The Handbook of Optical Communication Networks, Mohammad Ilyas and

Hussein T. Mouftah

The Industrial Electronics Handbook, J. David Irwin

The Measurement, Instrumentation, and Sensors Handbook, John G. Webster

The Mechanical Systems Design Handbook, Osita D.I. Nwokah and Yidirim Hurmuzlu

The Mechatronics Handbook, Second Edition, Robert H. Bishop

The Mobile Communications Handbook, Second Edition, Jerry D. Gibson

The Ocean Engineering Handbook, Ferial El-Hawary

The RF and Microwave Handbook, Second Edition, Mike Golio

The Technology Management Handbook, Richard C. Dorf

Transforms and Applications Handbook, Third Edition, Alexander D. Poularikas

The VLSI Handbook, Second Edition, Wai-Kai Chen

SECTION I Analysis Methods for MIMO Linear Systems

1 Numerical and Computational Issues in Linear Control and System Theory	1-1
<i>A.J. Laub, R.V. Patel, and P.M. Van Dooren</i>	
2 Multivariable Poles, Zeros, and Pole-Zero Cancellations	2-1
<i>Joel Douglas and Michael Athans</i>	
3 Fundamentals of Linear Time-Varying Systems	3-1
<i>Edward W. Kamen</i>	
4 Balanced Realizations, Model Order Reduction, and the Hankel Operator	4-1
<i>Jacquelin M.A. Scherpen</i>	
5 Geometric Theory of Linear Systems	5-1
<i>Fumio Hamano</i>	
6 Polynomial and Matrix Fraction Descriptions	6-1
<i>David F. Delchamps</i>	
7 Robustness Analysis with Real Parametric Uncertainty	7-1
<i>Roberto Tempo and Franco Blanchini</i>	
8 MIMO Frequency Response Analysis and the Singular Value Decomposition	8-1
<i>Stephen D. Patek and Michael Athans</i>	
9 Stability Robustness to Unstructured Uncertainty for Linear Time Invariant Systems	9-1
<i>Alan Chao and Michael Athans</i>	
10 Trade-Offs and Limitations in Feedback Systems	10-1
<i>Douglas P. Looze, James S. Freudenberg, Julio H. Braslavsky, and Richard H. Middleton</i>	
11 Modeling Deterministic Uncertainty	11-1
<i>Jörg Raisch and Bruce Francis</i>	

SECTION II Kalman Filter and Observers

12	Linear Systems and White Noise	12-1
	<i>William S. Levine</i>	
13	Kalman Filtering	13-1
	<i>Michael Athans</i>	
14	Riccati Equations and Their Solution	14-1
	<i>Vladimír Kučera</i>	
15	Observers	15-1
	<i>Bernard Friedland</i>	

SECTION III Design Methods for MIMO LTI Systems

16	Eigenstructure Assignment	16-1
	<i>Kenneth M. Sobel, Eliezer Y. Shapiro, and Albert N. Andry, Jr.</i>	
17	Linear Quadratic Regulator Control	17-1
	<i>Leonard Lublin and Michael Athans</i>	
18	\mathcal{H}_2 (LQG) and \mathcal{H}_∞ Control	18-1
	<i>Leonard Lublin, Simon Grocott, and Michael Athans</i>	
19	ℓ_1 Robust Control: Theory, Computation, and Design	19-1
	<i>Munther A. Dahleh</i>	
20	The Structured Singular Value (μ) Framework	20-1
	<i>Gary J. Balas and Andy Packard</i>	
21	Algebraic Design Methods	21-1
	<i>Vladimír Kučera</i>	
22	Quantitative Feedback Theory (QFT) Technique	22-1
	<i>Constantine H. Houppis</i>	
23	Robust Servomechanism Problem	23-1
	<i>Edward J. Davison</i>	
24	Linear Matrix Inequalities in Control	24-1
	<i>Carsten Scherer and Siep Weiland</i>	
25	Optimal Control	25-1
	<i>Frank L. Lewis</i>	
26	Decentralized Control	26-1
	<i>M.E. Sezer and D.D. Šiljak</i>	
27	Decoupling	27-1
	<i>Trevor Williams and Panos J. Antsaklis</i>	
28	Linear Model Predictive Control in the Process Industries	28-1
	<i>Jay H. Lee and Manfred Morari</i>	

SECTION IV Analysis and Design of Hybrid Systems

- 29 Computation of Reach Sets for Dynamical Systems 29-1
Alex A. Kurzhanskiy and Pravin Varaiya
- 30 Hybrid Dynamical Systems: Stability and Stabilization 30-1
Hai Lin and Panos J. Antsaklis
- 31 Optimal Control of Switching Systems via Embedding into Continuous
 Optimal Control Problem 31-1
Sorin Bengea, Kasemsak Uthaichana, Milos Žefran, and Raymond A. DeCarlo

SECTION V Adaptive Control

- 32 Automatic Tuning of PID Controllers 32-1
Tore Hägglund and Karl J. Åström
- 33 Self-Tuning Control 33-1
David W. Clarke
- 34 Model Reference Adaptive Control 34-1
Petros Ioannou
- 35 Robust Adaptive Control 35-1
Petros Ioannou and Simone Baldi
- 36 Iterative Learning Control 36-1
Douglas A. Bristow, Kira L. Barton, and Andrew G. Alleyne

SECTION VI Analysis and Design of Nonlinear Systems

- 37 Nonlinear Zero Dynamics 37-1
Alberto Isidori and Christopher I. Byrnes
- 38 The Lie Bracket and Control 38-1
V. Jurdjevic
- 39 Two Timescale and Averaging Methods 39-1
Hassan K. Khalil
- 40 Volterra and Fliess Series Expansions for Nonlinear Systems 40-1
Françoise Lamnabhi-Lagarrigue
- 41 Integral Quadratic Constraints 41-1
Alexandre Megretski, Ulf T. Jönsson, Chung-Yao Kao, and Anders Rantzer
- 42 Control of Nonholonomic and Underactuated Systems 42-1
*Kevin M. Lynch, Anthony M. Bloch, Sergey V. Drakunov, Mahmut Reyhanoglu,
 and Dmitry Zenkov*

SECTION VII Stability

- 43 Lyapunov Stability43-1
Hassan K. Khalil
- 44 Input–Output Stability44-1
A.R. Teel, T.T. Georgiou, L. Praly, and Eduardo D. Sontag
- 45 Input-to-State Stability45-1
Eduardo D. Sontag

SECTION VIII Design

- 46 Feedback Linearization of Nonlinear Systems46-1
Alberto Isidori and Maria Domenica Di Benedetto
- 47 The Steady-State Behavior of a Nonlinear System47-1
Alberto Isidori and Christopher I. Byrnes
- 48 Nonlinear Output Regulation48-1
Alberto Isidori and Lorenzo Marconi
- 49 Lyapunov Design49-1
Randy A. Freeman and Petar V. Kokotović
- 50 Variable Structure, Sliding-Mode Controller Design50-1
Raymond A. DeCarlo, S.H. Žak, and Sergey V. Drakunov
- 51 Control of Bifurcations and Chaos51-1
Eyad H. Abed, Hua O. Wang, and Alberto Tesi
- 52 Open-Loop Control Using Oscillatory Inputs52-1
J. Baillieul and B. Lehman
- 53 Adaptive Nonlinear Control53-1
Miroslav Krstić and Petar V. Kokotović
- 54 Intelligent Control54-1
Kevin M. Passino
- 55 Fuzzy Control55-1
Kevin M. Passino and Stephen Yurkovich
- 56 Neural Control56-1
Marios M. Polycarpou and Jay A. Farrell

SECTION IX System Identification

- 57 System Identification57-1
Lennart Ljung

SECTION X Stochastic Control

- 58 Discrete Time Markov Processes58-1
Adam Shwartz
- 59 Stochastic Differential Equations59-1
John A. Gubner
- 60 Linear Stochastic Input–Output Models 60-1
Torsten Söderström
- 61 Dynamic Programming61-1
P.R. Kumar
- 62 Approximate Dynamic Programming62-1
Draguna Vrabie and Frank L. Lewis
- 63 Stability of Stochastic Systems63-1
Kenneth A. Loparo
- 64 Stochastic Adaptive Control for Continuous-Time Linear Systems64-1
T.E. Duncan and B. Pasik-Duncan
- 65 Probabilistic and Randomized Tools for Control Design65-1
Fabrizio Dabbene and Roberto Tempo
- 66 Stabilization of Stochastic Nonlinear Continuous-Time Systems66-1
Miroslav Krstić and Shu-Jun Liu

SECTION XI Control of Distributed Parameter Systems

- 67 Control of Systems Governed by Partial Differential Equations67-1
Kirsten Morris
- 68 Controllability of Thin Elastic Beams and Plates68-1
J.E. Lagnese and G. Leugering
- 69 Control of the Heat Equation69-1
Thomas I. Seidman
- 70 Observability of Linear Distributed-Parameter Systems 70-1
David L. Russell
- 71 Boundary Control of PDEs: The Backstepping Approach 71-1
Miroslav Krstić and Andrey Smyshlyaev
- 72 Stabilization of Fluid Flows72-1
Miroslav Krstić and Rafael Vazquez

SECTION XII Networks and Networked Controls

- 73 Control over Digital Networks73-1
Nuno C. Martins

74 Decentralized Control and Algebraic Approaches.....74-1
Michael C. Rotkowitz

75 Estimation and Control across Analog Erasure Channels 75-1
Vijay Gupta

76 Passivity Approach to Network Stability Analysis and Distributed
Control Synthesis76-1
Murat Arcak

Index.....Index-1

Preface to the Second Edition

As you may know, the first edition of *The Control Handbook* was very well received. Many copies were sold and a gratifying number of people took the time to tell me that they found it useful. To the publisher, these are all reasons to do a second edition. To the editor of the first edition, these same facts are a modest disincentive. The risk that a second edition will not be as good as the first one is real and worrisome. I have tried very hard to insure that the second edition is at least as good as the first one was. I hope you agree that I have succeeded.

I have made two major changes in the second edition. The first is that all the *Applications* chapters are new. It is simply a fact of life in engineering that once a problem is solved, people are no longer as interested in it as they were when it was unsolved. I have tried to find especially inspiring and exciting applications for this second edition.

Secondly, it has become clear to me that organizing the *Applications* book by academic discipline is no longer sensible. Most control applications are interdisciplinary. For example, an automotive control system that involves sensors to convert mechanical signals into electrical ones, actuators that convert electrical signals into mechanical ones, several computers and a communication network to link sensors and actuators to the computers does not belong solely to any specific academic area. You will notice that the applications are now organized broadly by application areas, such as automotive and aerospace.

One aspect of this new organization has created a minor and, I think, amusing problem. Several wonderful applications did not fit into my new taxonomy. I originally grouped them under the title Miscellaneous. Several authors objected to the slightly pejorative nature of the term “miscellaneous.” I agreed with them and, after some thinking, consulting with literate friends and with some of the library resources, I have renamed that section “Special Applications.” Regardless of the name, they are all interesting and important and I hope you will read those articles as well as the ones that did fit my organizational scheme.

There has also been considerable progress in the areas covered in the *Advanced Methods* book. This is reflected in the roughly two dozen articles in this second edition that are completely new. Some of these are in two new sections, “Analysis and Design of Hybrid Systems” and “Networks and Networked Controls.”

There have even been a few changes in the *Fundamentals*. Primarily, there is greater emphasis on sampling and discretization. This is because most control systems are now implemented digitally.

I have enjoyed editing this second edition and learned a great deal while I was doing it. I hope that you will enjoy reading it and learn a great deal from doing so.

Acknowledgments

The people who were most crucial to the second edition were the authors of the articles. It took a great deal of work to write each of these articles and I doubt that I will ever be able to repay the authors for their efforts. I do thank them very much.

The members of the advisory/editorial board for the second edition were a very great help in choosing topics and finding authors. I thank them all. Two of them were especially helpful. Davor Hrovat took responsibility for the automotive applications and Richard Braatz was crucial in selecting the applications to industrial process control.

It is a great pleasure to be able to provide some recognition and to thank the people who helped bring this second edition of *The Control Handbook* into being. Nora Konopka, publisher of engineering and environmental sciences for Taylor & Francis/CRC Press, began encouraging me to create a second edition quite some time ago. Although it was not easy, she finally convinced me. Jessica Vakili and Kari Budyk, the project coordinators, were an enormous help in keeping track of potential authors as well as those who had committed to write an article. Syed Mohamad Shajahan, senior project executive at Techset, very capably handled all phases of production, while Richard Tressider, project editor for Taylor & Francis/CRC Press, provided direction, oversight, and quality control. Without all of them and their assistants, the second edition would probably never have appeared and, if it had, it would have been far inferior to what it is.

Most importantly, I thank my wife Shirley Johannesen Levine for everything she has done for me over the many years we have been married. It would not be possible to enumerate all the ways in which she has contributed to each and everything I have done, not just editing this second edition.

Editor

William S. Levine received B.S., M.S., and Ph.D. degrees from the Massachusetts Institute of Technology. He then joined the faculty of the University of Maryland, College Park where he is currently a research professor in the Department of Electrical and Computer Engineering. Throughout his career he has specialized in the design and analysis of control systems and related problems in estimation, filtering, and system modeling. Motivated by the desire to understand a collection of interesting controller designs, he has done a great deal of research on mammalian control of movement in collaboration with several neurophysiologists.

He is co-author of *Using MATLAB to Analyze and Design Control Systems*, March 1992. Second Edition, March 1995. He is the coeditor of *The Handbook of Networked and Embedded Control Systems*, published by Birkhauser in 2005. He is the editor of a series on control engineering for Birkhauser. He has been president of the IEEE Control Systems Society and the American Control Council. He is presently the chairman of the SIAM special interest group in control theory and its applications.

He is a fellow of the IEEE, a distinguished member of the IEEE Control Systems Society, and a recipient of the IEEE Third Millennium Medal. He and his collaborators received the Schroers Award for outstanding rotorcraft research in 1998. He and another group of collaborators received the award for outstanding paper in the *IEEE Transactions on Automatic Control*, entitled “Discrete-Time Point Processes in Urban Traffic Queue Estimation.”

1.1 Introduction

This chapter provides a survey of various aspects of the numerical solution of selected problems in linear systems, control, and estimation theory. Space limitations preclude an exhaustive survey and extensive list of references. The interested reader is referred to [1,4,10,14] for sources of additional detailed information.

* This material is based on a paper written by the same authors and published in Patel, R.V., Laub, A.J., and Van Dooren, P.M., Eds., *Numerical Linear Algebra Techniques for Systems and Control*, Selected Reprint Series, IEEE Press, New York, pp. 1–29 1994, copyright 1994 IEEE.

Many of the problems considered in this chapter arise in the study of the “standard” linear model

$$\dot{x}(t) = Ax(t) + Bu(t), \quad (1.1)$$

$$y(t) = Cx(t) + Du(t). \quad (1.2)$$

Here, $x(t)$ is an n -vector of states, $u(t)$ is an m -vector of controls or inputs, and $y(t)$ is a p -vector of outputs. The standard discrete-time analog of Equations 1.1 and 1.2 takes the form

$$x_{k+1} = Ax_k + Bu_k, \quad (1.3)$$

$$y_k = Cx_k + Du_k. \quad (1.4)$$

Of course, considerably more elaborate models are also studied, including time-varying, stochastic, and nonlinear versions of the above, but these are not discussed in this chapter. In fact, the above linear models are usually derived from linearizations of nonlinear models regarding selected nominal points.

The matrices considered here are, for the most part, assumed to have real coefficients and to be small (of order a few hundred or less) and dense, with no particular exploitable structure. Calculations for most problems in classical single-input, single-output control fall into this category. Large sparse matrices or matrices with special exploitable structures may significantly involve different concerns and methodologies than those discussed here.

The systems, control, and estimation literature is replete with *ad hoc* algorithms to solve the computational problems that arise in the various methodologies. Many of these algorithms work quite well on some problems (e.g., “small-order” matrices) but encounter numerical difficulties, often severe, when “pushed” (e.g., on larger order matrices). The reason for this is that little or no attention has been paid to the way algorithms perform in “finite arithmetic,” that is, on a finite word length digital computer.

A simple example by Moler and Van Loan [14, p. 649]* illustrates a typical pitfall. Suppose it is desired to compute the matrix e^A in single precision arithmetic on a computer which gives six decimal places of precision in the fractional part of floating-point numbers. Consider the case

$$A = \begin{bmatrix} -49 & 24 \\ -64 & 31 \end{bmatrix}$$

and suppose the computation is attempted with the Taylor series formula

$$e^A = \sum_{k=0}^{+\infty} \frac{1}{k!} A^k. \quad (1.5)$$

This is easily coded and it is determined that the first 60 terms in the series suffice for the computation, in the sense that the terms for $k \geq 60$ of the order 10^{-7} no longer add anything significant to the sum. The resulting answer is

$$\begin{bmatrix} -22.2588 & -1.43277 \\ -61.4993 & -3.47428 \end{bmatrix}.$$

Surprisingly, the true answer is (correctly rounded)

$$\begin{bmatrix} -0.735759 & 0.551819 \\ -1.47152 & 1.10364 \end{bmatrix}.$$

What happened here was that the intermediate terms in the series became very large before the factorial began to dominate. The 17th and 18th terms, for example, are of the order of 10^7 but of opposite signs so

* The page number indicates the location of the appropriate reprint in [14].

that the less significant parts of these numbers, while significant for the final answer, are “lost” because of the finiteness of the arithmetic.

For this particular example, various fixes and remedies are available. However, in more realistic examples, one seldom has the luxury of having the “true answer” available so that it is not always easy to simply inspect or test a computed solution and determine that it is erroneous. Mathematical analysis (truncation of the series, in the example above) alone is simply not sufficient when a problem is analyzed or solved in finite arithmetic (truncation of the arithmetic). Clearly, a great deal of care must be taken.

The finiteness inherent in representing real or complex numbers as floating-point numbers on a digital computer manifests itself in two important ways: floating-point numbers have only finite precision and finite range. The degree of attention paid to these two considerations distinguishes many reliable algorithms from more unreliable counterparts.

The development in systems, control, and estimation theory of stable, efficient, and reliable algorithms that respect the constraints of finite arithmetic began in the 1970s and still continues. Much of the research in numerical analysis has been directly applicable, but there are many computational issues in control (e.g., the presence of hard or structural zeros) where numerical analysis does not provide a ready answer or guide. A symbiotic relationship has developed, especially between numerical linear algebra and linear system and control theory, which is sure to provide a continuing source of challenging research areas.

The abundance of numerically fragile algorithms is partly explained by the following observation:

If an algorithm is amenable to “easy” manual calculation, it is probably a poor method if implemented in the finite floating-point arithmetic of a digital computer.

For example, when confronted with finding the eigenvalues of a 2×2 matrix, most people would find the characteristic polynomial and solve the resulting quadratic equation. But when extrapolated as a general method for computing eigenvalues and implemented on a digital computer, this is a very poor procedure for reasons such as roundoff and overflow/underflow. The preferred method now would generally be the double Francis QR algorithm (see [17] for details) but few would attempt that manually, even for very small-order problems.

Many algorithms, now considered fairly reliable in the context of finite arithmetic, are not amenable to manual calculations (e.g., various classes of orthogonal similarities). This is a kind of converse to the observation quoted above. Especially in linear system and control theory, we have been too easily tempted by the ready availability of closed-form solutions and numerically naive methods to implement those solutions. For example, in solving the initial value problem

$$\dot{x}(t) = Ax(t); \quad x(0) = x_0, \quad (1.6)$$

it is not at all clear that one should explicitly compute the intermediate quantity e^{tA} . Rather, it is the vector $e^{tA}x_0$ that is desired, a quantity that may be computed by treating Equation 1.6 as a system of (possibly stiff) differential equations and using an implicit method for numerically integrating the differential equation. But such techniques are definitely not attractive for manual computation.

The awareness of such numerical issues in the mathematics and engineering community has increased significantly in the last few decades. In fact, some of the background material well known to numerical analysts has already filtered down to undergraduate and graduate curricula in these disciplines. This awareness and education has affected system and control theory, especially linear system theory. A number of numerical analysts were attracted by the wealth of interesting numerical linear algebra problems in linear system theory. At the same time, several researchers in linear system theory turned to various methods and concepts from numerical linear algebra and attempted to modify them in developing reliable algorithms and software for specific problems in linear system theory. This cross-fertilization has been greatly enhanced by the widespread use of software packages and by developments over the last couple of decades in numerical linear algebra. This process has already begun to have a significant impact on the future directions and development of system and control theory, and on applications, as evident

from the growth of computer-aided control system design (CACSD) as an intrinsic tool. Algorithms implemented as mathematical software are a critical “inner” component of a CACSD system.

In the remainder of this chapter, we survey some results and trends in this interdisciplinary research area. We emphasize numerical aspects of the problems/algorithms, which is why we also spend time discussing appropriate numerical tools and techniques. We discuss a number of control and filtering problems that are of widespread interest in control.

Before proceeding further, we list here some notations to be used:

$\mathbb{F}^{n \times m}$	the set of all $n \times m$ matrices with coefficients in the field \mathbb{F} (\mathbb{F} is generally \mathbb{R} or \mathbb{C})
A^T	the transpose of $A \in \mathbb{R}^{n \times m}$
A^H	the complex-conjugate transpose of $A \in \mathbb{C}^{n \times m}$
A^+	the Moore–Penrose pseudoinverse of A
$\ A\ $	the spectral norm of A (i.e., the matrix norm subordinate to the Euclidean vector norm: $\ A\ = \max_{\ x\ _2=1} \ Ax\ _2$)
$\text{diag}(a_1, \dots, a_n)$	the diagonal matrix $\begin{bmatrix} a_1 & & 0 \\ & \ddots & \\ 0 & & a_n \end{bmatrix}$
$\Lambda(A)$	the set of eigenvalues $\lambda_1, \dots, \lambda_n$ (not necessarily distinct) of $A \in \mathbb{F}^{n \times n}$
$\lambda_i(A)$	the i th eigenvalue of A
$\Sigma(A)$	the set of singular values $\sigma_1, \dots, \sigma_m$ (not necessarily distinct) of $A \in \mathbb{F}^{n \times m}$
$\sigma_i(A)$	the i th singular value of A

Finally, let us define a particular number to which we make frequent reference in the following. The *machine epsilon* or *relative machine precision* is defined, roughly speaking, as the smallest positive number ϵ that, when added to 1 on our computing machine, gives a number greater than 1. In other words, any machine representable number δ less than ϵ gets “rounded off” when (floating-point) added to 1 to give exactly 1 again as the rounded sum. The number ϵ , of course, varies depending on the kind of computer being used and the precision of the computations (single precision, double precision, etc.). But the fact that such a positive number ϵ exists is entirely a consequence of finite word length.

1.2 Numerical Background

In this section, we give a very brief discussion of two concepts fundamentally important in numerical analysis: *numerical stability* and *conditioning*. Although this material is standard in textbooks such as [8], it is presented here for completeness and because the two concepts are frequently confused in the systems, control, and estimation literature.

Suppose we have a mathematically defined problem represented by f which acts on data d belonging to some set of data \mathcal{D} , to produce a solution $f(d)$ in a solution set \mathcal{S} . These notions are kept deliberately vague for expository purposes. Given $d \in \mathcal{D}$, we desire to compute $f(d)$. Suppose d^* is some approximation to d . If $f(d^*)$ is “near” $f(d)$, the problem is said to be well conditioned. If $f(d^*)$ may potentially differ greatly from $f(d)$ even when d^* is near d , the problem is said to be ill-conditioned. The concept of “near” can be made precise by introducing norms in the appropriate spaces. We can then define the condition of the problem f with respect to these norms as

$$\kappa[f(d)] = \lim_{\delta \rightarrow 0} \sup_{d_2(d, d^*) = \delta} \left[\frac{d_1(f(d), f(d^*))}{\delta} \right], \quad (1.7)$$

where $d_i(\cdot, \cdot)$ are distance functions in the appropriate spaces. When $\kappa[f(d)]$ is infinite, the problem of determining $f(d)$ from d is *ill-posed* (as opposed to *well-posed*). When $\kappa[f(d)]$ is finite and *relatively large* (or *relatively small*), the problem is said to be *ill-conditioned* (or *well-conditioned*).

A simple example of an ill-conditioned problem is the following. Consider the $n \times n$ matrix

$$A = \begin{bmatrix} 0 & 1 & 0 & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & 1 \\ 0 & \cdot & \cdot & \cdot & \cdot & \cdot & 0 \end{bmatrix},$$

with n eigenvalues at 0. Now, consider a small perturbation of the data (the n^2 elements of A) consisting of adding the number 2^{-n} to the first element in the last (n th) row of A . This perturbed matrix then has n distinct eigenvalues $\lambda_1, \dots, \lambda_n$ with $\lambda_k = 1/2 \exp(2k\pi j/n)$, where $j := \sqrt{-1}$. Thus, we see that this small perturbation in the data has been magnified by a factor on the order of 2^n resulting in a rather large perturbation in solving the problem of computing the eigenvalues of A . Further details and related examples can be found in [9,17].

Thus far, we have not mentioned how the problem f above (computing the eigenvalues of A in the example) was to be solved. Conditioning is a function solely of the problem itself. To solve a problem numerically, we must implement some numerical procedures or algorithms which we denote by f^* . Thus, given $d, f^*(d)$ is the result of applying the algorithm to d (for simplicity, we assume d is “representable”; a more general definition can be given when some approximation d^{**} to d must be used). The algorithm f^* is said to be numerically (backward) stable if, for all $d \in \mathcal{D}$, there exists $d^* \in \mathcal{D}$ near d so that $f^*(d)$ is near $f(d^*)$, ($f(d^*)$ = the exact solution of a nearby problem). If the problem is well-conditioned, then $f(d^*)$ is near $f(d)$ so that $f^*(d)$ is near $f(d)$ if f^* is numerically stable. In other words, f^* does not introduce any more sensitivity to perturbation than is inherent in the problem. Example 1.1 further illuminates this definition of stability which, on a first reading, can seem somewhat confusing.

Of course, one cannot expect a stable algorithm to solve an ill-conditioned problem any more accurately than the data warrant, but an unstable algorithm can produce poor solutions even to well-conditioned problems. Example 1.2, illustrates this phenomenon. There are thus two separate factors to consider in determining the accuracy of a computed solution $f^*(d)$. First, if the algorithm is stable, $f^*(d)$ is near $f(d^*)$, for some d^* , and second, if the problem is well conditioned, then, as above, $f(d^*)$ is near $f(d)$. Thus, $f^*(d)$ is near $f(d)$ and we have an “accurate” solution.

Rounding errors can cause unstable algorithms to give disastrous results. However, it would be virtually impossible to account for every rounding error made at every arithmetic operation in a complex series of calculations. This would constitute a *forward* error analysis. The concept of *backward* error analysis based on the definition of numerical stability given above provides a more practical alternative. To illustrate this, let us consider the singular value decomposition (SVD) of an arbitrary $m \times n$ matrix A with coefficients in \mathbb{R} or \mathbb{C} [8] (see also Section 1.3.3),

$$A = U \Sigma V^H . \tag{1.8}$$

Here U and V are $m \times m$ and $n \times n$ unitary matrices, respectively, and Σ is an $m \times n$ matrix of the form

$$\Sigma = \left[\begin{array}{c|c} \Sigma_r & 0 \\ \hline 0 & 0 \end{array} \right]; \quad \Sigma_r = \text{diag}\{\sigma_1, \dots, \sigma_r\} \tag{1.9}$$

with the *singular values* σ_i positive and satisfying $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_r > 0$. The computation of this decomposition is, of course, subject to rounding errors. Denoting computed quantities by an overbar, for some

error matrix E_A ,

$$\bar{A} = A + E_A = \overline{U\Sigma V^H}. \quad (1.10)$$

The computed decomposition thus corresponds exactly to a *perturbed* matrix \bar{A} . When using the SVD algorithm available in the literature [8], this perturbation can be bounded by

$$\|E_A\| \leq \pi \epsilon \|A\|, \quad (1.11)$$

where ϵ is the machine precision and π is some quantity depending on the dimensions m and n , but reasonably close to 1 (see also [14, p. 74]). Thus, the *backward error* E_A induced by this algorithm has roughly the same norm as the *input error* E_i resulting, for example, when reading the data A into the computer. Then, according to the definition of numerical stability given above, when a bound such as that in Equation 1.11 exists for the error induced by a numerical algorithm, the algorithm is said to be *backward stable* [17]. Note that backward stability does not guarantee any bounds on the errors in the result \bar{U} , $\bar{\Sigma}$, and \bar{V} . In fact, this depends on how perturbations in the data (namely, $E_A = \bar{A} - A$) affect the resulting decomposition (namely, $E_U = \bar{U} - U$, $E_\Sigma = \bar{\Sigma} - \Sigma$, and $E_V = \bar{V} - V$). This is commonly measured by the condition $\kappa[f(A)]$.

Backward stability is a property of an algorithm, and the condition is associated with a problem and the specific data for that problem. The errors in the result depend on the stability of the algorithm used and the condition of the problem solved. A *good* algorithm should, therefore, be backward stable because the size of the errors in the result is then mainly due to the condition of the problem, not to the algorithm. An unstable algorithm, on the other hand, may yield a large error even when the problem is well conditioned.

Bounds of the type Equation 1.11 are obtained by an error analysis of the algorithm used, and the condition of the problem is obtained by a sensitivity analysis; for example, see [9,17].

We close this section with two simple examples to illustrate some of the concepts introduced.

Example 1.1:

Let x and y be two floating-point computer numbers and let $fl(x * y)$ denote the result of multiplying them in floating-point computer arithmetic. In general, the product $x * y$ requires more precision to be represented exactly than was used to represent x or y . But for most computers

$$fl(x * y) = x * y(1 + \delta), \quad (1.12)$$

where $|\delta| < \epsilon$ (ϵ = relative machine precision). In other words, $fl(x * y)$ is $x * y$ correct to within a unit in the last place. Another way to write Equation 1.12 is as follows:

$$fl(x * y) = x(1 + \delta)^{1/2} * y(1 + \delta)^{1/2}, \quad (1.13)$$

where $|\delta| < \epsilon$. This can be interpreted as follows: the computed result $fl(x * y)$ is the exact product of the two slightly perturbed numbers $x(1 + \delta)^{1/2}$ and $y(1 + \delta)^{1/2}$. The slightly perturbed data (not unique) may not even be representable as floating-point numbers. The representation of Equation 1.13 is simply a way of accounting for the roundoff incurred in the algorithm by an initial (small) perturbation in the data.

Example 1.2:

Gaussian elimination with no pivoting for solving the linear system of equations

$$Ax = b \tag{1.14}$$

is known to be numerically unstable; see for example [8] and Section 1.3. The following data illustrate this phenomenon. Let

$$A = \begin{bmatrix} 0.0001 & 1.000 \\ 1.000 & -1.000 \end{bmatrix}, \quad b = \begin{bmatrix} 1.000 \\ 0.000 \end{bmatrix}.$$

All computations are carried out in four-significant-figure decimal arithmetic. The “true answer” $x = A^{-1}b$ is

$$\begin{bmatrix} 0.9999 \\ 0.9999 \end{bmatrix}.$$

Using row 1 as the “pivot row” (i.e., subtracting $10,000 \times$ row 1 from row 2) we arrive at the equivalent triangular system

$$\begin{bmatrix} 0.0001 & 1.000 \\ 0 & -1.000 \times 10^4 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} 1.000 \\ -1.000 \times 10^4 \end{bmatrix}.$$

The coefficient multiplying x_2 in the second equation should be $-10,001$, but because of roundoff, becomes $-10,000$. Thus, we compute $x_2 = 1.000$ (a good approximation), but back substitution in the equation

$$0.0001x_1 = 1.000 - fl(1.000 * 1.000)$$

yields $x_1 = 0.000$. This extremely bad approximation to x_1 is the result of numerical instability. The problem, it can be shown, is quite well conditioned.

1.3 Fundamental Problems in Numerical Linear Algebra

In this section, we give a brief overview of some of the fundamental problems in numerical linear algebra that serve as building blocks or “tools” for the solution of problems in systems, control, and estimation.

1.3.1 Linear Algebraic Equations and Linear Least-Squares Problems

Probably the most fundamental problem in numerical computing is the calculation of a vector x which satisfies the linear system

$$Ax = b, \tag{1.15}$$

where $A \in \mathbb{R}^{n \times n}$ (or $\mathbb{C}^{n \times n}$) and has rank n . A great deal is now known about solving Equation 1.15 in finite arithmetic both for the general case and for a large number of special situations, for example, see [8,9].

The most commonly used algorithm for solving Equation 1.15 with general A and small n (say $n \leq 1000$) is Gaussian elimination with some sort of pivoting strategy, usually “partial pivoting.” This amounts to factoring some permutation of the rows of A into the product of a unit lower triangular matrix L and an upper triangular matrix U . The algorithm is effectively stable, that is, it can be proved that the computed solution is near the exact solution of the system

$$(A + E)x = b \tag{1.16}$$

with $|e_{ij}| \leq \phi(n) \gamma \beta \epsilon$, where $\phi(n)$ is a modest function of n depending on details of the arithmetic used, γ is a “growth factor” (which is a function of the pivoting strategy and is usually—but not always—small), β behaves essentially like $\|A\|$, and ϵ is the machine precision. In other words, except for moderately pathological situations, E is “small”—on the order of $\epsilon \|A\|$.

The following question then arises. If, because of rounding errors, we are effectively solving Equation 1.16 rather than Equation 1.15, what is the relationship between $(A + E)^{-1}b$ and $A^{-1}b$? To answer this question, we need some elementary perturbation theory and this is where the notion of condition number arises. A condition number for Equation 1.15 is given by

$$\kappa(A) := \|A\| \|A^{-1}\|. \quad (1.17)$$

Simple perturbation results can show that perturbation in A and/or b can be magnified by as much as $\kappa(A)$ in the computed solution. Estimating $\kappa(A)$ (since, of course, A^{-1} is unknown) is thus a crucial aspect of assessing solutions of Equation 1.15 and the particular estimating procedure used is usually the principal difference between competing linear equation software packages. One of the more sophisticated and reliable condition estimators presently available is implemented in LINPACK [5] and its successor LAPACK [2]. LINPACK and LAPACK also feature many codes for solving Equation 1.14 in case A has certain special structures (e.g., banded, symmetric, or positive definite).

Another important class of linear algebra problems, and one for which codes are available in LINPACK and LAPACK, is the linear least-squares problem

$$\min \|Ax - b\|_2, \quad (1.18)$$

where $A \in \mathbb{R}^{m \times n}$ and has rank k , with (in the simplest case) $k = n \leq m$, for example, see [8]. The solution of Equation 1.18 can be written formally as $x = A^+b$. The method of choice is generally based on the QR factorization of A (for simplicity, let $\text{rank}(A) = n$)

$$A = QR, \quad (1.19)$$

where $R \in \mathbb{R}^{n \times n}$ is upper triangular and $Q \in \mathbb{R}^{m \times n}$ has orthonormal columns, that is, $Q^T Q = I$. With special care and analysis, the case $k < n$ can also be handled similarly. The factorization is effected through a sequence of Householder transformations H_i applied to A . Each H_i is symmetric and orthogonal and of the form $I - 2uu^T/u^T u$, where $u \in \mathbb{R}^m$ is specially chosen so that zeros are introduced at appropriate places in A when it is premultiplied by H_i . After n such transformations,

$$H_n H_{n-1} \dots H_1 A = \begin{bmatrix} R \\ 0 \end{bmatrix},$$

from which the factorization Equation 1.19 follows. Defining c and d by

$$\begin{bmatrix} c \\ d \end{bmatrix} := H_n H_{n-1} \dots H_1 b,$$

where $c \in \mathbb{R}^n$, it is easily shown that the least-squares solution x of Equation 1.18 is given by the solution of the linear system of equations

$$Rx = c. \quad (1.20)$$

The above algorithm is numerically stable and, again, a well-developed perturbation theory exists from which condition numbers can be obtained, this time in terms of

$$\kappa(A) := \|A\| \|A^+\|.$$

Least-squares perturbation theory is fairly straightforward when $\text{rank}(A) = n$, but is considerably more complicated when A is rank deficient. The reason for this is that, although the inverse is a continuous

function of the data (i.e., the inverse is a continuous function in a neighborhood of a nonsingular matrix), the pseudoinverse is discontinuous. For example, consider

$$A = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} = A^+$$

and perturbations

$$E_1 = \begin{bmatrix} 0 & 0 \\ \delta & 0 \end{bmatrix} \quad \text{and} \quad E_2 = \begin{bmatrix} 0 & 0 \\ 0 & \delta \end{bmatrix}$$

with δ being small. Then

$$(A + E_1)^+ = \begin{bmatrix} \frac{1}{1 + \delta^2} & \frac{\delta}{1 + \delta^2} \\ 0 & 0 \end{bmatrix},$$

which is close to A^+ but

$$(A + E_2)^+ = \begin{bmatrix} 1 & 0 \\ 0 & \frac{1}{\delta} \end{bmatrix},$$

which gets arbitrarily far from A^+ as δ is decreased toward 0.

In lieu of Householder transformations, Givens transformations (elementary rotations or reflections) may also be used to solve the linear least-squares problem [8]. Givens transformations have received considerable attention for solving linear least-squares problems and systems of linear equations in a parallel computing environment. The capability of introducing zero elements selectively and the need for only local interprocessor communication make the technique ideal for “parallelization.”

1.3.2 Eigenvalue and Generalized Eigenvalue Problems

In the algebraic eigenvalue/eigenvector problem for $A \in \mathbb{R}^{n \times n}$, one seeks nonzero solutions $x \in \mathbb{C}^n$ and $\lambda \in \mathbb{C}$, which satisfy

$$Ax = \lambda x. \tag{1.21}$$

The classic reference on the numerical aspects of this problem is Wilkinson [17]. A briefer textbook introduction is given in [8].

Quality mathematical software for eigenvalues and eigenvectors is available; the EISPACK [7,15] collection of subroutines represents a pivotal point in the history of mathematical software. The successor to EISPACK (and LINPACK) is LAPACK [2], in which the algorithms and software have been restructured to provide high efficiency on vector processors, high-performance workstations, and shared memory multiprocessors.

The most common algorithm now used to solve Equation 1.21 for general A is the QR algorithm of Francis [17]. A shifting procedure enhances convergence and the usual implementation is called the double-Francis-QR algorithm. Before the QR process is applied, A is initially reduced to upper Hessenberg form A_H ($a_{ij} = 0$ if $i - j \geq 2$). This is accomplished by a finite sequence of similarities of the Householder form discussed above. The QR process then yields a sequence of matrices orthogonally similar to A and converging (in some sense) to a so-called quasi-upper triangular matrix S also called the real Schur form (RSF) of A . The matrix S is block upper triangular with 1×1 diagonal blocks corresponding to real eigenvalues of A and 2×2 diagonal blocks corresponding to complex-conjugate pairs of eigenvalues. The quasi-upper triangular form permits all arithmetic to be real rather than complex as would be necessary for convergence to an upper triangular matrix. The orthogonal transformations from both the Hessenberg reduction and the QR process may be accumulated in a single orthogonal transformation U so that

$$U^T A U = R \tag{1.22}$$

compactly represents the entire algorithm. An analogous process can be applied in the case of symmetric A , and considerable simplifications and specializations result.

Closely related to the QR algorithm is the QZ algorithm for the generalized eigenvalue problem

$$Ax = \lambda Mx, \quad (1.23)$$

where $A, M \in \mathbb{R}^{n \times n}$. Again, a Hessenberg-like reduction, followed by an iterative process, is implemented with orthogonal transformations to reduce Equation 1.23 to the form

$$QAZy = \lambda QMZy, \quad (1.24)$$

where QAZ is quasi-upper triangular and QMZ is upper triangular. For a review and references to results on stability, conditioning, and software related to Equation 1.23 and the QZ algorithm, see [8]. The generalized eigenvalue problem is both theoretically and numerically more difficult to handle than the ordinary eigenvalue problem, but it finds numerous applications in control and system theory [14, p. 109].

1.3.3 The Singular Value Decomposition and Some Applications

One of the basic and most important tools of modern numerical analysis, especially numerical linear algebra, is the SVD. Here we make a few comments about its properties and computation as well as its significance in various numerical problems.

Singular values and the SVD have a long history, especially in statistics and numerical linear algebra. These ideas have found applications in the control and signal processing literature, although their use there has been overstated somewhat in certain applications. For a survey of the SVD, its history, numerical details, and some applications in systems and control theory, see [14, p. 74].

The fundamental result was stated in Section 1.2 (for the complex case). The result for the real case is similar and is stated below.

Theorem 1.1:

Let $A \in \mathbb{R}^{m \times n}$ with $\text{rank}(A) = r$. Then there exist orthogonal matrices $U \in \mathbb{R}^{m \times m}$ and $V \in \mathbb{R}^{n \times n}$ so that

$$A = U\Sigma V^T, \quad (1.25)$$

where

$$\Sigma = \begin{bmatrix} \Sigma_r & 0 \\ 0 & 0 \end{bmatrix}$$

and $\Sigma_r = \text{diag} \{ \sigma_1, \dots, \sigma_r \}$ with $\sigma_1 \geq \dots \geq \sigma_r > 0$.

The proof of Theorem 1.1 is straightforward and can be found, for example, in [8]. Geometrically, the theorem says that bases can be found (separately) in the domain and codomain spaces of a linear map with respect to which the matrix representation of the linear map is diagonal. The numbers $\sigma_1, \dots, \sigma_r$, together with $\sigma_{r+1} = 0, \dots, \sigma_n = 0$, are called the singular values of A , and they are the positive square roots of the eigenvalues of $A^T A$. The columns $\{u_k, k = 1, \dots, m\}$ of U are called the left singular vectors of A (the orthonormal eigenvectors of AA^T), while the columns $\{v_k, k = 1, \dots, n\}$ of V are called the right singular vectors of A (the orthonormal eigenvectors of $A^T A$). The matrix A can then be written (as a dyadic expansion) also in terms of the singular vectors as follows:

$$A = \sum_{k=1}^r \sigma_k u_k v_k^T.$$

The matrix A^T has m singular values, the positive square roots of the eigenvalues of AA^T . The r ($= \text{rank}(A)$) nonzero singular values of A and A^T are, of course, the same. The choice of $A^T A$ rather than

AA^T in the definition of singular values is arbitrary. Only the nonzero singular values are usually of any real interest and their number, given the SVD, is the rank of the matrix. Naturally, the question of how to distinguish nonzero from zero singular values in the presence of rounding error is a nontrivial task.

It is not generally advisable to compute the singular values of A by first finding the eigenvalues of $A^T A$, tempting as that is. Consider the following example, where μ is a real number with $|\mu| < \sqrt{\epsilon}$ (so that $fl(1 + \mu^2) = 1$, where $fl(\cdot)$ denotes floating-point computation). Let

$$A = \begin{bmatrix} 1 & 1 \\ \mu & 0 \\ 0 & \mu \end{bmatrix}.$$

Then

$$fl(A^T A) = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}.$$

So we compute $\hat{\sigma}_1 = \sqrt{2}$, $\hat{\sigma}_2 = 0$ leading to the (erroneous) conclusion that the rank of A is 1. Of course, if we could compute in infinite precision, we would find

$$A^T A = \begin{bmatrix} 1 + \mu^2 & \mu \\ \mu & 1 + \mu^2 \end{bmatrix}$$

with $\sigma_1 = \sqrt{2 + \mu^2}$, $\sigma_2 = |\mu|$ and thus $\text{rank}(A) = 2$. The point is that by working with $A^T A$ we have unnecessarily introduced μ^2 into the computations. The above example illustrates a potential pitfall in attempting to form and solve the normal equations in a linear least-squares problem and is at the heart of what makes square root filtering so attractive numerically. Very simplistically, square root filtering involves working directly on an “ A -matrix,” for example, updating it, as opposed to updating an “ $A^T A$ -matrix.”

Square root filtering is usually implemented with the QR factorization (or some closely related algorithm) as described previously rather than SVD. Moreover, critical information may be lost irrecoverably by simply forming $A^T A$.

Returning now to the SVD, two features of this matrix factorization make it attractive in finite arithmetic: first, it can be computed in a numerically stable way, and second, singular values are well conditioned. Specifically, there is an efficient and numerically stable algorithm by Golub and Reinsch [8] which works directly on A to give the SVD. This algorithm has two phases. In the first phase, it computes orthogonal matrices U_1 and V_1 so that $B = U_1^T A V_1$ is in bidiagonal form, that is, only the elements on its diagonal and first superdiagonal are nonzero. In the second phase, the algorithm uses an iterative procedure to compute orthogonal matrices U_2 and V_2 so that $U_2^T B V_2$ is diagonal and nonnegative. The SVD defined in Equation 1.25 is then $\Sigma = U^T B V$, where $U = U_1 U_2$ and $V = V_1 V_2$. The computed U and V are orthogonal approximately to the working precision, and the computed singular values are the exact σ_i 's for $A + E$, where $\|E\|/\|A\|$ is a modest multiple of ϵ . Fairly sophisticated implementations of this algorithm can be found in [5,7]. The well-conditioned nature of the singular values follows from the fact that if A is perturbed to $A + E$, then it can be proved that

$$\|\sigma_i(A + E) - \sigma_i(A)\| \leq \|E\|.$$

Thus, the singular values are computed with small absolute error although the relative error of sufficiently small singular values is not guaranteed to be small.

It is now acknowledged that the singular value decomposition is the most generally reliable method of determining rank numerically (see [14, p. 589] for a more elaborate discussion). However, it is considerably more expensive to compute than, for example, the QR factorization which, with column pivoting [5], can usually give equivalent information with less computation. Thus, while the SVD is a useful theoretical tool, its use for actual computations should be weighed carefully against other approaches.

The problem of numerical determination of rank is now well understood. The essential idea is to try to determine a “gap” between “zero” and the “smallest nonzero singular value” of a matrix A . Since the computed values are exact for a matrix near A , it makes sense to consider the ranks of all matrices in some δ -ball (with respect to the spectral norm $\|\cdot\|$, say) around A . The choice of δ may also be based on measurement errors incurred in estimating the coefficients of A , or the coefficients may be uncertain because of rounding errors incurred in a previous computation. However, even with SVD, numerical determination of rank in finite arithmetic is a difficult problem.

That other methods of rank determination are potentially unreliable is demonstrated by the following example. Consider the Ostrowski matrix $A \in \mathbb{R}^{n \times n}$ whose diagonal elements are all -1 , whose upper triangle elements are all $+1$, and whose lower triangle elements are all 0 . This matrix is clearly of rank n , that is, is invertible. It has a good “solid” upper triangular shape. All of its eigenvalues (-1) are well away from zero. Its determinant $(-1)^n$ is definitely not close to zero. But this matrix is, in fact, very nearly singular and becomes more nearly so as n increases. Note, for example, that

$$\begin{bmatrix} -1 & +1 & \cdots & \cdots & +1 \\ 0 & \ddots & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & & \ddots & \ddots \\ \vdots & & & \ddots & \ddots \\ 0 & \cdots & \cdots & 0 & -1 \end{bmatrix} \begin{bmatrix} 1 \\ 2^{-1} \\ \vdots \\ 2^{-n+1} \end{bmatrix} = \begin{bmatrix} -2^{-n+1} \\ -2^{-n+1} \\ \vdots \\ -2^{-n+1} \end{bmatrix} \rightarrow \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad (n \rightarrow +\infty).$$

Moreover, adding 2^{-n+1} to every element in the first column of A gives an exactly singular matrix. Arriving at such a matrix by, say, Gaussian elimination would give no hint as to the near singularity. However, it is easy to check that $\sigma_n(A)$ behaves as 2^{-n+1} . A corollary for control theory is that eigenvalues do not necessarily give a reliable measure of “stability margin.” It is useful to note that in this example of an invertible matrix, the crucial quantity, $\sigma_n(A)$, which measures nearness to singularity, is simply $1/\|A^{-1}\|$, and the result is familiar from standard operator theory. There is nothing intrinsic about singular values in this example and, in fact, $\|A^{-1}\|$ might be more cheaply computed or estimated in other matrix norms.

Because rank determination, in the presence of rounding error, is a nontrivial problem, the same difficulties naturally arise in any problem equivalent to, or involving, rank determination, such as determining the independence of vectors, finding the dimensions of certain subspaces, etc. Such problems arise as basic calculations throughout systems, control, and estimation theory. Selected applications are discussed in more detail in [14, p. 74] and in [1,4,10].

Finally, let us close this section with a brief example illustrating a totally inappropriate use of SVD. The rank condition

$$\text{rank } [B, AB, \dots, A^{n-1}B] = n \tag{1.26}$$

for the controllability of Equation 1.1 is too well known. Suppose

$$A = \begin{bmatrix} 1 & \mu \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 \\ \mu \end{bmatrix}$$

with $|\mu| < \sqrt{\epsilon}$. Then

$$f[B, AB] = \begin{bmatrix} 1 & 1 \\ \mu & \mu \end{bmatrix},$$

and now even applying SVD, the erroneous conclusion of uncontrollability is reached. Again the problem is in just forming AB ; not even SVD can come to the rescue after that numerical *faux pas*.

1.4 Applications to Systems and Control

A reasonable approach to developing numerically reliable algorithms for computational problems in linear system theory would be to reformulate the problems as concatenations of subproblems for which numerically stable algorithms are available. Unfortunately, one cannot ensure that the stability of algorithms for the subproblems results in the stability of the overall algorithm. This requires separate analysis that may rely on the sensitivity or condition of the subproblems. In the next section, we show that delicate (i.e., badly conditioned) subproblems should be avoided whenever possible; a few examples are given where a possibly badly conditioned step is circumvented by carefully modifying or completing existing algorithms; see, for example, [14, p. 109].

A second difficulty is the ill-posedness of some of the problems occurring in linear system theory. Two approaches can be adopted. One can develop an acceptable perturbation theory for such problems, using a concept such as *restricted condition*, which is, the condition under perturbations for which a certain property holds, for example, fixed rank [14, p. 109]. One then looks for restricting assumptions that make the problem well posed. Another approach is to delay any such *restricting choices* to the end and leave it to the user to decide which choice to make by looking at the results. The algorithm then provides quantitative measures that help the user make this choice; see, for example, [14, p. 171, 529]. By this approach, one may avoid artificial restrictions of the first approach that sometimes do not respect the practical significance of the problem.

A third possible *pitfall* is that many users almost always prefer fast algorithms to slower ones. However, slower algorithms are often more reliable.

In the subsections that follow, we survey a representative selection of numerical linear algebra problems arising in linear systems, control, and estimation theory, which have been examined with some of the techniques described in the preceding sections. Many of these topics are discussed briefly in survey papers such as [11] and [16] and in considerably more detail in the papers included or referenced in [14] and in [1,4,10]. Some of the scalar algorithms discussed here do not extend trivially to the matrix case. When they do, we mention only the matrix case. Moreover, we discuss only the numerical aspects here; for the system-theoretical background, we refer the reader to the control and systems literature.

1.4.1 Some Typical Techniques

Most of the reliable techniques in numerical linear algebra are based on the use of orthogonal transformations. Typical examples of this are the QR decomposition for least-squares problems, the Schur decomposition for eigenvalue and generalized eigenvalue problems, and the SVD for rank determinations and generalized inverses. Orthogonal transformations also appear in most of the reliable linear algebra techniques for control theory. This is partly due to the direct application of existing linear algebra decompositions to problems in control. Obvious examples of this are the Schur approach for solving algebraic Riccati equations, both continuous- and discrete-time [14, p. 529, 562, 573], for solving Lyapunov equations [14, p. 430] and for performing pole placement [14, p. 415]. New orthogonal decompositions have also been introduced that rely heavily on the same principles but were specifically developed for problems encountered in control. Orthogonal state-space transformations on a system $\{A, B, C\}$ result in a new state-space representation $\{U^H A U, U^H B, C U\}$, where U performs some kind of decomposition on the matrices A, B , and C . These special forms, termed “condensed forms,” include

- The state Schur form [14, p. 415]
- The state Hessenberg form [14, p. 287]
- The observer Hessenberg form [14, p. 289, 392]
- The controller Hessenberg form [14, p. 128, 357].

Staircase forms or block Hessenberg forms are other variants of these condensed forms that have proven useful in dealing with MIMO systems [14, p. 109, 186, 195].

There are two main reasons for using these orthogonal state-space transformations:

- The numerical sensitivity of the control problem being solved is not affected by these transformations because sensitivity is measured by norms or angles of certain spaces and these are unaltered by orthogonal transformations.
- Orthogonal transformations have minimum condition number, essential in proving bounded error propagation and establishing numerical stability of the algorithm that uses such transformations.

More details on this are given in [14, p. 128] and in subsequent sections where some of these condensed forms are used for particular applications.

1.4.2 Transfer Functions, Poles, and Zeros

In this section, we discuss important structural properties of linear systems and the numerical techniques available for determining them. The transfer function $R(\lambda)$ of a linear system is given by a polynomial representation $V(\lambda)T^{-1}(\lambda)U(\lambda) + W(\lambda)$ or by a state-space model $C(\lambda I - A)^{-1}B + D$. The results in this subsection hold for both the discrete-time case (where λ stands for the shift operator z) and the continuous-time case (where λ stands for the differentiation operator D).

1.4.2.1 The Polynomial Approach

One is interested in a number of structural properties of the transfer function $R(\lambda)$, such as poles, transmission zeros, decoupling zeros, etc. In the scalar case, where $\{T(\lambda), U(\lambda), V(\lambda), W(\lambda)\}$ are scalar polynomials, all of this can be found with a greatest common divisor (GCD) extraction routine and a rootfinder, for which reliable methods exist. In the matrix case, the problem becomes much more complex and the basic method for GCD extraction, the Euclidean algorithm, becomes unstable (see [14, p. 109]). Moreover, other structural elements (null spaces, etc.) come into the picture, making the polynomial approach less attractive than the state-space approach [14, p. 109, and references therein].

1.4.2.2 The State-Space Approach

The structural properties of interest are poles and zeros of $R(\lambda)$, decoupling zeros, controllable and unobservable subspaces, supremal (A, B) -invariant and controllability subspaces, factorizability of $R(\lambda)$, left and right null spaces of $R(\lambda)$, etc. These concepts are fundamental in several design problems and have received considerable attention over the last few decades; see, for example, [14, p. 74, 109, 174, 186, 529]. In [14, p. 109], it is shown that all the concepts mentioned above can be considered generalized eigenstructure problems and that they can be computed via the Kronecker canonical form of the pencils

$$\begin{array}{cc} [\lambda I - A] & [\lambda I - A \mid B] \\ \left[\begin{array}{c|c} \lambda I - A & B \\ \hline -C & D \end{array} \right] & \left[\begin{array}{c|c} \lambda I - A & B \\ \hline -C & D \end{array} \right] \end{array} \quad (1.27)$$

or from other pencils derived from these. Backward stable software is also available for computing the Kronecker structure of an arbitrary pencil. A remaining problem here is that determining several of the structural properties listed above may be ill-posed in some cases in which one has to develop the notion of restricted condition (see [14, p. 109]). A completely different approach is to reformulate the problem as an approximation or optimization problem for which *quantitative measures* are derived, leaving the final choice to the user. Results in this vein are obtained for controllability, observability [14, p. 171, 186, 195] (almost) (A, B) -invariant, and controllability subspaces.

1.4.3 Controllability and Other “Abilities”

The various “abilities” such as controllability, observability, reachability, reconstructibility, stabilizability, and detectability are basic to the study of linear control and system theory. These concepts can also be viewed in terms of decoupling zeros, controllable and unobservable subspaces, controllability subspaces, etc. mentioned in the previous section. Our remarks here are confined, but not limited, to the notion of controllability.

A large number of algebraic and dynamic characterizations of controllability have been given; see [11] for a sample. But each one of these has difficulties when implemented in finite arithmetic. For a survey of this topic and numerous examples, see [14, p. 186]. Part of the difficulty in dealing with controllability numerically lies in the intimate relationship with the invariant subspace problem [14, p. 589]. The controllable subspace associated with Equation 1.1 is the smallest A -invariant subspace (subspace spanned by eigenvectors or principal vectors) containing the range of B . Since the A -invariant subspaces can be extremely sensitive to perturbation, it follows that, so too, is the controllable subspace. Similar remarks apply to the computation of the so-called controllability indices. The example discussed in the third paragraph of Section 1.2 dramatically illustrates these remarks. The matrix A has but one eigenvector (associated with 0), whereas the slightly perturbed A has n eigenvectors associated with the n distinct eigenvalues.

Attempts have been made to provide numerically stable algorithms for the pole placement problem discussed in a later section. It suffices to mention here that the problem of pole placement by state feedback is closely related to controllability. Work on developing numerically stable algorithms for pole placement is based on the reduction of A to a Hessenberg form; see, for example, [14, p. 357, 371, 380]. In the single-input case, a good approach is the controller Hessenberg form mentioned above where the state matrix A is upper Hessenberg and the input vector B is a multiple of $(1, 0, \dots, 0)^T$. The pair (A, B) is then controllable if, and only if, all $(n - 1)$ subdiagonal elements of A are nonzero. If a subdiagonal element is 0, the system is uncontrollable, and a basis for the uncontrollable subspace is easily constructed. The transfer function gain or first nonzero Markov parameter is also easily constructed from this “canonical form.” In fact, the numerically more robust system Hessenberg form, playing an ever-increasing role in system theory, is replacing the numerically more fragile special case of the companion or rational canonical or Luenberger canonical form.

A more important aspect of controllability is a topological notion such as “near uncontrollability.” But there are numerical difficulties here also, and we refer to Parts 3 and 4 of [14] for further details. Related to this is an interesting system-theoretic concept called “balancing” discussed in Moore’s paper [14, p. 171]. The computation of “balancing transformations” is discussed in [14, p. 642].

There are at least two distinct notions of near uncontrollability [11] in the parametric sense and in the energy sense. In the parametric sense, a controllable pair (A, B) is said to be near uncontrollable if the parameters of (A, B) need be perturbed by only a relatively small amount for (A, B) to become uncontrollable. In the energy sense, a controllable pair is near-uncontrollable if large amounts of control energy ($\int u^T u$) are required for a state transfer. The pair

$$A = \begin{bmatrix} 0 & 1 & & \cdots & 0 \\ \vdots & \ddots & \ddots & & \vdots \\ \vdots & & & \ddots & 1 \\ 0 & \cdots & \cdots & \cdots & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}$$

is very near-uncontrollable in the energy sense but not as badly as in the parametric sense. Of course, both measures are coordinate dependent and “balancing” is one attempt to remove this coordinate bias. The pair (A, B) above is in “controllable canonical form.” It is now known that matrices in this form

(specifically, the A matrix in rational canonical form) almost always exhibit poor numerical behavior and are “close to” uncontrollable (unstable, etc.) as the size n increases. For details, see [14, p. 59].

1.4.4 Computation of Objects Arising in the Geometric Theory of Linear Multivariable Control

A great many numerical problems arise in the geometric approach to control of systems modeled as Equations 1.1 and 1.2. Some of these are discussed in the paper by Klema and Laub [14, p. 74]. The power of the geometric approach derives in large part from the fact that it is independent of specific coordinate systems or matrix representations. Numerical issues are a separate concern.

A very thorough numerical treatment of numerical problems in linear system theory has been given by Van Dooren [14, p. 109]. This work has applications for most calculations with linear state-space models. For example, one by-product is an extremely reliable algorithm (similar to an orthogonal version of Silverman’s structure algorithm) for the computation of multivariable system zeros [14, p. 271]. This method involves a generalized eigenvalue problem (the Rosenbrock pencil), but the “infinite zeros” are first removed by deflating the given matrix pencil.

1.4.5 Frequency Response Calculations

Many properties of a linear system such as Equations 1.1 and 1.2 are known in terms of its frequency response matrix

$$G(j\omega) := C(j\omega I - A)^{-1}B + D; \quad (\omega \geq 0) \quad (1.28)$$

(or $G(e^{j\theta})$; $\theta \in [0, 2\pi]$ for Equations 1.3 and 1.4). In fact, various norms of the return difference matrix $I + G(j\omega)$ and related quantities have been investigated in control and system theory to providing robust linear systems with respect to stability, noise response, disturbance attenuation, sensitivity, etc.

Thus it is important to compute $G(j\omega)$ efficiently, given A , B , and C for a (possibly) large number of values of ω (for convenience we take D to be 0, because if it is nonzero it is trivial to add to G). An efficient and generally applicable algorithm for this problem is presented in [14, p. 287]. Rather than solving the linear equation $(j\omega I - A)X = B$ with dense unstructured A , which would require $O(n^3)$ operations for each successive value of ω , the new method initially reduces A to upper Hessenberg form H . The orthogonal state-space coordinate transformations used to obtain the Hessenberg form of A are incorporated into B and C giving \tilde{B} and \tilde{C} . As ω varies, the coefficient matrix in the linear equation $(j\omega I - H)X = \tilde{B}$ remains in upper Hessenberg form. The advantage is that X can now be found in $O(n^2)$ operations rather than $O(n^3)$ as before, a substantial saving. Moreover, the method is numerically very stable (via either LU or QR factorization) and has the advantage of being independent of the eigenstructure (possibly ill-conditioned) of A . Another efficient and reliable algorithm for frequency response computation [14, p. 289] uses the observer Hessenberg form mentioned in Section 1.4.1 together with a determinant identity and a property of the LU decomposition of a Hessenberg matrix.

The methods above can also be extended to state-space models in implicit form, that is, where Equation 1.1 is replaced by

$$E\dot{x} = Ax + Bu. \quad (1.29)$$

Then Equation 1.28 is replaced with

$$G(j\omega) = C(j\omega E - A)^{-1}B + D, \quad (1.30)$$

and the initial triangular/Hessenberg reduction [8] can be employed again to reduce the problem to updating the diagonal of a Hessenberg matrix and consequently an $O(n^2)$ problem.

An improvement for the frequency response evaluation problem is using matrix interpolation methods to achieve even greater computational efficiency.

1.4.6 Numerical Solution of Linear Ordinary Differential Equations and Matrix Exponentials

The “simulation” or numerical solution of linear systems of ordinary differential equations (ODEs) of the form

$$\dot{x}(t) = Ax(t) + f(t), \quad x(0) = x_0, \tag{1.31}$$

is a standard problem that arises in finding the time response of a system in state-space form. However, there is still debate as to the most effective numerical algorithm, particularly when A is defective (i.e., when A is $n \times n$ and has fewer than n linearly independent eigenvectors) or nearly defective. The most common approach involves computing the matrix exponential e^{tA} , because the solution of Equation 1.31 can be written simply as

$$x(t) = e^{tA}x_0 + \int_0^t e^{(t-s)A}f(s) ds.$$

A delightful survey of computational techniques for matrix exponentials is given in [14, p. 649]. Nineteen “dubious” ways are explored (there are many more ways not discussed) but no clearly superior algorithm is singled out. Methods based on Padé approximation or reduction of A to RSF are generally attractive while methods based on Taylor series or the characteristic polynomial of A are generally found unattractive. An interesting open problem is the design of a special algorithm for the matrix exponential when the matrix is known *a priori* to be stable ($\Lambda(A)$ in the left half of the complex plane).

The reason for the adjective “dubious” in the title of [14, p. 649] is that in many (maybe even most) circumstances, it is better to treat Equation 1.31 as a system of differential equations, typically stiff, and to apply various ODE techniques, specially tailored to the linear case. ODE techniques are preferred when A is large and sparse for, in general, e^{tA} is unmanageably large and dense.

1.4.7 Lyapunov, Sylvester, and Riccati Equations

Certain matrix equations arise naturally in linear control and system theory. Among those frequently encountered in the analysis and design of continuous-time systems are the Lyapunov equation

$$AX + XA^T + Q = 0, \tag{1.32}$$

and the Sylvester equation

$$AX + XF + Q = 0. \tag{1.33}$$

The appropriate discrete-time analogs are

$$AXA^T - X + Q = 0 \tag{1.34}$$

and

$$AXF - X + Q = 0. \tag{1.35}$$

Various hypotheses are posed for the coefficient matrices A , F , and Q to ensure certain properties of the solution X .

The literature in control and system theory on these equations is voluminous, but most of it is ad hoc, at best, from a numerical point of view, with little attention to questions of numerical stability, conditioning, machine implementation, and the like.

For the Lyapunov equation, the best overall algorithm in terms of efficiency, accuracy, reliability, availability, and ease of use is that of Bartels and Stewart [14, p. 430]. The basic idea is to reduce A to quasi-upper triangular form (or RSF) and to perform a back substitution for the elements of X .

An attractive algorithm for solving Lyapunov equations has been proposed by Hammarling [14, p. 500]. This algorithm is a variant of the Bartels–Stewart algorithm but instead solves directly for the Cholesky

factor Y of X : $Y^T Y = X$ and Y is upper triangular. Clearly, given Y , X is easily recovered if necessary. But in many applications, for example, [14, p. 642] only the Cholesky factor is required.

For the Lyapunov equation, when A is stable, the solutions of the equations above are also equal to the reachability and observability Grammians $P_r(T)$ and $P_o(T)$, respectively, for $T = +\infty$ for the system $\{A, B, C\}$:

$$\begin{aligned} P_r(T) &= \int_0^T e^{tA} B B^T e^{tA^T} dt; & P_o(T) &= \int_0^T e^{tA^T} C^T C e^{tA} dt \\ P_r(T) &= \sum_{k=0}^T A^k B B^T (A^T)^k; & P_o(T) &= \sum_{k=0}^T (A^T)^k C^T C A^k. \end{aligned} \quad (1.36)$$

These can be used along with some additional transformations (see [14, p. 171, 642]) to compute the so-called *balanced* realizations $\{\tilde{A}, \tilde{B}, \tilde{C}\}$. For these realizations, both P_o and P_r are equal and diagonal. These realizations have some nice sensitivity properties with respect to poles, zeros, truncation errors in digital filter implementations, etc. [14, p. 171]. They are, therefore, recommended whenever the choice of a realization is left to the user. When A is not stable, one can still use the *finite range* Grammians Equation 1.36, for $T < +\infty$, for balancing [14, p. 171]. A reliable method for computing integrals and sums of the type Equation 1.36 can be found in [14, p. 681]. It is also shown in [14, p. 171] that the reachable subspace and the unobservable subspace are the image and the kernel of $P_r(T)$ and $P_o(T)$, respectively. From these relationships, sensitivity properties of the spaces under perturbations of $P_r(T)$ and $P_o(T)$ can be derived.

For the Sylvester equation, the Bartels–Stewart algorithm reduces both A and F to RSF and then a back substitution is done. It has been demonstrated in [14, p. 495] that some improvement in this procedure is possible by only reducing the larger of A and F to upper Hessenberg form. The stability of this method has been analyzed in [14, p. 495]. Although only *weak stability* is obtained, this is satisfactory in most cases.

Algorithms are also available in the numerical linear algebra literature for the more general Sylvester equation

$$A_1 X F_1^T + A_2 X F_2^T + Q = 0$$

and its symmetric Lyapunov counterpart

$$A X F^T + F X A^T + Q = 0.$$

Questions remain about estimating the condition of Lyapunov and Sylvester equations efficiently and reliably in terms of the coefficient matrices. A deeper analysis of the Lyapunov and Sylvester equations is probably a prerequisite to at least a better understanding of condition of the Riccati equation for which, again, there is considerable theoretical literature but not as much known from a purely numerical point of view. The symmetric $n \times n$ algebraic Riccati equation takes the form

$$Q + A X + X A^T - X G X = 0 \quad (1.37)$$

for continuous-time systems and

$$A^T X A - X - A^T X G_1 (G_2 + G_1^T X G_1)^{-1} G_1^T X A + Q = 0 \quad (1.38)$$

for discrete-time systems. These equations appear in several design/analysis problems, such as optimal control, optimal filtering, spectral factorization, for example, see the papers in Part 7 of [14] and references therein. Again, appropriate assumptions are made on the coefficient matrices to guarantee the existence and/or uniqueness of certain kinds of solutions X . Nonsymmetric Riccati equations of the form

$$Q + A_1 X + X A_2 - X G X = 0 \quad (1.39)$$

for the continuous-time case (along with an analog for the discrete-time case) are also studied and can be solved numerically by the techniques discussed below.

Several algorithms have been proposed based on different approaches. One of the more reliable general-purpose methods for solving Riccati equations is the Schur method [14, p. 529]. For the case of Equation 1.37, for example, this method is based on reducing the associated $2n \times 2n$ Hamiltonian matrix

$$\begin{bmatrix} A & -G \\ -Q & -A^T \end{bmatrix} \quad (1.40)$$

to RSF. If the RSF is ordered so that its stable eigenvalues (there are exactly n of them under certain standard assumptions) are in the upper left corner, the corresponding first n vectors of the orthogonal matrix, which effects the reduction, forms a basis for the stable eigenspace from which the nonnegative definite solution X is then easily found.

Extensions to the basic Schur method have been made [14, p. 562, 573], which were prompted by the following situations:

- G in Equation 1.37 is of the form $BR^{-1}B^T$, where R may be nearly singular, or G_2 in Equation 1.38 may be exactly or nearly singular.
- A in Equation 1.38 is singular (A^{-1} is required in the classical approach involving a symplectic matrix that plays a role analogous to Equation 1.40).

This resulted in the generalized eigenvalue approach requiring the computation of a basis for the deflating subspace corresponding to the stable generalized eigenvalues. For the solution of Equation 1.37, the generalized eigenvalue problem is given by

$$\lambda \begin{bmatrix} I & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & 0 \end{bmatrix} - \begin{bmatrix} A & 0 & B \\ -Q & -A^T & 0 \\ 0 & B^T & R \end{bmatrix}; \quad (1.41)$$

for Equation 1.38, the corresponding problem is

$$\lambda \begin{bmatrix} I & 0 & 0 \\ 0 & A^T & 0 \\ 0 & G_1^T & 0 \end{bmatrix} - \begin{bmatrix} A & 0 & -G_1 \\ -Q & I & 0 \\ 0 & 0 & G_2 \end{bmatrix}. \quad (1.42)$$

The extensions above can be generalized even further, as the following problem illustrates. Consider the optimal control problem

$$\min \frac{1}{2} \int_0^{+\infty} [x^T Qx + 2x^T Su + u^T Ru] dt \quad (1.43)$$

subject to

$$E\dot{x} = Ax + Bu. \quad (1.44)$$

The Riccati equation associated with Equations 1.43 and 1.44 then takes the form

$$E^T XBR^{-1}B^T XE - (A - BR^{-1}S^T)^T XE - E^T X(A - BR^{-1}S^T) - Q + SR^{-1}S^T = 0 \quad (1.45)$$

or

$$(E^T XB + S)R^{-1}(B^T XE + S^T) - A^T XE - E^T XA - Q = 0. \quad (1.46)$$

This so-called “generalized” Riccati equation can be solved by considering the associated matrix pencil

$$\begin{bmatrix} A & 0 & B \\ -Q & -A^T & -S \\ S^T & B^T & R \end{bmatrix} - \lambda \begin{bmatrix} E & 0 & 0 \\ 0 & E^T & 0 \\ 0 & 0 & 0 \end{bmatrix}. \quad (1.47)$$

Note that S in Equation 1.43 and E in Equation 1.44 are handled directly and no inverses appear. The presence of a nonsingular E in state-space models of the form Equation 1.44 adds no particular difficulty

to the solution process and is numerically the preferred form if E is, for example, near singular or even sparse. Similar remarks apply to the frequency response problem in Equations 1.29 and 1.30 and, indeed, throughout all of linear control and system theory. The stability and conditioning of these approaches are discussed in [14, p. 529, 573]. Other methods, including Newton's method and iterative refinement, have been analyzed in, for example, [14, p. 517]. Numerical algorithms for handling Equations 1.41, 1.42, and 1.47 and a large variety of related problems are described in [14, p. 421, 573]. A thorough survey of the Schur method, generalized eigenvalue/eigenvector extensions, and the underlying algebraic structure in terms of "Hamiltonian pencils" and "symplectic pencils" is included in [3,12].

Schur techniques can also be applied to Riccati differential and difference equations and to nonsymmetric Riccati equations that arise, for example, in invariant imbedding methods for solving linear two-point boundary value problems.

As with the linear Lyapunov and Sylvester equations, satisfactory results have been obtained concerning condition of Riccati equations, a topic of great interest independent of the solution method used, be it a Schur-type method or one of numerous alternatives. We refer to [1] for a further discussion on this.

A very interesting class of invariant-subspace-based algorithms for solving the Riccati equation and related problems uses the so-called matrix sign function. These methods, which are particularly attractive for very large-order problems, are described in detail in [14, p. 486] and the references therein. These algorithms are based on Newton's method applied to a certain matrix equation. A new family of iterative algorithms of arbitrary order convergence has been developed in [14, p. 624]. This family of algorithms can be parallelized easily and yields a viable method of solution for very high-order Riccati equations.

1.4.8 Pole Assignment and Observer Design

Designing state or output feedback for a linear system, so that the resulting closed-loop system has a desired set of poles, can be considered an inverse eigenvalue problem. The state feedback pole assignment problem is as follows: Given a pair (A, B) , one looks for a matrix F so that the eigenvalues of the matrix

$$A_F = A + BF$$

lie at specified locations or in specified regions. Many approaches have been developed for solving this problem. However, the emphasis is on numerically reliable methods and consideration of the numerical sensitivity of the problem, for example, see the papers in Part 6 of [14]. Special cases of the pole assignment problem arise in observer design [14, p. 407], and in deadbeat control for discrete-time systems (where $A + BF$ is required to be nilpotent) [14, p. 392]. The numerically reliable methods for pole assignment are based on reducing A to either an RSF, [14, p. 415], or to a Hessenberg or block Hessenberg (staircase) form [14, p. 357, 380]. The latter may be regarded a numerically robust alternative to the controllable or Luenberger canonical form whose computation is known to be numerically unreliable [14, p. 59]. For multi-input systems, the additional freedom available in the state-feedback matrix can be used for eigenvector assignment and sensitivity minimization for the closed-loop poles [14, p. 333]. There the resulting matrix A_F is not computed directly, but instead the matrices Λ and X of the decomposition

$$A_F = X\Lambda X^{-1}$$

are computed via an iterative technique. The iteration aims to minimize the sensitivity of the placed eigenvalues λ_i or to maximize the orthogonality of the eigenvectors x_i .

Pole assignment by output feedback is more difficult, theoretically as well as computationally. Consequently, there are a few numerically reliable algorithms available [14, p. 371]. Other works on pole assignment have been concerned with generalized state-space or descriptor systems.

The problem of observer design for a given state-space system $\{A, B, C\}$ is finding matrices T , A_K , and K so that

$$TA_K - AT = KC \tag{1.48}$$

whereby the spectrum of A_K is specified. Because this is an underdetermined (and nonlinear) problem in the unknown parameters of T , A_K , and K , one typically sets $T = I$ and Equation 1.48 then becomes

$$A_K = A + KC,$$

which is a transposed pole placement problem. In this case, the above techniques of pole placement automatically apply here. In reduced order design, T is nonsquare and thus cannot be equated to the identity matrix. One can still solve Equation 1.48 via a recurrence relationship when assuming A_K in Schur form [14, p. 407].

1.4.9 Robust Control

In the last decade, there has been significant growth in the theory and techniques of robust control; see, for example, [6] and the references therein. However, the area of robust control is still evolving and its numerical aspects have just begun to be addressed [13]. Consequently, it is premature to survey reliable numerical algorithms in the area. To suggest the flavor of the numerical and computational issues involved, in this section we consider a development in robust control that has attracted a great deal of attention, the so-called H_∞ approach. H_∞ and the related structured singular value approach have provided a powerful framework for synthesizing *robust* controllers for linear systems. The controllers are robust, because they achieve desired system performance despite a significant amount of uncertainty in the system.

In this section, we denote by $\mathbb{R}(s)^{n \times m}$ the set of proper real rational matrices of dimension $n \times m$. The H_∞ norm of a stable matrix $G(s) \in \mathbb{R}(s)^{n \times m}$ is defined as

$$\|G(s)\|_\infty := \sup_{\omega \in \mathbb{R}} \sigma_{\max}[G(j\omega)], \tag{1.49}$$

where $\sigma_{\max}[\cdot]$ denotes the largest singular value of a (complex) matrix. Several iterative methods are available for computing this norm. In one approach, a relationship is established between the singular values of $G(j\omega)$ and the imaginary eigenvalues of a Hamiltonian matrix obtained from a state-space realization of $G(s)$. This result is then used to develop an efficient bisection algorithm for computing the H_∞ norm of $G(s)$.

To describe the basic H_∞ approach, consider a linear, time-invariant system described by the state-space equations

$$\begin{aligned} \dot{x}(t) &= Ax(t) + B_1 w(t) + B_2 u(t), \\ z(t) &= C_1 x(t) + D_{11} w(t) + D_{12} u(t), \\ y(t) &= C_2 x(t) + D_{21} w(t) + D_{22} u(t), \end{aligned} \tag{1.50}$$

where $x(t) \in \mathbb{R}^n$ denotes the state vector; $w(t) \in \mathbb{R}^{m_1}$ is the vector of disturbance inputs; $u(t) \in \mathbb{R}^{m_2}$ is the vector of control inputs; $z(t) \in \mathbb{R}^{p_1}$ is the vector of error signals; and $y(t) \in \mathbb{R}^{p_2}$ is the vector of measured variables. The transfer function relating the inputs $\begin{bmatrix} w \\ u \end{bmatrix}$ to the outputs $\begin{bmatrix} z \\ y \end{bmatrix}$ is

$$G(s) := \begin{bmatrix} G_{11}(s) & G_{12}(s) \\ G_{21}(s) & G_{22}(s) \end{bmatrix} \tag{1.51}$$

$$= \begin{bmatrix} D_{11} & D_{12} \\ D_{21} & D_{22} \end{bmatrix} + \begin{bmatrix} C_1 \\ C_2 \end{bmatrix} (sI - A)^{-1} \begin{bmatrix} B_1 & B_2 \end{bmatrix}. \tag{1.52}$$

Implementing a feedback controller defined by

$$u = K(s)y \tag{1.53}$$

where $K(s) \in \mathbb{R}(s)^{m_2 \times p_2}$, we obtain the closed-loop transfer matrix $T_{zw}(s) \in \mathbb{R}(s)^{p_1 \times m_1}$ from the disturbance w to the regulated output z

$$T_{zw} := G_{11} + G_{12}K(I - G_{22}K)^{-1}G_{21}. \quad (1.54)$$

Next, define the set \mathcal{K} of all internally stabilizing feedback controllers for the system in Equation 1.50, that is,

$$\mathcal{K} := \{K(s) \in \mathbb{R}(s)^{m_2 \times p_2} : T_{zw}(s) \text{ is internally stable}\}.$$

Now let $K(s) \in \mathcal{K}$, and define

$$\gamma := \|T_{zw}(s)\|_{\infty}. \quad (1.55)$$

Then the H_{∞} control problem is to find a controller $K(s) \in \mathcal{K}$ that minimizes γ . The optimal value of γ is defined as

$$\gamma_{\text{opt}} := \inf_{K \in \mathcal{K}} \|T_{zw}(s)\|_{\infty}. \quad (1.56)$$

The original formulation of this problem was in an input–output setting, and the early methods for computing γ_{opt} used either an iterative search involving spectral factorization and solving the resulting Nehari problem or computed the spectral norm of the associated Hankel plus Toeplitz operator. In a state-space formulation for computing γ_{opt} , promising from the viewpoint of numerical computation, the problem is formulated in terms of two algebraic Riccati equations that depend on a gain parameter γ . Then, under certain assumptions [13], it can be shown that for a controller $K(s) \in \mathcal{K}$ to exist so that $\|T_{zw}\|_{\infty} < \gamma$, three conditions have to be satisfied, namely, stabilizing solutions exist for the two Riccati equations, and the spectral radius of the product of the solutions is bounded by γ^2 . If these conditions are satisfied for a particular value of γ , the corresponding controller $K(s)$ can be obtained from the solutions of the Riccati equations. The optimal gain, γ_{opt} , is the infimum over all suboptimal values of γ such that the three conditions are satisfied.

The approach above immediately suggests a bisection-type algorithm for computing γ_{opt} . However, such an algorithm can be very slow in the neighborhood of the optimal value. To obtain speedup near the solution, a gradient approach is proposed in [13]. The behavior of the Riccati solution as a function of γ is used to derive an algorithm that couples a gradient method with bisection. It has been pointed out in [13] that the Riccati equation can become ill-conditioned as the optimal value of γ is approached. It is therefore recommended in [13] that, instead of computing the Riccati solutions explicitly, invariant subspaces of the associated Hamiltonian matrices should be used.

1.5 Mathematical Software

1.5.1 General Remarks

The previous sections have highlighted some topics from numerical linear algebra and their application to numerical problems arising in systems, control, and estimation theory. These problems represent only a very small subset of numerical problems of interest in these fields but, even for problems apparently “simple” from a mathematical viewpoint, the myriad of details that constitute a sophisticated implementation become so overwhelming that the only effective means of communicating an algorithm is through mathematical software. Mathematical or numerical software is an implementation on a computer of an algorithm for solving a mathematical problem. Ideally, such software would be reliable, portable, and unaffected by the machine or system environment.

The prototypical work on reliable, portable mathematical software for the standard eigenproblem began in 1968. EISPACK, Editions I and II [7,15], were an outgrowth of that work. Subsequent efforts of interest to control engineers include LINPACK [5] for linear equations and linear least-squares problems, FUNPACK (Argonne) for certain function evaluations, MINPACK (Argonne) for certain optimization problems, and various ODE and PDE codes. High-quality algorithms are published regularly in the

ACM Transactions on Mathematical Software. LAPACK, the successor to LINPACK and EISPACK, is designed to run efficiently on a wide range of machines, including vector processors, shared-memory multiprocessors, and high-performance workstations.

Technology to aid in developing mathematical software in Fortran has been assembled as a package called TOOLPACK. Mechanized code development offers other advantages with respect to modifications, updates, versions, and maintenance.

Inevitably, numerical algorithms are strengthened when their mathematical software is portable, because they can be used widely. Furthermore, such a software is markedly faster, by factors of 10 to 50, than earlier and less reliable codes.

Many other features besides portability, reliability, and efficiency characterize “good” mathematical software, for example,

- High standards of documentation and style so as to be easily understood and used
- Ease of use; ability of the user to interact with the algorithm
- Consistency/compatibility/modularity in the context of a larger package or more complex problem
- Error control, exception handling
- Robustness in unusual situations
- Graceful performance degradation as problem domain boundaries are approached
- Appropriate program size (a function of intended use, e.g., low accuracy, real-time applications)
- Availability and maintenance
- “Tricks” such as underflow-/overflow-proofing, if necessary, and the implementation of column-wise or rowwise linear algebra

Clearly, the list can go on.

What becomes apparent from these considerations is that evaluating mathematical software is a challenging task. The quality of software is largely a function of its operational specifications. It must also reflect the numerical aspects of the algorithm being implemented. The language used and the compiler (e.g., optimizing or not) for that language have an enormous impact on quality, perceived and real, as does the underlying hardware and arithmetic. Different implementations of the same algorithm can have markedly different properties and behavior.

One of the most important and useful developments in mathematical software for most control engineers has been very high-level systems such as MATLAB[®] and Scilab. These systems spare the engineer the drudgery of working at a detailed level with languages such as Fortran and C, and they provide a large number of powerful computational “tools” (frequently through the availability of formal “toolboxes”). For many problems, the engineer must still have some knowledge of the algorithmic details embodied in such a system.

1.5.2 Mathematical Software in Control

Many aspects of systems, control, and estimation theory are at the stage from which one can start the research and design necessary to produce reliable, portable mathematical software. Certainly, many of the underlying linear algebra tools (e.g., in EISPACK, LINPACK, and LAPACK) are considered sufficiently reliable to be used as black, or at least gray, boxes by control engineers. An important development in this area is the SLICOT library, which is described in [1, p. 60]. Much of that theory and methodology can and has been carried over to control problems, but this applies only to a few basic control problems. Typical examples are Riccati equations, Lyapunov equations, and certain basic state-space transformations and operations. Much of the work in control, particularly design and synthesis, is simply not amenable to nice, “clean” algorithms. The ultimate software must be capable of enabling a dialogue between the computer and the control engineer, but with the latter probably still making the final engineering decisions.

1.6 Concluding Remarks

Several numerical issues and techniques from numerical linear algebra together with a number of important applications of these ideas have been outlined. A key question in these and other problems in systems, control, and estimation theory is what can be computed reliably and used in the presence of parameter uncertainty or structural constraints (e.g., certain “hard zeros”) in the original model, and rounding errors in the calculations. However, because the ultimate goal is to solve real problems, reliable tools (mathematical software) and experience must be available to effect real solutions or strategies. The interdisciplinary effort during the last few decades has significantly improved our understanding of the issues involved in reaching this goal and has resulted in some high-quality control software based on numerically reliable and well-tested algorithms. This provides clear evidence of the fruitful symbiosis between numerical analysis and numerical problems from control. We expect this symbiotic relationship to flourish, as control engineering realizes the full potential of the computing power becoming more widely available in multiprocessing systems and high-performance workstations. However, as in other applications areas, software continues to act as a constraint and a vehicle for progress. Unfortunately, high-quality software is very expensive.

In this chapter, we have focused only on dense numerical linear algebra problems in systems and control. Several related topics that have not been covered here are, for example, parallel algorithms, algorithms for sparse or structured matrices, optimization algorithms, ODE algorithms, algorithms for differential-algebraic systems, and approximation algorithms. These areas are well established in their own right, but for control applications a lot of groundwork remains undone. The main reason we have confined ourselves to dense numerical linear algebra problems in systems and control is that, in our opinion, this area has reached a mature level where definitive statements and recommendations can be made about various algorithms and other developments.

2.1 Introduction

In this chapter we will introduce the basic building blocks necessary to understand linear time-invariant, multivariable systems. We will examine solutions of linear systems in both the time domain and frequency domain. An important issue is our ability to change the system's response by applying different inputs. We will thus introduce the concept of controllability. Similarly, we will introduce the concept of observability to quantify how well we can determine what is happening internally in our model when we can observe only the outputs of the system. An important issue in controllability and observability is the role of zeros. We will define them for multivariable systems and show their role in these concepts. Throughout, we will introduce the linear algebra tools necessary for multivariable systems.

2.2 Unforced Linear Systems

2.2.1 Eigenvectors and Eigenvalues

Given a matrix $A \in \mathcal{R}^{n \times n}$, the eigenstructure of A is defined by n complex numbers λ_i . When the λ_i are all different, each λ_i has corresponding vectors $v_i \in \mathcal{C}^n$ and $w_i \in \mathcal{C}^n$ so that

$$Av_i = \lambda_i v_i; \quad w_i^H A = \lambda_i w_i^H; \quad i = 1 \dots n \quad (2.1)$$

where w^H is the complex conjugate transpose of w . The complex numbers λ_i are called the eigenvalues of A . The vectors v_i are called the right eigenvectors, and the vectors w_i are called the left eigenvectors. Notice that any multiple of an eigenvector is also an eigenvector.

The left and right eigenvectors are mutually orthogonal, that is, they satisfy the property

$$w_i^H v_j = \delta_{ij} \triangleq \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases} \quad (2.2)$$

We assume throughout that the eigenvalues are distinct; that is, they are all different. The case where eigenvalues repeat is much more complicated, both theoretically and computationally. The case of repeated eigenvalues is covered in Kailath [1].

One other formula useful for describing linear systems is the dyadic formula. This formula shows how the matrix A can be formed from its eigenvalues and eigenvectors. It is given by

$$A = \sum_{i=1}^n \lambda_i v_i w_i^H \quad (2.3)$$

2.2.2 The Matrix Exponential

The matrix exponential, e^A , is defined by

$$e^A = I + A + \frac{1}{2}A^2 + \frac{1}{6}A^3 + \dots \quad (2.4)$$

$$= \sum_{k=0}^{\infty} \frac{1}{k!} A^k \quad (2.5)$$

The matrix exponential solves the following matrix differential equation

$$\dot{x}(t) = Ax(t), \quad x(0) = \xi \quad (2.6)$$

The solution is

$$x(t) = e^{At} \xi \quad (2.7)$$

The matrix exponential can be calculated from the eigenstructure of the matrix A . If A has the eigenstructure as in Equation 2.1, then

$$e^A = \sum_{i=1}^n e^{\lambda_i} v_i w_i^H \quad \text{and} \quad e^{At} = \sum_{i=1}^n e^{\lambda_i t} v_i w_i^H \quad (2.8)$$

This can be seen by writing the matrix exponential using the infinite sum, substituting in the dyadic formula (Equation 2.3), and using Equation 2.2.

Taking the Laplace transform of Equation 2.6,

$$s x(s) - \xi = A x(s) \quad (2.9)$$

where we have used the initial condition $x(0) = \xi$. Thus, the solution is

$$x(s) = (sI - A)^{-1} \xi \quad (2.10)$$

Therefore, $(sI - A)^{-1}$ is the Laplace transform of e^{At} .

2.2.3 Definition of Modes

The solution to the unforced system Equation 2.6 can be written in terms of the eigenstructure of A as

$$x(t) = e^{At}\xi = \sum_{i=1}^n e^{\lambda_i t} v_i (w_i^H \xi) \quad (2.11)$$

The i th mode is $e^{\lambda_i t} v_i$, defined by the direction of the right eigenvector v_i , and the exponential associated with the eigenvalue λ_i . $w_i^H \xi$ is a scalar, specifying the degree to which the initial condition ξ excites the i th mode.

Taking Laplace transforms,

$$x(s) = \sum_{i=1}^n \frac{1}{s - \lambda_i} v_i w_i^H \xi \quad (2.12)$$

From this equation,

$$x(s) = (sI - A)^{-1} \xi = \sum_{i=1}^n \frac{1}{s - \lambda_i} v_i w_i^H \xi \quad (2.13)$$

When the initial condition is equal to one of the right eigenvectors, only the mode associated with that eigenvector is excited. To see this, let $\xi = v_j$. Then, using Equation 2.2,

$$x(t) = \sum_{i=1}^n e^{\lambda_i t} v_i (w_i^H v_j) = e^{\lambda_j t} v_j \quad (2.14)$$

A mode is called stable if the dynamics of the modal response tend to zero asymptotically. This is, therefore, equivalent to

$$\operatorname{Re}(\lambda_i) < 0 \quad (2.15)$$

A system is said to be stable if all of its modes are stable. Thus, for any initial condition, $x(t) \rightarrow 0$ if the system is stable.

2.2.4 Multivariable Poles

Consider the system

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (2.16)$$

$$y(t) = Cx(t) + Du(t) \quad (2.17)$$

The multivariable poles are defined as the eigenvalues of A . Thus, the system is stable if all of its poles are strictly in the left half of the s -plane. The poles are therefore the roots of the equation

$$\det(sI - A) = 0 \quad (2.18)$$

2.3 Forced Linear Time-Invariant Systems

2.3.1 Solution to Forced Systems

We consider the dynamical system

$$\dot{x}(t) = Ax(t) + Bu(t), \quad x(0) = \xi \quad (2.19)$$

$$y(t) = Cx(t) + Du(t) \quad (2.20)$$

The solution $x(t)$ to this equation is

$$x(t) = e^{At}\xi + \int_0^t e^{A(t-\tau)}Bu(\tau) d\tau \quad (2.21)$$

This can be seen by differentiating the solution, and substituting in Equation 2.19. The output $y(t)$ is thus

$$y(t) = Cx(t) + Du(t) = Ce^{At}\xi + \int_0^t Ce^{A(t-\tau)}Bu(\tau) d\tau + Du(t) \quad (2.22)$$

Using the eigenstructure of A , we can write

$$y(t) = \sum_{i=1}^n e^{\lambda_i t} (Cv_i)(w_i^H \xi) \quad (2.23)$$

$$+ \sum_{i=1}^n e^{\lambda_i t} (Cv_i)(w_i^H B) \int_0^t e^{-\lambda_i \tau} u(\tau) d\tau + Du(t) \quad (2.24)$$

Applying the Laplace Transform to the system Equations 2.19 and 2.20,

$$y(s) = C(sI - A)^{-1}Bu(s) + Du(s) \quad (2.25)$$

Using the eigenstructure of A , we can substitute for $(sI - A)^{-1}$ to get the Laplace Transform equation

$$y(s) = \sum_{i=1}^n \frac{Cv_i w_i^H B}{s - \lambda_i} u(s) + Du(s) \quad (2.26)$$

The matrix $\frac{Cv_i w_i^H B}{(s - \lambda_i)}$ is called the residue matrix at the pole $s = \lambda_i$.

We can see that $w_i^H B$ is an indication of how much the i th mode is excited by the inputs, and Cv_i indicates how much the i th mode is observed in the outputs. This is the basis for the concepts of controllability and observability, respectively.

2.3.2 Controllability and Observability

Controllability is concerned with how much an input affects the states of a system. The definition is general enough to handle nonlinear systems and time-varying systems.

Definition 2.1:

The nonlinear time-invariant (LTI) system

$$\dot{x}(t) = f[x(t), u(t)], \quad x(0) = \xi, \quad (2.27)$$

is called completely controllable if, for any initial state ξ and any final state θ , we can find a piecewise, continuous bounded function $u(t)$ for $0 \leq t \leq T$, $T < \infty$, so that $x(T) = \theta$. A system which is not completely controllable is called uncontrollable.

Observability is defined similarly.

Definition 2.2:

The nonlinear time-invariant system

$$\dot{x}(t) = f[x(t), u(t)], \quad x(0) = \xi \quad (2.28)$$

$$y(t) = g[x(t), u(t)] \quad (2.29)$$

is observable if one can calculate the initial state ξ based upon measurements of the input $u(t)$ and output $y(t)$ for $0 \leq t \leq T$, $T < \infty$. A system which is not observable is called unobservable.

For LTI systems, there are simple tests to determine if a system is controllable and observable. The i th mode is uncontrollable if, and only if,

$$w_i^H B = 0 \quad (2.30)$$

Thus a mode is called uncontrollable if none of the inputs can excite the mode. The system is uncontrollable if it is uncontrollable from any mode. Thus, a system is controllable if

$$w_i^H B \neq 0 \quad i = 1, \dots, n \quad (2.31)$$

Similarly, the i th mode is unobservable if, and only if,

$$C v_i = 0 \quad (2.32)$$

Thus a mode is called unobservable if we can not see its effects in any of the outputs. The system is unobservable if it is unobservable from any mode. Thus, a system is unobservable if

$$C v_i \neq 0, \quad i = 1, \dots, n \quad (2.33)$$

2.3.3 Other Tests for Controllability and Observability

There is a simple algebraic test for controllability and observability. Let us define the controllability matrix M_c as

$$M_c = [B \quad AB \quad A^2B \quad \dots \quad A^{n-1}B] \quad (2.34)$$

The system is controllable if, and only if, $\text{rank}(M_c) = n$. Note that if the rank of M_c is less than n , we do not know anything about the controllability of individual modes. We only know that at least one mode is uncontrollable.

There is a similar test to determine the observability of the system. We form the observability matrix M_o as

$$M_o = \begin{bmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{bmatrix}. \quad (2.35)$$

The system is observable if, and only if, $\text{rank}(M_o) = n$. Again, this test provides no insight into the observability of the modes of the system. It only determines whether or not the whole system is observable.

We now have tests for controllability and observability. We will now relate the loss of controllability and observability to pole-zero cancellations. First, we need to define the concept of a zero for a multi-input multioutput system.

2.4 Multivariable Transmission Zeros

There are several ways in which zeros can be defined for multivariable systems. The one we will examine is based on a generalized eigenvalue problem and has an interesting physical interpretation. Another approach to defining and calculating the zeros of MIMO systems can be found in Kailath [1].

2.4.1 Definition of MIMO Transmission Zeros

To define the multi-input, multi-output (MIMO) transmission zeros, we will first assume that we have a system with the same number of inputs and outputs. This is referred to as a square system. We will later extend the definition to nonsquare systems. For square systems, we can represent the system in the time domain as

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (2.36)$$

$$y(t) = Cx(t) + Du(t) \quad (2.37)$$

where $x(t) \in \mathcal{R}^n$, $u(t) \in \mathcal{R}^m$, and $y(t) \in \mathcal{R}^m$. We can also write the transfer function matrix as

$$G(s) = C(sI - A)^{-1}B + D \quad (2.38)$$

where $G(s) \in \mathcal{C}^{m \times m}$. Given this system, we have the following definition:

Definition 2.3:

The plant has a zero at the (complex) value z_k if vectors $\xi_k \in \mathcal{C}^n$ and $u_k \in \mathcal{C}^m$ exist which are not both zero, so that the solution to the equations

$$\dot{x}(t) = Ax(t) + Bu_k e^{z_k t}, \quad x(0) = \xi_k \quad (2.39)$$

$$y(t) = Cx(t) + Du(t) \quad (2.40)$$

has the property that

$$y(t) \equiv 0 \quad \forall t > 0 \quad (2.41)$$

This property of transmission zeros is sometimes called transmission blocking. When zeros repeat, this definition still holds but a more complicated transmission blocking property also holds [2].

As an example, let us show that this definition is consistent with the standard definition of zeros for single-input, single-output systems.

Example 2.1:

Let us consider the following plant:

$$g(s) = \frac{s+1}{s(s-1)} \quad (2.42)$$

Then a state-space representation of this is

$$\dot{x}_1(t) = x_2(t) \quad (2.43)$$

$$\dot{x}_2(t) = x_2(t) + u(t) \quad (2.44)$$

$$y(t) = x_1(t) + x_2(t) \quad (2.45)$$

Let us define $u(t) = 2e^{-t}$, so that $u_k = 2$ and $z_k = -1$. Let us also define the vector ξ_k as

$$\xi_k = \begin{bmatrix} 1 \\ -1 \end{bmatrix} \quad (2.46)$$

Then

$$\dot{x}_2(t) = x_2(t) + 2e^{-t}, \quad x_2(0) = -1 \quad (2.47)$$

$$\Rightarrow x_2(t) = -e^t + e^t \int_0^t e^{-\tau} 2e^{-\tau} d\tau = -e^{-t} \quad (2.48)$$

$$\dot{x}_1(t) = x_2(t), \quad x_1(0) = 1 \quad (2.49)$$

$$\Rightarrow x_1(t) = 1 + e^{-t} - 1 = e^{-t} \quad (2.50)$$

Thus,

$$y(t) = x_1(t) + x_2(t) = 0 \quad (2.51)$$

So we have confirmed that $z = -1$ is a transmission zero of the system.

From the definition, we can see how transmission zeros got their name. If an input is applied at the frequency of the transmission zero in the correct direction (u_k), and the initial condition is in the correct direction ξ_k , then nothing is transmitted through the system.

2.4.2 Calculation of Transmission Zeros

To calculate the transmission zero, we can rewrite the definition of the transmission zero in matrix form as

$$\begin{bmatrix} z_k I - A & -B \\ -C & -D \end{bmatrix} \begin{bmatrix} \xi_k \\ u_k \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (2.52)$$

This is in the form of a generalized eigenvalue problem, typically written as

$$Gv_i = z_i Mv_i \quad (2.53)$$

$$w_i^H G = z_i w_i^H M \quad (2.54)$$

where z_i is a generalized eigenvalue, with right and left generalized eigenvectors v_i and w_i , respectively. The generalized eigenvalues are the roots of the equation

$$\det(zM - G) = 0 \quad (2.55)$$

Note that if M is invertible, there are n generalized eigenvalues. Otherwise, there are less than n .

Equation 2.52 is a generalized eigenvalue problem with

$$G = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \quad M = \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \quad (2.56)$$

Let us look at the implication of the generalized eigenvalue problem. Let z_k be a transmission zero. Then it must be true that

$$0 = \det \begin{bmatrix} z_k I - A & -B \\ -C & -D \end{bmatrix} \quad (2.57)$$

If there are no common poles and zeros, then $z_k I - A$ is invertible, and we can write

$$0 = \det(z_k I - A) \det[C(z_k I - A)^{-1}B + D] \quad (2.58)$$

$$= \det(z_k I - A) \det[G(z_k)] \quad (2.59)$$

Since we assume there are no common poles and zeros in the system, then $\det(z_k I - A) \neq 0$, and so it must be true that

$$\det(G(z_k)) = 0 \quad (2.60)$$

Thus, in the case that there are no common poles and zeros, the MIMO transmission zeros are the roots of Equation 2.60. To check for transmission zeros at the same frequencies as the poles, we must use the generalized eigenvalue problem.

Let us now give a multivariable example.

Example 2.2:

Consider the system given by Equations 2.36 and 2.37, with the matrices given by

$$A = \begin{bmatrix} -2 & 0 & 0 \\ 0 & -3 & 0 \\ 0 & 0 & -4 \end{bmatrix} \quad B = \begin{bmatrix} -1 & 0 \\ -1 & 0 \\ 0 & 1 \end{bmatrix} \quad (2.61)$$

$$C = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \end{bmatrix} \quad D = \begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix} \quad (2.62)$$

Solving the generalized eigenvalue problem Equation 2.52, we find that there are two zeros, given by

$$z_1 = -1 \quad z_2 = -3 \quad (2.63)$$

$$\xi_1 = \begin{bmatrix} 2 \\ 1 \\ 1 \end{bmatrix} \quad \xi_2 = \begin{bmatrix} 0 \\ 1 \\ -1 \end{bmatrix} \quad (2.64)$$

$$u_1 = \begin{bmatrix} -2 \\ 3 \end{bmatrix} \quad u_2 = \begin{bmatrix} 0 \\ -1 \end{bmatrix} \quad (2.65)$$

Let us also check the transfer function calculation. The transfer function matrix for this system is given by

$$G(s) = \begin{bmatrix} \frac{s+1}{s+2} & 0 \\ \frac{s+2}{s+3} & \frac{1}{s+4} \end{bmatrix} \quad (2.66)$$

To find transmission zeros at locations other than the poles of the system, we take the determinant and set it equal to zero to find

$$0 = \det(G(z)) = \frac{s+1}{(s+2)(s+4)} \quad (2.67)$$

Thus we find a transmission zero at $z = -1$. Notice that we have correctly found the transmission zero which is not at the pole frequency, but in this case we did not find the transmission zero at the same frequency as the pole at $s = -3$. It is also important to realize that, although one of the SISO transfer functions has a zero at $s = -2$, this is not a transmission zero of the MIMO system.

Also notice that this frequency domain method does not give us the directions of the zeros. We need to use the generalized eigenvalue problem to determine the directions.

2.4.3 Transmission Zeros for Nonsquare Systems

When we have a nonsquare system, we differentiate between right zeros and left zeros. In the following, we will assume we have a system with n states, m inputs, and p outputs.

Definition 2.4:

z_k is a right zero of the system,

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (2.68)$$

$$y(t) = Cx(t) + Du(t) \quad (2.69)$$

if vectors $\xi_k \in \mathcal{C}^n$ and $u_k \in \mathcal{C}^m$ exist, both not zero, so that

$$\begin{bmatrix} z_k I - A & -B \\ -C & -D \end{bmatrix} \begin{bmatrix} \xi_k \\ u_k \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (2.70)$$

Definition 2.5:

z_k is a left zero of the system,

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (2.71)$$

$$y(t) = Cx(t) + Du(t) \quad (2.72)$$

if it is a right zero of the system,

$$\dot{x}(t) = A^T x(t) + C^T u(t) \quad (2.73)$$

$$y(t) = B^T x(t) + D^T u(t) \quad (2.74)$$

In other words, z_k is a left zero of our system if vectors $\eta_k \in \mathcal{C}^n$ and $\gamma_k \in \mathcal{C}^p$ exist, both not zero, so that

$$\begin{bmatrix} \eta_k & \gamma_k \end{bmatrix} \begin{bmatrix} z_k I - A & -B \\ -C & -D \end{bmatrix} = \begin{bmatrix} 0 & 0 \end{bmatrix} \quad (2.75)$$

For square systems, the left and right zeros coincide; any frequency which is a right zero is also a left zero.

2.5 Multivariable Pole-Zero Cancellations

Now that we have defined the zeros of a multivariable system, we are in a position to describe pole-zero cancellations and what they imply in terms of controllability and observability.

First, we give a SISO example, which shows that a pole-zero cancellation implies loss of controllability or observability.

Example 2.3:

Consider the system given by the equations

$$\begin{bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t) \quad (2.76)$$

$$y(t) = \begin{bmatrix} 1 & -1 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} \quad (2.77)$$

The transfer function for this system is given by

$$g(s) = \frac{-s+1}{s^2-1} = -\frac{s-1}{(s+1)(s-1)} \quad (2.78)$$

Thus, there is a pole-zero cancellation at $s = 1$. To check for loss of controllability and observability, we will perform an eigenvalue decomposition of the system. The eigenvalues and associated left and right eigenvalues are given by

$$\lambda_1 = -1 \quad v_1 = \begin{bmatrix} 1 \\ -1 \end{bmatrix} \quad w_1 = [0.5 \quad -0.5] \quad (2.79)$$

$$\lambda_2 = 1 \quad v_2 = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \quad w_2 = [0.5 \quad 0.5] \quad (2.80)$$

It is easy to verify that the dyadic decomposition Equation 2.3 holds. We now can use the modal tests for controllability and observability. We can see that

$$Cv_1 = 2 \quad w_1^T B = -0.5 \quad (2.81)$$

This tells us that the first mode is both controllable and observable, as expected. For the second mode,

$$Cv_2 = 0 \quad w_2^T B = 0.5 \quad (2.82)$$

We see that the second mode is controllable, but unobservable. The conclusion is that this particular state-space realization has an unobservable mode, but is controllable.

Now let us examine what happens when we lose observability in more detail. We will assume we have the system described by Equations 2.36 through 2.38. Let us assume a pole with frequency λ_k and direction v_k , that is, A has an eigenvalue λ_k with associated eigenvector v_k . Thus

$$(\lambda_k I - A)v_k = 0 \quad (2.83)$$

Let us also assume a (right) zero at frequency z_k with direction given by $[\xi_k^T \quad u_k^T]^T$, that is,

$$(z_k I - A)\xi_k - Bu_k = 0 \quad (2.84)$$

$$C\xi_k + Du_k = 0 \quad (2.85)$$

If it is true that $\lambda_k = z_k$ and $\xi_k = \beta v_k$ with β any scalar, then

$$Bu_k = 0 \quad (2.86)$$

If we assume that the columns of B are linearly independent (which says we don't have redundant controls), then it must be true that $u_k = 0$. However, with $u_k = 0$,

$$Cv_k = 0 \Rightarrow \text{kth mode is unobservable} \quad (2.87)$$

On the other hand, let us assume that the k th mode is unobservable. Then we know that

$$Cv_k = 0 \quad (2.88)$$

where v_k is the eigenvector associated with the k th mode. We will show that there must be a pole-zero cancellation. Let us choose $u_k = 0$. If λ_k is the eigenvalue associated with the k th mode, then we know

$$(\lambda_k I - A)v_k = 0 \Rightarrow (\lambda_k I - A)v_k - Bu_k = 0 \quad (2.89)$$

$$Cv_k + Du_k = 0 \quad (2.90)$$

Thus, λ_k is also a zero with direction

$$\begin{bmatrix} v_k \\ 0 \end{bmatrix} \quad (2.91)$$

We have now proven the following theorem:

Theorem 2.1:

The k th mode, with eigenvalue λ_k and eigenvector v_k , is unobservable if, and only if, λ_k is a right transmission zero with direction given by Equation 2.91.

Following the exact same steps, we show that loss of controllability implies a pole-zero cancellation. Using the same steps as before, we can prove the following theorem.

Theorem 2.2:

Let the k th mode have eigenvalue λ_k and left eigenvector w_k . Then the k th mode is uncontrollable if, and only if, λ_k is a left transmission zero with direction given by

$$[w_k^T \ 0] \quad (2.92)$$

We conclude with an example.

Example 2.4:

Consider the system Equations 2.19 and 2.20, with matrices

$$A = \begin{bmatrix} -2.5 & -0.5 & 0.5 \\ 0.5 & -1.5 & 0.5 \\ 1 & 1 & -2 \end{bmatrix} \quad B = \begin{bmatrix} 1 \\ 1 \\ -2 \end{bmatrix} \quad (2.93)$$

$$C = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix} \quad D = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (2.94)$$

A has the following eigenstructure:

$$\lambda_1 = -1 \quad v_1 = \begin{bmatrix} 0 \\ 1 \\ 1 \end{bmatrix} \quad w_1^T = \begin{bmatrix} 1 & 1 & 1 \\ 2 & 2 & 2 \end{bmatrix} \quad (2.95)$$

$$\lambda_2 = -2 \quad v_2 = \begin{bmatrix} 1 \\ -1 \\ 0 \end{bmatrix} \quad w_2^T = \begin{bmatrix} 1 & -1 & 1 \\ 2 & -2 & 2 \end{bmatrix} \quad (2.96)$$

$$\lambda_3 = -3 \quad v_3 = \begin{bmatrix} 1 \\ 0 \\ -1 \end{bmatrix} \quad w_3^T = \begin{bmatrix} 1 & 1 & -1 \\ 2 & 2 & -2 \end{bmatrix} \quad (2.97)$$

Let us check for controllability and observability.

$$Cv_1 = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \quad w_1^T B = 0 \quad (2.98)$$

$$Cv_2 = \begin{bmatrix} 0 \\ -1 \end{bmatrix} \quad w_2^T B = -1 \quad (2.99)$$

$$\text{and } Cv_3 = \begin{bmatrix} -1 \\ 0 \end{bmatrix} \quad w_3^T B = 2. \quad (2.100)$$

The conclusion is, therefore, that all modes are observable and that the first mode is uncontrollable, but the second and third modes are controllable. It is easy to verify that $z = -1$ is a left zero of this system, with direction

$$[\eta^T \quad \gamma^T] = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} & \frac{1}{2} & 0 & 0 \end{bmatrix}. \quad (2.101)$$

Thus there is a pole-zero cancellation at $z = -1$, which makes the system uncontrollable.

3.1 Introduction

In this chapter, various fundamental elements of the theory of linear time-varying systems are studied in both the continuous-time and discrete-time cases. The chapter is a revised and updated version of Chapter 25 that appeared in the first edition of *The Control Handbook*. The revision includes material on the existence of coordinate transformations that transform time-varying system matrices into diagonal forms, and the connection to the concept of “dynamic” eigenvalues and eigenvectors. Also included in the revision is the use of a simplified expression derived in [11] for the feedback gain in the design of a state feedback controller in the single-input case based on the control canonical form. Generalizations to the multi-input multi-output case can be carried out using the results in [12]. The theory begins in Section 3.2 after the following comments.

The distinguishing characteristic of a time-varying system is that the values of the output response depend on when the input is applied to the system. Time variation is often a result of system parameters changing as a function of time, such as aerodynamic coefficients in high-speed aircraft, circuit parameters in electronic circuits, mechanical parameters in machinery, and diffusion coefficients in chemical processes. Time variation may also be a result of linearizing a nonlinear system about a family of operating points and/or about a time-varying operating point.

The values of the time-varying parameters in a system are often not known *a priori*, that is, before the system is put into operation, but can be measured or estimated during system operation. Systems whose parameters are not known *a priori* are often referred to as parameter varying systems, and the control of such systems is referred to as gain scheduling. Parameter varying systems and gain scheduling are considered in another chapter of this handbook, and are not pursued here. In some applications, time variations in the coefficients of the system model are known *a priori*. For example, this may be the case if the system model is a linearization of a nonlinear system about a known time-varying nominal trajectory. In such cases, the theory developed in this chapter can be directly applied.

In this chapter, the study of linear time-varying systems is carried out in terms of input/output equations and the state model. The focus is on the relationships between input/output and state models, the construction of canonical forms, the study of the system properties of stability, controllability, and observability, and the design of controllers. Both the continuous-time and the discrete-time cases are considered. In the last part of the chapter, an example is given on the application to state observers and state feedback control, and examples are given on checking for stability. Additional references on the theory of linear time-varying systems are given in Further Reading.

3.2 Analysis of Continuous-Time Causal Linear Time-Varying Systems

Consider the single-input single-output continuous-time system given the input/output relationship

$$y(t) = \int_{-\infty}^t h(t, \tau) u(\tau) d\tau \quad (3.1)$$

where t is the continuous-time variable, $y(t)$ is the output response resulting from input $u(t)$, and $h(t, \tau)$ is a real-valued continuous function of t and τ . It is assumed that there are conditions on $h(t, \tau)$ and/or $u(t)$, which insure that the integral in Equation 3.1 exists. The system given by Equation 3.1 is causal since the output $y(t)$ at time t depends only on the input $u(\tau)$ for $\tau \leq t$. The system is also linear since integration is a linear operation. Linearity means that if $y_1(t)$ is the output response resulting from input $u_1(t)$, and $y_2(t)$ is the output response resulting from input $u_2(t)$, then for any real numbers a and b , the output response resulting from input $au_1(t) + bu_2(t)$ is equal to $ay_1(t) + by_2(t)$.

Let $\delta(t)$ denote the unit impulse defined by $\delta(t) = 0$, $t \neq 0$ and $\int_{-\varepsilon}^{\varepsilon} \delta(\lambda) d\lambda = 1$ for any real number $\varepsilon > 0$. For any real number t_1 , the time-shifted impulse $\delta(t - t_1)$ is the unit impulse located at time $t = t_1$. Then from Equation 3.1 and the sifting property of the impulse, the output response $y(t)$ resulting from input $u(t) = \delta(t - t_1)$ is given by

$$y(t) = \int_{-\infty}^t h(t, \tau) u(\tau) d\tau = \int_{-\infty}^t h(t, \tau) \delta(\tau - t_1) d\tau = h(t, t_1)$$

Hence, the function $h(t, \tau)$ in Equation 3.1 is the *impulse response function* of the system, that is, $h(t, \tau)$ is the output response resulting from the impulse $\delta(t - \tau)$ applied to the system at time τ .

The linear system given by Equation 3.1 is *time invariant* (or *constant*) if and only if

$$h(t + \gamma, \tau + \gamma) = h(t, \tau), \quad \text{for all real numbers } t, \tau, \gamma \quad (3.2)$$

Time invariance means that if $y(t)$ is the response to $u(t)$, then for any real number t_1 , the time-shifted output $y(t - t_1)$ is the response to the time-shifted input $u(t - t_1)$. Setting $\gamma = -\tau$ in Equation 3.2 gives

$$h(t - \tau, 0) = h(t, \tau), \quad \text{for all real numbers } t, \tau \quad (3.3)$$

Hence, the system defined by Equation 3.1 is time invariant if and only if the impulse response function $h(t, \tau)$ is a function only of the difference $t - \tau$. In the time-invariant case, Equation 3.1 reduces to the

convolution relationship

$$y(t) = h(t) * u(t) = \int_{-\infty}^t h(t - \tau)u(\tau) d\tau \tag{3.4}$$

where $h(t) = h(t, 0)$ is the impulse response (i.e., the output response resulting from the impulse $\delta(t)$ applied to the system at time 0).

The linear system defined by Equation 3.1 is *finite-dimensional* or *lumped* if the input $u(t)$ and the output $y(t)$ are related by the n th-order input/output differential equation

$$y^{(n)}(t) + \sum_{i=0}^{n-1} a_i(t)y^{(i)}(t) = \sum_{i=0}^m b_i(t)u^{(i)}(t) \tag{3.5}$$

where $y^{(i)}(t)$ is the i th derivative of $y(t)$, $u^{(i)}(t)$ is the i th derivative of $u(t)$, and $a_i(t)$ and $b_i(t)$ are real-valued functions of t . In Equation 3.5, it is assumed that $m \leq n$. The linear system given by Equation 3.5 is time invariant if and only if all coefficients in Equation 3.5 are constants, that is, $a_i(t) = a_i$ and $b_i(t) = b_i$ for all i , where a_i and b_i are real constants.

3.2.1 State Model Realizations

A state model for the system given by Equation 3.5 can be constructed as follows. First, suppose that $m = 0$ so that Equation 3.5 becomes

$$y^{(n)}(t) + \sum_{i=0}^{n-1} a_i(t)y^{(i)}(t) = b_0(t)u(t). \tag{3.6}$$

Then defining the state variables

$$x_i(t) = y^{(i-1)}(t), \quad i = 1, 2, \dots, n, \tag{3.7}$$

the system defined by Equation 3.6 has the state model

$$\dot{x}(t) = A(t)x(t) + B(t)u(t) \tag{3.8}$$

$$y(t) = Cx(t) \tag{3.9}$$

where the coefficient matrices $A(t)$, $B(t)$, and C are given by

$$A(t) = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 & 0 \\ 0 & 0 & 1 & \dots & 0 & 0 \\ 0 & 0 & 0 & \dots & 0 & 0 \\ \vdots & & & \dots & & \vdots \\ 0 & 0 & 0 & \dots & 0 & 1 \\ -a_0(t) & -a_1(t) & -a_2(t) & \dots & -a_{n-2}(t) & -a_{n-1}(t) \end{bmatrix} \tag{3.10}$$

$$B(t) = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 0 \\ b_0(t) \end{bmatrix} \tag{3.11}$$

$$C = [1 \quad 0 \quad 0 \quad \dots \quad 0 \quad 0] \tag{3.12}$$

and $x(t)$ is the n -dimensional state vector given by

$$x(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_{n-1}(t) \\ x_n(t) \end{bmatrix}$$

When $m \geq 1$ in Equation 3.5, the definition in Equation 3.7 of the state variables will not yield a state model of the form given in Equations 3.8 and 3.9. If $m < n$, a state model can be generated by first rewriting Equation 3.5 in the form

$$D^n y(t) + \sum_{i=0}^{n-1} D^i [\alpha_i(t)y(t)] = \sum_{i=0}^m D^i [\beta_i(t)u(t)] \quad (3.13)$$

where D is the derivative operator and $\alpha_i(t)$ and $\beta_i(t)$ are real-valued functions of t . The form of the input/output differential equation given by Equation 3.13 exists if $a_i(t)$ and $b_i(t)$ are differentiable a suitable number of times. If $a_i(t)$ are constants so that $a_i(t) = a_i$ for all t , then $\alpha_i(t)$ are constants and $\alpha_i(t) = a_i$, $i = 0, 1, \dots, n-1$. If $b_i(t)$ are constants so that $b_i(t) = b_i$ for all t , then $\beta_i(t)$ are constants and $\beta_i(t) = b_i$, $i = 0, 1, \dots, m$.

When $a_i(t)$ and $b_i(t)$ are not constants, $\alpha_i(t)$ is a linear combination of $a_i(t)$ and the derivatives of $a_j(t)$ for $j = n-i-1, n-i-2, \dots, 1$, and $\beta_i(t)$ is a linear combination of $b_i(t)$ and the derivatives of $b_j(t)$ for $j = m-i-1, m-i-2, \dots, 1$. For example, when $n = 2$, $\alpha_0(t)$ and $\alpha_1(t)$ are given by

$$\alpha_0(t) = a_0(t) - \dot{a}_1(t) \quad (3.14)$$

$$\alpha_1(t) = a_1(t) \quad (3.15)$$

When $n = 3$, $\alpha_i(t)$ are given by

$$\alpha_0(t) = a_0(t) - \dot{a}_1(t) + \ddot{a}_2(t) \quad (3.16)$$

$$\alpha_1(t) = a_1(t) - 2\dot{a}_2(t) \quad (3.17)$$

$$\alpha_2(t) = a_2(t) \quad (3.18)$$

In the general case (n arbitrary), there is a one-to-one and onto correspondence between the coefficients $a_i(t)$ in the left-hand side of Equation 3.5 and the coefficients $\alpha_i(t)$ in the left-hand side of Equation 3.13. Similarly, there is a one-to-one and onto correspondence between the coefficients in the right-hand side of Equation 3.5 and the right-hand side of Equation 3.13.

Now given the system defined by Equation 3.5 written in the form of Equation 3.13, define the state variables

$$\begin{aligned} x_n(t) &= y(t) \\ x_{n-1}(t) &= Dx_n(t) + \alpha_{n-1}(t)x_n(t) - \beta_{n-1}(t)u(t) \\ x_{n-2}(t) &= Dx_{n-1}(t) + \alpha_{n-2}(t)x_n(t) - \beta_{n-2}(t)u(t) \\ &\vdots \\ x_1(t) &= Dx_2(t) + \alpha_1(t)x_n(t) - \beta_1(t)u(t) \end{aligned} \quad (3.19)$$

where $\beta_i(t) = 0$ for $i > m$. Then with the state variables defined by Equations 3.19, the system given by Equation 3.5 has the state model

$$\dot{x}(t) = A(t)x(t) + B(t)u(t) \quad (3.20)$$

$$y(t) = Cx(t) \quad (3.21)$$

where the coefficient matrices $A(t)$, $B(t)$, and C are given by

$$A(t) = \begin{bmatrix} 0 & 0 & 0 & \cdots & 0 & -\alpha_0(t) \\ 1 & 0 & 0 & \cdots & 0 & -\alpha_1(t) \\ 0 & 1 & 0 & \cdots & 0 & -\alpha_2(t) \\ \vdots & & & \cdots & & \vdots \\ 0 & 0 & 0 & \cdots & 0 & -\alpha_{n-2}(t) \\ 0 & 0 & 0 & \cdots & 1 & -\alpha_{n-1}(t) \end{bmatrix} \quad (3.22)$$

$$B(t) = \begin{bmatrix} \beta_0(t) \\ \beta_1(t) \\ \beta_2(t) \\ \vdots \\ \beta_{n-2}(t) \\ \beta_{n-1}(t) \end{bmatrix} \quad (3.23)$$

and

$$C = [0 \quad 0 \quad \cdots \quad 0 \quad 1] \quad (3.24)$$

The state model with $A(t)$ and C specified by Equations 3.22 and 3.24 is said to be in *observer canonical form*, which is observable as discussed below. Note that for this particular state realization, the row vector C is constant (independent of t).

In addition to the state model defined by Equations 3.22 through 3.24, there are other possible state models for the system given by Equation 3.5. For example, another state model can be constructed in the case when the left-hand side of Equation 3.5 can be expressed in a Floquet factorization form (see [1]), so that Equation 3.5 becomes

$$(D - p_1(t))(D - p_2(t)) \cdots (D - p_n(t))y(t) = \sum_{i=0}^m b_i(t)u^{(i)}(t) \quad (3.25)$$

where again D is the derivative operator and the $p_i(t)$ are real-valued or complex-valued functions of the time variable t . For example, consider the $n = 2$ case for which

$$\begin{aligned} (D - p_1(t))(D - p_2(t))y(t) &= (D - p_1(t))[\dot{y}(t) - p_2(t)y(t)] \\ (D - p_1(t))(D - p_2(t))y(t) &= \ddot{y}(t) - [p_1(t) + p_2(t)]\dot{y}(t) + [p_1(t)p_2(t) - \dot{p}_2(t)]y(t) \end{aligned} \quad (3.26)$$

With $n = 2$ and $m = 1$, the state variables may be defined by

$$x_1(t) = \dot{y}(t) - p_2(t)y(t) - b_1(t)u(t) \quad (3.27)$$

$$x_2(t) = y(t) \quad (3.28)$$

which results in the state model given by Equations 3.20 and 3.21 with

$$A(t) = \begin{bmatrix} p_1(t) & 0 \\ 1 & p_2(t) \end{bmatrix} \quad (3.29)$$

$$B(t) = \begin{bmatrix} b_0(t) - \dot{b}_1(t) + p_1(t)b_1(t) \\ b_1(t) \end{bmatrix} \quad (3.30)$$

and

$$C = [0 \quad 1] \quad (3.31)$$

In the general case given by Equation 3.25, there is a state model in the form of Equations 3.20 and 3.21 with $A(t)$ and C given by

$$A(t) = \begin{bmatrix} p_1(t) & 0 & 0 & 0 & \cdots & 0 & 0 \\ 1 & p_2(t) & 0 & 0 & \cdots & 0 & 0 \\ 0 & 1 & p_3(t) & 0 & \cdots & 0 & 0 \\ \vdots & & & & & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & p_{n-1}(t) & 0 \\ 0 & 0 & 0 & 0 & \cdots & 1 & p_n(t) \end{bmatrix} \quad (3.32)$$

$$C = [0 \quad 0 \quad 0 \quad \cdots \quad 1] \quad (3.33)$$

A very useful feature of the state model with $A(t)$ given by Equation 3.32 is the lower triangular form of $A(t)$. In particular, as discussed below, stability conditions can be specified in terms of $p_i(t)$, which can be viewed as “time-varying poles” of the system. However, in the time-varying case the computation of $p_i(t)$ based on the Floquet factorization given in the left-hand side of Equation 3.25 requires that nonlinear Riccati-type differential equations must be solved (see, e.g., [2,13]). The focus of [2] is on the computation of poles and zeros and the application to stability and transmission blocking, with the emphasis on time-varying difference equations. In [4], the authors generate a Floquet factorization given by the left-hand side of Equation 3.25 by utilizing successive Riccati transformations in a state-space setting.

A significant complicating factor in the theory of factoring polynomial operators with time-varying coefficients is that in general there are an infinite number of different “pole sets” $\{p_1(t), p_2(t), \dots, p_n(t)\}$. This raises the question as to whether one pole set may be “better” in some sense than another pole set. In the case of linear difference equations with time-varying coefficients, it is shown in [2] that poles can be computed using a nonlinear recursion and that uniqueness of pole sets can be achieved by specifying initial values for the poles. For recent work on the factorization of time-varying differential equations by using ground field extensions, see [6]. As discussed below, in [7] the definition and computation of time-varying poles is pursued by using Lyapunov coordinate transformations in a state-space setting.

3.2.2 The State Model

For an m -input p -output linear n -dimensional time-varying continuous-time system, the general form of the state model is

$$\dot{x}(t) = A(t)x(t) + B(t)u(t) \quad (3.34)$$

$$y(t) = C(t)x(t) + D(t)u(t) \quad (3.35)$$

where Equation 3.34 is the *state equation* and Equation 3.35 is the *output equation*. In Equations 3.34 and 3.35, $A(t)$ is the $n \times n$ *system matrix*, $B(t)$ is the $n \times m$ *input matrix*, $C(t)$ is the $p \times n$ *output matrix*, $D(t)$ is the $p \times m$ *direct feed matrix*, $u(t)$ is the m -dimensional input vector, $x(t)$ is the n -dimensional state vector, and $y(t)$ is the p -dimensional output vector. The term $D(t)u(t)$ in Equation 3.35 is of little significance in the theory, and thus $D(t)u(t)$ is usually omitted from Equation 3.35, which will be done here.

To solve Equation 3.34, first consider the homogeneous equation

$$\dot{x}(t) = A(t)x(t), \quad t > t_0 \quad (3.36)$$

with the initial condition $x(t_0)$ at initial time t_0 . For any $A(t)$ whose entries are continuous functions of t , it is well known (see, e.g., [8]) that for any initial condition $x(t_0)$, there is a unique continuously

differentiable solution of Equation 3.36 given by

$$x(t) = \Phi(t, t_0)x(t_0), \quad t > t_0 \quad (3.37)$$

where $\Phi(t, t_0)$ is an $n \times n$ matrix function of t and t_0 , called the *state-transition matrix*. The state-transition matrix has the following fundamental properties:

$$\Phi(t, t) = I = n \times n \text{ identity matrix, for all } t \quad (3.38)$$

$$\Phi(t, \tau) = \Phi(t, t_1)\Phi(t_1, \tau), \quad \text{for all } t_1, t, \tau \quad (3.39)$$

$$\Phi^{-1}(t, \tau) = \Phi(\tau, t), \quad \text{for all } t, \tau \quad (3.40)$$

$$\frac{\partial}{\partial t} \Phi(t, \tau) = A(t)\Phi(t, \tau), \quad \text{for all } t, \tau \quad (3.41)$$

$$\frac{\partial}{\partial \tau} \Phi(t, \tau) = -\Phi(t, \tau)A(\tau), \quad \text{for all } t, \tau \quad (3.42)$$

$$\det \Phi(t, \tau) = \exp \left[\int_{\tau}^t \text{tr}[A(\sigma)] d\sigma \right] \quad (3.43)$$

In Equation 3.43, “det” denotes the determinant and “tr” denotes the trace. Equation 3.39 is called the *composition property*. It follows from this property that $\Phi(t, \tau)$ can be written in the factored form

$$\Phi(t, \tau) = \Phi(t, 0)\Phi(0, \tau), \quad \text{for all } t, \tau \quad (3.44)$$

Another important property of the state-transition matrix $\Phi(\tau, t)$ is that it is a continuously differentiable matrix function of t and τ .

It follows from Equation 3.42 that the *adjoint equation*

$$\dot{\gamma}(t) = -A^T(t)\gamma(t) \quad (3.45)$$

has state-transition matrix equal to $\Phi^T(\tau, t)$, where again $\Phi(t, \tau)$ is the state-transition matrix for Equation 3.36 and superscript “ T ” denotes the transpose operation.

If the system matrix $A(t)$ is constant over the interval $[t_1, t_2]$, that is, $A(t) = A$, for all $t \in [t_1, t_2]$, then the state-transition matrix is equal to the matrix exponential over $[t_1, t_2]$:

$$\Phi(t, \tau) = e^{A(t-\tau)} \quad \text{for all } t, \tau \in [t_1, t_2] \quad (3.46)$$

If $A(t)$ is time varying and $A(t)$ commutes with its integral over the interval $[t_1, t_2]$, that is,

$$A(t) \left[\int_{\tau}^t A(\sigma) d\sigma \right] = \left[\int_{\tau}^t A(\sigma) d\sigma \right] A(t), \quad \text{for all } t, \tau \in [t_1, t_2] \quad (3.47)$$

then $\Phi(t, \tau)$ is given by

$$\Phi(t, \tau) = \exp \left[\int_{\tau}^t A(\tau) d\tau \right], \quad \text{for all } t, \tau \in [t_1, t_2] \quad (3.48)$$

Note that the commutativity condition in Equation 3.47 is always satisfied in the time-invariant case. It is also always satisfied in the one-dimensional ($n = 1$) time-varying case since scalars commute. Thus, $\Phi(t, \tau)$ is given by the exponential form in Equation 3.48 when $n = 1$. Unfortunately, the exponential form for $\Phi(t, \tau)$ does not hold for an arbitrary time-varying matrix $A(t)$ when $n > 1$, and, in general, there is no known closed-form expression for $\Phi(t, \tau)$ when $n > 1$. However, approximations to $\Phi(t, \tau)$ can be readily computed from $A(t)$ by numerical techniques, such as the method of successive approximations (see, e.g., [8]). Approximations to $\Phi(t, \tau)$ can also be determined by discretizing the time variable t as shown next.

Let k be an integer-valued variable, let T be a positive number, and let $a_{ij}(t)$ denote the i, j entry of the matrix $A(t)$. Suppose that by choosing T to be sufficiently small, the absolute values $|a_{ij}(t) - a_{ij}(kT)|$ can be made as small as desired over the interval $t \in [kT, kT + T]$ and for all integer values of k . Then for a suitably small T , $A(t)$ is approximately equal to $A(kT)$ for $t \in [kT, kT + T]$, and from Equation 3.46 the state-transition matrix $\Phi(t, kT)$ is given approximately by

$$\Phi(t, kT) = e^{A(kT)(t-kT)} \quad \text{for all } t \in [kT, kT + T] \quad \text{and} \quad \text{all } k \quad (3.49)$$

Setting $t = kT + T$ in Equation 3.49 yields

$$\Phi(kT + T, kT) = e^{A(kT)T} \quad \text{for all } k \quad (3.50)$$

The state-transition matrix $\Phi(kT + T, kT)$ given by Equation 3.50 can be computed by using a parameterized Laplace transform. To show this, first define the $n \times n$ matrix

$$q(k, t) = e^{A(kT)t} \quad (3.51)$$

Then $q(k, t)$ is equal to the inverse Laplace transform of

$$Q(k, s) = [sI - A(kT)]^{-1} \quad (3.52)$$

Note that the transform $Q(k, s)$ is parameterized by the integer-valued variable k . A closed-form expression for $q(k, t)$ as a function of t can be obtained by expanding the entries of $Q(k, s)$ into partial fraction expansions and then using standard Laplace transform pairs to determine the inverse transform of the terms in the partial fraction expansions. Then from Equation 3.51, setting $t = T$ in $q(k, t)$ yields $q(k, T) = \Phi(kT + T, kT)$.

Again consider the general case with the state equation given by Equation 3.34. Given the state-transition matrix $\Phi(t, \tau)$, for any given initial state $x(t_0)$ and input $u(t)$ applied for $t \geq t_0$, the complete solution to Equation 3.34 is

$$x(t) = \Phi(t, t_0)x(t_0) + \int_{t_0}^t \Phi(t, \tau)B(\tau)u(\tau) d\tau, \quad t > t_0 \quad (3.53)$$

Then, when $y(t) = C(t)x(t)$, the output response $y(t)$ is given by

$$y(t) = C(t)\Phi(t, t_0)x(t_0) + \int_{t_0}^t C(t)\Phi(t, \tau)B(\tau)u(\tau) d\tau, \quad t > t_0 \quad (3.54)$$

If the initial time t_0 is taken to be $-\infty$ and the initial state is zero, Equation 3.54 becomes

$$y(t) = \int_{-\infty}^t C(t)\Phi(t, \tau)B(\tau)u(\tau) d\tau \quad (3.55)$$

Comparing Equation 3.55 with the m -input, p -output version of Equation 3.1 reveals that

$$H(t, \tau) = \begin{cases} C(t)\Phi(t, \tau)B(\tau) & \text{for } t \geq \tau \\ 0 & \text{for } t < \tau \end{cases} \quad (3.56)$$

where $H(t, \tau)$ is the $p \times m$ impulse response function matrix. Inserting Equation 3.44 into Equation 3.56 reveals that $H(t, \tau)$ can be expressed in the factored form,

$$H(t, \tau) = H_1(t)H_2(\tau), \quad t \geq \tau \quad (3.57)$$

where

$$H_1(t) = C(t)\Phi(t, 0) \quad \text{and} \quad H_2(\tau) = \Phi(0, \tau)B(\tau) \quad (3.58)$$

It turns out [8] that a linear time-varying system with impulse response matrix $H(t, \tau)$ has a state realization given by Equations 3.34 and 3.35 with $D(t) = 0$ if and only if $H(t, \tau)$ can be expressed in the factored form given in Equation 3.57.

3.2.3 Change of State Variables

Suppose that the system under study has the n -dimensional state model

$$\dot{x}(t) = A(t)x(t) + B(t)u(t) \quad (3.59)$$

$$y(t) = C(t)x(t) \quad (3.60)$$

In the following development, the system given by Equations 3.59 and 3.60 will be denoted by the triple $[A(t), B(t), C(t)]$.

Given any $n \times n$ invertible continuously differentiable matrix $P(t)$, which is real or complex valued, another state model can be generated by defining the new state vector $z(t) = P^{-1}(t)x(t)$, where $P^{-1}(t)$ is the inverse of $P(t)$. The matrix $P^{-1}(t)$ (or the matrix $P(t)$) is called the transformation matrix and the process of going from $x(t)$ to $z(t)$ is referred to as a coordinate transformation. The state variables for the new state model (i.e., the $z_i(t)$) are linear combinations with time-varying coefficients of the state variables of the given state model. To determine the state equations for the new state model, first note that $P(t)z(t) = x(t)$. Then taking the derivative of both sides of $P(t)z(t) = x(t)$ gives

$$P(t)\dot{z}(t) + \dot{P}(t)z(t) = \dot{x}(t) \quad (3.61)$$

Inserting the expression for $\dot{x}(t)$ given by Equation 3.59 yields

$$P(t)\dot{z}(t) + \dot{P}(t)z(t) = A(t)x(t) + B(t)u(t) \quad (3.62)$$

and replacing $x(t)$ by $P(t)z(t)$ in Equation 3.62 and rearranging terms results in

$$P(t)\dot{z}(t) = [A(t)P(t) - \dot{P}(t)]z(t) + B(t)u(t) \quad (3.63)$$

Finally, multiplying both sides of Equation 3.63 on the left by $P^{-1}(t)$ gives

$$\dot{z}(t) = [P^{-1}(t)A(t)P(t) - P^{-1}(t)\dot{P}(t)]z(t) + P^{-1}(t)B(t)u(t) \quad (3.64)$$

and replacing $x(t)$ by $P(t)z(t)$ in Equation 3.60 yields

$$y(t) = C(t)P(t)z(t) \quad (3.65)$$

The state equations for the new state model are given by Equations 3.64 and 3.65. This new model will be denoted by the triple $[\bar{A}(t), \bar{B}(t), \bar{C}(t)]$ where

$$\bar{A}(t) = P^{-1}(t)A(t)P(t) - P^{-1}(t)\dot{P}(t) \quad (3.66)$$

$$\bar{B}(t) = P^{-1}(t)B(t) \quad (3.67)$$

$$\bar{C}(t) = C(t)P(t) \quad (3.68)$$

Multiplying both sides of Equation 3.66 on the left by $P(t)$ and rearranging the terms yield the result that the transformation matrix $P(t)$ satisfies the differential equation

$$\dot{P}(t) = A(t)P(t) - P(t)\bar{A}(t) \quad (3.69)$$

The state models $[A(t), B(t), C(t)]$ and $[\bar{A}(t), \bar{B}(t), \bar{C}(t)]$ with $\bar{A}(t), \bar{B}(t), \bar{C}(t)$ given by Equations 3.66 through 3.68 are said to be *algebraically equivalent*. The state-transition matrix $\bar{\Phi}(t, \tau)$ for $[\bar{A}(t), \bar{B}(t), \bar{C}(t)]$ is given by

$$\bar{\Phi}(t, \tau) = P^{-1}(t)\Phi(t, \tau)P(\tau) \quad (3.70)$$

where $\Phi(t, \tau)$ is the state-transition matrix for $[A(t), B(t), C(t)]$.

Given an n -dimensional state model $[A(t), B(t), C(t)]$ and any $n \times n$ continuous matrix function $\Gamma(t)$, there is a transformation matrix $P(t)$ that transforms $A(t)$ into $\Gamma(t)$, that is, $\bar{A}(t) = \Gamma(t)$. To show this, define $P(t)$ by

$$P(t) = \Phi(t, 0)\bar{\Phi}(0, t) \quad (3.71)$$

where $\bar{\Phi}(t, \tau)$ is the state-transition matrix for $\dot{z}(t) = \Gamma(t)z(t)$. Note that $P(t)$ is continuously differentiable since $\Phi(t, 0)$ and $\bar{\Phi}(0, t)$ are continuously differentiable, and $P(t)$ is invertible since state-transition matrices are invertible. Then taking the derivative of both sides of Equation 3.71 gives

$$\dot{P}(t) = \Phi(t, 0)\dot{\bar{\Phi}}(0, t) + \dot{\Phi}(t, 0)\bar{\Phi}(0, t) \quad (3.72)$$

Using Equations 3.41 and 3.42 in Equation 3.72 yields

$$\dot{P}(t) = -\Phi(t, 0)\bar{\Phi}(0, t)\Gamma(t) + A(t)\Phi(t, 0)\bar{\Phi}(0, t) \quad (3.73)$$

Finally, inserting Equation 3.71 into Equation 3.73 results in Equation 3.69 with $\bar{A}(t) = \Gamma(t)$, and thus, $P(t)$ transforms $A(t)$ into $\Gamma(t)$.

This result shows that via a change of state, $A(t)$ can be transformed to any desired continuous matrix $\Gamma(t)$. The fact that any continuous system matrix $A(t)$ can be transformed to any other continuous matrix raises some interesting issues. For example, suppose that the transformation $z(t) = P^{-1}(t)x(t)$ is defined so that the new system matrix $\bar{A}(t)$ is equal to a diagonal matrix $\Lambda(t)$ with real or complex-valued functions $\lambda_1(t), \lambda_2(t), \dots, \lambda_n(t)$ on the diagonal. Then from Equation 3.66,

$$\Lambda(t) = P^{-1}(t)A(t)P(t) - P^{-1}(t)\dot{P}(t) \quad (3.74)$$

and multiplying both sides of Equation 3.74 on the left by $P(t)$ gives

$$P(t)\Lambda(t) = A(t)P(t) - \dot{P}(t) \quad (3.75)$$

Now for $i = 1, 2, \dots, n$, let $\gamma_i(t)$ denote the i th column of the transformation matrix $P(t)$. Then from Equation 3.75, it follows that

$$\lambda_i(t)\gamma_i(t) = A(t)\gamma_i(t) - \dot{\gamma}_i(t), \quad i = 1, 2, \dots, n \quad (3.76)$$

Rearranging terms in Equation 3.76 gives

$$[A(t) - \lambda_i(t)I]\gamma_i(t) = \dot{\gamma}_i(t), \quad i = 1, 2, \dots, n \quad (3.77)$$

where I is the $n \times n$ identity matrix.

Equation 3.77 has appeared in the literature on linear time-varying systems, and has sometimes been used as the justification for referring to the $\lambda_i(t)$ as “dynamic” eigenvalues or poles, and the corresponding $\gamma_i(t)$ as eigenvectors, of the time-varying system having system matrix $A(t)$. But since Equation 3.77 holds for any continuous scalar-valued functions $\lambda_1(t), \lambda_2(t), \dots, \lambda_n(t)$, or for any constants $\lambda_1, \lambda_2, \dots, \lambda_n$, the existence of $\lambda_i(t)$ and $\gamma_i(t)$ satisfying Equation 3.77 is not useful unless further conditions are placed on the transformation matrix $P(t)$. For example, one can consider stronger notions of equivalence such as *topological equivalence*. This means that, in addition to being algebraically equivalent, the transformation matrix $P(t)$ has the properties

$$|\det P(t)| \geq c_0 \quad \text{for all } t \quad (3.78)$$

$$|p_{ij}(t)| \leq c_1 \quad \text{for all } t \quad \text{and} \quad i, j = 1, 2, \dots, n \quad (3.79)$$

where $p_{ij}(t)$ is the i, j entry of $P(t)$, and c_0 and c_1 are finite positive constants. The conditions given in Equations 3.78 and 3.79 are equivalent to requiring that $P(t)$ and its inverse $P^{-1}(t)$ be bounded

matrix functions of t . A transformation $z(t) = P^{-1}(t)x(t)$ with $P(t)$ satisfying Equations 3.78 and 3.79 is called a *Lyapunov transformation*. As noted in Section 3.2.4, stability is preserved under a Lyapunov transformation.

If the transformation $z(t) = P^{-1}(t)x(t)$ is a Lyapunov transformation and puts the system matrix $A(t)$ into the diagonal form $\Lambda(t) = \text{diag}(\lambda_1(t), \lambda_2(t), \dots, \lambda_n(t))$, then the $\lambda_i(t)$ are of interest since they determine the stability of the system. However, in the general linear time-varying case, the existence of a Lyapunov transformation that puts $A(t)$ into a diagonal form is a strong condition. A much weaker condition is the existence of a Lyapunov transformation that puts $A(t)$ into an upper or lower triangular form (see, e.g., [7]). This is briefly discussed in Section 3.2.4.

3.2.4 Stability

Given a system with n -dimensional state model $[A(t), B(t), C(t)]$, again consider the homogeneous equation

$$\dot{x}(t) = A(t)x(t), \quad t > t_0 \quad (3.80)$$

with solution

$$x(t) = \Phi(t, t_0)x(t_0), \quad t > t_0 \quad (3.81)$$

The system is said to be *asymptotically stable* if for some initial time t_0 , the solution $x(t)$ satisfies the condition $\|x(t)\| \rightarrow 0$ as $t \rightarrow \infty$ for any initial state $x(t_0)$ at initial time t_0 . Here $\|x(t)\|$ denotes the *Euclidean norm* of the state $x(t)$ given by

$$\|x(t)\| = \sqrt{x^T(t)x(t)} = \sqrt{x_1^2(t) + x_2^2(t) + \dots + x_n^2(t)} \quad (3.82)$$

where $x(t) = [x_1(t) \ x_2(t) \ \dots \ x_n(t)]^T$. A system is asymptotically stable if and only if

$$\|\Phi(t, t_0)\| \rightarrow 0 \quad \text{as } t \rightarrow \infty \quad (3.83)$$

where $\|\Phi(t, t_0)\|$ is the matrix norm equal to the square root of the largest eigenvalue of $\Phi^T(t, t_0)\Phi(t, t_0)$, where t is viewed as a parameter.

A stronger notion of stability is *exponential stability*, which requires that for some initial time t_0 , there exist finite positive constants c and λ such that for any $x(t_0)$, the solution $x(t)$ to Equation 3.80 satisfies

$$\|x(t)\| \leq ce^{-\lambda(t-t_0)} \|x(t_0)\|, \quad t \geq t_0 \quad (3.84)$$

If the condition in Equation 3.84 holds for all t_0 with the constants c and λ fixed, the system is said to be *uniformly exponentially stable*. Uniform exponential stability is equivalent to requiring that there exists finite positive constants γ and λ such that

$$\|\Phi(t, \tau)\| \leq \gamma e^{-\lambda(t-\tau)} \quad \text{for all } t, \tau \text{ such that } t \geq \tau \quad (3.85)$$

Uniform exponential stability is also equivalent to requiring that, given any positive constant δ , there exists a positive constant T such that for any t_0 and $x(t_0)$, the solution $x(t)$ to Equation 3.80 satisfies

$$\|x(t)\| \leq \delta \|x(t_0)\| \quad \text{for } t \geq t_0 + T \quad (3.86)$$

It follows from Equation 3.85 that uniform exponential stability is preserved under a Lyapunov transformation $z(t) = P^{-1}(t)x(t)$. To see this, let $\Phi(t, \tau)$ denote the state-transition matrix for $\dot{z}(t) = \bar{A}(t)z(t)$,

where

$$\bar{A}(t) = P^{-1}(t)A(t)P(t) - P^{-1}(t)\dot{P}(t) \quad (3.87)$$

Then using Equation 3.70 gives

$$\|\bar{\Phi}(t, \tau)\| \leq \|P^{-1}(t)\| \|\Phi(t, \tau)\| \|P(\tau)\| \quad (3.88)$$

But Equations 3.78 and 3.79 imply that

$$\|P(\tau)\| \leq M_1 \quad \text{and} \quad \|P^{-1}(t)\| \leq M_2 \quad (3.89)$$

for some finite constants M_1 and M_2 . Then inserting Equations 3.85 and 3.89 into Equation 3.88 yields

$$\|\bar{\Phi}(t, \tau)\| \leq \gamma M_1 M_2 e^{-\lambda(t-\tau)} \quad \text{for all } t, \tau \text{ such that } t \geq \tau \quad (3.90)$$

which verifies that $\dot{z}(t) = \bar{A}(t)z(t)$ is uniformly exponentially stable.

If $P(t)$ and $P^{-1}(t)$ are bounded only for $t \geq t_1$ for some finite t_1 , the coordinate transformation $z(t) = P^{-1}(t)x(t)$ preserves exponential stability of the given system. This can be proved using constructions similar to those given above. The details are omitted.

When $n = 1$ so that $A(t) = a(t)$ is a scalar-valued function of t , as seen from Equation 3.48,

$$\Phi(t, t_0) = \exp \left[\int_{t_0}^t a(\tau) d\tau \right]. \quad (3.91)$$

It follows that the system is asymptotically stable if and only if

$$\int_{t_0}^t a(\sigma) d\sigma \rightarrow -\infty \text{ as } t \rightarrow \infty \quad (3.92)$$

and the system is uniformly exponentially stable if a positive constant λ exists so that

$$\int_{\tau}^t a(\sigma) d\sigma \leq -\lambda(t - \tau) \quad \text{for all } t, \tau \text{ such that } t \geq \tau \quad (3.93)$$

When $n > 1$, if $A(t)$ commutes with its integral for $t > t_1$ for some $t_1 \geq t_0$ (see Equation 3.47), then

$$\Phi(t, t_1) = \exp \left[\int_{t_1}^t A(\sigma) d\sigma \right], \quad t > t_1 \quad (3.94)$$

and a sufficient condition for exponential stability (not uniform in general) is that the matrix function

$$\frac{1}{t} \int_{t_2}^t A(\sigma) d\sigma \quad (3.95)$$

be a bounded function of t and its *pointwise eigenvalues* have real parts $\leq -\beta$ for $t > t_2$ for some $t_2 \geq t_1$, where β is a positive constant. The pointwise eigenvalues of a time-varying matrix $M(t)$ are the eigenvalues of the constant matrix $M(\tau)$ for each fixed value of τ viewed as a time-independent parameter. If $A(t)$ is upper or lower triangular with $p_1(t), p_2(t), \dots, p_n(t)$ on the diagonal, then a sufficient condition for uniform exponential stability is that the off-diagonal entries of $A(t)$ be bounded and the scalar systems

$$\dot{x}_i(t) = p_i(t)x_i(t) \quad (3.96)$$

be uniformly exponentially stable for $i = 1, 2, \dots, n$. Note that the system matrix $A(t)$ given by Equation 3.32 is lower triangular, and thus, in this case, the system with this particular system matrix is uniformly exponentially stable if the poles $p_i(t)$ in the Floquet factorization given in the left-hand side of

Equation 3.25 are stable in the sense that the scalar systems in Equation 3.96 are uniformly exponentially stable.

If there exists a Lyapunov transformation $z(t) = P^{-1}(t)x(t)$ that puts the system matrix $A(t)$ into an upper or lower triangular form with $p_1(t), p_2(t), \dots, p_n(t)$ on the diagonal, then sufficient conditions for uniform exponential stability are that the off-diagonal entries of the triangular form be bounded and the scalar systems defined by Equation 3.96 be uniformly exponentially stable. The construction of a Lyapunov transformation that puts $A(t)$ into an upper triangular form is given in [7]. In that paper, the authors define the set $\{p_1(t), p_2(t), \dots, p_n(t)\}$ of elements on the diagonal of the upper triangular form to be a pole set of the linear time-varying system with system matrix $A(t)$.

Another condition for uniform exponential stability is that a symmetric positive-definite matrix $Q(t)$ exists with $c_1I \leq Q(t) \leq c_2I$ for some positive constants c_1, c_2 , such that

$$A^T(t)Q(t) + Q(t)A(t) + \dot{Q}(t) \leq -c_3I \tag{3.97}$$

for some positive constant c_3 . Here $F \leq G$ means that F and G are symmetric matrices and $G - F$ is positive semidefinite (all pointwise eigenvalues are ≥ 0). This stability test is referred to as the Lyapunov criterion. For more details, see [8].

Finally, it is noted that if the entries of $B(t)$ and $C(t)$ are bounded, then uniform exponential stability implies that the system is *bounded-input, bounded-output (BIBO) stable*, that is, a bounded input $u(t)$ always results in a bounded output response $y(t)$.

3.2.5 Controllability and Observability

Given a system with the n -dimensional state model $[A(t), B(t), C(t)]$, it is now assumed that the entries of $A(t), B(t)$, and $C(t)$ are at least continuous functions of t . The system is said to be *controllable* on the interval $[t_0, t_1]$, where $t_1 > t_0$, if for any states x_0 and x_1 , a continuous input $u(t)$ exists that drives the system to the state $x(t_1) = x_1$ at time $t = t_1$ starting from the state $x(t_0) = x_0$ at time $t = t_0$.

Define the *controllability Gramian* which is the $n \times n$ matrix given by

$$W(t_0, t_1) = \int_{t_0}^{t_1} \Phi(t_0, t)B(t)B^T(t)\Phi^T(t_0, t) dt \tag{3.98}$$

The controllability Gramian $W(t_0, t_1)$ is symmetric positive semidefinite and is the solution to the matrix differential equation

$$\begin{aligned} \frac{d}{dt}W(t, t_1) &= A(t)W(t, t_1) + W(t, t_1)A^T(t) - B(t)B^T(t), \\ W(t_1, t_1) &= 0 \end{aligned} \tag{3.99}$$

Then the system is controllable on $[t_0, t_1]$ if and only if $W(t_0, t_1)$ is invertible, in which case a continuous input $u(t)$ that drives the system from $x(t_0) = x_0$ to $x(t_1) = x_1$ is

$$u(t) = -B^T(t)\Phi^T(t_0, t)W^{-1}(t_0, t_1)[x_0 - \Phi(t_0, t_1)x_1], \quad t_0 \leq t \leq t_1 \tag{3.100}$$

There is a sufficient condition for controllability that does not require that the controllability Gramian be computed: Given a positive integer q , suppose that the entries of $B(t)$ are $q - 1$ times continuously differentiable and the entries of $A(t)$ are $q - 2$ times continuously differentiable, and define the $n \times m$ matrices

$$K_0(t) = B(t) \tag{3.101}$$

$$K_i(t) = -A(t)K_{i-1}(t) + \dot{K}_{i-1}(t), \quad i = 1, 2, \dots, q - 1 \tag{3.102}$$

Finally, let $K(t)$ denotes the $n \times mq$ matrix whose i th block column is equal to $K_{i-1}(t)$, that is

$$K(t) = [K_0(t) K_1(t) \dots K_{q-1}(t)] \quad (3.103)$$

Then a sufficient condition for the system $[A(t), B(t), C(t)]$ to be controllable on the interval $[t_0, t_1]$ is that the $n \times mq$ matrix $K(t)$ defined by Equation 3.103 has rank n for at least one value of $t \in [t_0, t_1]$. This condition was first derived in [9].

The rank condition on the matrix $K(t)$ is preserved under a change of state variables. To show this, suppose the coordinate transformation $z(t) = P^{-1}(t)x(t)$ results in the state model $[\bar{A}(t), \bar{B}(t), \bar{C}(t)]$. For this model, define

$$\bar{K}(t) = [\bar{K}_0(t) \bar{K}_1(t) \dots \bar{K}_{q-1}(t)] \quad (3.104)$$

where the $\bar{K}_i(t)$ are given by Equations 3.101 and 3.102 with $A(t)$ and $B(t)$ replaced by $\bar{A}(t)$ and $\bar{B}(t)$, respectively. It is assumed that $\bar{A}(t)$ and $\bar{B}(t)$ satisfy the same differentiability requirements as given above for $A(t)$ and $B(t)$ so that $\bar{K}(t)$ is well defined. Then it follows that

$$P^{-1}(t)K(t) = \bar{K}(t) \quad (3.105)$$

Now since $P^{-1}(t)$ is invertible for all t , $P^{-1}(t)$ has rank n for all $t \in [t_0, t_1]$, and thus $\bar{K}(t)$ has rank n for some $t_c \in [t_0, t_1]$ if and only if $K(t_c)$ has rank n . Therefore, the system defined by $[A(t), B(t), C(t)]$ is controllable on the interval $[t_0, t_1]$ if and only if the transformed system $[\bar{A}(t), \bar{B}(t), \bar{C}(t)]$ is controllable on $[t_0, t_1]$.

If the matrix $K(t)$ has rank n for all t , the $n \times n$ matrix $K(t)K^T(t)$ is invertible for all t , and in this case Equation 3.105 can be solved for $P^{-1}(t)$. This gives

$$P^{-1}(t) = \bar{K}(t)K^T(t) \left[K(t)K^T(t) \right]^{-1} \quad (3.106)$$

Note that Equation 3.106 can be used to compute the transformation matrix $P^{-1}(t)$ directly from the coefficient matrices of the state models $[A(t), B(t), C(t)]$ and $[\bar{A}(t), \bar{B}(t), \bar{C}(t)]$.

Now suppose that the system input $u(t)$ is zero, so that the state model is given by

$$\dot{x}(t) = A(t)x(t) \quad (3.107)$$

$$y(t) = C(t)x(t) \quad (3.108)$$

Inserting Equation 3.108 into the solution of Equation 3.107 results in the output response $y(t)$ resulting from initial state $x(t_0)$:

$$y(t) = C(t)\Phi(t, t_0)x(t_0), \quad t > t_0 \quad (3.109)$$

The system is said to be observable on the interval $[t_0, t_1]$ if any initial state $x(t_0)$ can be determined from the output response $y(t)$ given by Equation 3.109 for $t \in [t_0, t_1]$. Define the *observability Gramian* which is the $n \times n$ matrix given by

$$M(t_0, t_1) = \int_{t_0}^{t_1} \Phi^T(t, t_0)C^T(t)C(t)\Phi(t, t_0) dt \quad (3.110)$$

The observability Gramian $M(t_0, t_1)$ is symmetric positive semidefinite and is the solution to the matrix differential equation

$$\begin{aligned} \frac{d}{dt}M(t, t_1) &= -A^T(t)M(t, t_1) - M(t, t_1)A(t) - C^T(t)C(t), \\ M(t_1, t_1) &= 0 \end{aligned} \quad (3.111)$$

Then the system is *observable* on $[t_0, t_1]$ if and only if $M(t_0, t_1)$ is invertible, in which case the initial state $x(t_0)$ is given by

$$x(t_0) = M^{-1}(t_0, t_1) \int_{t_0}^{t_1} \Phi^T(t, t_0) C^T(t) y(t) dt \quad (3.112)$$

Again given an m -input p -output n -dimensional system with state model $[A(t), B(t), C(t)]$, the *adjoint system* is the p -input m -output n -dimensional system with state model $[-A^T(t), C^T(t), B^T(t)]$. The adjoint system is given by the state equations

$$\dot{\gamma}(t) = -A^T(t)\gamma(t) + C^T(t)v(t) \quad (3.113)$$

$$\eta(t) = B^T(t)\gamma(t) \quad (3.114)$$

where $\gamma(t)$, $v(t)$, and $\eta(t)$ are the state, input, and output, respectively, of the adjoint system. As noted above in Section 3.2.2, the state-transition matrix of the adjoint system $[-A^T(t), C^T(t), B^T(t)]$ is equal to $\Phi^T(\tau, t)$, where $\Phi(t, \tau)$ is the state-transition matrix for the given system $[A(t), B(t), C(t)]$. Using this fact and the definition of the input and output coefficient matrices of the adjoint system given by Equations 3.113 and 3.114, it is clear that the controllability Gramian of the adjoint system is identical to the observability Gramian of the given system. Thus, the given system is observable on $[t_0, t_1]$ if and only if the adjoint system is controllable on $[t_0, t_1]$. In addition, the observability Gramian of the adjoint system is identical to the controllability Gramian of the given system. Hence, the given system is controllable on $[t_0, t_1]$ if and only if the adjoint system is observable on $[t_0, t_1]$.

A sufficient condition for observability is given next in terms of the system matrix $A(t)$ and the output matrix $C(t)$: Consider the system with state model $[A(t), B(t), C(t)]$, and define the $p \times n$ matrices

$$L_0(t) = C(t) \quad (3.115)$$

$$L_i(t) = L_{i-1}(t)A(t) + \dot{L}_{i-1}(t), \quad i = 1, 2, \dots, q-1 \quad (3.116)$$

where q is a positive integer. Consider the $pq \times n$ matrix $L(t)$ whose i th block row is equal to $L_{i-1}(t)$, that is,

$$L(t) = \begin{bmatrix} L_0(t) \\ L_1(t) \\ \vdots \\ L_{q-1}(t) \end{bmatrix} \quad (3.117)$$

It is assumed that the entries of $C(t)$ are $q-1$ times differentiable and the entries of $A(t)$ are $q-2$ times differentiable, so that $L(t)$ is well defined. Then as first shown in [9], the system is observable on $[t_0, t_1]$ if the $pq \times n$ matrix $L(t)$ defined by Equations 3.115 through 3.117 has rank n for at least one value of $t \in [t_0, t_1]$.

Now consider the $n \times pq$ matrix $U(t) = [U_0(t) U_1(t) \dots U_{q-1}(t)]$ generated from the adjoint system $[-A^T(t), C^T(t), B^T(t)]$, where

$$U_0(t) = C^T(t) \quad (3.118)$$

$$U_i(t) = A^T(t)U_{i-1}(t) + \dot{U}_{i-1}(t), \quad i = 1, 2, \dots, q-1 \quad (3.119)$$

Then from Equations 3.115 through 3.119, it is seen that the transpose $U^T(t)$ of the $n \times pq$ matrix $U(t)$ is equal to the $pq \times n$ matrix $L(t)$ of the given system with state model $[A(t), B(t), C(t)]$. Since the transpose operation does not affect the rank of a matrix, the sufficient condition rank $L(t) = n$ for observability of the system $[A(t), B(t), C(t)]$ implies that the adjoint system $[-A^T(t), C^T(t), B^T(t)]$ is controllable. In addition, the rank condition for observability of the adjoint system implies that the given system is controllable. It also follows from the above constructions that the rank condition for observability of the system $[A(t), B(t), C(t)]$ is preserved under a coordinate transformation.

3.2.6 Control Canonical Form and Controller Design

Now suppose that the system with state model $[A(t), B(t), C(t)]$ has a single input ($m = 1$) so that the input matrix $B(t)$ is an n -element column vector. Assuming that $B(t)$ and $A(t)$ can be differentiated an appropriate number of times, let $R(t)$ denote the $n \times n$ matrix whose columns $r_i(t)$ are defined by

$$r_1(t) = B(t) \quad (3.120)$$

$$r_{i+1}(t) = A(t)r_i(t) - \dot{r}_i(t), \quad i = 1, 2, \dots, n-1 \quad (3.121)$$

Note that $R(t)$ is a minor variation of the $n \times n$ matrix $K(t)$ defined by Equations 3.101 through 3.103 with $q = n$. In fact, since $R(t)$ is equal to $K(t)$ with a sign change in the columns, $R(t)$ has rank n for all t if and only if $K(t)$ has rank n for all t . Thus, $R(t)$ is invertible for all t if and only if the matrix $K(t)$ has rank n for all t .

In some textbooks, such as [1], the matrix $R(t)$ is called the *controllability matrix* of the system with state model $[A(t), B(t), C(t)]$.

Assuming that $R(t)$ is invertible for all t , define the n -element column vector

$$\eta(t) = -R^{-1}(t)r_{n+1}(t) \quad (3.122)$$

where $r_{n+1}(t)$ is defined by Equation 3.121 with $i = n$. The vector $\eta(t)$ is invariant under any change of state $z(t) = P^{-1}(t)x(t)$. In other words, if Equations 3.120 through 3.122 are evaluated for the new state model $[\bar{A}(t), \bar{B}(t), \bar{C}(t)]$ resulting from the transformation $z(t) = P^{-1}(t)x(t)$, Equation 3.122 will yield the same result for $\eta(t)$. In addition, if $A(t) = A$ and $B(t) = B$ where A and B are constant matrices, the vector η is constant and is given by

$$\eta = [a_0 \ a_1 \ \dots \ a_{n-1}]^T \quad (3.123)$$

where a_i are the coefficients of the characteristic polynomial of A , that is,

$$\det(sI - A) = s^n + \sum_{i=0}^{n-1} a_i s^i \quad (3.124)$$

Given the analogy with the time-invariant case, the vector $\eta(t)$ given by Equation 3.122 can be viewed as a time-varying version of the *characteristic vector* of the system.

If the $n \times n$ matrix $R(t)$ with columns defined by Equations 3.120 and 3.121 is invertible for all t , there is a coordinate transformation $z(t) = P^{-1}(t)x(t)$, which converts $[A(t), B(t), C(t)]$ into the *control canonical form* $[\bar{A}(t), \bar{B}, \bar{C}(t)]$ with $\bar{A}(t)$ and \bar{B} given by

$$\bar{A}(t) = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 & 0 \\ 0 & 0 & 1 & \dots & 0 & 0 \\ 0 & 0 & 0 & \dots & 0 & 0 \\ \vdots & & & \dots & & \vdots \\ 0 & 0 & 0 & \dots & 0 & 1 \\ -\psi_0(t) & -\psi_1(t) & -\psi_2(t) & \dots & -\psi_{n-2}(t) & -\psi_{n-1}(t) \end{bmatrix} \quad (3.125)$$

$$\bar{B} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix} \quad (3.126)$$

This form was first derived in [10].

A recursive procedure for computing the rows $c_i(t)$ of the matrix $P^{-1}(t)$ in the transformation $z(t) = P^{-1}(t)x(t)$ to the control canonical form was derived in [11], and is given by

$$c_1(t) = (e_n)^T R^{-1}(t) \quad (3.127)$$

$$c_{i+1}(t) = c_i(t)A(t) + \dot{c}_i(t), \quad i = 1, 2, \dots, n-1 \quad (3.128)$$

where

$$(e_n)^T = [0 \quad 0 \quad 0 \quad \dots \quad 0 \quad 1] \quad (3.129)$$

As shown in [11], the entries $\psi_i(t)$ in the bottom row of $\bar{A}(t)$ are given by

$$\psi(t) = [\psi_0(t) \quad \psi_1(t) \quad \dots \quad \psi_{n-1}(t)] = -(c_n(t)A(t) + \dot{c}_n(t))P(t) \quad (3.130)$$

Now consider the system in the control canonical form given by the state equation

$$\dot{z}(t) = \bar{A}(t)z(t) + \bar{B}u(t) \quad (3.131)$$

where $\bar{A}(t)$ and \bar{B} are defined by Equations 3.125 and 3.126. Then with the *state feedback control* $u(t) = -\bar{g}(t)z(t)$, where $\bar{g}(t)$ is an n -element row vector, from Equation 3.131 the state equation for the resulting closed-loop system is

$$\dot{z}(t) = [\bar{A}(t) - \bar{B}\bar{g}(t)]z(t) \quad (3.132)$$

Let $d = [d_0 \quad d_1 \quad \dots \quad d_{n-1}]$ be an n -element row vector with any desired constants d_0, d_1, \dots, d_{n-1} . Then from the form of $\bar{A}(t)$ and \bar{B} , it is clear that if $\bar{g}(t)$ is taken to be $\bar{g}(t) = d - \psi(t)$, then the resulting closed-loop system matrix $\bar{A}(t) - \bar{B}\bar{g}(t)$ is equal to the matrix in the right-hand side of Equation 3.125 with the elements $-d_0, -d_1, \dots, -d_{n-1}$ in the bottom row. Thus, the matrix $\bar{A}(t) - \bar{B}\bar{g}(t)$ is constant and its characteristic polynomial is equal to $s^n + d_{n-1}s^{n-1} + \dots + d_1s + d_0$. The coefficients of the characteristic polynomial can be assigned to have any desired values d_0, d_1, \dots, d_{n-1} .

The state feedback $u(t) = -\bar{g}(t)z(t)$ in the control canonical form can be expressed in terms of the state $x(t)$ of the given system $[A(t), B(t), C(t)]$ by using the coordinate transformation $z(t) = P^{-1}(t)x(t)$. This results in

$$u(t) = -\bar{g}(t)z(t) = -\bar{g}(t)P^{-1}(t)x(t) = -[d - \psi(t)]P^{-1}(t)x(t) \quad (3.133)$$

Inserting the feedback $u(t)$ given by Equation 3.133 into the state equation $\dot{x}(t) = A(t)x(t) + B(t)u(t)$ for the system $[A(t), B(t), C(t)]$ yields the following equation for the resulting closed-loop system:

$$\dot{x}(t) = (A(t) - B(t)g(t))x(t) \quad (3.134)$$

where the feedback gain vector $g(t)$ is given by

$$g(t) = \bar{g}(t)P^{-1}(t) = [d - \psi(t)]P^{-1}(t) \quad (3.135)$$

By the above constructions, the coordinate transformation $z(t) = P^{-1}(t)x(t)$ transforms the system matrix $A(t) - B(t)g(t)$ of the closed-loop system defined by Equation 3.134 into the system matrix $\bar{A}(t) - \bar{B}\bar{g}(t)$ of the closed-loop system given by Equation 3.132.

As shown in [11], the gain vector $g(t)$ defined by Equation 3.135 can be computed without having to determine $\bar{A}(t)$ by using the following formula:

$$g(t) = - \left[c_{n+1}(t) + \sum_{i=0}^{n-1} d_i c_{i+1} \right] \quad (3.136)$$

where the $c_i(t)$ are given by Equations 3.127 and 3.128 with $i = 1, 2, \dots, n$. If the zeros of the characteristic polynomial of $\bar{A}(t) - \bar{B}\bar{g}(t)$ are chosen so that they are located in the open left half of the complex plane and if the coordinate transformation $z(t) = P^{-1}(t)x(t)$ is a Lyapunov transformation, then the closed-loop system given by Equation 3.134 is uniformly exponentially stable. If $P(t)$ and $P^{-1}(t)$ are bounded only for $t \geq t_1$ for some finite t_1 , then the closed-loop system is exponentially stable. In Section 3.4, an example is given which illustrates the computation of the feedback gain $g(t)$.

3.3 Discrete-Time Linear Time-Varying Systems

A discrete-time causal linear time-varying system with single-input $u(k)$ and single-output $y(k)$ can be modeled by the input/output relationship

$$y(k) = \sum_{j=-\infty}^k h(k, j)u(j) \quad (3.137)$$

where k is an integer-valued variable (the discrete-time index) and $h(k, j)$ is the output response resulting from the unit pulse $\delta(k - j)$ (where $\delta(k - j) = 1$ for $k = j$ and $= 0$ for $k \neq j$) applied at time j . It is assumed that $u(k)$ and/or $h(k, j)$ is constrained so that the summation in Equation 3.137 is well defined. The system defined by Equation 3.137 is time invariant if and only if $h(k, j)$ is a function of only the difference $k - j$, in which case Equation 3.137 reduces to the convolution relationship

$$y(k) = h(k) * u(k) = \sum_{j=-\infty}^k h(k - j)u(j) \quad (3.138)$$

where $h(k - j) = h(k - j, 0)$.

The system defined by Equation 3.138 is finite dimensional if the input $u(k)$ and the output $y(k)$ are related by the n th-order difference equation

$$y(k + n) + \sum_{i=0}^{n-1} a_i(k)y(k + i) = \sum_{i=0}^m b_i(k)u(k + i) \quad (3.139)$$

where $m \leq n$ and the $a_i(k)$ and the $b_i(k)$ are real-valued functions of the discrete-time variable k . The system given by Equation 3.139 is time invariant if and only if all coefficients in Equation 3.139 are constants, that is, $a_i(k) = a_i$ and $b_i(k) = b_i$ for all i , where a_i and b_i are constants.

When $m < n$ the system defined by Equation 3.139 has the n -dimensional state model

$$x(k + 1) = A(k)x(k) + B(k)u(k) \quad (3.140)$$

$$y(k) = Cx(k) \quad (3.141)$$

where

$$A(k) = \begin{bmatrix} 0 & 0 & 0 & \cdots & 0 & -a_0(k) \\ 1 & 0 & 0 & \cdots & 0 & -a_1(k-1) \\ 0 & 1 & 0 & \cdots & 0 & -a_2(k-2) \\ \vdots & & & \cdots & & \vdots \\ 0 & 0 & 0 & \cdots & 0 & -a_{n-2}(k-n+2) \\ 0 & 0 & 0 & \cdots & 1 & -a_{n-1}(k-n+1) \end{bmatrix} \quad (3.142)$$

$$B(k) = \begin{bmatrix} b_0(k) \\ b_1(k-1) \\ b_2(k-2) \\ \vdots \\ b_{n-2}(k-n+2) \\ b_{n-1}(k-n+1) \end{bmatrix} \quad (3.143)$$

and

$$C = [0 \quad 0 \quad \cdots \quad 0 \quad 1]$$

where $b_i(k) = 0$ for $i > m$. This particular state model is referred to as the observer canonical form. As in the continuous-time case, there are other possible state realizations of Equation 3.139, but these will not

be considered here. It is interesting to note that the entries of $A(k)$ and $B(k)$ in the observer canonical form are simply time shifts of the coefficients of the input/output difference Equation 3.139, whereas as shown above, in the continuous-time case this relationship is rather complicated.

3.3.1 State Model in the General Case

For an m -input p -output linear n -dimensional time-varying discrete-time system, the general form of the state model is

$$x(k+1) = A(k)x(k) + B(k)u(k) \quad (3.144)$$

$$y(k) = C(k)x(k) + D(k)u(k) \quad (3.145)$$

where the system matrix $A(k)$ is $n \times n$, the input matrix $B(k)$ is $n \times m$, the output matrix $C(k)$ is $p \times n$, and the direct feed matrix $D(k)$ is $p \times m$. The state model given by Equations 3.144 and 3.145 may arise as a result of sampling a continuous-time system given by the state model

$$\dot{x}(t) = A(t)x(t) + B(t)u(t) \quad (3.146)$$

$$y(t) = C(t)x(t) + D(t)u(t) \quad (3.147)$$

If the sampling interval is equal to T , then setting $t = kT$ in Equation 3.147 yields an output equation of the form in Equation 3.145, where $C(k) = C(t)|_{t=kT}$ and $D(k) = D(t)|_{t=kT}$. To “discretize” Equation 3.146, first recall (see Equation 3.53) that the solution to Equation 3.146 is

$$x(t) = \Phi(t, t_0)x(t_0) + \int_{t_0}^t \Phi(t, \tau)B(\tau)u(\tau) d\tau, \quad t > t_0 \quad (3.148)$$

Then setting $t = kT + T$ and $t_0 = kT$ in Equation 3.148 yields

$$x(kT + T) = \Phi(kT + T, kT)x(kT) + \int_{kT}^{kT+T} \Phi(kT + T, \tau)B(\tau)u(\tau) d\tau \quad (3.149)$$

The second term on the right-hand side of Equation 3.149 can be approximated by

$$\left[\int_{kT}^{kT+T} \Phi(kT + T, \tau)B(\tau) d\tau \right] u(kT)$$

and thus Equation 3.149 is in the form of Equation 3.144 with

$$A(k) = \Phi(kT + T, kT) \quad (3.150)$$

$$B(k) = \int_{kT}^{kT+T} \Phi(kT + T, \tau)B(\tau) d\tau \quad (3.151)$$

Note that the matrix $A(k)$ given by Equation 3.150 is always invertible since $\Phi(kT + T, kT)$ is always invertible (see the property given by Equation 3.40). As discussed below, this implies that discretized or sampled data systems are “reversible.”

From Equations 3.150 and 3.151 it is seen that the computation of $A(k)$ and $B(k)$ requires knowledge of the state-transition matrix $\Phi(t, \tau)$ for $t = kT + T$ and $\tau \in [kT, kT + T)$. As discussed in Section 3.3, if $A(t)$ in Equation 3.146 is a continuous function of t and the variation of $A(t)$ over the intervals

$[kT, kT + T]$ is sufficiently small for all k , then $\Phi(kT + T, \tau)$ can be approximated by

$$\Phi(kT + T, \tau) = e^{A(kT)(kT+T-\tau)} \quad \text{for } \tau \in [kT, kT + T] \quad (3.152)$$

and hence, $A(k)$ and $B(k)$ can be determined using

$$A(k) = e^{A(kT)T} \quad (3.153)$$

$$B(k) = \int_{kT}^{kT+T} e^{A(kT)(kT+T-\tau)} B(\tau) d\tau \quad (3.154)$$

Given the discrete-time system defined by Equations 3.144 and 3.145, the solution to Equation 3.144 is

$$x(k) = \Phi(k, k_0)x(k_0) + \sum_{j=k_0}^{k-1} \Phi(k, j+1)B(j)u(j), \quad k > k_0 \quad (3.155)$$

where the $n \times n$ state-transition matrix $\Phi(k, j)$ is given by

$$\Phi(k, k_0) = \begin{cases} \text{not defined for} & k < k_0 \\ I, & k = k_0 \\ A(k-1)A(k-2) \dots A(k_0), & k > k_0 \end{cases} \quad (3.156)$$

It follows directly from Equation 3.156 that $\Phi(k, k_0)$ is invertible for $k > k_0$ only if $A(k)$ is invertible for $k \geq k_0$. Thus, in general, the initial state $x(k_0)$ cannot be determined from the relationship $x(k) = \Phi(k, k_0)x(k_0)$. In other words, a discrete-time system is not necessarily *reversible*, although any continuous-time system given by Equations 3.146 and 3.147 is reversible since $\Phi(t, t_0)$ is always invertible. However, as noted above, any sampled data system is reversible.

The state-transition matrix $\Phi(k, k_0)$ satisfies the composition property:

$$\Phi(k, k_0) = \Phi(k, k_1)\Phi(k_1, k_0), \quad \text{where } k_0 \leq k_1 \leq k \quad (3.157)$$

and in addition,

$$\Phi(k+1, k_0) = A(k)\Phi(k, k_0), \quad k \geq k_0 \quad (3.158)$$

If $A(k)$ is invertible for all k , $\Phi(k, k_0)$ can be written in the factored form

$$\Phi(k, k_0) = \Phi_1(k)\Phi_2(k_0), \quad k \geq k_0 \quad (3.159)$$

where

$$\Phi_1(k) = \begin{cases} A(k-1)A(k-2) \dots A(0), & k \geq 1 \\ I, & k = 0 \\ A^{-1}(k-2)A^{-1}(k-3) \dots A^{-1}(-1), & k < 0 \end{cases} \quad (3.160)$$

$$\Phi_2(k_0) = \begin{cases} A^{-1}(0)A^{-1}(1) \dots A^{-1}(k_0-1), & k_0 > 0 \\ I, & k_0 = 0 \\ A(-1)A(-2) \dots A(k_0), & k_0 < 0 \end{cases} \quad (3.161)$$

When the direct feed matrix $D(k)$ in Equation 3.145 is zero, so that $y(k) = C(k)x(k)$, the output response $y(k)$ is given by

$$y(k) = C(k)\Phi(k, k_0)x(k_0) + \sum_{j=k_0}^{k-1} C(k)\Phi(k, j+1)B(j)u(j), \quad k > k_0 \quad (3.162)$$

If the initial time k_0 is set equal to $-\infty$ and the initial state is zero, Equation 3.162 becomes

$$y(k) = \sum_{j=-\infty}^{k-1} C(k)\Phi(k, j+1)B(j)u(j) \quad (3.163)$$

Comparing Equation 3.163 with the m -input p -output version of the input/output Equation 3.137 reveals that

$$H(k, j) = \begin{cases} C(k)\Phi(k, j+1)B(j), & k > j \\ 0, & k \leq j \end{cases} \quad (3.164)$$

where $H(k, j)$ is the $p \times m$ unit-pulse response function matrix. Note that if $A(k)$ is invertible so that $\Phi(k, k_0)$ has the factorization given in Equation 3.159, then $H(k, j)$ can be expressed in the factored form as

$$H(k, j) = [C(k)\Phi_1(k)][\Phi_2(j+1)B(j)] \quad \text{for } k > j. \quad (3.165)$$

As in the continuous-time case, this factorization is a fundamental property of unit-pulse response matrices $H(k, j)$ that are realizable by a state model (with invertible $A(k)$).

3.3.2 Stability

Given an n -dimensional discrete-time system defined by Equations 3.144 and 3.145, consider the homogeneous equation

$$x(k+1) = A(k)x(k), \quad k \geq k_0. \quad (3.166)$$

The solution is

$$x(k) = \Phi(k, k_0)x(k_0), \quad k > k_0 \quad (3.167)$$

where $\Phi(k, k_0)$ is the state-transition matrix defined by Equation 3.156.

The system is said to be asymptotically stable if for some initial time k_0 , the solution $x(k)$ satisfies the condition $\|x(k)\| \rightarrow 0$ as $k \rightarrow \infty$ for any initial state $x(k_0)$ at time k_0 . This is equivalent to requiring that

$$\|\Phi(k, k_0)\| \rightarrow 0, \quad \text{as } k \rightarrow \infty \quad (3.168)$$

The system is exponentially stable if for some initial time k_0 , there exist finite positive constants c and ρ with $\rho < 1$, such that for any $x(k_0)$ the solution $x(k)$ satisfies

$$\|x(k)\| \leq c\rho^{k-k_0} \|x(k_0)\|, \quad k > k_0 \quad (3.169)$$

If Equation 3.169 holds for all k_0 with the constants c and ρ fixed, the system is said to be uniformly exponentially stable. This is equivalent to requiring that there exist a finite positive constant γ and a nonnegative constant ρ with $\rho < 1$ such that

$$\|\Phi(k, j)\| \leq \gamma\rho^{k-j}, \quad \text{for all } k, j \text{ such that } k \geq j \quad (3.170)$$

Uniform exponential stability is also equivalent to requiring that given any positive constant δ , there exists a positive integer q such that for any k_0 and $x(k_0)$, the solution to Equation 3.166 satisfies

$$\|x(k)\| \leq \delta \|x(k_0)\|, \quad k \geq k_0 + q \quad (3.171)$$

Uniform exponential stability is also equivalent to the existence of a finite positive constant β such that

$$\sum_{i=j+1}^k \|\Phi(k, i)\| \leq \beta \quad \text{for all } k, j \text{ such that } k \geq j+1 \quad (3.172)$$

Another necessary and sufficient condition for uniform exponential stability is that a symmetric positive-definite matrix $Q(k)$ exists with $c_1I \leq Q(k) \leq c_2I$ for some positive constants c_1 and c_2 so that

$$A^T(k)Q(k+1)A(k) - Q(k) \leq -c_3I \quad (3.173)$$

for some positive constant c_3 .

3.3.3 Controllability and Observability

The discrete-time system defined by Equations 3.144 and 3.145 with $D(k) = 0$ will be denoted by the triple $[A(k), B(k), C(k)]$. The system is said to be controllable on the interval $[k_0, k_1]$ with $k_1 > k_0$ if, for any states x_0 and x_1 , an input $u(k)$ exists that drives the system to the state $x(k_1) = x_1$ at time $k = k_1$ starting from the state $x(k_0) = x_0$ at time $k = k_0$. To determine a necessary and sufficient condition for controllability, first solve Equation 3.144 to find the state $x(k_1)$ at time $k = k_1$ resulting from state $x(k_0)$ at time $k = k_0$ and the input sequence $u(k_0), u(k_0 + 1), \dots, u(k_1 - 1)$. The solution is

$$x(k_1) = \Phi(k_1, k_0)x(k_0) + \Phi(k_1, k_0 + 1)B(k_0)u(k_0) + \Phi(k_1, k_0 + 2)B(k_0 + 1)u(k_0 + 1) \\ + \dots + \Phi(k_1, k_1 - 1)B(k_1 - 2)u(k_1 - 2) + B(k_1 - 1)u(k_1 - 1) \quad (3.174)$$

Let $R(k_1, k_0)$ be the *controllability (or reachability) matrix* with n rows and $(k_1 - k_0)m$ columns defined by

$$R(k_0, k_1) = [B(k_1 - 1) \Phi(k_1, k_1 - 1)B(k_1 - 2) \dots \Phi(k_1, k_0 + 2)B(k_0 + 1) \Phi(k_1, k_0 + 1)B(k_0)] \quad (3.175)$$

Then Equation 3.174 can be written the form

$$x(k_1) = \Phi(k_1, k_0)x(k_0) + R(k_0, k_1)U(k_0, k_1) \quad (3.176)$$

where $U(k_0, k_1)$ is the $(k_1 - k_0)m$ -element column vector of inputs given by

$$U(k_0, k_1) = \left[u^T(k_1 - 1) u^T(k_1 - 2) \dots u^T(k_0 + 1) u^T(k_0) \right]^T \quad (3.177)$$

Now for any states $x(k_0) = x_0$ and $x(k_1) = x_1$, from Equation 3.176, there is a sequence of inputs given by $U(k_0, k_1)$ that drives the system from x_0 to x_1 if and only if the matrix $R(k_0, k_1)$ has rank n . If this is the case, Equation 3.176 can be solved for $U(k_0, k_1)$, giving

$$U(k_0, k_1) = R^T(k_0, k_1) \left[R(k_0, k_1)R^T(k_0, k_1) \right]^{-1} [x_1 - \Phi(k_1, k_0)x_0] \quad (3.178)$$

Hence, rank $R(k_0, k_1) = n$ is a necessary and sufficient condition for controllability over the interval $[k_0, k_1]$.

Given a fixed positive integer N , set $k_0 = k - N + 1$ and $k_1 = k + 1$ in $R(k_0, k_1)$, which results in the matrix $R(k - N + 1, k + 1)$. Note that $R(k - N + 1, k + 1)$ is a function of only the integer variable k and that the size of the matrix $R(k - N + 1, k + 1)$ is equal to $n \times Nm$ since $k_1 - k_0 = N$. The $n \times Nm$ matrix $R(k - N + 1, k + 1)$ will be denoted by $R(k)$. By definition of the state-transition matrix $\Phi(k, k_0)$, $R(k)$ can be written in the form

$$R(k) = [R_0(k) R_1(k) \dots R_{N-1}(k)] \quad (3.179)$$

where the block columns $R_i(k)$ of $R(k)$ are given by

$$R_0(k) = B(k) \quad (3.180)$$

$$R_i(k) = A(k)R_{i-1}(k - 1), \quad i = 1, 2, \dots, N - 1 \quad (3.181)$$

The system is said to be *uniformly N -step controllable* if rank $R(k) = n$ for all k . Uniformly N -step controllable means that the system is controllable on the interval $[k - N + 1, k + 1]$ for all k .

Now suppose that the system input $u(k)$ is zero, so that the state model is given by

$$x(k + 1) = A(k)x(k) \quad (3.182)$$

$$y(k) = C(k)x(k) \quad (3.183)$$

From Equations 3.182 and 3.183, the output response $y(k)$ resulting from initial state $x(k_0)$ is given by

$$y(k) = C(k)\Phi(k, k_0)x(k_0), \quad k \geq k_0 \quad (3.184)$$

Then the system is said to be observable on the interval $[k_0, k_1]$ if any initial state $x(k_0) = x_0$ can be determined from the output response $y(k)$ given by Equation 3.184 for $k = k_0, k_0 + 1, \dots, k_1 - 1$. Using

Equation 3.184 for $k = k_0$ to $k = k_1 - 1$ yields

$$\begin{bmatrix} y(k_0) \\ y(k_0 + 1) \\ \vdots \\ y(k_1 - 2) \\ y(k_1 - 1) \end{bmatrix} = \begin{bmatrix} C(k_0)x_0 \\ C(k_0 + 1)\Phi(k_0 + 1, k_0)x_0 \\ \vdots \\ C(k_1 - 2)\Phi(k_1 - 2, k_0)x_0 \\ C(k_1 - 1)\Phi(k_1 - 1, k_0)x_0 \end{bmatrix} \quad (3.185)$$

The right-hand side of Equation 3.185 can be written in the form $O(k_0, k_1)x_0$ where $O(k_0, k_1)$ is the $(k_1 - k_0)p \times n$ observability matrix defined by

$$O(k_0, k_1) = \begin{bmatrix} C(k_0) \\ C(k_0 + 1)\Phi(k_0 + 1, k_0) \\ \vdots \\ C(k_1 - 2)\Phi(k_1 - 2, k_0) \\ C(k_1 - 1)\Phi(k_1 - 1, k_0) \end{bmatrix} \quad (3.186)$$

Equation 3.185 can be solved for any initial state x_0 if and only if $\text{rank } O(k_0, k_1) = n$, which is a necessary and sufficient condition for observability on $[k_0, k_1]$. If the rank condition holds, the solution of Equation 3.185 for x_0 is

$$x_0 = \left[O^T(k_0, k_1)O(k_0, k_1) \right]^{-1} O^T(k_0, k_1)Y(k_0, k_1) \quad (3.187)$$

where $Y(k_0, k_1)$ is the $(k_1 - k_0)p$ -element column vector of outputs given by

$$Y(k_0, k_1) = \left[y^T(k_0) y^T(k_0 + 1) \cdots y^T(k_1 - 2) y^T(k_1 - 1) \right]^T \quad (3.188)$$

Given a positive integer N , setting $k_0 = k$ and $k_1 = k + N$ in $O(k_0, k_1)$ yields the $Np \times n$ matrix $O(k, k + N)$, which will be denoted by $O(k)$. By definition of the state-transition matrix $\Phi(k, k_0)$, $O(k)$ can be written in the form

$$O(k) = \begin{bmatrix} O_0(k) \\ O_1(k) \\ \vdots \\ O_{N-1}(k) \end{bmatrix} \quad (3.189)$$

where the block rows $O_i(k)$ of $O(k)$ are given by

$$O_0(k) = C(k) \quad (3.190)$$

$$O_i(k) = O_{i-1}(k+1)A(k), \quad i = 1, 2, \dots, N-1 \quad (3.191)$$

The system is said to be *uniformly N -step observable* if $\text{rank } O(k) = n$ for all k . Uniformly N -step observable means that the system is observable on the interval $[k, k + N]$ for all k .

3.3.4 Change of State Variables and Canonical Forms

Again, consider the discrete-time system with state model $[A(k), B(k), C(k)]$. For any $n \times n$ invertible matrix $P(k)$, another state model can be generated by defining the new state vector $z(k) = P^{-1}(k)x(k)$.

The new state model is given by

$$z(k+1) = \bar{A}(k)z(k) + \bar{B}(k)u(k) \quad (3.192)$$

$$y(k) = \bar{C}(k)z(k) \quad (3.193)$$

where

$$\bar{A}(k) = P^{-1}(k+1)A(k)P(k) \quad (3.194)$$

$$\bar{B}(k) = P^{-1}(k+1)B(k) \quad (3.195)$$

$$\bar{C}(k) = C(k)P(k) \quad (3.196)$$

The state-transition matrix $\bar{\Phi}(k, k_0)$ for the new state model is given by

$$\bar{\Phi}(k, k_0) = P^{-1}(k)\Phi(k, k_0)P(k_0) \quad (3.197)$$

where $\Phi(k, k_0)$ is the state-transition matrix for $[A(k), B(k), C(k)]$. The new state model, which will be denoted by $[\bar{A}(k), \bar{B}(k), \bar{C}(k)]$, and the given state model $[A(k), B(k), C(k)]$ are said to be algebraically equivalent.

Given an n -dimensional state model $[A(k), B(k), C(k)]$ and any $n \times n$ invertible matrix function $\Gamma(k)$, if $A(k)$ is invertible, there is an invertible coordinate transformation matrix $P(k)$ for $k \geq k_0$, which transforms $A(k)$ into $\Gamma(k)$ for $k \geq k_0$, that is, $\bar{A}(k) = \Gamma(k)$, $k \geq k_0$. To show this, define $P(k)$ by the matrix difference equation

$$P(k+1) = A(k)P(k)\Gamma^{-1}(k), \quad k \geq k_0 \quad (3.198)$$

with initial condition $P(k_0) = I = n \times n$ identity matrix. Then multiplying both sides of Equation 3.198 on the right by $\Gamma(k)$ and multiplying the resulting equation on the left by $P^{-1}(k+1)$ yields Equation 3.194 with $\bar{A}(k) = \Gamma(k)$ for $k \geq k_0$. This result shows that an invertible matrix $A(k)$ can be put into a diagonal form via a coordinate transformation with any desired nonzero functions or constants on the diagonal. Thus, as in the continuous-time case, there is no useful generalization of the notion of eigenvalues and eigenvectors in the time-varying case, unless additional conditions are placed on the coordinate transformation. For example, one can require that the transformation be a Lyapunov transformation, which means that both $P(k)$ and its inverse $P^{-1}(k)$ are bounded matrix functions of the integer variable k . It follows from Equation 3.197 that uniform exponential stability is preserved under a Lyapunov transformation.

Suppose that the systems $[A(k), B(k), C(k)]$ and $[\bar{A}(k), \bar{B}(k), \bar{C}(k)]$ are algebraically equivalent and let $R(k)$ denote the $n \times Nm$ controllability matrix for the system $[A(k), B(k), C(k)]$, where $R(k)$ is defined by Equations 3.179 through 3.181. Similarly, for the system given by $[\bar{A}(k), \bar{B}(k), \bar{C}(k)]$ define

$$\bar{R}(k) = [\bar{R}_0(k) \bar{R}_1(k) \dots \bar{R}_{n-1}(k)] \quad (3.199)$$

where the $\bar{R}_i(k)$ are given by Equations 3.180 and 3.181 with $A(k)$ and $B(k)$ replaced by $\bar{A}(k)$ and $\bar{B}(k)$, respectively. Then the coordinate transformation $P^{-1}(k)$ is given by

$$P^{-1}(k+1)R(k) = \bar{R}(k) \quad (3.200)$$

If the system $[A(k), B(k), C(k)]$ is uniformly N -step controllable, $R(k)$ has rank n for all k , and the $n \times n$ matrix $R(k)R^T(k)$ is invertible. Thus, Equation 3.200 can be solved for $P^{-1}(k+1)$, which gives

$$P^{-1}(k+1) = \bar{R}(k)R^T(k)[R(k)R^T(k)]^{-1} \quad (3.201)$$

It follows from Equation 3.200 that uniform N -step controllability is preserved under a change of state variables.

Now suppose that the n -dimensional system with state model $[A(k), B(k), C(k)]$ is uniformly N -step controllable with $N = n$ and that the system has a single input ($m = 1$) so that $B(k)$ is an n -element column vector and $R(k)$ is a $n \times n$ invertible matrix. Define

$$R_n(k) = A(k)R_{n-1}(k-1) \tag{3.202}$$

$$\eta(k) = -R^{-1}(k)R_n(k) \tag{3.203}$$

where $R_{n-1}(k)$ is the column vector defined by Equation 3.181 with $i = n-1$. The n -element column vector $\eta(k)$ defined by Equation 3.203 is invariant under any change of state $z(k) = P^{-1}(k)x(k)$, and in the time-invariant case, η is constant and is given by

$$\eta = [a_0 \quad a_1 \quad \cdots \quad a_{n-1}]^T \tag{3.204}$$

where the a_i are the coefficients of the characteristic polynomial of A .

Given $\eta(k)$ defined by Equation 3.203, write $\eta(k)$ in the form

$$\eta(k) = [\eta_0(k) \quad \eta_1(k) \quad \cdots \quad \eta_{n-1}(k)] \tag{3.205}$$

Then as proved in [3], there is a transformation $P(k)$ which converts $[A(k), B(k), C(k)]$ into the control canonical form $[\bar{A}(k), \bar{B}, \bar{C}(k)]$, with $\bar{A}(k)$ and \bar{B} given by

$$\bar{A}(k) = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 & 0 \\ 0 & 0 & 1 & \cdots & 0 & 0 \\ 0 & 0 & 0 & \cdots & 0 & 0 \\ \vdots & & & \cdots & & \vdots \\ 0 & 0 & 0 & \cdots & 0 & 1 \\ -\eta_0(k) & -\eta_1(k+1) & -\eta_2(k+2) & \cdots & -\eta_{n-2}(k+n-2) & -\eta_{n-1}(k+n-1) \end{bmatrix} \tag{3.206}$$

$$\bar{B} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix} \tag{3.207}$$

The transformation matrix $P^{-1}(k)$ that yields the control canonical form can be determined using Equation 3.201. As in the continuous-time case, the control canonical form can be used to design a state feedback control which results in a uniformly exponentially stable closed-loop system if the coordinate transformation defined by $P^{-1}(k)$ is a Lyapunov transformation. If $P(k)$ and $P^{-1}(k)$ are bounded only for $k \geq k_1$ for some finite k_1 , the resulting closed-loop system is exponentially stable. The details are a straightforward modification of the continuous-time case, and thus are not pursued here.

3.4 Applications and Examples

In Section 3.4.1, an example is given on the construction of canonical forms and the design of observers and controllers.

3.4.1 Observer and Controller Design

Consider the single-input single-output linear time-varying continuous-time system given by the input/output differential equation

$$\ddot{y}(t) + e^{-t}\dot{y}(t) + y(t) = \dot{u}(t) \quad (3.208)$$

To determine the state model, which is in observer canonical form, write Equation 3.208 in the form

$$\ddot{y}(t) + D[\alpha_1(t)y(t)] + \alpha_0(t)y(t) = \dot{u}(t) \quad (3.209)$$

In this case,

$$\alpha_1(t) = e^{-t} \quad \text{and} \quad \alpha_0(t) = 1 + e^{-t} \quad (3.210)$$

Then from Equations 3.22 through 3.24, the observer canonical form of the state model is

$$\begin{bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \end{bmatrix} = \begin{bmatrix} 0 & -1 - e^{-t} \\ 1 & -e^{-t} \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t) \quad (3.211)$$

$$y(t) = \begin{bmatrix} 0 & 1 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} \quad (3.212)$$

The state variables $x_1(t)$ and $x_2(t)$ in this state model are given by

$$x_1(t) = \dot{y}(t) + e^{-t}y(t) - u(t) \quad (3.213)$$

$$x_2(t) = y(t) \quad (3.214)$$

If the output $y(t)$ of the system can be differentiated, then $x_1(t)$ and $x_2(t)$ can be directly determined from the input $u(t)$ and the output $y(t)$ by using Equations 3.213 and 3.214. In practice, however, differentiation of signals should be avoided, and thus directly determining $x_1(t)$ using Equation 3.213 is usually not viable. As discussed next, by using a state observer, the state $x(t)$ can be estimated without having to differentiate signals. Actually, in this particular example it is necessary to estimate only $x_1(t)$ since the output $y(t) = x_2(t)$ is known, and thus a reduced-order observer could be used, but this is not considered here.

An observer for the state $x(t)$ is given by

$$\frac{d}{dt}\hat{x}(t) = A(t)\hat{x}(t) + H(t)[y(t) - C(t)\hat{x}(t)] + B(t)u(t) \quad (3.215)$$

where $H(t)$ is the n -element observer gain vector and $\hat{x}(t)$ is the estimate of $x(t)$. With the estimation error $e(t)$ defined by $e(t) = x(t) - \hat{x}(t)$, the error is given by the differential equation

$$\dot{e}(t) = [A(t) - H(t)C(t)]e(t), \quad t > t_0 \quad (3.216)$$

with initial error $e(t_0)$ at initial time t_0 . The objective is to choose the gain vector $H(t)$ so that, for any initial error $e(t_0)$, $\|e(t)\| \rightarrow 0$ as $t \rightarrow \infty$, with some desired rate of convergence.

For the system given by Equations 3.211 and 3.212, the error Equation 3.216 is

$$\dot{e}(t) = \begin{bmatrix} 0 & -1 - e^{-t} - h_1(t) \\ 1 & -e^{-t} - h_2(t) \end{bmatrix} e(t) \quad (3.217)$$

where $H(t) = [h_1(t) \quad h_2(t)]^T$. From Equation 3.217, it is obvious that by setting

$$h_1(t) = m_0 - 1 - e^{-t} \quad (3.218)$$

$$h_2(t) = m_1 - e^{-t} \quad (3.219)$$

where m_0 and m_1 are constants, the coefficient matrix on the right-hand side of Equation 3.217 is constant, and its eigenvalues can be assigned by choosing m_0 and m_1 . Hence, any desired rate of convergence to zero can be achieved for the error $e(t)$.

The estimate $\hat{x}(t)$ of $x(t)$ can then be used to realize a feedback control law of the form

$$u(t) = -g(t)\hat{x}(t) \quad (3.220)$$

where $g(t)$ is the feedback gain vector. The first step in pursuing this is to consider the extent to which the system can be controlled by state feedback of the form given in Equation 3.220 with $\hat{x}(t)$ replaced by $x(t)$; in other words, the true system state $x(t)$ is assumed to be available. In particular, we can ask whether or not there is a gain vector $g(t)$ so that with $u(t) = -g(t)x(t)$, the state of the resulting closed-loop system decays to zero exponentially with some desired rate of convergence. This can be answered by attempting to transform the state model given by Equations 3.211 and 3.212 to control canonical form. Following the procedure given in Section 3.2, the steps are as follows.

Let $R(t)$ denote the 2×2 matrix whose columns $r_i(t)$ are defined by Equations 3.120 and 3.121 with $n = 2$. This yields

$$r_1(t) = B(t) = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \quad (3.221)$$

$$r_2(t) = A(t)r_1(t) + \dot{r}_1(t) = \begin{bmatrix} -1 - e^{-t} \\ -e^{-t} \end{bmatrix} \quad (3.222)$$

Then

$$R(t) = [r_1(t) \quad r_2(t)] = \begin{bmatrix} 0 & -1 - e^{-t} \\ 1 & -e^{-t} \end{bmatrix} \quad (3.223)$$

and

$$\det[R(t)] = 1 + e^{-t} \quad \text{for all } t \quad (3.224)$$

where “det” denotes the determinant. Since $\det[R(t)] \neq 0$ for all t , $R(t)$ has rank 2 for all t , and thus the control canonical form exists for the system given by Equations 3.211 and 3.212.

The rows $c_i(t)$ of the matrix $P^{-1}(t)$ in the transformation $z(t) = P^{-1}(t)x(t)$ to the control canonical form are computed using Equations 3.127 and 3.128. This yields

$$c_1(t) = [-(1 + e^{-t})^{-1} \quad 0] \quad \text{and} \quad c_2(t) = [-e^{-t}(1 + e^{-t})^{-2} \quad 1] \quad (3.225)$$

and thus

$$P^{-1}(t) = \begin{bmatrix} -(1 + e^{-t})^{-1} & 0 \\ -e^{-t}(1 + e^{-t})^{-2} & 1 \end{bmatrix} \quad \text{and} \quad P(t) = \begin{bmatrix} -(1 + e^{-t}) & 0 \\ -e^{-t}(1 + e^{-t})^{-1} & 1 \end{bmatrix} \quad (3.226)$$

Now choose the coefficients of the characteristic polynomial of the closed-loop system matrix in the control canonical form to be d_0 and d_1 . Then from Equation 3.136, the feedback gain vector $g(t)$ back in the original state coordinates is given by

$$g(t) = -(c_3(t) + d_0c_1(t) + d_1c_2(t)) \quad (3.227)$$

where

$$c_3(t) = c_2(t)A(t) + \dot{c}_2(t) \quad (3.228)$$

$$c_3(t) = [1 - 2e^{-2t}(1 + e^{-t})^{-3} + e^{-t}(1 + e^{-t})^{-2} \quad e^{-t}(1 + e^{-t})^{-1} - e^{-t}] \quad (3.229)$$

Inserting the expressions for $c_1(t)$, $c_2(t)$, and $c_3(t)$ given by Equations 3.225 and 3.229 into Equation 3.227 results in the feedback gain vector $g(t)$.

Since $P(t)$ and $P^{-1}(t)$ given by Equation 3.226 are bounded for $t \geq t_1$ for any finite t_1 , by choosing appropriate values for d_0 and d_1 it follows that via the state feedback control given by $u(t) = -g(t)x(t)$, the resulting closed-loop system is exponentially stable with any desired rate λ of convergence to zero. It also follows that with the state feedback control $u(t) = -g(t)\hat{x}(t)$, where $\hat{x}(t)$ is the estimated state, the resulting closed-loop system is also exponentially stable with any desired rate of convergence to zero.

3.4.2 Exponential Systems

A system with n -dimensional state model $[A(t), B(t), C(t)]$ is said to be an *exponential system* if its state-transition matrix $\Phi(t, \tau)$ can be written in the matrix exponential form

$$\Phi(t, \tau) = e^{\Gamma(t, \tau)} \quad (3.230)$$

where $\Gamma(t, \tau)$ is a $n \times n$ matrix function of t and τ . The form given in Equation 3.230 is valid (at least locally, that is, when t is close to τ) for a large class of time-varying systems. In fact, as noted above, for $t \in [\tau, \tau + T]$, $\Phi(t, \tau)$ can be approximated by the matrix exponential $e^{A(kT)(t-\tau)}$ if $A(t)$ is approximately equal to $A(\tau)$ for $t \in [\tau, \tau + T]$. For a mathematical development of the matrix exponential form, see [5].

As noted previously, the exponential form in Equation 3.230 is valid for any system where $A(t)$ commutes with its integral (see Equation 3.47), in which case

$$\Gamma(t, \tau) = \int_{\tau}^t A(\sigma) d\sigma \quad (3.231)$$

The class of systems for which $A(t)$ commutes with its integral is actually fairly large; in particular, this is the case for any $A(t)$ given by

$$A(t) = \sum_{i=1}^r f_i(t) A_i \quad (3.232)$$

where $f_i(t)$ are arbitrary real-valued functions of t and the A_i are arbitrary constant $n \times n$ matrices that satisfy the commutativity conditions

$$A_i A_j = A_j A_i, \quad \text{for all integers } 1 \leq i, j \leq r \quad (3.233)$$

For example, suppose that

$$A(t) = \begin{bmatrix} f_1(t) & c_1 f_2(t) \\ c_2 f_2(t) & f_1(t) \end{bmatrix} \quad (3.234)$$

where $f_1(t)$ and $f_2(t)$ are arbitrary real-valued functions of t and c_1 and c_2 are arbitrary constants. Then

$$A(t) = f_1(t) A_1 + f_2(t) A_2 \quad (3.235)$$

where $A_1 = I$ and

$$A_2 = \begin{bmatrix} 0 & c_1 \\ c_2 & 0 \end{bmatrix} \quad (3.236)$$

Obviously, A_1 and A_2 commute, and thus $\Phi(t, \tau)$ is given by Equations 3.230 and 3.231. In this case, $\Phi(t, \tau)$ can be written in the form

$$\Phi(t, \tau) = \exp \left[\left(\int_{\tau}^t f_1(\sigma) d\sigma \right) I \right] \exp \left[\left(\int_{\tau}^t f_2(\sigma) d\sigma \right) A_2 \right] \quad (3.237)$$

Given an n -dimensional system with exponential state-transition matrix $\Phi(t, \tau) = e^{\Gamma(t, \tau)}$, $\Phi(t, \tau)$ can be expressed in terms of scalar functions using the Laplace transform as in the time-invariant case.

In particular, let

$$\Phi(t, \beta, \tau) = \text{inverse transform of } [sI - (1/\beta)\Gamma(\beta, \tau)]^{-1} \tag{3.238}$$

where $\Gamma(\beta, \tau) = \Gamma(t, \tau)|_{t=\beta}$ and β is viewed as a parameter. Then

$$\Phi(t, \tau) = \Phi(t, \beta, \tau)|_{\beta=t} \tag{3.239}$$

For example, suppose that

$$A(t) = \begin{bmatrix} f_1(t) & f_2(t) \\ -f_2(t) & f_1(t) \end{bmatrix} \tag{3.240}$$

where $f_1(t)$ and $f_2(t)$ are arbitrary functions of t with the constraint that $f_2(t) \geq 0$ for all t . Then

$$\Gamma(t, \tau) = \int_{\tau}^t A(\sigma) d\sigma \tag{3.241}$$

and $\Phi(t, \beta, \tau)$ is equal to the inverse transform of

$$\Phi(s, \beta, \tau) = \begin{bmatrix} s - \gamma_1(\beta, \tau) & -\gamma_2(\beta, \tau) \\ \gamma_2(\beta, \tau) & s - \gamma_1(\beta, \tau) \end{bmatrix}^{-1} \tag{3.242}$$

where

$$\gamma_1(\beta, \tau) = (1/\beta) \int_{\tau}^{\beta} f_1(\sigma) d\sigma \tag{3.243}$$

$$\gamma_2(\beta, \tau) = (1/\beta) \int_{\tau}^{\beta} f_2(\sigma) d\sigma \tag{3.244}$$

Computing the inverse Laplace transform of $\Phi(s, \beta, \tau)$ and using Equation 3.239 give (for $t > 0$)

$$\Phi(t, \tau) = \begin{bmatrix} e^{\gamma_1(t, \tau)t} \cos[\gamma_2(t, \tau)t] & e^{\gamma_1(t, \tau)t} \sin[\gamma_2(t, \tau)t] \\ -e^{\gamma_1(t, \tau)t} \sin[\gamma_2(t, \tau)t] & e^{\gamma_1(t, \tau)t} \cos[\gamma_2(t, \tau)t] \end{bmatrix} \tag{3.245}$$

3.4.3 Stability

Again consider an n -dimensional exponential system $[A(t), B(t), C(t)]$ with state-transition matrix $\Phi(t, \tau) = e^{\Gamma(t, \tau)}$. A sufficient condition for exponential stability of the differential equation $\dot{x}(t) = A(t)x(t)$ is that the $n \times n$ matrix $(1/t)\Gamma(t, \tau)$ be bounded as a function of t and its pointwise eigenvalues have real parts $\leq -\nu$ for some $\nu > 0$ and all $t > \tau$ for some finite τ . For example, suppose that $A(t)$ is given by Equation 3.234 so that

$$(1/t)\Gamma(t, \tau) = \begin{bmatrix} \gamma_1(t, \tau) & c_1\gamma_2(t, \tau) \\ c_2\gamma_2(t, \tau) & \gamma_1(t, \tau) \end{bmatrix} \tag{3.246}$$

where $\gamma_1(t, \tau)$ and $\gamma_2(t, \tau)$ are given by Equations 3.243 and 3.244 with $\beta = t$. Then

$$\det[sI - (1/t)\Gamma(t, \tau)] = s^2 - 2\gamma_1(t, \tau)s + \gamma_1^2(t, \tau) - c_1c_2\gamma_2^2(t, \tau) \tag{3.247}$$

and the pointwise eigenvalues of $(1/t)\Gamma(t, \tau)$ have real parts $\leq -\nu$ for all $t > \tau$ for some $\nu > 0$ and τ if

$$\gamma_1(t, \tau) \leq \nu_1, \quad \text{for all } t > \tau \quad \text{and} \quad \text{some } \nu_1 < 0, \tag{3.248}$$

$$\gamma_1^2(t, \tau) - c_1c_2\gamma_2^2(t, \tau) \geq \nu_2 \quad \text{for all } t > \tau \quad \text{and} \quad \text{some } \nu_2 > 0 \tag{3.249}$$

Therefore, if Equations 3.248 and 3.249 are satisfied and $\gamma_1(t, \tau)$ and $\gamma_2(t, \tau)$ are bounded functions of t , the solutions to $\dot{x}(t) = A(t)x(t)$ with $A(t)$ given by Equation 3.234 decay to zero exponentially.

It is well known that in general there is no pointwise eigenvalue condition on the system matrix $A(t)$ that insures exponential stability, or even asymptotic stability. For an example (taken from [8]), suppose that

$$A(t) = \begin{bmatrix} -1 + \alpha(\cos^2 t) & 1 - \alpha(\sin t)(\cos t) \\ -1 - \alpha(\sin t)(\cos t) & -1 + \alpha(\sin^2 t) \end{bmatrix} \quad (3.250)$$

where α is a real parameter. The pointwise eigenvalues of $A(t)$ are equal to

$$\frac{\alpha - 2 \pm \sqrt{\alpha^2 - 4}}{2} \quad (3.251)$$

which are strictly negative if $0 < \alpha < 2$. But

$$\Phi(t, 0) = \begin{bmatrix} e^{(\alpha-1)t}(\cos t) & e^{-t}(\sin t) \\ -e^{(\alpha-1)t}(\sin t) & e^{-t}(\cos t) \end{bmatrix} \quad (3.252)$$

and thus, the system is obviously not asymptotically stable if $\alpha > 1$.

3.4.4 The Lyapunov Criterion

By using the Lyapunov criterion (see Equation 3.97), it is possible to derive sufficient conditions for uniform exponential stability without computing the state-transition matrix. For example, suppose that

$$A(t) = \begin{bmatrix} 0 & 1 \\ -1 & -a(t) \end{bmatrix} \quad (3.253)$$

where $a(t)$ is a real-valued function of t with $a(t) \geq c$ for all $t > t_1$, for some t_1 and some constant $c > 0$. Now in Equation 3.97, choose

$$Q(t) = \begin{bmatrix} a(t) + \frac{2}{a(t)} & 1 \\ 1 & \frac{2}{a(t)} \end{bmatrix} \quad (3.254)$$

Then, $c_1 I \leq Q(t) \leq c_2$, for all $t > t_1$ for some constants $c_1 > 0$ and $c_2 > 0$. Now

$$Q(t)A(t) + A^T(t)Q(t) + \dot{Q}(t) = \begin{bmatrix} -2 + \dot{a}(t) - \frac{\dot{a}(t)}{a^2(t)} & 0 \\ 0 & -1 - \frac{\dot{a}(t)}{a^2(t)} \end{bmatrix} \quad (3.255)$$

Hence, if

$$-2 + \dot{a}(t) - \frac{\dot{a}(t)}{a^2(t)} \leq -c_3 \quad \text{for } t > t_1 \quad \text{for some } c_3 > 0 \quad (3.256)$$

and

$$-1 - \frac{\dot{a}(t)}{a^2(t)} \leq -c_4 \quad \text{for } t > t_1 \quad \text{for some } c_4 > 0 \quad (3.257)$$

the system is uniformly exponentially stable. For instance, if $a(t) = b - \cos t$, then Equations 3.256 and 3.257 are satisfied if $b > 2$, in which case the system is uniformly exponentially stable.

Now suppose that

$$A(t) = \begin{bmatrix} 0 & 1 \\ -a_1(t) & -a_2(t) \end{bmatrix} \quad (3.258)$$

As suggested in [8, p. 109], sufficient conditions for uniform exponential stability can be derived by taking

$$Q(t) = \begin{bmatrix} a_1(t) + a_2(t) + \frac{a_1(t)}{a_2(t)} & 1 \\ 1 & 1 + \frac{1}{a_2(t)} \end{bmatrix} \quad (3.259)$$

3.5 Defining Terms

State model: For linear time-varying systems, this is a mathematical representation of the system in terms of state equations of the form $\dot{x}(t) = A(t)x(t) + B(t)u(t)$, $y(t) = C(t)x(t) + D(t)u(t)$.

State-transition matrix: The matrix $\Phi(t, t_0)$ where $\Phi(t, t_0)x(t_0)$ is the state at time t starting with state $x(t_0)$ at time t_0 and with no input applied for $t \geq t_0$.

Exponential system: A system whose state-transition matrix $\Phi(t, \tau)$ can be written in the exponential form $e^{\Gamma(t, \tau)}$ for some $n \times n$ matrix function $\Gamma(t, \tau)$.

Reversible system: A system whose state-transition matrix is invertible.

Sampled data system: A discrete-time system generated by sampling the inputs and outputs of a continuous-time system.

Change of state: A transformation $z(t) = P^{-1}(t)x(t)$ from the state vector $x(t)$ to the new state vector $z(t)$.

Algebraic equivalence: Refers to two state models of the same system related by a change of state.

Lyapunov transformation: A change of state $z(t) = P^{-1}(t)x(t)$ where $P(t)$ and its inverse $P^{-1}(t)$ are both bounded functions of t .

Canonical form: A state model $[A(t), B(t), C(t)]$ with one or more of the coefficient matrices $A(t), B(t), C(t)$ in a special form.

Control canonical form: In the single-input case, a canonical form for $A(t)$ and $B(t)$ that facilitates the study of state feedback control.

Observer canonical form: In the single-output case, a canonical form for $A(t)$ and $C(t)$ that facilitates the design of a state observer.

Characteristic vector: A time-varying generalization corresponding to the vector of coefficients of the characteristic polynomial in the time-invariant case.

Asymptotic stability: Convergence of the solutions of $\dot{x}(t) = A(t)x(t)$ to zero for any initial state $x(t_0)$.

Exponential stability: Convergence of the solutions of $\dot{x}(t) = A(t)x(t)$ to zero at an exponential rate.

Uniform exponential stability: Convergence of the solutions of $\dot{x}(t) = A(t)x(t)$ to zero at an exponential rate uniformly with respect to the initial time.

Pointwise eigenvalues: The eigenvalues of a $n \times n$ time-varying matrix $M(t)$ with t replaced by τ , where τ is viewed as a time-independent parameter.

Controllability: The existence of inputs that drive a system from any initial state to any desired state.

Observability: The ability to compute the initial state $x(t_0)$ from knowledge of the output response $y(t)$ for $t \geq t_0$.

State feedback control: A control signal of the form $u(t) = -F(t)x(t)$ where $F(t)$ is the feedback gain matrix and $x(t)$ is the system state.

Observer: A system which provides an estimate $\hat{x}(t)$ of the state $x(t)$ of a system.

Acknowledgment

The author wishes to thank Professor Wilson J. Rugh of the Johns Hopkins University for his comments regarding a technical issue involving the concept of uniform exponential stability in the time-varying case.

4.1 Introduction

In many engineering applications, processes are described by increasingly complex models that are difficult to analyze and difficult to control. Reduction of the order of the model may overcome some of these difficulties, but it is quite possible that model reduction incurs a significant loss of accuracy. Therefore, the system has to be analyzed in a manner that is useful for the application purpose. Simplification of the model based on this analysis usually results in a model of lower complexity which is easier to handle, and in a corresponding simplification of synthesis procedures for control and filtering problems. Furthermore, the simplification decreases the computational effort. Every application has its own demands, and different model reduction methods have different properties.

In [1] two types of approximation methods for large-scale linear systems are discussed, namely singular-value decomposition (SVD) and Krylov methods. The Krylov methods are based on matching the moments of the impulse response of the linear system up to a certain level. This can be interpreted in terms of the series expansions of the transfer function; see, for example, [1] and the references therein. The key to the success of these methods is that they can be implemented iteratively and are able to handle much higher-order systems than the SVD methods. Nevertheless, they are not always resulting in models that are useful for control, for example, stability may not be preserved, and no *a priori* error bounds for the reduced order system can be given. Furthermore, an extension of these methods to nonlinear systems is still largely unexplored. Only recently, the first steps toward such extension is presented by [2]. The

SVD methods based on balanced realizations, on the other hand, offer a clear structure for analysis of the system based on controllability and observability properties, and model reduction by balanced truncation does preserve stability and other properties and does have an *a priori* error bound for the reduced order system. Furthermore, the extension of balancing to nonlinear systems has been studied in the past two decades as well.

Kalman's minimal realization theory (e.g., [27]) offers a clear picture of the structure of linear systems. However, the accompanying algorithms are not very satisfactory, since they are only textbook algorithms, which are numerically deficient. Moore [32] showed that there are very useful tools that may be used to cope with this problem. He used the principal component analysis which was introduced in statistics in the 1930s to analyze a linear system, and specifically to apply it to model reduction. The most important contribution of [32] is the introduction of balancing for stable minimal linear systems. The balancing method offers a tool to measure the contribution of the different state components to the past input and future output energy of the system, which are measures of controllability and observability. The algorithmic methods corresponding to the balancing theory nowadays are standard toolboxes in simulation packages like MATLAB®.

In the theory of continuous-time linear systems, the system Hankel operator plays an important role in a number of realization problems. For example, when viewed as a mapping from past inputs to future outputs, it plays a direct role in the abstract definition of *state*. It also plays a central role in minimality theory, in model reduction problems, and related to these, in linear identification methods. Specifically, the Hankel operator supplies a set of similarity invariants, the so-called Hankel singular values, which can be used to quantify the importance of each state in the corresponding input–output system. The Hankel operator can also be factored into the composition of an observability and controllability operator, from which Gramian matrices can be defined and the notion of a balanced realization follows. The Hankel singular values are most easily computed in a state-space setting using the product of the Gramian matrices, though intrinsically they depend only on the given input–output mapping. For linear systems, the Hankel operator offers an immediate relation with the frequency domain setting of balancing for linear systems, for example, [63].

Furthermore, these methods have proved to be very useful for application purposes. To mention a few older applications, we refer to [16,62]. Reference [62] successfully applies methods based on balanced realizations on the controller design of the Philips CD player. In [16], several balanced controller designs and algorithms for sensor and actuator placement based on balanced realizations are given and demonstrated for the NASA Deep Space Network Antenna.

For nonlinear systems, the first step toward extension of the linear balancing methods has been set in [45], where a balancing formalism is developed for stable nonlinear continuous-time state-space systems based on the idea that state components that correspond to low control costs and high output energy generation (in the sense of L_2 energy in a signal) are important for the description of the dynamics of the input–output behavior of the system, while state components with high control costs and low output energy generation can be left out of the description. Since then, many results on state-space balancing, modifications based on sliding time windows, and modifications based on proper orthogonal decomposition (POD), and computational issues for model reduction and related minimality considerations for nonlinear systems have appeared in the literature; for example, [18,20,28,37,38,58,59,64]. The relations of the original nonlinear balancing method of [45] with minimality are later explored in [47], and a more constructive approach that includes a strong relation with the nonlinear input–output operators, the nonlinear Hankel operator, and the Hankel norm of the system is presented in [10,12,48]. Model reduction based on these studies is recently treated in [13,14].

Here we first review the Hankel operator, balancing and balanced truncation for stable linear systems. Then unstable systems and closed-loop balancing are reviewed for linear systems. Finally, the extension of the linear theory to nonlinear systems is treated, based on balancing procedures in a neighborhood (possibly large, almost global) of an equilibrium point.

4.2 Linear Systems

In this section, we briefly review the well-known linear system definitions of the system Hankel matrix; the Hankel operator; the controllability and observability operators, Gramians and functions; and the balanced realization and the corresponding model reduction procedure.

4.2.1 The Hankel, Controllability, and Observability Operator

Consider a continuous-time, causal linear input–output system $\Sigma : u \rightarrow y$, with m -dimensional input space $u \in U$ and p -dimensional output space $y \in Y$, and with impulse response $H(t)$. Let

$$H(t) = \sum_{k=0}^{\infty} H_{k+1} \frac{t^k}{k!}, \quad t \geq 0 \quad (4.1)$$

denote its Taylor series expansion about $t = 0$, where $H_k \in \mathbb{R}^{p \times m}$ for each k . The system Hankel matrix is defined as $\hat{\mathcal{H}} = [\hat{\mathcal{H}}_{i,j}]$, where $\hat{\mathcal{H}}_{i,j} = H_{i+j-1}$ for $i, j \geq 1$. If Σ is also (bounded input bounded output) BIBO stable, then the system Hankel operator is the well-defined mapping

$$\begin{aligned} \mathcal{H} : L_2^m[0, +\infty) &\rightarrow L_2^p[0, +\infty), \\ \hat{u} &\rightarrow \hat{y}(t) = \int_0^{\infty} H(t + \tau) \hat{u}(\tau) d\tau. \end{aligned} \quad (4.2)$$

mapping the past inputs to the future outputs. If we define the *time flipping* operator as

$$\begin{aligned} \tilde{\mathcal{F}} : L_2^m[0, +\infty) &\rightarrow L_2^m(-\infty, 0] \\ \hat{u} &\rightarrow u(t) = \begin{cases} \hat{u}(-t) & t < 0 \\ 0 & t \geq 0, \end{cases} \end{aligned}$$

then clearly $\mathcal{H}(\hat{u}) = (\Sigma \circ \tilde{\mathcal{F}})(\hat{u})$; see the illustration in Figure 4.1. The lower side of the figure depicts the input–output behavior of the original operator Σ . The upper side depicts the input–output behavior of the Hankel operator of Σ , where the signal in the upper left side is the time-flipped signal of the lower left side signal. The flipping operator \mathcal{F} is defined by $\mathcal{F}(u(t)) := u(-t)$. The upper right side signal is the truncated signal (to the space $L_2[0, \infty)$) of the lower left side signal. The corresponding truncation operator is given by

$$\mathcal{T}(y(t)) := \begin{cases} 0 & (t < 0) \\ y(t) & (t \geq 0) \end{cases},$$

and $\tilde{\mathcal{F}} = \mathcal{T} \circ \mathcal{F}$. The definition of a Hankel operator implies that it describes the mapping from the input to the output generated by the state at $t = 0$. Hence, we can analyze the relationship between the state and the input–output behavior of the original operator Σ by investigating its Hankel operator.

When \mathcal{H} is known to be a compact operator, then its (Hilbert) adjoint operator, \mathcal{H}^* , is also compact, and the composition $\mathcal{H}^*\mathcal{H}$, is a self-adjoint compact operator with a well-defined spectral decomposition:

$$\mathcal{H}^*\mathcal{H} = \sum_{i=1}^{\infty} \sigma_i^2 \langle \cdot, \Psi_i \rangle_{L_2} \Psi_i, \quad \sigma_i \geq 0, \quad (4.3)$$

$$\langle \Psi_i, \Psi_j \rangle_{L_2} = \delta_{ij}, \quad \langle \Psi_i, (\mathcal{H}^*\mathcal{H})(\Psi_i) \rangle_{L_2} = \sigma_i^2, \quad (4.4)$$

where σ_i^2 is an eigenvalue of $\mathcal{H}^*\mathcal{H}$ with the corresponding eigenvector Ψ_i , ordered as $\sigma_1 \geq \dots \geq \sigma_n > \sigma_{n+1} = \sigma_{n+2} = 0$, and called the *Hankel singular values* for the input–output system Σ .

FIGURE 4.1 Hankel operator \mathcal{H} of Σ .

Let (A, B, C) be a state-space realization of Σ with dimension n , that is, consider a linear system:

$$\begin{aligned} \dot{x} &= Ax + Bu, \\ y &= Cx, \end{aligned} \tag{4.5}$$

where $u \in \mathbb{R}^m$, $x \in \mathbb{R}^n$, and $y \in \mathbb{R}^p$. We assume that Equation 4.5 is *stable and minimal*, that is, controllable and observable. Any such realization induces a factorization of the system Hankel matrix into the form $\hat{\mathcal{H}} = \hat{\mathcal{O}}\hat{\mathcal{C}}$, where $\hat{\mathcal{O}}$ and $\hat{\mathcal{C}}$ are the (extended) observability and controllability matrices. If the realization is asymptotically stable, then the Hankel operator can be written as the composition of uniquely determined observability and controllability operators; that is, $\mathcal{H} = \mathcal{O}\mathcal{C}$, where the controllability and observability operators are defined as

$$\begin{aligned} \mathcal{C} : L_2^m[0, +\infty) &\rightarrow \mathbb{R}^n : \hat{u} \rightarrow \int_0^\infty e^{At} B \hat{u}(t) dt, \\ \mathcal{O} : \mathbb{R}^n &\rightarrow L_2^p[0, +\infty) : x \rightarrow \hat{y}(t) = Ce^{At} x. \end{aligned}$$

Since \mathcal{C} and \mathcal{O} have a finite dimensional range and domain, respectively, they are compact operators; and the composition $\mathcal{O}\mathcal{C}$ is also a compact operator. From the definition of the (Hilbert) adjoint operator, it is easily shown that \mathcal{C} and \mathcal{O} have corresponding adjoints

$$\begin{aligned} \mathcal{C}^* : \mathbb{R}^n &\rightarrow L_2^m[0, +\infty) : x \rightarrow B^T e^{A^T t} x, \\ \mathcal{O}^* : L_2^p[0, +\infty) &\rightarrow \mathbb{R}^n : y \rightarrow \int_0^\infty e^{A^T t} C^T y(t) dt. \end{aligned}$$

4.2.2 Balanced State-Space Realizations

The above input–output setting can be related with the well-known Gramians that are related to the state-space realization. In order to do so, we consider the energy functions given in the following definition.

Definition 4.1:

The controllability and observability functions of a smooth state-space system are defined as

$$L_c(x_0) = \min_{\substack{u \in L_2(-\infty, 0) \\ x(-\infty)=0, x(0)=x_0}} \frac{1}{2} \int_{-\infty}^0 \|u(t)\|^2 dt \quad (4.6)$$

and

$$L_o(x_0) = \frac{1}{2} \int_0^{\infty} \|y(t)\|^2 dt, \quad x(0) = x_0, \quad u(t) \equiv 0, \quad 0 \leq t < \infty, \quad (4.7)$$

respectively.

The value of the controllability function at x_0 is the minimum amount of input energy required to reach the state x_0 from the zero state, and the value of the observability function at x_0 is the amount of output energy generated by the state x_0 . The following results are well known:

Theorem 4.1:

Consider the system (Equation 4.5). Then $L_c(x_0) = \frac{1}{2}x_0^T P^{-1}x_0$ and $L_o(x_0) = \frac{1}{2}x_0^T Qx_0$, where $P = \int_0^{\infty} e^{At} BB^T e^{A^T t} dt$ is the controllability Gramian and $Q = \int_0^{\infty} e^{A^T t} C^T C e^{At} dt$ is the observability Gramian. Furthermore, P and Q are symmetric and positive definite, and are unique solutions of the Lyapunov equations

$$AP + PA^T = -BB^T \quad (4.8)$$

and

$$A^T Q + QA = -C^T C, \quad (4.9)$$

respectively.

From the form of the Gramians in this theorem, it follows immediately that for any $x_1, x_2 \in \mathbb{R}^n$,

$$\begin{aligned} \langle x_1, CC^* x_2 \rangle &= x_1^T \int_0^{\infty} e^{At} BB^T e^{A^T t} dt x_2, \\ &= x_1^T P x_2 \end{aligned} \quad (4.10)$$

$$\begin{aligned} \langle x_1, O^* O x_2 \rangle &= x_1^T \int_0^{\infty} e^{A^T t} C^T C e^{At} dt x_2, \\ &= x_1^T Q x_2 \end{aligned} \quad (4.11)$$

and the relation with the energy functions is given as

$$L_c(x) = \frac{1}{2} x^T P^{-1} x = \frac{1}{2} \langle x, (CC^*)^{-1} x \rangle, \quad (4.12)$$

$$L_o(x) = \frac{1}{2} x^T Q x = \frac{1}{2} \langle x, (O^* O) x \rangle. \quad (4.13)$$

The following (balancing) theorem is originally due to [32].

Theorem 4.2: [32]

The eigenvalues of QP are similarity invariants, that is, they do not depend on the choice of the state-space coordinates. There exists a state-space representation where

$$\Sigma := Q = P = \begin{pmatrix} \sigma_1 & & 0 \\ & \ddots & \\ 0 & & \sigma_n \end{pmatrix}, \quad (4.14)$$

with $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n > 0$ the square roots of the eigenvalues of QP. Such representations are called balanced, and the system is in balanced form. Furthermore, the σ_i 's, $i = 1, \dots, n$, equal the Hankel singular values, that is, the singular values of the Hankel operator (Equation 4.2).

Two other representations that may be obtained from Equation 4.14 by coordinate transformations $x = \Sigma^{-\frac{1}{2}} \bar{x}$ and $x = \Sigma^{\frac{1}{2}} \tilde{x}$, respectively, follow easily from the above theorem.

Definition 4.2: [32]

A state-space representation is an input-normal/output-diagonal representation if $P = I$ and $Q = \Sigma^2$, where Σ is given by Equation 4.14. Furthermore, it is an output-normal/input-diagonal representation if $P = \Sigma^2$ and $Q = I$.

The largest Hankel singular value is equal to the Hankel norm of the system, that is,

$$\|G\|_H^2 = \max_{\substack{x \in \mathbb{R}^n \\ x \neq 0}} \frac{L_o(x)}{L_c(x)} = \max_{\substack{x \in \mathbb{R}^n \\ x \neq 0}} \frac{x^T Q x}{x^T P^{-1} x} = \max_{\substack{x \in \mathbb{R}^n \\ x \neq 0}} \frac{\bar{x}^T \Sigma^2 \bar{x}}{\bar{x}^T \bar{x}} = \sigma_1^2, \quad (4.15)$$

where $G = C(sI - A)^{-1}B$ is the transfer matrix of the system. This gives a characterization of the largest Hankel singular value. The other Hankel singular values may be characterized inductively in a similar way; we refer to [6,15].

So far, we have assumed the state-space representation to be minimal. However, if we consider non-minimal state-space realizations, that is, the system is not controllable and/or observable, then we obtain σ_i 's that are zero, corresponding to the noncontrollable or nonobservable part of the system, and thus, to the nonminimal part of the system. Related to this observation, we have that the minimal realization of a linear input-output system has a dimension n that is equal to the Hankel rank, or in other words, it equals the rank of the Hankel matrix. A well-known result related to the latter is the following theorem for example, [63].

Theorem 4.3:

If (A, B, C) is asymptotically stable, then the realization is minimal if and only if $P > 0$ and $Q > 0$.

4.2.3 Model Reduction

Once the state-space system is in balanced form, an order reduction procedure based on this form may be applied. Thus, in order to proceed, we assume that the system (Equation 4.5) is in balanced form. Then

the controllability and observability function are $\bar{L}_c(\bar{x}_0) = \frac{1}{2}\bar{x}_0^T \Sigma^{-1} \bar{x}_0$ and $\bar{L}_c(\bar{x}_0) = \frac{1}{2}\bar{x}_0^T \Sigma \bar{x}_0$, respectively. For small σ_i , the amount of control energy required to reach the state $\tilde{x} = (0, \dots, 0, x_i, 0, \dots, 0)$ is large while the output energy generated by this state \tilde{x} is small. Hence, if $\sigma_k \gg \sigma_{k+1}$, the state components x_{k+1} to x_n are far less important from this energy point of view and may be removed to reduce the number of state components of the model. We partition the system (Equation 4.5) in a corresponding way as follows:

$$A = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}, \quad B = \begin{pmatrix} B_1 \\ B_2 \end{pmatrix}, \quad C = (C_1 \quad C_2), \quad (4.16)$$

$$x^1 = (x_1, \dots, x_k)^T, \quad x^2 = (x_{k+1}, \dots, x_n)^T, \quad \Sigma = \begin{pmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{pmatrix},$$

where $\Sigma_1 = \text{diag}(\sigma_1, \dots, \sigma_k)$ and $\Sigma_2 = \text{diag}(\sigma_{k+1}, \dots, \sigma_n)$.

Theorem 4.4:

Both subsystems (A_{ii}, B_i, C_i) , $i = 1, 2$, are again in balanced form, and their controllability and observability Gramians are equal to Σ_i , $i = 1, 2$.

The following result has been proved by [43].

Theorem 4.5:

Assume that $\sigma_k > \sigma_{k+1}$. Then both subsystems (A_{ii}, B_i, C_i) , $i = 1, 2$, are asymptotically stable.

The subsystem (A_{11}, B_1, C_1) may be used as an approximation of the full order system (Equation 4.5). The optimality of this approximation in the Hankel and \mathcal{H}_∞ -norm has been studied by [17], and an upper bound for the error is given. The \mathcal{H}_∞ -norm of $G(s) = C(sI - A)^{-1}B$ is defined as

$$\|G\|_\infty = \sup_{\omega \in \mathbb{R}} \lambda_{\max}^{\frac{1}{2}}(G(-j\omega)^T G(j\omega)),$$

where $\lambda_{\max}^{\frac{1}{2}}(G(-j\omega)^T G(j\omega))$ is the square root of the maximum eigenvalue of $G(-j\omega)^T G(j\omega)$. Denote the transfer matrix of the reduced order system (A_{11}, B_1, C_1) by $\tilde{G}(s) = C_1(sI - A_{11})^{-1}B_1$. The following error bound was originally proved in [17]. A number of proofs can be found in [63].

Theorem 4.6: [17]

$$\|G - \tilde{G}\|_H \leq \|G - \tilde{G}\|_\infty \leq 2(\sigma_{k+1} + \dots + \sigma_n).$$

Hence, if we remove the state components x_{k+1}, \dots, x_n that correspond to small Hankel singular values $\sigma_{k+1}, \dots, \sigma_n$ (small compared to the rest of the singular values, that is, $\sigma_k \gg \sigma_{k+1}$), then the error is small, and the reduced order system (A_{11}, B_1, C_1) constitutes a good approximation in terms of the Hankel norm to the full order system.

The model reduction method that we gave above consists of simply truncating the model. It is also possible to reduce the model in a different way see, for example, [8,21]. Instead of setting

$x^2 = (x_{k+1}, \dots, x_n) = 0$ we approximate the system by setting $\dot{x}^2 = 0$ (thus interpreting x^2 as a very fast stable state, which may be approximated by a constant function of x^1 and u). The resulting algebraic equation can be solved for x^2 as (note that A_{22}^{-1} exists by Theorem 4.5)

$$x^2 = -A_{22}^{-1} (A_{21}x^1 + B_2u).$$

Substitution in Equation 4.5 leads to a reduced order model $(\hat{A}, \hat{B}, \hat{C})$ defined as

$$\begin{aligned}\hat{A} &:= A_{11} - A_{12}A_{22}^{-1}A_{21}, \\ \hat{B} &:= B_1 - A_{12}A_{22}^{-1}B_2, \\ \hat{C} &:= C_1 - C_2A_{22}^{-1}A_{21},\end{aligned}$$

The system $(\hat{A}, \hat{B}, \hat{C})$ also gives an approximation to the full order system (Equation 4.5). Theorems 4.4 through 4.6 also hold if we replace the system (A_{11}, B_1, C_1) by $(\hat{A}, \hat{B}, \hat{C})$.

4.2.4 Unstable Systems, Closed-Loop Balancing

4.2.4.1 Linear Quadratic Gaussian Balancing

A major drawback of the original balancing method as described in Section 4.2.2 is that it only applies to stable systems. Furthermore, the method emphasizes the (open-loop) input-output characteristics of the system, while it is *a priori* not clear if it yields good approximations in closed-loop configurations. In this section, we treat (linear quadratic Gaussian) LQG balancing for linear systems, which was introduced by [25,26] (see also [57]). In [41], this concept is further developed. LQG balancing was introduced with the aim of finding a model reduction method for a system (not necessarily stable) together with its corresponding LQG compensator. LQG balancing has been treated from another point of view in [61]. First, we give a review of the formulation of [26,41].

LQG compensation is formulated for a minimal state-space system

$$\begin{aligned}\dot{x} &= Ax + Bu + Bd, \\ y &= Cx + v,\end{aligned}\tag{4.17}$$

where $u \in \mathbb{R}^m$, $x \in \mathbb{R}^n$, $y \in \mathbb{R}^p$, and d and v are independent Gaussian white-noise processes with covariance functions $I\delta(t - \tau)$. The criterion

$$J(x_0, u(\cdot)) = E \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T [x^T(t)C^T Cx(t) + u^T(t)u(t)] dt\tag{4.18}$$

is required to be minimized. The resulting optimal compensator is given by

$$\begin{aligned}\dot{z} &= Az + Bu + SC^T(y - Cz), \\ u &= -B^T Pz.\end{aligned}\tag{4.19}$$

Here S is the stabilizing solution (i.e., $\sigma(A - SC^T C) \subset \mathbb{C}^-$) to the filter algebraic Riccati equation (FARE)

$$AS + SA^T + BB^T - SC^T CS = 0,\tag{4.20}$$

and P is the stabilizing solution (i.e., $\sigma(A - BB^T P) \subset \mathbb{C}^-$) to the control algebraic Riccati equation (CARE)

$$A^T P + PA + C^T C - PBB^T P = 0.\tag{4.21}$$

Theorem 4.7: [26,41]

The eigenvalues of PS are similarity invariants and there exists a state-space representation where

$$M := P = S = \begin{pmatrix} \mu_1 & & 0 \\ & \ddots & \\ 0 & & \mu_n \end{pmatrix}, \quad (4.22)$$

with $\mu_1 \geq \mu_2 \geq \dots \geq \mu_n > 0$. This is called an LQG balanced representation or LQG balanced form.

Jonckheere and Silverman [26] and Opdenacker and Jonckheere [41] argue that if $\mu_k \gg \mu_{k+1}$ then the state components x_1 up to x_k are more difficult both to control and to filter than x_{k+1} up to x_n and a synthesis based only on the state components x_1 up to x_k probably retains the essential properties of the system in a closed-loop configuration. Corresponding to the partitioning of the state in the first k components and the last $n - k$ components, the partitioning of the matrices is done as in (4.16), and the reduced order system is

$$\begin{aligned} \dot{x} &= A_{11}x + B_1u + B_1d, \\ y &= C_1x + v. \end{aligned} \quad (4.23)$$

Theorem 4.8: [26,41]

Assume $\mu_k > \mu_{k+1}$. Then (A_{11}, B_1, C_1) is minimal, the reduced order system (Equation 4.23) is again LQG balanced and the optimal compensator for system (Equation 4.23) is the reduced order optimal compensator of the full order system (Equation 4.17).

As explained in Section 4.2.2, the original idea of balancing stable linear systems, as introduced by [32], considers the Hankel singular values σ_i , $i = 1, \dots, n$, which are a measure for the importance of a state component in a balanced representation. This balancing technique is based on the input energy which is necessary to reach this state component and the output energy which is generated by this state component. A similar kind of reasoning, using a different pair of energy functions, may be used to achieve the similarity invariants μ_i , $i = 1, \dots, n$, as above; see [61]. To follow this reasoning, we consider the minimal system (Equation 4.17) *without noise*, that is,

$$\begin{aligned} \dot{x} &= Ax + Bu, \\ y &= Cx, \end{aligned} \quad (4.24)$$

where $u \in \mathbb{R}^m$, $x \in \mathbb{R}^n$, and $y \in \mathbb{R}^p$. We define the energy functions

$$\begin{aligned} K^-(x_0) &:= \min_{\substack{u \in L_2(-\infty, 0) \\ x(-\infty)=0, x(0)=x_0}} \frac{1}{2} \int_{-\infty}^0 (\|y(t)\|^2 + \|u(t)\|^2) dt, \\ K^+(x_0) &:= \min_{\substack{u \in L_2(0, \infty) \\ x(\infty)=0, x(0)=x_0}} \frac{1}{2} \int_0^{\infty} (\|y(t)\|^2 + \|u(t)\|^2) dt. \end{aligned}$$

$K^-(x_0)$ is called the *past energy* and $K^+(x_0)$ the *future energy* of the system in the state x_0 .

Theorem 4.9: [61]

$K^-(x_0) = \frac{1}{2}x_0^T S^{-1}x_0$ and $K^+(x_0) = \frac{1}{2}x_0^T P x_0$, where S and P are the stabilizing solutions of the FARE and the CARE, Equations 4.20 and 4.21, respectively.

For the LQG balanced representation of Theorem 4.7, the past and future energy function are $K^-(x_0) = \frac{1}{2}x_0^T M^{-1}x_0$ and $K^+(x_0) = \frac{1}{2}x_0^T M x_0$, respectively, where M is diagonal. The importance of the state $\tilde{x} = (0, \dots, 0, x_i, 0, \dots, 0)$ in terms of past and future energy may be measured by the similarity invariant μ_i . For large μ_i the influence of the state \tilde{x} on the future energy is large while the influence on the past energy is small. Hence, if $\mu_k \gg \mu_{k+1}$, the state components x_{k+1} to x_n are “not important” from this energy point of view and may be removed to reduce the number of state components of the model.

4.2.4.2 Balancing of the Normalized Coprime Representation

In [29,39], balancing of the normalized coprime representation of a linear system is treated. Balancing of the normalized coprime representation was introduced with the aim of finding a model reduction method for unstable linear systems. In [29], balancing of the normalized *right* coprime factorization is treated, while in [39], balancing of the normalized *left* coprime factorization is treated. Here we provide a brief review on this subject.

We consider the system (Equation 4.24) and its transfer function $G(s) = C(sI - A)^{-1}B$. Furthermore, we consider the stabilizing solution P to the CARE (Equation 4.21) and the stabilizing solution S to the FARE (Equation 4.20), leading to the stable matrices $\hat{A} := A - BB^T P$ and $\tilde{A} := A - SC^T C$. First we treat normalized right coprime factorizations and then normalized left coprime factorizations.

We may write any transfer matrix $G(s) = C(sI - A)^{-1}B$ as a right fraction $G(s) = N(s)D(s)^{-1}$ of stable transfer matrices $N(s)$ and $D(s)$. If we choose (e.g., [36]),

$$\begin{aligned} N(s) &:= C(sI - \hat{A})^{-1}B, \\ D(s) &:= I - B^T P(sI - \hat{A})^{-1}B, \end{aligned}$$

then the *factorization* is *right coprime*, that is, $N(s)$ and $D(s)$ have no common zeros at the same place in the closed right half plane. A state-space realization of the transfer matrix (the so-called graph operator)

$$\begin{pmatrix} N(s) \\ D(s) \end{pmatrix}$$

is

$$\begin{aligned} \dot{x} &= (A - BB^T P)x + Bw, \\ \begin{pmatrix} y \\ u \end{pmatrix} &= \begin{pmatrix} C \\ -B^T P \end{pmatrix} x + \begin{pmatrix} 0 \\ I \end{pmatrix} w, \end{aligned} \quad (4.25)$$

with w a (fictitious) input variable. Furthermore, we are able to find stable transfer matrices $U(s)$ and $V(s)$, such that the Bezout identity

$$U(s)N(s) + V(s)D(s) = I. \quad (4.26)$$

is fulfilled. Indeed, take $U(s) = B^T P(sI - \tilde{A})^{-1}SC^T$ and $V(s) = I + B^T P(sI - \tilde{A})^{-1}B$ (see, e.g., [36,60]). The fact that we are able to find a stable left inverse of the graph operator, that is, we can find the solutions $U(s)$ and $V(s)$ to the Bezout identity (Equation 4.26), is equivalent to the factorization being right coprime.

Furthermore, the graph operator is inner, that is,

$$\left\| \begin{pmatrix} N \\ D \end{pmatrix} w \right\|_2 = \|w\|_2$$

or

$$N(-s)^T N(s) + D(-s)^T D(s) = I.$$

Therefore, the factorization is called *normalized*. It is easily checked that the observability Gramian of the system (Equation 4.25) is P . Denote its controllability Gramian by R .

In a similar way, we may write the transfer matrix $G(s)$ as a left fraction $G(s) = \tilde{D}(s)^{-1} \tilde{N}(s)$ of stable transfer matrices $\tilde{D}(s)$ and $\tilde{N}(s)$. If we choose (e.g., [36])

$$\begin{aligned} \tilde{N}(s) &:= C(sI - \tilde{A})^{-1} B, \\ \tilde{D}(s) &= C(sI - \tilde{A})^{-1} S C^T - I, \end{aligned}$$

then this is a *left factorization*. Obviously, $\hat{y}(s) = G(s)\hat{u}(s)$ is equivalent with $0 = \tilde{N}(s)\hat{u}(s) - \tilde{D}(s)\hat{y}(s)$. Moreover, a state-space realization of the transfer matrix

$$\begin{pmatrix} \tilde{N}(s) & \tilde{D}(s) \end{pmatrix}$$

is

$$\begin{aligned} \dot{x} &= (A - S C^T C)x + (B \quad S C^T) \tilde{w}, \\ z &= Cx + \begin{pmatrix} 0 & -I \end{pmatrix} \tilde{w}. \end{aligned} \tag{4.27}$$

If we take

$$\tilde{w} = \begin{pmatrix} u \\ y \end{pmatrix}$$

as the input variable, then the dynamics resulting from setting $z = 0$ in Equation 4.27 is a state-space representation of $G(s)$. We are able to find stable transfer matrices such that the Bezout Identity is fulfilled, that is, there exist stable transfer matrices $\tilde{U}(s)$ and $\tilde{V}(s)$, such that

$$\tilde{N}(s)\tilde{U}(s) + \tilde{D}(s)\tilde{V}(s) = I. \tag{4.28}$$

Indeed, we may take $\tilde{U}(s) = B^T P(sI - \hat{A})^{-1} S C^T$ and $\tilde{V}(s) = I + C(sI - \hat{A})^{-1} S C^T$ (see, e.g., Vid,Ne). This proves that the factorization is *left coprime*. Furthermore $\begin{pmatrix} \tilde{N}(s) & \tilde{D}(s) \end{pmatrix}$ is co-inner, that is,

$$\tilde{N}(s)\tilde{N}(-s)^T + \tilde{D}(s)\tilde{D}(-s)^T = I,$$

which means that the factorization is *normalized*. Hence $\begin{pmatrix} \tilde{N}(s) & \tilde{D}(s) \end{pmatrix}$ represents the normalized left coprime factorization of system (Equation 4.24). The system (Equation 4.27) has as controllability Gramian the positive-definite matrix S and we denote its observability Gramian by the matrix Q . Note that the right factorization

$$\begin{pmatrix} N(s) \\ D(s) \end{pmatrix}$$

can be seen as an *image* representation of $G(s)$, while the left factorization

$$\begin{pmatrix} \tilde{N}(s) & \tilde{D}(s) \end{pmatrix}$$

can be regarded as a *kernel* representation of $G(s)$.

The following result follows rather straightforwardly.

Theorem 4.10:

The Hankel singular values of the right and left factorization (Equations 4.25 and 4.27), respectively, are the same.

Proof. It follows from the Lyapunov Equations 4.8 and 4.9 for the systems (Equations 4.25 and 4.27), that $R = (I + SP)^{-1}S$ and $Q = (I + PS)^{-1}P$. Now, it is easily obtained that PR and SQ have the same eigenvalues.

The Hankel singular values of Equation 4.25 (and, hence, of Equation 4.27) are called the *graph Hankel singular values* of the original system (Equation 4.24). These singular values have the following property:

Theorem 4.11: [29,39]

The graph Hankel singular values of system (Equation 4.24) are strictly less than one.

Denote the graph Hankel singular values by τ_i , $i = 1, \dots, n$, and assume $\tau_1 \geq \dots \geq \tau_n$. The relation between τ_i , $i = 1, \dots, n$, and the similarity invariants μ_i , $i = 1, \dots, n$, of Theorem 4.7 is given by the following theorem:

Theorem 4.12: [39,61]

$$\mu_i = \tau_i(1 - \tau_i^2)^{-\frac{1}{2}} \quad \text{for } i = 1, \dots, n.$$

This implies that the reduced model that is obtained by model reduction based on balancing the (left or right) normalized coprime factorization is the same as the reduced model that is obtained by model reduction based on LQG balancing. Consider the normalized right coprime representation (Equation 4.25) and assume that it is in balanced form with

$$\Lambda := P = R = \begin{pmatrix} \tau_1 & & 0 \\ & \ddots & \\ 0 & & \tau_n \end{pmatrix}.$$

Furthermore, assume that $\tau_k > \tau_{k+1}$ and define correspondingly $\Lambda =: \text{diag}\{\Lambda_1, \Lambda_2\}$. It follows, [29], that reducing the order of Equation 4.25 by truncating the system to the first k state components (the partitioning is done corresponding to Equation 4.16) again gives a normalized right coprime representation.

Theorem 4.13: [29]

The reduced order system of Equation 4.25 is of the form

$$\left(\left(A_{11} - B_1 B_1^T D_1 \right), B_1, \begin{pmatrix} C_1 \\ -B_1^T D_1 \end{pmatrix}, \begin{pmatrix} 0 \\ I \end{pmatrix} \right),$$

with controllability and observability Gramian Λ_1 . This system is the normalized right coprime representation of the system (A_{11}, B_1, C_1) , which is minimal.

4.2.4.3 Extensions to Other Types of Balancing

The methods described above can be put in a more general setting, and extended to the H_∞ case. H_∞ balancing for linear systems is introduced in [33–35]. For details, we refer to the latter references. In the H_∞ case, balancing is performed on Q_γ^- and Q_γ^+ , [46], which are defined as

$$Q_\gamma^-(x_0) = \min_{u \in L_2(-\infty, 0)} \frac{1}{2} \int_{-\infty}^0 (1 - \gamma^{-2}) \|y(t)\|^2 + \|u(t)\|^2 dt, \quad x(-\infty) = 0, \quad x(0) = x_0, \quad \forall \gamma$$

and

$$Q_\gamma^+(x_0) = \min_{u \in L_2(0, \infty)} \frac{1}{2} \int_0^\infty \|y(t)\|^2 + \frac{1}{1 - \gamma^{-2}} \|u(t)\|^2 dt, \quad x(\infty) = 0, \quad x(0) = x_0, \quad \text{for } \gamma > 1,$$

while if $\gamma < 1$, then

$$Q_\gamma^+(x_0) = \max_{u \in L_2(0, \infty)} \frac{1}{2} \int_0^\infty \|y(t)\|^2 + \frac{1}{1 - \gamma^{-2}} \|u(t)\|^2 dt, \quad x(\infty) = 0, \quad x(0) = x_0.$$

There is an immediate relation with the solutions to the H_∞ Filter and Control Algebraic Riccati equations, see, for example, [46].

Positive real and bounded real balancing can be done by considering dissipativity with respect to a quadratic supply rate that depends on the input and the output of the system:

$$s(u, y) = \frac{1}{2} [u^T \ y^T] J \begin{bmatrix} u \\ y \end{bmatrix}, \quad (4.29)$$

with $u \in \mathbb{R}^m$, $y \in \mathbb{R}^p$, and $J \in \mathbb{R}^{(m+p) \times (m+p)}$, such that $J = J^T$; see, for example, [23,52]. The bounded real balancing case, that is, $J = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix}$ is treated in [1,22,39,42]. The positive real balancing case,

that is balancing of strictly passive, asymptotically stable, minimal systems, that is $J = \begin{bmatrix} 0 & I \\ I & 0 \end{bmatrix}$, is treated in [1,7,19]. For all these methods it holds that truncation preserves the original balanced structure, and thus truncation based on bounded real or positive real balancing preserves bounded and positive realness, respectively. Furthermore, error bounds for model reduction based on several of the above mentioned methods are available; see, for example, [52].

Additionally, model reduction methods based on balancing methods that preserve some internal structure of the system currently receive a lot of interest due to applications that require this, such as electrical circuit simulators. For some results on Hamiltonian structure preservation, and second-order system structure preservation; see, for example, [30,54,55].

4.3 Balancing for Nonlinear Systems

Balanced realizations and the related model order reduction technique rely on singular-value analysis. The analysis is important since it extracts the gain structure of the operator, that is, it characterizes the largest input–output ratio and the corresponding input [51]. Since linear singular values are defined as eigenvalues of the composition of the given operator and its adjoint, it is natural to introduce a nonlinear version of adjoint operators to obtain a nonlinear counterpart of a singular value. There has been done quite some research on the nonlinear extension of adjoint operators, for example, [3,10,48], and the references therein. Here we do not explicitly use these definitions of nonlinear adjoint operators. We rely on a characterization of singular values for nonlinear operators based on the gain structure as studied in [9]. The balanced realization based on this analysis yields a realization that is based on the singular

values of the corresponding Hankel operator, and results in a method which can be viewed as a complete extension of the linear methods, both from an input–output and a state-space point of view [12].

The related model order reduction technique, nonlinear balanced truncation, preserves several important properties of the original system and the corresponding input–output operator, such as stability, controllability, observability, and the gain structure [11,14].

This section gives a very brief overview of the series of research on balanced realization and the related model order reduction method based on nonlinear singular-value analysis. We refer to [13] for more details.

4.3.1 Basics of Nonlinear Balanced Realizations

This section gives a nonlinear extension of balanced realization introduced in the Section 4.2. Let us consider the following asymptotically stable input-affine nonlinear system

$$\Sigma : \begin{cases} \dot{x} = f(x) + g(x)u & x(0) = x^0, \\ y = h(x), \end{cases} \quad (4.30)$$

where $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, and $y(t) \in \mathbb{R}^p$. The controllability operator $\mathcal{C} : U \rightarrow X$ with $X = \mathbb{R}^n$ and $U = L_2^m[0, \infty)$, and the observability operator $\mathcal{O} : X \rightarrow Y$ with $Y = L_2^p[0, \infty)$ for this system are defined by

$$\begin{aligned} \mathcal{C} : u \mapsto x^0 : & \begin{cases} \dot{x} = -f(x) - g(x)u & x(\infty) = 0 \\ x^0 = x(0) \end{cases} \\ \mathcal{O} : x^0 \mapsto y : & \begin{cases} \dot{x} = f(x) & x(0) = x^0 \\ y = h(x) \end{cases} \end{aligned}$$

This definition implies that the observability operator \mathcal{O} is a map from the initial condition $x(0) = x^0$ to the output L_2 signal when no input is applied. To interpret the meaning of \mathcal{C} , let us consider a time-reversal behavior of the \mathcal{C} operator as

$$\mathcal{C} : u \mapsto x^0 : \begin{cases} \dot{x} = f(x) + g(x)u(-t) & x(-\infty) = 0 \\ x^0 = x(0) \end{cases}$$

Then the controllability operator \mathcal{C} can be regarded as a mapping from the input L_2 signal to the terminal state $x(0) = x^0$ when the initial state is $x(-\infty) = 0$. Therefore, as in the linear case, \mathcal{C} and \mathcal{O} represent the input-to-state behavior and the state-to-output behavior, respectively, and the Hankel operator for the nonlinear system Σ in Equation 4.30 is given by the composition of \mathcal{C} and \mathcal{O}

$$\mathcal{H} := \mathcal{O} \circ \mathcal{C}. \quad (4.31)$$

To relate the Hankel, controllability and observability operator with the observability and controllability functions defined in Equations 4.6 and 4.7, we first introduce a norm-minimizing inverse $\mathcal{C}^\dagger : X \rightarrow U$ of \mathcal{C} .

$$\mathcal{C}^\dagger : x^0 \mapsto u := \arg \min_{\mathcal{C}(u)=x^0} \|u\|$$

The operators \mathcal{C}^\dagger and \mathcal{O} yield the definitions of the controllability function $L_c(x)$ and the observability function $L_o(x)$ that are generalizations of the controllability and observability Gramians, respectively

that is,

$$L_c(x^0) := \frac{1}{2} \| C^\dagger(x^0) \|^2 = \min_{\substack{u \in L_2(-\infty, 0] \\ x(-\infty) = 0, x(0) = x^0}} \frac{1}{2} \int_{-\infty}^0 \| u(t) \|^2 dt, \quad (4.32)$$

$$L_o(x^0) := \frac{1}{2} \| \mathcal{O}(x^0) \|^2 = \frac{1}{2} \int_0^\infty \| y(t) \|^2 dt, \quad x(0) = x^0, \quad u(t) \equiv 0, \quad 0 \leq t < \infty. \quad (4.33)$$

For linear systems, the relation with the Gramians is given in Theorem 4.1. Here the inverse of P appears in the equation for L_c because C^\dagger appears in the definition (Equation 4.32), whereas C can be used in the linear case. In order to obtain functions $L_c(x)$ and $L_o(x)$, we need to solve a Hamilton–Jacobi equation and a Lyapunov equation.

Theorem 4.14: [45]

Consider the system of Equation 4.30. Suppose that 0 is an asymptotically stable equilibrium point and that a smooth observability function $L_o(x)$ exists. Then $L_o(x)$ is the unique smooth solution of

$$\frac{\partial L_o(x)}{\partial x} f(x) + \frac{1}{2} h(x)^T h(x) = 0,$$

with $L_o(0) = 0$. Furthermore, assume that a smooth controllability function $L_c(x)$ exists. Then $L_c(x)$ is the unique smooth solution of

$$\frac{\partial L_c(x)}{\partial x} f(x) + \frac{1}{2} \frac{\partial L_c(x)}{\partial x} g(x) g(x)^T \frac{\partial L_c(x)}{\partial x} = 0,$$

with $L_c(0) = 0$ such that 0 is an asymptotically stable equilibrium point of $\dot{x} = -f(x) - g(x)g(x)^T (\partial L_c(x)/\partial x)^T$.

Similar to the linear case, the positive definiteness of the controllability and observability functions implies strong reachability and zero-state observability of the system Σ in Equation 4.30, respectively. Combining these two properties, we can obtain the following result on the minimality of the system.

Theorem 4.15: [47]

Consider the system of Equation 4.30, and assume it is analytic. Suppose that

$$0 < L_c(x) < \infty,$$

$$0 < L_o(x) < \infty,$$

hold for all $x \neq 0$. Then the system is a minimal realization as defined in and under the conditions from, [24].

$L_c(x)$ and $L_o(x)$ can be used to “measure the minimality” of a nonlinear dynamical system. Furthermore, a basis for nonlinear balanced realizations is obtained as a nonlinear generalization of Definition 4.2 in the linear case. For that, a factorization of $L_o(x)$ into a semiquadratic form needs to be done, that is, in a convex neighborhood of the equilibrium point 0, we can write

$$L_o(x) = \frac{1}{2} x^T M(x) x, \quad \text{with } M(0) = \frac{\partial^2 L_o}{\partial x^2}(0).$$

Now, an input-normal/output-diagonal form can be obtained.

Theorem 4.16: [45]

Consider the system of Equation 4.30 on a neighborhood W of 0. Suppose that 0 is an asymptotically stable equilibrium point, that it is zero-state observable, that smooth controllability and observability functions $L_c(x)$ and $L_o(x)$ exist on W , and that $(\partial^2 L_c / \partial x^2)(0) > 0$ and $(\partial^2 L_o / \partial x^2)(0) > 0$ hold. Furthermore, assume that the number of distinct eigenvalues of $M(x)$ is constant on W . Then there exists coordinates such that the controllability and observability functions $L_c(x)$ and $L_o(x)$ satisfy

$$L_c(x) = \frac{1}{2} \sum_{i=1}^n x_i^2, \quad (4.34)$$

$$L_o(x) = \frac{1}{2} \sum_{i=1}^n x_i^2 \tau_i(x), \quad (4.35)$$

where $\tau_1(x) \geq \tau_2(x) \geq \dots \geq \tau_n(x)$.

A state-space realization satisfying the conditions (Equations 4.34 and 4.35) is called an *input-normal form*, and the functions $\tau_i(x)$, $i = 1, 2, \dots, n$ are called singular-value functions. We refer to [45] for the construction of the coordinate transformation that brings the system in the form of Theorem 4.16. If a singular value function $\tau_i(x)$ is larger than $\tau_j(x)$, then the coordinate axis x_i plays a more important role than the coordinate axis x_j does. Thus this realization is similar to the linear input-normal/output-diagonal realization of Definition 4.2, and it directly yields a tool for model order reduction of a nonlinear systems. However, a drawback of the above realization is that the the singular-value functions $\tau_i(x)$'s and consequently, the corresponding realization are not unique, for example, [18]. For example, if the observability function is given by

$$L_o(x) = \frac{1}{2}(x_1^2 \tau_1(x) + x_2^2 \tau_2(x)) = \frac{1}{2}(2x_1^2 + x_2^2 + x_1^2 x_2^2),$$

with the state-space $x = (x_1, x_2)$, then the corresponding singular-value functions are

$$\begin{aligned} \tau_1(x) &= 2 + kx_2^2, \\ \tau_2(x) &= 1 + (1 - k)x_1^2, \end{aligned}$$

with an arbitrary scalar constant k . This example reveals that the singular value function are not uniquely determined by this characterization. To overcome these problems, balanced realizations based on non-linear singular value analysis is presented in the following section.

4.3.2 Balanced Realizations Based on Singular-Value Analysis of Hankel Operators

In this section, application of singular-value analysis to nonlinear Hankel operators determines a balanced realization with a direct input–output interpretation, whereas the balanced realization of Theorem 4.16 is completely determined based on state-space considerations only. To this end, we consider the Hankel operator $\mathcal{H} : U \rightarrow Y$ as defined in Equation 4.31 with $U = L_2^m[0, \infty)$ and $Y = L_2^p[0, \infty)$. Then a singular-value analysis based on the differential form, [12], is given by

$$(d\mathcal{H}(v))^* \mathcal{H}(v) = \lambda v, \quad \lambda \in \mathbb{R}, \quad v \in U, \quad (4.36)$$

with λ and v the eigenvalues and corresponding eigenvectors, respectively. Since we consider a singular-value analysis problem on L_2 spaces, we need to find state trajectories of certain Hamiltonian dynamics;

see, for example, [12]. In the linear case, we only need to solve an eigenvalue problem on a finite dimensional space $X = \mathbb{R}^n$ to obtain the singular values and singular vectors of the Hankel operator \mathcal{H} . Here we provide the nonlinear counterpart as follows.

Theorem 4.17: [12]

Consider the Hankel operator defined by Equation 4.31. Suppose that the operators C^\dagger and \mathcal{O} exist and are smooth. Moreover, suppose that $\lambda \in \mathbb{R}$ and $\xi \in X$ satisfy the following equation:

$$\frac{\partial L_o(\xi)}{\partial \xi} = \lambda \frac{\partial L_c(\xi)}{\partial \xi}, \quad \lambda \in \mathbb{R}, \quad \xi \in X. \quad (4.37)$$

Then λ is an eigenvalue of $(d\mathcal{H}(u))^* \mathcal{H}(u)$, and

$$v := C^\dagger(\xi). \quad (4.38)$$

That is, v defined above is a singular vector of \mathcal{H} .

Although the singular-value analysis problem, [13], is a nonlinear problem on an infinite dimensional signal space $U = L_2^m[0, \infty)$, the problem to be solved in the above theorem is a nonlinear algebraic equation on a finite dimensional space $X = \mathbb{R}^n$ which is also related to a nonlinear eigenvalue problem on X ; see [9].

In the linear case, Equation 4.37 reduces to

$$\xi^T Q = \lambda \xi^T P^{-1}$$

where P and Q are the controllability and observability Gramians, and λ and ξ are an eigenvalue and an eigenvector of PQ . Furthermore, Equation 4.38 characterizes the relationship between a singular vector v of \mathcal{H} and an eigenvector ξ of PQ . Also, in the linear case, there always exist n independent pairs of eigenvalues and eigenvectors of PQ . What happens in the nonlinear case? The answer is provided in the following theorem.

Theorem 4.18: [12]

Consider the system Σ in Equation 4.30 and the Hankel operator \mathcal{H} in Equation 4.31 with $X = \mathbb{R}^n$. Suppose that the Jacobian linearization of the system has n distinct Hankel singular values. Then Equation 4.37 has n independent solution curves $\xi = \xi_i(s)$, $s \in \mathbb{R}$, $i = 1, 2, \dots, n$ intersecting to each other at the origin and satisfying the condition

$$\|\xi_i(s)\| = |s|.$$

For linear systems, the solutions of Equation 4.37 are lines (orthogonally) intersecting at the origin. The above theorem shows that instead of these lines, in the nonlinear case n independent curves $x = \xi_i(s)$, $i = 1, 2, \dots, n$ exist. For instance, if the dimension of the state is $n = 2$, the solution of Equation 4.37 is illustrated in Figure 4.2.

We can relate the solutions $\xi_i(s)$ to the singular values of the Hankel operator \mathcal{H} . Let $v_i(s)$ and $\sigma_i(s)$ denote the singular vector and the singular-value parameterized by s corresponding to $\xi_i(s)$. Then we have

$$v_i(s) := C^\dagger(\xi_i(s)),$$

FIGURE 4.2 Configuration of $\xi_1(s)$ and $\xi_2(s)$ in the case $n = 2$.

$$\sigma_i(s) := \frac{\|\mathcal{H}(v_i(s))\|_{L_2}}{\|v_i(s)\|_{L_2}} = \frac{\|\mathcal{O}(\xi_i(s))\|_{L_2}}{\|C^\dagger(\xi_i(s))\|_{L_2}} = \sqrt{\frac{L_o(\xi_i(s))}{L_c(\xi_i(s))}}.$$

This expression yields an explicit expression of the singular values $\sigma_i(s)$'s of the Hankel operator \mathcal{H} . These functions $\sigma_i(s)$'s are called *Hankel singular values*. Without loss of generality we assume that the following equation holds for $i = 1, 2, \dots, n$ in a neighborhood of the origin

$$\min\{\sigma_i(s), \sigma_i(-s)\} > \max\{\sigma_{i+1}(s), \sigma_{i+1}(-s)\}. \tag{4.39}$$

As in the linear case, the solution curves $\xi_i(s)$ play the role of the coordinate axes of a balanced realization. By applying an isometric coordinate transformation which maps the solution curves $\xi_i(s)$'s into the coordinate axes, we obtain a realization whose (new) coordinate axes x_i are the solution of Equation 4.37, that is,

$$\left. \frac{\partial L_o(x)}{\partial x} \right|_{x=(0, \dots, 0, x_i, 0, \dots, 0)} = \lambda \left. \frac{\partial L_c(x)}{\partial x} \right|_{x=(0, \dots, 0, x_i, 0, \dots, 0)}, \tag{4.40}$$

$$\sigma_i(x_i) = \sqrt{\frac{L_o(0, \dots, 0, x_i, 0, \dots, 0)}{L_c(0, \dots, 0, x_i, 0, \dots, 0)}}. \tag{4.41}$$

Equation 4.41 implies that the new coordinate axes $x_i, i = 1, \dots, n$ are the solutions of Equation 4.37 for Hankel singular-value analysis. Therefore, the Hankel norm can be obtained by

$$\begin{aligned} \|\Sigma\|_H &= \sup_{u \neq 0} \frac{\|\mathcal{H}(u)\|_{L_2}}{\|u\|_{L_2}} = \sup_{s \in \mathbb{R}} \max_i \sigma_i(s) \\ &= \sup_{x_1 \in \mathbb{R}} \sqrt{\frac{L_o(x_1, 0, \dots, 0)}{L_c(x_1, 0, \dots, 0)}}, \end{aligned}$$

provided the ordering condition (Equation 4.39) holds for all $s \in \mathbb{R}$. Furthermore, apply this coordinate transformation recursively to all lower dimensional subspaces such as $(x_1, x_2, \dots, x_k, 0, \dots, 0)$, then we

obtain a state-space realization satisfying Equation 4.41 and

$$x_i = 0 \iff \frac{\partial L_o(x)}{\partial x_i} = 0 \iff \frac{\partial L_c(x)}{\partial x_i} = 0. \quad (4.42)$$

This property is crucial for balanced realization and model order reduction. Using tools from differential topology, for example, [31], we can prove that the obtained realization is diffeomorphic to the following *precise* input-normal/output-diagonal realization.

Theorem 4.19: [11,14]

Consider the system Σ in Equation 4.30. Suppose that the assumptions in Theorem 4.18 hold. Then there exists coordinates in a neighborhood of the origin such that the system is in input-normal/output-diagonal form satisfying

$$L_c(x) = \frac{1}{2} \sum_{i=1}^n x_i^2,$$

$$L_o(x) = \frac{1}{2} \sum_{i=1}^n x_i^2 \sigma_i(x_i)^2.$$

This realization is more precise than the realization in Theorem 4.16 in the following sense: (a) The solutions of Equation 4.37 coincide with the coordinate axes, that is, Equation 4.40 holds. (b) The ratio of the observability function L_o to the controllability function L_c equals the singular values $\sigma_i(x_i)$'s on the coordinate axes, that is, Equation 4.41 holds. (c) An exact balanced realization can be obtained by a coordinate transformation

$$z_i = \phi_i(x_i) := x_i \sqrt{\sigma_i(x_i)}, \quad (4.43)$$

which is well-defined in a neighborhood of the origin.

Corollary 4.1: [11,14]

The coordinate change (Equation 4.43) transforms the input-normal realization in Theorem 4.19 into the following balanced form:

$$L_c(z) = \frac{1}{2} \sum_{i=1}^n \frac{z_i^2}{\sigma_i(z_i)},$$

$$L_o(z) = \frac{1}{2} \sum_{i=1}^n z_i^2 \sigma_i(z_i).$$

Since we only use the coordinate transformation (Equation 4.43) preserving the coordinate axes, the realization obtained here also satisfies the properties (a) and (b) explained above. The controllability and observability functions can be written as

$$L_c(z) = \frac{1}{2} z^T \underbrace{\text{diag}(\sigma_1(z_1), \dots, \sigma_n(z_n))^{-1}}_{P(z)} z,$$

$$L_o(z) = \frac{1}{2} z^T \underbrace{\text{diag}(\sigma_1(z_1), \dots, \sigma_n(z_n))}_{Q(z)} z.$$

Here $P(z)$ and $Q(z)$ can be regarded as nonlinear counterparts of the balanced controllability and observability Gramians, since

$$P(z) = Q(z) = \text{diag}(\sigma_1(z_1), \sigma_2(z_2), \dots, \sigma_n(z_n)).$$

The axes of this realization are uniquely determined. We call this state-space realization a *balanced realization* of the nonlinear system Σ in Equation 4.30. As in the linear case, both the relationship between the input-to-state and state-to-output behavior and that among the coordinate axes are balanced.

4.3.3 Model Order Reduction

An important application of balanced realizations is that it is a tool for model order reduction called *balanced truncation*. Here, a model order reduction method preserving the Hankel norm of the original system is proposed. Suppose that the system of Equation 4.30 is balanced in the sense that it satisfies Equations 4.41 and 4.42. Note that the realizations in Theorem 4.19 and Corollary 4.1 satisfy these conditions. Suppose, that

$$\min\{\sigma_k(s), \sigma_k(-s)\} \gg \max\{\sigma_{k+1}(s), \sigma_{k+1}(-s)\}$$

holds with a certain k ($1 \leq k < n$). Divide the state into two vectors $x = (x^a, x^b)$

$$\begin{aligned} x^a &:= (x_1, \dots, x_k) \in \mathbb{R}^k, \\ x^b &:= (x_{k+1}, \dots, x_n) \in \mathbb{R}^{n-k}, \end{aligned}$$

and the vector field into two vector fields accordingly

$$\begin{aligned} f(x) &= \begin{pmatrix} f^a(x) \\ f^b(x) \end{pmatrix}, \\ g(x) &= \begin{pmatrix} g^a(x) \\ g^b(x) \end{pmatrix}, \end{aligned}$$

and truncate the state by substituting $x^b = 0$. Then we obtain a k -dimensional state-space model Σ^a with the state x^a (with a $(n - k)$ -dimensional residual model Σ^b with the state x^b).

$$\Sigma^a : \begin{cases} \dot{x}^a = f^a(x^a, 0) + g^a(x^a, 0)u^a \\ y^a = h(x^a, 0) \end{cases} \quad (4.44)$$

$$\Sigma^b : \begin{cases} \dot{x}^b = f^b(0, x^b) + g^b(0, x^b)u^b \\ y^b = h(0, x^b) \end{cases} \quad (4.45)$$

This procedure is called *balanced truncation*. The obtained reduced order models have preserved the following properties.

Theorem 4.20: [13,14]

Suppose that the system Σ satisfies Equations 4.41 and 4.42 and apply the balanced truncation procedure explained above. Then the controllability and observability functions of the reduced order models Σ^a and

Σ^b denoted by L_c^a , L_c^b , L_o^a , and L_o^b , respectively, satisfy the following equations:

$$\begin{aligned} L_c^a(x^a) &= L_c(x^a, 0), & L_o^a(x^a) &= L_o(x^a, 0), \\ L_c^b(x^b) &= L_c(0, x^b), & L_o^b(x^b) &= L_o(0, x^b), \end{aligned}$$

which implies

$$\begin{aligned} \sigma_i^a(x_i^a) &= \sigma_i(x_i^a), & i &= 1, 2, \dots, k, \\ \sigma_i^b(x_i^b) &= \sigma_{i+k}(x_i^b), & i &= 1, 2, \dots, n-k, \end{aligned}$$

with the singular values σ^a 's of the system Σ^a and the singular values σ^b of the system Σ^b . In particular, if σ_1 is defined globally, then

$$\|\Sigma^a\|_H = \|\Sigma\|_H.$$

Theorem 4.20 states that the important characteristics of the original system such as represented by the controllability and observability functions and Hankel singular values are preserved. Moreover, by Theorem 4.15, this implies that the controllability, observability, minimality, and the gain property is preserved under the model reduction. These preservation properties hold for truncation of any realization satisfying the conditions (Equations 4.41 and 4.42), such as the realizations in Theorem 4.19 and Corollary 4.1 [13,14]. Furthermore, concerning the stability, (global) Lyapunov stability and local asymptotic stability are preserved with this procedure as well. Note that this theorem is a natural nonlinear counterpart of the linear theory. However, a nonlinear counterpart of the error bound of the reduced order model has not been found yet.

4.3.4 Other Types of Balancing for Nonlinear Systems

As for linear systems, there exist extensions of LQG, and coprime balancing [49], H_∞ or L_2 -gain balancing [46], and positive/bounded real and dissipativity-based balancing [23]. In fact, in [23] a direct relation is obtained with Hankel operator analysis for augmented systems.

The presented work treats balanced realizations for nonlinear systems based on balancing in a (possibly large) region around an equilibrium point, where a relation with the Hankel operator, observability and controllability operators and functions, and minimality of the nonlinear system is obtained. A drawback of these methods is the computational effort that is needed to compute the balanced realization. As mentioned in the introduction, other extensions of the linear notion of balancing can be found in for example, [20,28,58,59].

4.4 Concluding Remarks

In this Chapter, balanced realizations for linear and nonlinear systems and model reduction based on these realizations are treated. There exists a vast amount of literature on this topic, and the reference list in this paper is certainly not complete. For example, some of the basics for linear balanced realizations can be found in [40], and we did not pay any attention to the balancing methods treating uncertain, and time- and parameter-varying linear systems; for example, [4,44], behavioral balancing, for example, [53], or the numerical side of balancing, for example, [5].

Recently, a lot of interest is taken in structure preserving order techniques for both linear and nonlinear systems, where the additional structure to be preserved is a physical structure, such as port-Hamiltonian structure, [56], and other physical structures, as mentioned in our linear systems section. For example, for circuit simulators with continuously growing orders of the models, a need for interpreting a reduced order model as a circuit is important, such as, [50]. Due to the explicit interconnection (input/output

like) structure of the circuits, order reduction methods based on balancing are attractive to apply to these circuits. However, structure preservation and circuit interpretation of the corresponding reduced order models is not possible yet, and is one of the motivators for further research to both linear and nonlinear structure preserving order reduction methods.

5.1 Introduction

In the late 1960s, Basile and Marro (1969) (and later Wonham and Morse, 1970) discovered that the behavior of time-invariant linear control systems can be seen as a manifestation of the subspaces similar to the invariant subspaces characterized by the system matrices. As a result, the system behavior can be predicted and the solvability of many control problems can be tested by examining the properties of such subspaces. In many instances, one can understand essential issues intuitively in geometric terms. Moreover, thanks to good algorithms and software available in the literature (see Basile and Marro, 1992), the above subspaces can be generated and the properties can be readily examined by using personal computers. Thus, a large class of problems involving feedback control laws and observability of linear systems can be solved effectively by this geometric method, for example, problems of disturbance localization, decoupling, unknown input observability and system inversion, observer design, regulation

* This chapter is dedicated to Professors G. Basile and G. Marro for their pioneering contributions in the development of geometric methods for linear systems.

and tracking, model following, robust control, and so on. Comprehensive treatments of the basic theory and many applications, including the ones mentioned above, can be found in the excellent books by Wonham (1985), Basile and Marro (1992), and Trentelman et al. (2002), with additional later results found in the newer books, for example, controlled and conditioned invariant subspaces and duality are treated in an organized fashion in the 2nd book and, in addition to the duality, an extension of the theory to include distributions as inputs and the relation between disturbance localization and H_2 optimal control problem are also given in the 3rd book. The method is also useful in the analysis and design of decentralized control systems (Hamano and Furuta, 1975), perfect and near-perfect signal decoupling (and its applications to other control problems) for nonminimum-phase systems (Marro and Zattoni, 2006), and failure/fault detection (Massoumnia et al., 1989). This chapter serves as an introduction to the subject. Regrettably, citations in this chapter are rather limited due to editorial restrictions. Extensive references can be found in the above-mentioned books as well as in the chapter by Marro (2008). To prepare the present chapter, the book by Basile and Marro (1992) has been used as the primary reference, and the majority of the proofs omitted in this chapter can be found in this reference.

Section 5.2 gives a review of elementary notions including invariant subspaces, reachability, controllability, observability, and detectability. It also provides convenient formulae for subspace calculations. Sections 5.3 through 5.7 describe the basic ingredients of the geometric theory (or approach). More specifically, Section 5.3 introduces the fundamental notions of $(A, \text{im } B)$ -controlled and $(A, \ker C)$ -conditioned invariants (which are subspaces of the state space), and Section 5.4 provides some algebraic properties of these invariants. In Section 5.5, “largest” controlled and “smallest” conditioned invariants are presented with respect to certain subspaces and Section 5.6 discusses well-structured special classes of controlled and conditioned invariants. Section 5.7 analyzes the above invariants in relation to stabilization. Sections 5.8 through 5.10 describe applications to demonstrate the use of the basic tools developed in the previous sections. For this goal, the disturbance localization problem is chosen and it is discussed in three different situations with varying degrees of sophistication. The disturbance localization problems are chosen since the methods used to solve the problems can be used or extended to solve other more involved problems. It also has historical significance as one of the first problems for which the geometric method was used. Section 5.11 provides the conclusion and brief statements about practical applications and about extensions of geometric notions and approach to more general or different systems.

Notation: Capital letters A, B , and so on denote the matrices (or linear maps) with I and I_n reserved, respectively, for an identity matrix (of appropriate dimension) and an $n \times n$ identity matrix. The transpose of a matrix A is denoted by A' . Capital script letters such as \mathcal{V}, \mathcal{W} represent vector spaces or subspaces. Small letters x, y , and so on are column vectors. Scalars are also denoted by small letters. The letter 0 is used for a zero matrix, vector, or scalar depending on the context. Notation “ $:=$ ” means “(the left-hand side, i.e., ‘:’ side) is defined by (the right-hand side, i.e., ‘=’ side).” Similarly for “ $=:$ ” where the roles of the left- and right-hand sides are reversed. The image (or range) and the kernel (or null space) of M are denoted by $\text{im } M$ and $\ker M$, respectively. The expression $\mathcal{V} + \mathcal{W}$ represents the sum of two subspaces \mathcal{V} and \mathcal{W} , that is, $\mathcal{V} + \mathcal{W} := \{v + w : v \in \mathcal{V} \text{ and } w \in \mathcal{W}\}$. If \mathcal{V} is a subspace of \mathcal{W} , we write $\mathcal{V} \subset \mathcal{W}$. If $\mathcal{V} \subset \mathcal{X}$, we use $A^{-1}\mathcal{V} := \{x \in \mathcal{X} : Ax \in \mathcal{V}\}$, that is, the set of all $x \in \mathcal{X}$ satisfying $Ax \in \mathcal{V}$. Similarly, $A^{-k}\mathcal{V} := \{x \in \mathcal{X} : A^k x \in \mathcal{V}\}, k = 1, 2, \dots$

5.2 Review of Elementary Notions

In this section we will review invariant subspaces and some of their basic roles in the context of the linear systems.

Definition 5.1:

A subspace \mathcal{V} of $\mathcal{X} := \mathbb{R}^n$ is said to be A -invariant if

$$A\mathcal{V} \subset \mathcal{V}, \quad (5.1)$$

that is, $x \in \mathcal{V} \Rightarrow Ax \in \mathcal{V}$.

An A -invariant subspace plays the following obvious but important role for an autonomous linear system. Consider the autonomous linear system described by

$$\dot{x}(t) = Ax(t), \quad x(0) = x_0, \quad (5.2)$$

where the column vectors $x(t) \in \mathcal{X} := \mathbb{R}^n$ and $x_0 \in \mathcal{X}$ are, respectively, the state of the system at time $t \geq 0$ and the initial state, and A is an $n \times n$ real matrix. Now, suppose a subspace \mathcal{V} is A -invariant. Clearly, if $x(t) \in \mathcal{V}$, then the rate of change $\dot{x}(t) \in \mathcal{V}$, which implies that the state remains in \mathcal{V} . More strongly, we have

Lemma 5.1:

Let $\mathcal{V} \subset \mathcal{X}$. For the autonomous linear system described by Equation 5.2, $x_0 \in \mathcal{V}$ implies $x(t) \in \mathcal{V}$ for all $t \geq 0$ if and only if \mathcal{V} is A -invariant.

Let \mathcal{V} be A -invariant, and introduce a new basis $\{e_1, \dots, e_n\}$, such that

$$\text{span}\{e_1, \dots, e_\nu\} = \mathcal{V}, \quad \nu \leq n. \quad (5.3)$$

Define a coordinate transformation by

$$x = [e_1 \dots e_n] \begin{bmatrix} \tilde{x}_1 \\ \tilde{x}_2 \end{bmatrix}, \quad x \in \mathbb{R}^n, \quad \tilde{x}_1 \in \mathbb{R}^\nu, \quad \tilde{x}_2 \in \mathbb{R}^{n-\nu}. \quad (5.4)$$

Then, it is easy to see that, with respect to the new basis, the state Equation 5.2 can be rewritten as

$$\begin{bmatrix} \dot{\tilde{x}}_1(t) \\ \dot{\tilde{x}}_2(t) \end{bmatrix} = \begin{bmatrix} \tilde{A}_{11} & \tilde{A}_{12} \\ 0 & \tilde{A}_{22} \end{bmatrix} \begin{bmatrix} \tilde{x}_1(t) \\ \tilde{x}_2(t) \end{bmatrix}, \quad (5.5)$$

$$\tilde{x}_1(0) = \tilde{x}_{10}, \quad \tilde{x}_2(0) = \tilde{x}_{20}. \quad (5.6)$$

Clearly, if $\tilde{x}_{20} = 0$, then $\tilde{x}_2(t) = 0$ for all $t \geq 0$, that is, $x_0 \in \mathcal{V}$ implies $x(t) \in \mathcal{V}$ for all $t \geq 0$ (which has been stated in Lemma 5.1).

Let \mathcal{V} be an A -invariant subspace in \mathcal{X} . The *restriction* $A|_{\mathcal{V}}$ of a linear map $A : \mathcal{X} \rightarrow \mathcal{X}$ (or an $n \times n$ real matrix A) to a subspace \mathcal{V} is a linear map from \mathcal{V} to \mathcal{V} , mapping $v \mapsto Av$ for all $v \in \mathcal{V}$. For $x \in \mathcal{X}$, we write $x + \mathcal{V} := \{x + v : v \in \mathcal{V}\}$ called the *coset* of x modulo \mathcal{V} , which represents a hyperplane passing through a point x . The set of cosets modulo \mathcal{V} is a vector space called the *factor space* (or *quotient space*) and it is denoted by \mathcal{X}/\mathcal{V} . An *induced map* $A|\mathcal{X}/\mathcal{V}$ is a linear map defined by $x + \mathcal{V} \mapsto Ax + \mathcal{V}$, $x \in \mathcal{X}$.

An A -invariant subspace \mathcal{V} is said to be *internally stable* if \tilde{A}_{11} in Equation 5.5 is stable, that is, all the eigenvalues have negative real parts, or equivalently, if $A|_{\mathcal{V}}$ is stable. Therefore, $x(t)$ converges to the zero state as $t \rightarrow \infty$ whenever $x_0 \in \mathcal{V}$ if and only if \mathcal{V} is internally stable. Also, an A -invariant subspace \mathcal{V} is said to be *externally stable* if \tilde{A}_{22} is stable, that is, if $A|\mathcal{X}/\mathcal{V}$ is stable. Clearly, $\tilde{x}_2(t)$ converges to zero as

$t \rightarrow \infty$, that is, $x(t)$ converges to \mathcal{V} as $t \rightarrow \infty$ if and only if \mathcal{V} is externally stable. Note that the eigenvalues of \tilde{A}_{11} and \tilde{A}_{22} do not depend on a particular choice of coordinates (as long as Equation 5.3 is satisfied).

Let us now consider a continuous time, time-invariant linear control system $\Sigma := [A, B, C]$ described by

$$\dot{x}(t) = Ax(t) + Bu(t), \quad x(0) = x_o, \quad (5.7)$$

$$y(t) = Cx(t), \quad (5.8)$$

where the column vectors $x(t) \in \mathcal{X} := \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, and $t(t) \in \mathbb{R}^p$ are, respectively, the state, input, and output of the system at time $t \geq 0$, $x_o \in \mathbb{R}^n$ is the initial state, and A, B , and C are real matrices with consistent dimensions. We assume that $u(t)$ is piecewise continuous. We are also interested in the closed-loop system, namely, we apply a linear state-feedback law of the form

$$u(t) = Fx(t), \quad (5.9)$$

then Equation 5.7 becomes

$$\dot{x}(t) = (A + BF)x(t), \quad x(0) = x_o, \quad (5.10)$$

where F is an $m \times n$ real matrix.

Some invariant subspaces are associated with reachability (controllability) and observability. A state \tilde{x} is said to be *reachable* (or *controllable*) if there is a control which drives the zero state to \tilde{x} (or, respectively, \tilde{x} to the zero state) in finite time, that is, if there is $u(t)$, $0 \leq t \leq t_f$ such that $x(0) = 0$ (or, respectively, \tilde{x}) and $x(t_f) = \tilde{x}$ (or, respectively 0) for some $0 < t_f < \infty$ (see Kalman et al., 1969, Chapter 2). The set of reachable (or controllable) states forms a subspace and it is called the *reachable* (or, respectively, *controllable*) *subspace*, which will be denoted as \mathcal{V}_{reach} (or, respectively, \mathcal{V}_{contr}). For an $n \times n$ matrix M and a subspace $\mathcal{I} \subset \mathcal{X}$, define

$$\mathcal{R}(M, \mathcal{I}) := \mathcal{I} + M\mathcal{I} + \dots + M^{n-1}\mathcal{I}.$$

The reachable and controllable subspaces are characterized by the following.

Theorem 5.1:

For the continuous-time system $\Sigma := [A, B, C]$,

$$\begin{aligned} \mathcal{V}_{reach} &= \mathcal{R}(A, \text{im } B) = \text{im} [B \ AB \ \dots \ A^{n-1}B], \\ &= \mathcal{R}(A + BF, \text{im } B) = \text{im} [B \ (A + BF)B \ \dots \ (A + BF)^{n-1}B] \end{aligned} \quad (5.11)$$

for any $m \times n$ real matrix F . Furthermore,

$$\mathcal{V}_{reach} = \mathcal{V}_{contr}. \quad (5.12)$$

Remark

The subspace $\mathcal{V}_{reach} = \mathcal{R}(A, \text{im } B)$ is the minimum A -invariant subspace containing $\text{im } B$. It is also $(A + BF)$ -invariant for any $m \times n$ real matrix F . (For a discrete-time system, Equation 5.12 does not hold; instead we have $\mathcal{V}_{reach} \subset \mathcal{V}_{contr}$.)

The pair (A, B) or system $\Sigma := [A, B, C]$ is said to be *reachable* (or *controllable*) if $\mathcal{V}_{reach} = \mathcal{X}$ (or, respectively, $\mathcal{V}_{contr} = \mathcal{X}$). The set $\Lambda := \{\lambda_1, \dots, \lambda_n\}$ of complex numbers is called a *symmetric* set if, whenever λ_j is not a real number, $\lambda_j = \lambda_i^*$ for some $j = 1, \dots, n$ where λ_i^* is the complex conjugate of λ_i . Denote by $\sigma(A + BF)$ the spectrum (or the eigenvalues) of $A + BF$. Then, we have

Theorem 5.2:

For any symmetric set $\Lambda := \{\lambda_1, \dots, \lambda_n\}$ of complex numbers $\lambda_1, \dots, \lambda_n$ there is an $m \times n$ real matrix F , such that $\sigma(A + BF) = \Lambda$ if and only if the pair (A, B) is reachable (or controllable).

Proof. See Wonham (1985); Basile and Marro (1992); and Heymann (1968).

Remark

Let $\dim \mathcal{V}_{reach} = r \leq n$. For any symmetric set $\Lambda_r := \{\lambda_1, \dots, \lambda_r\}$ of complex numbers $\lambda_1, \dots, \lambda_r$, there is an $m \times n$ real matrix F , such that $\sigma(A + BF|_{\mathcal{V}_{reach}}) = \Lambda_r$. In fact, since \mathcal{V}_{reach} is A -invariant, using the same state coordinate transformation given by Equations 5.3 and 5.4 with $\mathcal{V} = \mathcal{V}_{reach}$ and $v = r$, we obtain, from Equation 5.7,

$$\begin{bmatrix} \dot{\tilde{x}}_1(t) \\ \dot{\tilde{x}}_2(t) \end{bmatrix} = \begin{bmatrix} \tilde{A}_{11} & \tilde{A}_{12} \\ 0 & \tilde{A}_{22} \end{bmatrix} \begin{bmatrix} \tilde{x}_1(t) \\ \tilde{x}_2(t) \end{bmatrix} + \begin{bmatrix} \tilde{B}_1 \\ 0 \end{bmatrix} u(t).$$

It is easy to show $\dim \text{im} \begin{bmatrix} \tilde{B}_1 & \tilde{A}_{11}\tilde{B}_1 & \dots & \tilde{A}_{11}^{r-1}\tilde{B}_1 \end{bmatrix} = r$, that is, the pair $(\tilde{A}_{11}, \tilde{B}_1)$ of the r -dimensional subsystem is reachable. The eigenvalue assignment for \mathcal{V}_{reach} follows by applying Theorem 5.2.

The pair (A, B) is said to be *stabilizable* if there is a real matrix F , such that the eigenvalues of $A + BF$ have negative real parts. We have (see Basile and Marro, 1992).

Corollary 5.1:

Pair (A, B) is stabilizable if and only if \mathcal{V}_{reach} is externally stable.

The state \tilde{x} of the system Σ is said to be *unobservable* if it produces zero output when the input is not applied, that is, if $x(0) = \tilde{x}$ and $u(t) = 0$ for all $t \geq 0$ implies $y(t) = 0$ for all $t \geq 0$. The set of unobservable states forms a subspace which is called the *unobservable subspace*. This will be denoted by \mathcal{S}_{unobs} .

Theorem 5.3:

$$\begin{aligned} \mathcal{S}_{unobs} &= \ker \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{n-1} \end{bmatrix} = \ker \begin{bmatrix} C \\ C(A + GC) \\ \vdots \\ C(A + GC)^{n-1} \end{bmatrix} \\ &= \ker C \cap A^{-1} \ker C \cap \dots \cap A^{-(n-1)} \ker C \\ &= \ker C \cap (A + GC)^{-1} \ker C \cap \dots \cap (A + GC)^{-(n-1)} \ker C \end{aligned} \quad (5.13)$$

for any $n \times p$ real matrix G .

Remark

The subspace \mathcal{S}_{unobs} is A -invariant. It is also $(A + GC)$ -invariant for any $n \times p$ real matrix G .

The pair (A, C) or system Σ is said to be *observable* if $\mathcal{S}_{unobs} = \{0\}$, and the pair (A, C) is said to be *detectable* if $A + GC$ is stable for some real matrix G . For observability and detectability we have the following facts.

Theorem 5.4:

For any symmetric set $\Lambda := \{\lambda_1, \dots, \lambda_n\}$ of complex numbers $\lambda_1, \dots, \lambda_n$, there is an $n \times p$ real matrix G such that $\sigma(A + GC) = \Lambda$ if and only if the pair (A, C) is observable.

Corollary 5.2:

The pair (A, C) is detectable if and only if S_{unobs} is internally stable.

The following formulae are useful for subspace calculations.

Lemma 5.2:

Let $\mathcal{V}, \mathcal{V}_1, \mathcal{V}_2, \mathcal{V}_3 \subset \mathcal{X}$. Then, letting $\mathcal{V}^\perp := \{x \in \mathcal{X} : x'v = 0 \text{ for all } v \in \mathcal{V}\}$,

$$\begin{aligned} (\mathcal{V}^\perp)^\perp &= \mathcal{V}, \\ (\mathcal{V}_1 + \mathcal{V}_2)^\perp &= \mathcal{V}_1^\perp \cap \mathcal{V}_2^\perp, \\ (\mathcal{V}_1 \cap \mathcal{V}_2)^\perp &= \mathcal{V}_1^\perp + \mathcal{V}_2^\perp, \\ A(\mathcal{V}_1 + \mathcal{V}_2) &= A\mathcal{V}_1 + A\mathcal{V}_2, \\ A(\mathcal{V}_1 \cap \mathcal{V}_2) &\subset A\mathcal{V}_1 \cap A\mathcal{V}_2, \end{aligned}$$

$(A_1 + A_2)\mathcal{V} = A_1\mathcal{V} + A_2\mathcal{V}$, where A_1 and A_2 are $n \times n$ matrices,

$$\begin{aligned} (A\mathcal{V})^\perp &= A'^{-1}\mathcal{V}^\perp, \\ \mathcal{V}_1 + (\mathcal{V}_2 \cap \mathcal{V}_3) &\subset (\mathcal{V}_1 + \mathcal{V}_2) \cap (\mathcal{V}_1 + \mathcal{V}_3), \\ \mathcal{V}_1 \cap (\mathcal{V}_2 + \mathcal{V}_3) &\supset (\mathcal{V}_1 \cap \mathcal{V}_2) + (\mathcal{V}_1 \cap \mathcal{V}_3), \end{aligned}$$

$\mathcal{V}_1 \cap (\mathcal{V}_2 + \mathcal{V}_3) = \mathcal{V}_2 + (\mathcal{V}_1 \cap \mathcal{V}_3)$, provided $\mathcal{V}_1 \supset \mathcal{V}_2$.

5.3 $(A, \text{im } B)$ -Controlled and $(A, \ker C)$ -Conditioned Invariant Subspaces and Duality

In this section, we introduce important subspaces associated with system $\Sigma := [A, B, C]$ described by Equation 5.7 (or Equation 5.10) and Equation 5.8 with a state feedback law (Equation 5.9). According to Lemma 5.1, for an autonomous linear system described by Equation 5.2, an A -invariant subspace is a subspace having the property that any state trajectory starting in the subspace remains in it. However, for a linear system $\Sigma := [A, B, C]$ with input, A -invariance is not necessary in order for a subspace to have the above trajectory confinement property. In fact, let $\mathcal{V} \subset \mathcal{X}$. A state trajectory can be confined in \mathcal{V} if and only if $\dot{x}(t) \in \mathcal{V}$, and to produce $\dot{x}(t) \in \mathcal{V}$ whenever $x(t) \in \mathcal{V}$, we need $\dot{x}(t) = Ax(t) + Bu(t) = v(t) \in \mathcal{V}$, that is, $Ax(t) = v(t) - Bu(t)$ for some $u(t)$ and $v(t)$, which implies $A\mathcal{V} \subset \mathcal{V} + \text{im } B$. The converse also holds. Summarizing, we have

Lemma 5.3:

Consider the system described by Equation 5.7. For each initial state $x_0 \in \mathcal{V}$, there is an (admissible) input $u(t)$, $t \geq 0$ such that the corresponding $x(t) \in \mathcal{V}$ for all $t \geq 0$ if and only if

$$A\mathcal{V} \subset \mathcal{V} + \text{im } B. \quad (5.14)$$

Subspaces satisfying Equation 5.14 play a fundamental role in the geometric approach, and we introduce

Definition 5.2:

A subspace \mathcal{V} is said to be an $(A, \text{im } B)$ -controlled invariant (subspace) (Basile and Marro, 1969, 1992) or an (A, B) -invariant subspace (Wonham and Morse, 1970; Wonham, 1985) if it is A -invariant modulo $\text{im } B$, that is, if Equation 5.14 holds.

An important property of the above subspace is described by

Theorem 5.5:

Let $\mathcal{V} \subset \mathcal{X}$. Then, there exists an $m \times n$ real matrix F , such that

$$(A + BF)\mathcal{V} \subset \mathcal{V}, \quad (5.15)$$

if and only if \mathcal{V} is an $(A, \text{im } B)$ -controlled invariant.

Remark

If the state feedback control law (Equation 5.9) is applied to the system $\Sigma := [A, B, C]$, the corresponding state equation is described by Equation 5.10. Therefore, recalling Lemma 5.1, if \mathcal{V} is an $(A, \text{im } B)$ -controlled invariant, then there is an F for Equation 5.10 such that $x(t) \in \mathcal{V}$ for all $t \geq 0$, provided $x_0 \in \mathcal{V}$.

Another class of important subspaces is now introduced (Basile and Marro 1969, 1992).

Definition 5.3:

A subspace \mathcal{S} of \mathcal{X} is said to be an $(A, \ker C)$ -conditioned invariant (subspace), if

$$A(\mathcal{S} \cap \ker C) \subset \mathcal{S}. \quad (5.16)$$

There is a duality between controlled invariants and conditioned invariants in the following sense. By taking the orthogonal complements of the quantities on both sides of Equation 5.16, we see that Equation 5.16 is equivalent to $\{A(\mathcal{S} \cap \ker C)\}^\perp \supset \mathcal{S}^\perp$, which, in turn, is equivalent to $A'^{-1}(\mathcal{S}^\perp + \text{im } C') \supset \mathcal{S}^\perp$, that is, $A'\mathcal{S}^\perp \subset \mathcal{S}^\perp + \text{im } C'$. Similarly, Equation 5.14 holds if and only if $A'(\mathcal{V}^\perp \cap \ker B') \subset \mathcal{V}^\perp$. Thus, we have

Lemma 5.4:

A subspace S is an $(A, \ker C)$ -conditioned invariant if and only if S^\perp is an $(A', \text{im } C')$ -controlled invariant. Also, a subspace \mathcal{V} is an $(A, \text{im } B)$ -controlled invariant if and only if \mathcal{V}^\perp is an $(A', \ker B')$ -conditioned invariant.

Due to the above lemma, the previous theorem can be translated easily into the following property (Basile and Marro, 1969, 1992).

Theorem 5.6:

Let $S \subset \mathcal{X}$. Then, there exists an $n \times p$ real matrix G satisfying

$$(A + GC)S \subset S, \quad (5.17)$$

if and only if S is an $(A, \ker C)$ -conditioned invariant.

The conditioned invariants are naturally associated with dynamic observers (not necessarily asymptotic). The following Lemma 5.5 summarizes the meaning of the invariants in this context.

Consider the system $\Sigma := [A, B, C]$ described by Equations 5.7 and 5.8. To focus on the state observation aspect of the system, we assume that $u(t) = 0$ for all $t \geq 0$. (It is straightforward to extend the result to include the nonzero measurable input.) We define the full-order and reduced order observers Σ_{obs} and $\Sigma_{obs,red}$, respectively, as follows:

$$\begin{aligned} \Sigma_{obs} : \dot{\hat{x}}(t) &= (A + GC) \hat{x}(t) - Gy(t) = (A + GC) \hat{x}(t) - GCx(t), \\ \Sigma_{obs,red} : \dot{z}(t) &= Nz(t) - My(t) = Nz(t) - MCx(t). \end{aligned}$$

Here, $\hat{x}(t)$ and $z(t)$ are column vectors with dimensions n and n_z (to be determined), respectively, and N and M are, respectively, $n_z \times n_z$ and $n_z \times p$ real matrices. Then, we have

Lemma 5.5:

Let $S \subset \mathcal{X} := \mathbb{R}^n$. The following statements are equivalent:

- i. S is $(A, \ker C)$ -conditioned invariant, that is, Equation 5.16 holds.
- ii. There exists a real matrix G with an appropriate dimension and an observer Σ_{obs} such that

$$\hat{x}(0) = x(0) \pmod{S}, \quad \text{that is } \hat{x}(0) - x(0) \in S$$

implies

$$\hat{x}(t) = x(t) \pmod{S}, \quad \text{that is } \hat{x}(t) - x(t) \in S, \quad \text{for all } t > 0.$$

- iii. There exist real matrices M, N , and H , satisfying $\ker H = S$, with suitable dimensions and an observer $\Sigma_{obs,red}$ such that

$$z(0) = Hx(0) \Rightarrow z(t) = Hx(t), \quad \text{for all } t > 0.$$

Remark

The statement (iii) in the above lemma is used by Willems (1981) as the definition of the conditioned invariant. Also, see Trentelman et al. (2001, Section 5.1).

Proof of Lemma 5.5. (i) \Rightarrow (ii) : Suppose Equation 5.16 holds. In view of Theorem 5.6 choose G , so that Equation 5.17 holds. Define the observer error by $e_{rr}(t) := \hat{x}(t) - x(t)$. The equations for Σ and Σ_{obs} lead to $\dot{e}_{rr}(t) = (A + GC)e_{rr}(t)$. Since \mathcal{S} is $(A + GC)$ -invariant, $e_{rr}(0) \in \mathcal{S} \Rightarrow e_{rr}(t) \in \mathcal{S}$ for all $t > 0$. (ii) \Rightarrow (iii): Basically, a modulo \mathcal{S} version of Σ_{obs} in (ii) is a reduced order observer $\Sigma_{obs,red}$. To be explicit, choose a new basis $\{e_1, \dots, e_{n_S}, \dots, e_n\}$ for $\mathcal{X} := R^n$ so that $\{e_1, \dots, e_{n_S}\}$ is a basis of subspace $\mathcal{S} \subset \mathcal{X} := R^n$, where $n_S := \dim \mathcal{S}$. Define $T := [e_1 \dots e_{n_S} \dots e_n]$ and apply the state coordinate transformation $x(t) = T\tilde{x}(t)$ to Σ (with zero inputs) to obtain $\tilde{\Sigma} : \dot{\tilde{x}}(t) = T^{-1}AT\tilde{x}(t), y(t) = CT\tilde{x}(t)$, where $\tilde{x}(t) = [\tilde{x}'_1(t) \ \tilde{x}'_2(t)]'$, $\tilde{x}_1(t) \in R^{n_S}$, and $\tilde{x}_2(t) \in R^{n-n_S}$. We apply the same coordinate transformation to Σ_{obs} , that is, $\hat{x}(t) = T\tilde{\hat{x}}(t)$, to obtain $\tilde{\Sigma}_{obs} : \dot{\tilde{\hat{x}}}(t) = T^{-1}(A + GC)T\tilde{\hat{x}}(t) - T^{-1}Gy(t)$, which has the following structure:

$$\tilde{\Sigma}_{obs} : \begin{bmatrix} \dot{\tilde{\hat{x}}}_1(t) \\ \dot{\tilde{\hat{x}}}_2(t) \end{bmatrix} = \begin{bmatrix} \tilde{A}_{G11} & \tilde{A}_{G12} \\ 0 & \tilde{A}_{G22} \end{bmatrix} \begin{bmatrix} \tilde{\hat{x}}_1(t) \\ \tilde{\hat{x}}_2(t) \end{bmatrix} - \begin{bmatrix} \tilde{G}_1 \\ \tilde{G}_2 \end{bmatrix} y(t),$$

where $\tilde{\hat{x}}_1(t) \in R^{n_S}, \tilde{\hat{x}}_2(t) \in R^{n-n_S}, \tilde{A}_{G22} \in R^{(n-n_S) \times (n-n_S)}, \tilde{G}_2 \in R^{(n-n_S) \times p}$, and $\tilde{A}_{G11}, \tilde{A}_{G12}$, and \tilde{G}_1 with consistent dimensions. Note that the 0 block in matrix $T^{-1}(A + GC)T$ is due to $(A + GC)$ -invariance of \mathcal{S} . The corresponding observer error $[\tilde{e}'_{rr1}(t) \ \tilde{e}'_{rr2}(t)]' := [\tilde{\hat{x}}'_1(t) \ \tilde{\hat{x}}'_2(t)]' - [\tilde{x}'_1(t) \ \tilde{x}'_2(t)]'$ satisfies

$$\begin{bmatrix} \dot{\tilde{e}}_{rr1}(t) \\ \dot{\tilde{e}}_{rr2}(t) \end{bmatrix} = \begin{bmatrix} \tilde{A}_{G11} & \tilde{A}_{G12} \\ 0 & \tilde{A}_{G22} \end{bmatrix} \begin{bmatrix} \tilde{e}_{rr1}(t) \\ \tilde{e}_{rr2}(t) \end{bmatrix}.$$

The reduced order observer $\Sigma_{obs,red}$ can be chosen as follows:

$$\Sigma_{obs,red} : \dot{\tilde{\hat{x}}}_2(t) = \tilde{A}_{G22}\tilde{\hat{x}}_2(t) - \tilde{G}_2y(t).$$

Define H by $H := [0 \ I_{n-n_S}]T^{-1}$. Then,

$$\tilde{\hat{x}}_2(0) - Hx(0) = \tilde{\hat{x}}_2(0) - \tilde{x}_2(0) = \tilde{e}_{rr2}(0) = 0$$

implies

$$\tilde{\hat{x}}_2(t) - Hx(t) = \tilde{\hat{x}}_2(t) - \tilde{x}_2(t) = \tilde{e}_{rr2}(t) = e^{\tilde{A}_{G22}t}\tilde{e}_{rr2}(0) = 0.$$

(iii) \Rightarrow (i) : Let $x(0) = x_0 \in \mathcal{S} \cap \ker C$ and choose $z(0) = Hx_0 = 0$. Then, we have $\dot{z}(0) = Nz(0) - My(0) = Nz(0) - MCx(0) = 0$. Since $z(t) = Hx(t)$ this implies $H\dot{x}(0) = HAx(0) = HAx_0 = 0$, that is, $Ax_0 \in \ker H = \mathcal{S}$ (for every $x_0 \in \mathcal{S} \cap \ker C$). QED

A subspace may be both controlled and conditioned invariant. In such a case, we have the following (Basile and Marro, 1992; Hamano and Furuta, 1975):

Lemma 5.6:

There exists an $m \times p$ real matrix K , such that

$$(A + BKC)\mathcal{V} \subset \mathcal{V}, \tag{5.18}$$

if and only if \mathcal{V} is both an $(A, \text{im } B)$ -controlled invariant and an $(A, \ker C)$ -conditioned invariant.

Proof. [Only if part]. The controlled invariance and conditioned invariance follow trivially by Theorems 5.5 and 5.6, respectively.

[If part]. For $C = 0$ or $\ker C = 0$ or $\mathcal{V} = 0$, the statement of the lemma trivially holds. So we prove the lemma assuming such trivialities do not occur. Since by assumption \mathcal{V} is an $(A, \text{im } B)$ -controlled invariant,

there is an $m \times n$ real matrix \bar{F} satisfying $(A + B\bar{F})\mathcal{V} \subset \mathcal{V}$. Assuming $\mathcal{V} \cap \ker C \neq \{0\}$, let $\{v_1 \dots v_\mu\}$ be a basis of $\mathcal{V} \cap \ker C$. Complete the basis $\{v_1 \dots v_\mu \dots v_\nu \dots v_n\}$ of \mathcal{X} in such a way that $\{v_1 \dots v_\mu \dots v_\nu\}$ is a basis of \mathcal{V} where $1 \leq \mu \leq \nu \leq n$. Define an $m \times n$ real matrix \tilde{F} by

$$\tilde{F}v_i = \begin{cases} \bar{F}v_i, & i = \mu + 1, \dots, \nu \\ 0, & i = 1, \dots, \mu \\ \text{arbitrary,} & \text{otherwise} \end{cases} \quad (5.19)$$

Choose K so that $\tilde{F} = KC$, that is, $\tilde{F}[v_{\mu+1} \dots v_\nu] = K[Cv_{\mu+1} \dots Cv_\nu]$. Note that due to the particular choice of basis, the columns of $[Cv_{\mu+1} \dots Cv_\nu]$ are linearly independent, and so the above K certainly exists. To show that Equation 5.18 holds, let $v \in \mathcal{V}$. Then, $v = \sum_{i=1}^{\mu} \alpha_i v_i + \sum_{i=\mu+1}^{\nu} \alpha_i v_i$ for some numbers α_i 's. Therefore, by the above choice of K ,

$$(A + BKC)v = A \sum_{i=1}^{\mu} \alpha_i v_i + (A + B\tilde{F}) \sum_{i=\mu+1}^{\nu} \alpha_i v_i.$$

But, the first sum belongs to \mathcal{V} by Equation 5.16 (where $S = \mathcal{V}$) and the second sum is an element of \mathcal{V} by the choice of \tilde{F} . Thus, $(A + BKC)v \in \mathcal{V}$.

If $\mathcal{V} \cap \ker C = \{0\}$, the basis for $\mathcal{V} \cap \ker C$ is empty and Equation 5.19 can be modified by dropping the second row and setting $\mu = 0$. Equation 5.18 follows similarly to the above. QED

5.4 Algebraic Properties of Controlled and Conditioned Invariants

An $(A, \text{im } B)$ -controlled invariant has the following properties in addition to the ones discussed in the previous section. The proofs are omitted. They can be found in Basile and Marro (1992, Chapter 4).

Lemma 5.7:

If \mathcal{V}_1 and \mathcal{V}_2 are $(A, \text{im } B)$ -controlled invariants, so is $\mathcal{V}_1 + \mathcal{V}_2$.

Remark

But, the intersection of two $(A, \text{im } B)$ -controlled invariants is not in general an $(A, \text{im } B)$ -controlled invariant.

Lemma 5.8:

Let \mathcal{V}_1 and \mathcal{V}_2 be $(A, \text{im } B)$ -controlled invariants. Then, there is an $m \times n$ real matrix F satisfying

$$(A + BF)\mathcal{V}_i \subset \mathcal{V}_i, \quad i = 1, 2, \quad (5.20)$$

if and only if $\mathcal{V}_1 \cap \mathcal{V}_2$ is an $(A, \text{im } B)$ -controlled invariant.

By duality, we have

Lemma 5.9:

If S_1 and S_2 are $(A, \ker C)$ -conditioned invariants, so is $S_1 \cap S_2$.

Remark

$S_1 + S_2$ is not necessarily an $(A, \ker C)$ -conditioned invariant.

Lemma 5.10:

Let S_1 and S_2 be $(A, \ker C)$ -conditioned invariants. Then, there is an $n \times p$ real matrix G satisfying

$$(A + GC)S_i \subset S_i, \quad i = 1, 2, \tag{5.21}$$

if and only if $S_1 + S_2$ is an $(A, \ker C)$ -conditioned invariant.

5.5 Maximum-Controlled and Minimum-Conditioned Invariants

Let $\mathcal{K} \subset \mathcal{X}$, and consider the set of $(A, \text{im } B)$ -controlled invariants contained in \mathcal{K} (by subspace inclusion). Lemma 5.7 states that the set of $(A, \text{im } B)$ -controlled invariants is closed under subspace addition. As a result, the set of $(A, \text{im } B)$ -controlled invariants contained in \mathcal{K} has a largest element or supremum. This element is a unique subspace that contains (by subspace inclusion) any other $(A, \text{im } B)$ -controlled invariants contained in \mathcal{K} , and is called the *maximum* (or *supremum*) $(A, \text{im } B)$ -controlled invariant contained in \mathcal{K} . This is denoted in the sequel as $\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$. Similarly, let $\mathcal{I} \subset \mathcal{X}$. Then, owing to Lemma 5.9, it can be shown that the set of $(A, \ker C)$ -conditioned invariants containing \mathcal{I} has a smallest element or infimum. This is a unique $(A, \ker C)$ -conditioned invariant contained in all other $(A, \ker C)$ -conditioned invariants containing \mathcal{I} , and is called the *minimum* (or *infimum*) $(A, \ker C)$ -conditioned invariant containing \mathcal{I} . This subspace will be denoted as $\mathcal{S}_{\min}(A, \ker C, \mathcal{I})$. The subspaces $\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$ and $\mathcal{S}_{\min}(A, \ker C, \mathcal{I})$ are important because they can be computed in a finite number of steps (in at most n iterations) and because testing the solvability of control problems typically reduces to checking the conditions involving these subspaces. The geometric algorithms to compute $\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$ and $\mathcal{S}_{\min}(A, \ker C, \mathcal{I})$ are given below.

Algorithm to compute $\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$:

$$\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K}) = \mathcal{V}_{\dim \mathcal{K}}, \tag{5.22a}$$

where

$$\mathcal{V}_0 = \mathcal{K}, \tag{5.22b}$$

$$\mathcal{V}_i = \mathcal{K} \cap A^{-1}(\mathcal{V}_{i-1} + \text{im } B), \quad i = 1, \dots, \dim \mathcal{K}. \tag{5.22c}$$

Proof of Equation 5.22a. See Basile and Marro (1992) or Wonham (1985).

Remark

The algorithm defined by Equations 5.22 has the following properties:

- i. $\mathcal{V}_1 \supset \mathcal{V}_2 \supset \dots \supset \mathcal{V}_{\dim \mathcal{K}}$.
- ii. If $\mathcal{V}_\ell = \mathcal{V}_{\ell+1}$, then $\mathcal{V}_\ell = \mathcal{V}_{\ell+1} = \dots = \mathcal{V}_{\dim \mathcal{K}}$.

Remark

For an algorithm to compute F such that $(A + BF)\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K}) \subset \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$, see Basile and Marro (1992).

The following is the dual of the above algorithm (see Basile and Marro, 1992).

Algorithm to calculate $\mathcal{S}_{\min}(A, \ker C, \mathcal{I})$:

$$\mathcal{S}_{\min}(A, \ker C, \mathcal{I}) = \mathcal{S}_{n-\dim \mathcal{I}}, \quad (5.23a)$$

where

$$\mathcal{S}_0 = \mathcal{I}, \quad (5.23b)$$

$$\mathcal{S}_i = \mathcal{I} + A(\mathcal{S}_{i-1} \cap \ker C), \quad i = 1, \dots, n - \dim \mathcal{I}. \quad (5.23c)$$

Remark

The algorithm generates a monotonically nondecreasing sequence:

- (i) $\mathcal{S}_1 \subset \mathcal{S}_2 \subset \dots \subset \mathcal{S}_{n-\dim \mathcal{I}}$.
- (ii) If $\mathcal{S}_\ell = \mathcal{S}_{\ell+1}$, then $\mathcal{S}_\ell = \mathcal{S}_{\ell+1} = \dots = \mathcal{S}_{n-\dim \mathcal{I}}$.

5.6 Self-Bounded-Controlled and Self-Hidden-Conditioned Invariants and Constrained Reachability and Observability

Let \mathcal{V}_o be an $(A, \text{im } B)$ -controlled invariant contained in \mathcal{K} , and consider all possible state trajectories (with different controls) starting at x_o in \mathcal{V}_o and confined in \mathcal{K} . We know that there is at least one control for which the state trajectory remains in \mathcal{V}_o , but that there may be another control for which the state trajectory goes out of \mathcal{V}_o while remaining in \mathcal{K} . However, some $(A, \text{im } B)$ -controlled invariant contained in \mathcal{K} , say \mathcal{V} , has a stronger property that, for any initial state in \mathcal{V} , there is no control which drives the state (initially in \mathcal{V}) out of \mathcal{V} while maintaining the state trajectory in \mathcal{K} , that is, the state trajectory must go out of \mathcal{K} if it ever goes out of $\mathcal{V} \subset \mathcal{K}$. The subspace $\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$ is one of those since it contains all states that can be controlled to remain in \mathcal{K} . Such an $(A, \text{im } B)$ -controlled invariant \mathcal{V} contained in \mathcal{K} is in general characterized by

$$\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K}) \cap \text{im } B \subset \mathcal{V}, \quad (5.24)$$

and we have (Basile and Marro, 1982, 1992)

Definition 5.4:

An $(A, \text{im } B)$ -controlled invariant \mathcal{V} contained in \mathcal{K} is said to be self-bounded with respect to \mathcal{K} if Equation 5.24 holds.

Remark

The left-hand side of inclusion 5.24 represents the set of all possible influences of control on the state velocity at each instant of time that do not pull the state out of \mathcal{K} .

Self-bounded $(A, \text{im } B)$ -controlled invariants have the following properties.

For each \mathcal{K} we can choose a single state-feedback control law, which works for all the self-bounded $(A, \text{im } B)$ -controlled invariants with respect to \mathcal{K} . More precisely,

Lemma 5.11:

Let F be an $m \times n$ real matrix satisfying

$$(A + BF)\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K}) \subset \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K}). \quad (5.25)$$

Then, every self-bounded $(A, \text{im } B)$ -controlled invariant \mathcal{V} with respect to \mathcal{K} satisfies

$$(A + BF)\mathcal{V} \subset \mathcal{V}. \quad (5.26)$$

Proof. See Basile and Marro (1992).

It can be shown that the set of self-bounded $(A, \text{im } B)$ -controlled invariants in \mathcal{K} is closed under subspace intersection, that is, if \mathcal{V}_1 and \mathcal{V}_2 are self-bounded $(A, \text{im } B)$ -controlled invariants with respect to \mathcal{K} , so is $\mathcal{V}_1 \cap \mathcal{V}_2$. Therefore, the above set has a minimum element which is called *the minimum self-bounded $(A, \text{im } B)$ -controlled invariant with respect to \mathcal{K}* (Basile and Marro, 1982, 1992), denoted in this chapter by $\mathcal{V}_{sb,\min}(A, \text{im } B, \mathcal{K})$. The subspace $\mathcal{V}_{sb,\min}(A, \text{im } B, \mathcal{K})$ is related to $\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$ and $\mathcal{S}_{\min}(A, \mathcal{K}, \text{im } B)$ as follows.

Theorem 5.7:

$$\mathcal{V}_{sb,\min}(A, \text{im } B, \mathcal{K}) = \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K}) \cap \mathcal{S}_{\min}(A, \mathcal{K}, \text{im } B). \quad (5.27)$$

Proof. See Basile and Marro (1992, Chapter 4) and Morse (1973).

The minimum self-bounded $(A, \text{im } B)$ -controlled invariant is closely related to constrained reachability. The set of all states that can be reached from the zero state through state trajectories constrained in \mathcal{K} in finite time is called the *reachable set* (or *reachable subspace*, since the set forms a subspace) *in \mathcal{K}* (Basile and Marro, 1992). It is also called the *supremal (A, B) -controllability subspace contained in \mathcal{K}* (Wonham, 1985). This set will be denoted by $\mathcal{V}_{\text{reach}}(\mathcal{K})$. Clearly, it has the following properties.

Lemma 5.12:

$$\mathcal{V}_{\text{reach}}(\mathcal{K}) \subset \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K}) \subset \mathcal{K}, \quad (5.28)$$

$$\mathcal{V}_{\text{reach}}(\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})) = \mathcal{V}_{\text{reach}}(\mathcal{K}). \quad (5.29)$$

To examine $\mathcal{V}_{\text{reach}}(\mathcal{K})$ further, let F be a matrix satisfying Equation 5.25. It is easy to observe that the set of $\dot{x}(t)$ (and so the trajectories) in $\mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$ (or in \mathcal{K}) that can be generated by the state Equation 5.7, when $x(t) \in \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$, is identical to those generated by $\dot{x}(t) = (A + BF)x(t) + BL\tilde{u}(t)$ for a matrix L satisfying $\text{im } BL = \text{im } B \cap \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$ and the admissible inputs $\tilde{u}(t)$. Then, by Equation 5.11, $\mathcal{V}_{\text{reach}}(\mathcal{K}) = \mathcal{R}(A + BF, \text{im } B \cap \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K}))$, where $\mathcal{V}_{\max}(\mathcal{K}) := \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$. Clearly, $\mathcal{V}_{\text{reach}}(\mathcal{K}) \supset \text{im } B \cap \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$ and the subspace $\mathcal{V}_{\text{reach}}(\mathcal{K})$ is the minimum $(A + BF)$ -invariant satisfying this inclusion (see the remark immediately after Theorem 5.1), that is, it is the minimum $(A, \text{im } B)$ -controlled invariant self-bounded with respect to \mathcal{K} . Thus, we have

Theorem 5.8:

Let F be a real matrix satisfying $(A + BF)\mathcal{V}_{\max}(\mathcal{K}) \subset \mathcal{V}_{\max}(\mathcal{K})$, where $\mathcal{V}_{\max}(\mathcal{K}) := \mathcal{V}_{\max}(A, \text{im } B, \mathcal{K})$. Then,

$$\mathcal{V}_{\text{reach}}(\mathcal{K}) = \mathcal{R}(A + BF, \text{im } B \cap \mathcal{V}_{\max}(\mathcal{K})) = \mathcal{V}_{sb,\min}(A, \text{im } B, \mathcal{K}). \quad (5.30)$$

Dual to the above results we have

Definition 5.5:

An $(A, \ker C)$ -conditioned invariant \mathcal{S} containing \mathcal{I} is said to be self-hidden with respect to \mathcal{I} if

$$\mathcal{S} \subset \mathcal{S}_{\min}(A, \ker C, \mathcal{I}) + \ker C. \quad (5.31)$$

Lemma 5.13:

Let G be an $n \times p$ real matrix satisfying

$$(A + GC)\mathcal{S}_{\min}(A, \ker C, \mathcal{I}) \subset \mathcal{S}_{\min}(A, \ker C, \mathcal{I}). \quad (5.32)$$

Then, every $(A, \ker C)$ -conditioned invariant \mathcal{S} (containing \mathcal{I}) self-hidden with respect to \mathcal{I} satisfies

$$(A + GC)\mathcal{S} \subset \mathcal{S}. \quad (5.33)$$

If $(A, \ker C)$ -conditioned invariants \mathcal{S}_1 and \mathcal{S}_2 containing \mathcal{I} are self-hidden with respect to \mathcal{I} , so is $\mathcal{S}_1 + \mathcal{S}_2$. Therefore, the above set has a maximum element which is called *the maximum self-hidden $(A, \ker C)$ -conditioned invariant with respect to \mathcal{I}* denoted by $\mathcal{S}_{sh, \max}(A, \ker C, \mathcal{I})$. The subspace $\mathcal{S}_{sh, \max}(A, \ker C, \mathcal{I})$ is related to $\mathcal{V}_{\max}(A, \mathcal{I}, \ker C)$ and $\mathcal{S}_{\min}(A, \ker C, \mathcal{I})$ as follows.

Theorem 5.9:

$$\mathcal{S}_{sh, \max}(A, \ker C, \mathcal{I}) = \mathcal{S}_{\min}(A, \ker C, \mathcal{I}) + \mathcal{V}_{\max}(A, \mathcal{I}, \ker C). \quad (5.34)$$

Furthermore, we have

Theorem 5.10:

$$\begin{aligned} \mathcal{S}_{sh, \max}(A, \ker C, \mathcal{I}) = & (\ker C + \mathcal{S}_{\min}(\mathcal{I})) \cap (A + GC)^{-1}(\ker C + \mathcal{S}_{\min}(\mathcal{I})) \\ & \cap \dots \cap (A + GC)^{-(n-1)}(\ker C + \mathcal{S}_{\min}(\mathcal{I})), \end{aligned} \quad (5.35)$$

where $\mathcal{S}_{\min}(\mathcal{I}) := \mathcal{S}_{\min}(A, \ker C, \mathcal{I})$ and the matrix G satisfies Equation 5.32, that is, $(A + GC)\mathcal{S}_{\min}(\mathcal{I}) \subset \mathcal{S}_{\min}(\mathcal{I})$.

Remark

The right-hand side of Equation 5.35 represents the largest $A + GC$ invariant subspace contained in $\ker C + \mathcal{S}_{\min}(\mathcal{I})$.

Remark

Equation 5.35 indicates that $\mathcal{S}_{sh, \max}(A, \ker C, \mathcal{I})$ represents the set of unobservable states through a dynamic observer when unknown disturbances are present if \mathcal{I} represents the disturbance channel. See Basile and Marro (1992, Section 4.1.3) for details on the topic.

5.7 Internal, External Stabilizability

We now introduce the notions of stability associated with controlled and conditioned invariants.

Definition 5.6:

An $(A, \text{im } B)$ -controlled invariant \mathcal{V} is said to be internally stabilizable if, for any initial state $x_0 \in \mathcal{V}$, there is a control $u(t)$ such that $x(t) \in \mathcal{V}$ for all $t \geq 0$ and $x(t)$ converges to the zero state as $t \rightarrow \infty$, or, alternatively (and, in fact, equivalently), if there exists an $m \times n$ real matrix F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$ and $(A + BF)|_{\mathcal{V}}$ is stable.

Definition 5.7:

An $(A, \text{im } B)$ -controlled invariant \mathcal{V} is said to be externally stabilizable if, for any initial state $x_0 \in \mathcal{X}$, there is a control $u(t)$ such that $x(t)$ converges to \mathcal{V} as $t \rightarrow \infty$, or, alternatively (and, equivalently), if there exists an $m \times n$ real matrix F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$ and $(A + BF)|_{\mathcal{X}/\mathcal{V}}$ is stable.

Internal and external stabilizabilities can be easily examined by applying appropriate coordinate transformations (consisting of new sets of basis vectors) for the state and input spaces. For this, let \mathcal{V} be an $(A, \text{im } B)$ -controlled invariant. Also, let $n_r := \dim \mathcal{V}_{\text{reach}}(\mathcal{V})$, $n_{\mathcal{V}} := \dim \mathcal{V}$, and $n_S := \dim \mathcal{S}_{\min}(A, \mathcal{V}, \text{im } B)$. Define $n \times n$ and $m \times m$ nonsingular matrices $T = [T_1 \ T_2 \ T_3 \ T_4]$ and $U = [U_1 \ U_2]$, respectively, as follows: Choose U_1, T_1 , and T_2 , so that $\text{im } BU_1 = \mathcal{V} \cap \text{im } B$, $\text{im } T_1 = \mathcal{V}_{\text{reach}}(\mathcal{V})$, and $\text{im } [T_1 \ T_2] = \mathcal{V}$. Also, choose U_2 , so that $\text{im } B[U_1 \ U_2] = \text{im } B$. Noting that $\mathcal{V}_{\text{reach}}(\mathcal{V}) = \mathcal{V} \cap \mathcal{S}_{\min}(A, \mathcal{V}, \text{im } B)$ (see Equations 5.27 and 5.30; let $\mathcal{K} = \mathcal{V}$), select T_3 satisfying $\text{im } [T_1 \ T_3] = \mathcal{S}_{\min}(A, \mathcal{V}, \text{im } B)$ with $\text{im } BU_2 \subset \text{im } T_3$. Then, we have

$$\tilde{A} := T^{-1}AT = \begin{bmatrix} \tilde{A}_{11} & \tilde{A}_{12} & \tilde{A}_{13} & \tilde{A}_{14} \\ 0 & \tilde{A}_{22} & \tilde{A}_{23} & \tilde{A}_{24} \\ \tilde{A}_{31} & \tilde{A}_{32} & \tilde{A}_{33} & \tilde{A}_{34} \\ 0 & 0 & \tilde{A}_{43} & \tilde{A}_{44} \end{bmatrix}, \quad (5.36)$$

$$\tilde{B} := T^{-1}BU = \begin{bmatrix} \tilde{B}_{11} & 0 \\ 0 & 0 \\ 0 & \tilde{B}_{32} \\ 0 & 0 \end{bmatrix}. \quad (5.37)$$

Here, \tilde{A} is divided into blocks in accordance with the ranks of T_1, T_2, T_3, T_4 , that is, $\tilde{A}_{11}, \tilde{A}_{12}, \dots, \tilde{A}_{44}$ respectively have dimensions $n_1 \times n_1, n_1 \times n_2, \dots, n_4 \times n_4$, where $n_1 := \text{rank } T_1 = n_r, n_2 := \text{rank } T_2 = n_{\mathcal{V}} - n_r, \dots$, and \tilde{B} is divided similarly, for example, \tilde{B}_{11} and \tilde{B}_{32} have dimensions $n_1 \times m_1$ and $n_3 \times m_2$, where m_1 and m_2 are, respectively, the numbers of columns of U_1 and U_2 . Note that the zero matrix in the second block row of \tilde{A} is due to the following facts: $\mathcal{V}_{\text{reach}}(\mathcal{V})$ is $(A + BF)$ -invariant for every F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$, but the second block row of \tilde{B} is zero (which makes F ineffective in the block). The fourth block row of \tilde{A} has zero blocks since \mathcal{V} is $(A + BF)$ -invariant for any F defined above, but the fourth block row of \tilde{B} is zero. Now, using F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$, consider $A + BF$ with respect to the new bases. Noting that $\tilde{A}_{31} + \tilde{B}_{32}\tilde{F}_{21} = 0$ and $\tilde{A}_{32} + \tilde{B}_{32}\tilde{F}_{22} = 0$ by construction, we obtain

$$\tilde{A} + \tilde{B}\tilde{F} = T^{-1}(A + BF)T = \begin{bmatrix} \tilde{A}_{11} + \tilde{B}_{11}\tilde{F}_{11} & \tilde{A}_{12} + \tilde{B}_{11}\tilde{F}_{12} & \tilde{A}_{13} + \tilde{B}_{11}\tilde{F}_{13} & \tilde{A}_{14} + \tilde{B}_{11}\tilde{F}_{14} \\ 0 & \tilde{A}_{22} & \tilde{A}_{23} & \tilde{A}_{24} \\ 0 & 0 & \tilde{A}_{33} + \tilde{B}_{32}\tilde{F}_{23} & \tilde{A}_{34} + \tilde{B}_{32}\tilde{F}_{24} \\ 0 & 0 & \tilde{A}_{43} & \tilde{A}_{44} \end{bmatrix} \quad (5.38)$$

where

$$\tilde{F} = \begin{bmatrix} \tilde{F}_{11} & \tilde{F}_{12} & \tilde{F}_{13} & \tilde{F}_{14} \\ \tilde{F}_{21} & \tilde{F}_{22} & \tilde{F}_{23} & \tilde{F}_{24} \end{bmatrix}, \quad \tilde{A} := T^{-1}AT, \quad \tilde{B} := T^{-1}BU, \quad \text{and} \quad \tilde{F} := U^{-1}FT.$$

Note that \tilde{A}_{22} cannot be altered by any linear state feedback satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$, that is, the (2,2)-block of $\tilde{A} + \tilde{B}\tilde{F}$ remains \tilde{A}_{22} for any real \tilde{F} satisfying

$$(\tilde{A} + \tilde{B}\tilde{F})\text{im} \begin{bmatrix} I_{n_1} & 0 \\ 0 & I_{n_2} \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \subset \text{im} \begin{bmatrix} I_{n_1} & 0 \\ 0 & I_{n_2} \\ 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad (5.39)$$

where 0's are zero matrices with suitable dimensions. Thus,

Lemma 5.14:

$$\sigma((A + BF)|_{\mathcal{V}/\mathcal{V}_{reach}(\mathcal{V})}) = \sigma(\tilde{A}_{22}) \quad (5.40)$$

(i.e., fixed) for all F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$. Here, $(A + BF)|_{\mathcal{V}/\mathcal{V}_{reach}(\mathcal{V})}$ is the induced map of $A + BF$ restricted to $\mathcal{V}/\mathcal{V}_{reach}(\mathcal{V})$.

Note also that by construction the pair (A_{11}, B_{11}) is reachable. Hence, by Theorem 5.2, we have

Lemma 5.15:

$\sigma((A + BF)|_{\mathcal{V}_{reach}(\mathcal{V})}) = \sigma(\tilde{A}_{11} + \tilde{B}_{11}\tilde{F}_{11})$ can be freely assigned by an appropriate choice of F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$ (or \tilde{F} satisfying Equation 5.39).

The eigenvalues of $(A + BF)|_{\mathcal{V}/\mathcal{V}_{reach}(\mathcal{V})}$ are called the *internal unassignable eigenvalues* of \mathcal{V} . The internal unassignable eigenvalues of $\mathcal{V}_{\max}(A, \text{im } B, \ker C)$ are called *invariant zero's* of the system $\Sigma := [A, B, C]$ (or triple (A, B, C)), which are equal to the transmission zero's of $C(sI - A)^{-1}B$ if (A, B) is reachable and (A, C) is observable. Table 5.1 shows how freely the eigenvalues can be assigned for $A + BF$ by choosing F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$ given an $(A, \text{im } B)$ -controlled invariant. Theorems 5.11 and 5.12 given below easily follow from the above lemmas and Table 5.1.

Theorem 5.11:

An $(A, \text{im } B)$ -controlled invariant \mathcal{V} is internally stabilizable if and only if all its internal unassignable eigenvalues have negative real parts.

TABLE 5.1 Spectral Assignability of $(A + BF)|_{\mathcal{W}}$, Given an $(A, \text{im } B)$ -Controlled Invariant \mathcal{V}

\mathcal{W}	$\mathcal{X}/(\mathcal{V} + \mathcal{V}_{reach})$	$(\mathcal{V} + \mathcal{V}_{reach})/\mathcal{V}$	$\mathcal{V}/\mathcal{V}_{reach}(\mathcal{V})$	$\mathcal{V}_{reach}(\mathcal{V})$
Assignability	Fixed	Free	Fixed	Free

Note: The table indicates that $\sigma((A + BF)|_{\mathcal{X}/(\mathcal{V} + \mathcal{V}_{reach})})$ is fixed for all F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$, $\sigma((A + BF)|_{(\mathcal{V} + \mathcal{V}_{reach})/\mathcal{V}})$ is freely assignable (up to a symmetric set) by choosing an appropriate F satisfying $(A + BF)\mathcal{V} \subset \mathcal{V}$, and so on.

Theorem 5.12:

An $(A, \text{im } B)$ -controlled invariant \mathcal{V} is externally stabilizable if and only if $\mathcal{V} + \mathcal{V}_{reach}$ is externally stable.

Remark

$\mathcal{V} + \mathcal{V}_{reach}$ is A -invariant since $A(\mathcal{V} + \mathcal{V}_{reach}) = A\mathcal{V} + A\mathcal{V}_{reach} = \mathcal{V} + \text{im } B + \mathcal{V}_{reach} = \mathcal{V} + \mathcal{V}_{reach}$.

Lemma 5.16:

If the pair (A, B) is stabilizable, then all $(A, \text{im } B)$ -controlled invariants are externally stabilizable.

Remark

The matrix F can be defined independently on \mathcal{V} and on \mathcal{X}/\mathcal{V} .

Dual to the above internal and external stabilizabilities for a controlled invariant are, respectively, external and internal stabilizabilities for a conditioned invariant which will be defined below.

Definition 5.8:

An $(A, \ker C)$ -conditioned invariant \mathcal{S} is said to be externally stabilizable if there exists an $n \times p$ real matrix G satisfying $(A + GC)\mathcal{S} \subset \mathcal{S}$ and $(A + GC)|_{\mathcal{X}/\mathcal{S}}$ is stable.

Definition 5.9:

An $(A, \ker C)$ -conditioned invariant \mathcal{S} is said to be internally stabilizable if there exists an $n \times p$ real matrix G satisfying $(A + GC)\mathcal{S} \subset \mathcal{S}$ and $(A + GC)|_{\mathcal{S}}$ is stable.

How freely the eigenvalues can be chosen for $A + GC$ by means of G is given in Table 5.2, from which necessary and sufficient conditions of the stabilizabilities follow easily. (See Basile and Marro (1992) for further discussions on the topic of the internal and external stabilizabilities.)

5.8 Disturbance Localization (or Decoupling) Problem

One of the first problems to which the geometric notions were applied is the problem of disturbance localization (or disturbance decoupling). As we see below, the solution to the problem is remarkably simple in geometric terms. The solution and analysis of this problem can also be used to solve other

TABLE 5.2 Spectral Assignability of $(A + GC) |_{\mathcal{W}}$, Given an $(A, \ker C)$ -Conditioned Invariant \mathcal{S}

\mathcal{W}	$\mathcal{X}/\mathcal{S}_{sh,max}(A, \ker C, \mathcal{S})$	$\mathcal{S}_{sh,max}(A, \ker C, \mathcal{S})/\mathcal{S}$	$\mathcal{S}/\mathcal{S} \cap \mathcal{S}_{unobs}$	$\mathcal{S} \cap \mathcal{S}_{unobs}$
Assignability	Free	Fixed	Free	Fixed

Note: The table indicates that $\sigma((A + BF)|_{\mathcal{X}/\mathcal{S}_{sh,max}(A, \ker C, \mathcal{S})})$ is freely assignable (up to a symmetric set) by choosing an appropriate G satisfying $(A + GC)\mathcal{S} \subset \mathcal{S}$, $\sigma((A + BF)|_{\mathcal{S}_{sh,max}(A, \ker C, \mathcal{S})/\mathcal{S}})$ is fixed for all G satisfying $(A + GC)\mathcal{S} \subset \mathcal{S}$, and so on.

more involved problems (e.g., model following, decoupling, and disturbance decoupling in decentralized systems).

We will be concerned with a time-invariant linear control system $\Sigma_d := [A, B, D, C]$ described by

$$\dot{x}(t) = Ax(t) + Bu(t) + Dw(t), \quad x(0) = x_o, \quad (5.41)$$

$$y(t) = Cx(t), \quad (5.42)$$

where the column vectors $x(t) \in \mathcal{X} := R^n$, $u(t) \in R^m$, $y(t) \in R^p$, and $w(t) \in R^{m_d}$ are, respectively, the state, input, output, and unknown disturbance of the system at time $t \geq 0$, the vector $x_o \in R^n$ is the initial state and the real matrices A , B , C , and D have consistent dimensions. We assume that $u(t)$ and $w(t)$ are piecewise continuous. Here, $w(t)$ is called a “disturbance” and it can neither be measured nor controlled. The above notation will be standard in the sequel. If we apply the linear state feedback control law

$$u(t) = Fx(t) \quad (5.43)$$

to the above system, we obtain the state equation

$$\dot{x}(t) = (A + BF)x(t) + Dw(t), \quad x(0) = x_o, \quad (5.44)$$

where F is an $m \times n$ real matrix. Our problem is to choose the control law (Equation 5.43) so that the disturbance does not affect the output in the resulting closed-loop system given by Equations 5.44 and 5.42, that is, so that $y(t) = 0$ for all $t \geq 0$ for any $w(t)$, $t \geq 0$, provided $x(0) = x_o = 0$. By virtue of Theorem 5.1, note that at any time $t \geq 0$ all the possible states due to all the admissible $w(\tau)$, $0 \leq \tau < t$ are characterized by

$$\mathcal{R}(A + BF, \text{im } D) := \text{im } D + (A + BF) \text{im } D + \cdots + (A + BF)^{n-1} \text{im } D. \quad (5.45)$$

Therefore, in algebraic terms, the above problem can be restated as

Problem 5.1: Disturbance Localization (or Disturbance Decoupling) Problem

Given $n \times n$, $n \times m$, $n \times m_d$, and $p \times n$ real matrices A , B , D , and C , find an $m \times n$ real matrix F satisfying

$$\mathcal{R}(A + BF, \text{im } D) \subset \ker C. \quad (5.46)$$

It is not always possible to find F satisfying Inclusion 5.46. The following theorem gives the necessary and sufficient condition for the existence of such an F in terms of given matrices. (See Basile and Marro (1992, Section 4.2) and Wonham (1985, Section 4.3).)

Theorem 5.13:

There exists an $m \times n$ real matrix F satisfying Inclusion 5.46 if and only if

$$\text{im } D \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C) \quad (5.47)$$

Proof. [Only if part.] Trivially, $\text{im } D \subset \mathcal{R}(A + BF, \text{im } D)$. Since $\mathcal{R}(A + BF, \text{im } D)$ is an $(A + BF)$ -invariant, it is an $(A, \text{im } B)$ -controlled invariant in view of Theorem 5.5, and, by assumption, is contained in $\ker C$. Therefore, $\mathcal{R}(A + BF, \text{im } D) \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C)$. Thus, Equation 5.47 holds.

[If part] Let F be such that

$$(A + BF)\mathcal{V}_{\max}(A, \text{im } B, \ker C) \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C). \quad (5.48)$$

Inclusion 5.47 implies, consecutively, $(A + BF)\text{im } D \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C), \dots, (A + BF)^{n-1}\text{im } D \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C)$. Therefore, $\mathcal{R}(A + BF, \text{im } D) \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C) \subset \ker C$. QED

Remark

Let $n^* := \dim \mathcal{V}_{\max}(A, \text{im } B, \ker C)$, and let T be a real nonsingular matrix for which the first n^* columns form a basis of $\mathcal{V}_{\max}(A, \text{im } B, \ker C)$. Then, Inclusion 5.47 means that, with an $m \times n$ real matrix F satisfying Inclusion 5.48, the coordinate transformation $x(t) = T\tilde{x}(t)$ transforms Equations 5.44 and 5.42 to

$$\begin{bmatrix} \dot{\tilde{x}}_1(t) \\ \dot{\tilde{x}}_2(t) \end{bmatrix} = \begin{bmatrix} \tilde{A}_{11} + \tilde{B}_1\tilde{F}_1 & \tilde{A}_{12} + \tilde{B}_1\tilde{F}_2 \\ 0 & \tilde{A}_{22} + \tilde{B}_2\tilde{F}_2 \end{bmatrix} \begin{bmatrix} \tilde{x}_1(t) \\ \tilde{x}_2(t) \end{bmatrix} + \begin{bmatrix} \tilde{D}_1 \\ 0 \end{bmatrix} w(t) \quad (5.49)$$

and

$$y(t) = \begin{bmatrix} 0 & \tilde{C}_2 \end{bmatrix} \begin{bmatrix} \tilde{x}_1(t) \\ \tilde{x}_2(t) \end{bmatrix}, \quad (5.50)$$

where $[\tilde{F}_1 \ \tilde{F}_2] = FT$. Clearly, $w(t)$ does not affect $\tilde{x}_2(t)$; hence, no effect on $y(t)$.

5.9 Disturbance Localization with Stability

In the previous section, the disturbance localization problem without additional constraints was solved. In this section, the problem is examined with an important constraint of stability. For the system $\Sigma_d := [A, B, D, C]$ described by Equations 5.44 and 5.42, or for the matrices A, B, D , and C , we have the following.

Problem 5.2: Disturbance Localization Problem with Stability

Find (if possible) an $m \times n$ real matrix F , such that (1) Inclusion 5.46 holds and (2) $A + BF$ is stable, that is, the eigenvalues of $A + BF$ have negative real parts.

Trivially, for condition (2) to be true, it is necessary that the pair (A, B) is stabilizable. We have (see Basile and Marro, 1992, Section 4.2)

Theorem 5.14:

Let A, B, D , and C be as before, and assume that the pair (A, B) is stabilizable. Then, the disturbance localization problem with stability has a solution if and only if (1) Inclusion 5.47 holds and (2) $\mathcal{V}_{sb, \min}(A, \text{im } B + \text{im } D, \ker C)$ is an internally stabilizable $(A, \text{im } B)$ -controlled invariant.

Remark

An alternative condition can be found in Wonham (1985, Theorem 5.8).

We will first prove that the above two conditions are sufficient. This part of the proof leads to a constructive procedure to find a matrix F which solves the problem.

Sufficiency proof of Theorem 5.14. The condition (2) means that there is a real matrix F , such that $(A + BF)\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C) \subset \mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)$ and $\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)$ is internally stable. Since the pair (A, B) is stabilizable, $\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)$ is externally stabilizable by virtue of Lemma 5.16. Since the internal stability of $\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)$ (with respect to $A + BF$) is determined by $F|_{\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)}$ and since the external stability depends only on $F|_{\mathcal{X}/\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)}$, the matrix F can be chosen so that the controlled invariant is both internally and externally stable, hence, $A + BF$ is stable. It remains to show that Equation 5.46 holds. Since $\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)$ is self-bounded with respect to $\ker C$, and since Equation 5.47 holds, we have

$$\begin{aligned} \mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C) &\supset (\text{im } B + \text{im } D) \cap \mathcal{V}_{\max}(A, \text{im } B + \text{im } D, \ker C) \\ &\supset (\text{im } B + \text{im } D) \cap \mathcal{V}_{\max}(A, \text{im } B, \ker C) \\ &= (\text{im } B \cap \mathcal{V}_{\max}(A, \text{im } B, \ker C)) + \text{im } D \supset \text{im } D. \end{aligned}$$

This inclusion and the $(A + BF)$ -invariance of $\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)$ imply $\mathcal{R}(A + BF, \text{im } D) \subset \mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C) \subset \ker C$. QED

Remark

In the remark after Theorem 5.13, redefine $n^* := \dim \mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)$. Then, $\sigma(A + BF|_{\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)}) = \sigma(\tilde{A}_{11} + \tilde{B}_1 \tilde{F}_1)$ and $\sigma(A + BF|_{\mathcal{X}/\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)}) = \sigma(\tilde{A}_{22} + \tilde{B}_2 \tilde{F}_2)$. Therefore, we choose \tilde{F}_1 and \tilde{F}_2 so that $\tilde{A}_{11} + \tilde{B}_1 \tilde{F}_1$ and $\tilde{A}_{22} + \tilde{B}_2 \tilde{F}_2$ are stable and $\tilde{A}_{21} + \tilde{B}_2 \tilde{F}_1 = 0$. Then, the desired F is given by $F = [\tilde{F}_1 \quad \tilde{F}_2] T^{-1}$.

To prove the necessity we use the following

Lemma 5.17:

If there exists an internally stabilizable $(A, \text{im } B)$ -controlled invariant \mathcal{V} satisfying $\mathcal{V} \subset \ker C$ and $\text{im } D \subset \mathcal{V}$, then $\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)$ is an internally stabilizable $(A, \text{im } B)$ -controlled invariant, that is, it is $(A + BF)$ -invariant and $A + BF|_{\mathcal{V}_{sb,\min}(A, \text{im } B + \text{im } D, \ker C)}$ is stable for some real matrix F .

Proof. The lemma follows from Schumacher (1983, Propositions 3.1 and 4.1). It is also an immediate consequence of Lemma 4.2.1 in Basile and Marro (1992).

Necessity proof of Theorem 5.14. Suppose that the problem has a solution, that is, there is a real matrix F such that $A + BF$ is stable and $\mathcal{V} := \mathcal{R}(A + BF, \text{im } D) \subset \ker C$. Clearly, $\text{im } D \subset \mathcal{V}$. Also, \mathcal{V} is an $(A + BF)$ -invariant contained in $\ker C$. Hence, $\mathcal{V} \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C)$. Therefore, condition (i) holds. To show condition (ii), note that \mathcal{V} is internally (and externally) stable with respect to $A + BF$, $\mathcal{V} \subset \ker C$, and $\text{im } D \subset \mathcal{V}$. Condition (ii) follows by Lemma 5.17. QED

5.10 Disturbance Localization by Dynamic Compensator

In the previous section, we used the (static) state-feedback control law $u(t) = Fx(t)$ to achieve disturbance rejection and stability. In this section, we use measurement output feedback with a dynamic compensator Σ_c placed in the feedback loop to achieve the same objectives.

More specifically, we are concerned with the system $\Sigma_{dm} := [A, B, D, C, C_{meas}]$ described by

$$\dot{x}(t) = Ax(t) + Bu(t) + Dw(t), \quad x(0) = x_0 \quad (5.41)$$

$$y(t) = Cx(t), \quad (5.42)$$

$$y_{meas}(t) = C_{meas}x(t), \quad (5.51)$$

where $y_{meas}(t) \in \mathcal{Y}_{meas} := R^{p_m}$ stands for a measurement output and C_{meas} is a $p_m \times n$ real matrix. Define the dynamic compensator $\Sigma_c := [A_c, B_c, C_c, K_c]$ by

$$\dot{x}_c(t) = A_c x_c(t) + B_c y_{meas}(t), \quad x_c(0) = x_{co}, \quad (5.52)$$

$$u(t) = C_c x_c(t) + K_c y_{meas}(t), \quad (5.53)$$

where $x_c(t)$, $x_{co} \in \mathcal{X}_c := R^{n_c}$, and A_c, B_c, C_c , and K_c are, respectively, $n_c \times n_c$, $n_c \times p_m$, $p_m \times n_c$, $p_m \times n_c$ real matrices. We wish to determine A_c, B_c, C_c , and K_c such that (1) $y(t) = 0$ for all $t \geq 0$ for any (admissible) $w(t)$, $t \geq 0$ provided $x_o = 0$ and $x_{co} = 0$, and (2) $x(t)$ and $x_c(t)$ converges to zero as $t \rightarrow +\infty$ for all $x_o \in \mathcal{X}$ and $x_{co} \in \mathcal{X}_c$. For this, it is convenient to introduce the *extended state* defined by

$$\hat{x} := \begin{bmatrix} x \\ x_c \end{bmatrix} \in \hat{\mathcal{X}} := \mathcal{X} \times \mathcal{X}_c = R^{n+n_c},$$

where $x \in \mathcal{X}$ and $x_c \in \mathcal{X}_c$. Then, the overall system (including Σ_{dm} and Σ_c) can be rewritten as

$$\dot{\hat{x}}(t) = \hat{A}\hat{x}(t) + \hat{D}w(t), \quad \hat{x}(0) = \hat{x}_o, \quad (5.54)$$

$$y(t) = \hat{C}\hat{x}(t), \quad (5.55)$$

where $\hat{x}_o := [x'_o \quad x'_{co}]'$ and the matrices are defined by

$$\hat{A} := \begin{bmatrix} A + BK_c C_{meas} & BC_c \\ B_c C_{meas} & A_c \end{bmatrix}, \quad \hat{D} := \begin{bmatrix} D \\ 0 \end{bmatrix}, \quad \hat{C} := [C \quad 0]. \quad (5.56)$$

Remark

Define

$$\hat{A}_o := \begin{bmatrix} A & 0 \\ 0 & 0 \end{bmatrix}, \quad \hat{B}_o := \begin{bmatrix} B & 0 \\ 0 & I_{n_c} \end{bmatrix}, \quad \hat{C}_{meas} := \begin{bmatrix} C_{meas} & 0 \\ 0 & I_{n_c} \end{bmatrix},$$

$$\hat{K}_c := \begin{bmatrix} K_c & C_c \\ B_c & A_c \end{bmatrix}. \quad (5.57)$$

Then, it is easy to verify that

$$\hat{A} = \hat{A}_o + \hat{B}_o \hat{K}_c \hat{C}_{meas}. \quad (5.58)$$

(See Basile and Marro (1992, Section 5.1) and Willems and Commault (1981).)

Remark

An important special case of Σ_c is a state estimate feedback through an observer. More specifically, let L_1 and L_2 satisfy

$$L_1 C_{meas} + L_2 = I_n, \quad (5.59)$$

and consider an asymptotic observer (or state estimator) described by

$$\dot{x}_c(t) = Ax_c(t) + Bu(t) + G\{C_{meas}x_c(t) - y_{meas}(t)\}, \quad x_c(0) = x_{co}, \quad (5.60)$$

$$x_{est}(t) = L_2 x_c(t) + L_1 y_{meas}(t), \quad (5.61)$$

where $x_{est}(t) \in R^n$ is an “estimate” of $x(t)$ (under proper conditions) and G, L_1 , and L_2 are real matrices with appropriate dimensions. If we use a state estimate feedback law

$$u(t) = Fx_{est}(t) \quad (5.62)$$

with an $m \times n$ real matrix F , then the overall system reduces to Equations 5.54 and 5.55, where \hat{A}, \hat{D} , and \hat{C} are given, instead of Equation 5.56, by

$$\hat{A} := \begin{bmatrix} A + BFL_1C_{meas} & BFL_2 \\ (BFL_1 - G)C_{meas} & A + BFL_2 + GC_{meas} \end{bmatrix}, \quad \hat{D} := \begin{bmatrix} D \\ 0 \end{bmatrix}, \quad \hat{C} := [C \quad 0]. \quad (5.63)$$

It should also be noted that, if we apply the coordinate transformation

$$\hat{x} = \begin{bmatrix} I_n & 0 \\ I_n & -I_n \end{bmatrix} \bar{x},$$

Equations 5.54 and 5.63 can be rewritten as

$$\dot{\hat{x}}(t) = \bar{A}\bar{x}(t) + \bar{D}w(t), \quad \bar{x}(0) = \bar{x}_0, \quad (5.64)$$

where

$$\bar{A} := \begin{bmatrix} A + BF & -BFL_2 \\ 0 & A + GC_{meas} \end{bmatrix}, \quad \bar{D} := \begin{bmatrix} D \\ D \end{bmatrix}, \quad (5.65)$$

from which it is apparent that F and G can be selected independently (based on Theorem 5.2 and its dual) to make \bar{A} stable, that is, the separation property holds. (See Basile and Marro (1992, Sections 3.4.2, 5.1.2) for further discussions.)

With the above notation the problem can be restated in geometric terms as:

Problem 5.3: Disturbance Localization Problem with Stability by Dynamic Compensator

Find (if possible) a number $n_c (= \dim \mathcal{X}_c)$ and real matrices A_c, B_c, C_c , and K_c of dimensions $n_c \times n_c, n_c \times p_m, m \times n_c$, and $m \times p_m$, respectively, such that

$$(i) \quad \mathcal{R}(\hat{A}, \text{im } \hat{D}) \subset \ker \hat{C}, \quad (5.66)$$

and

$$(ii) \quad \hat{A} \text{ is stable.} \quad (5.67)$$

Remark

Noting that $\mathcal{R}(\hat{A}, \text{im } \hat{D})$ is the minimum \hat{A} -invariant containing $\text{im } \hat{D}$, it is easy to see that condition (i) is equivalent to the following condition:

(i)' there is an \hat{A} -invariant \hat{V} satisfying

$$\text{im } \hat{D} \subset \hat{V} \subset \ker \hat{C}. \quad (5.68)$$

The conditions under which the above problem is solvable are given by the following theorems.

Theorem 5.15:

Let (A, B) be stabilizable, and also let (A, C_{meas}) be detectable. Then, the disturbance localization problem with stability by dynamic compensator has a solution if and only if there exists an internally stabilizable

$(A, \text{im } B)$ -controlled invariant \mathcal{V} and an externally stabilizable $(A, \ker C_{meas})$ -conditioned invariant \mathcal{S} satisfying the condition

$$\text{im } D \subset \mathcal{S} \subset \mathcal{V} \subset \ker C. \quad (5.69)$$

Proof. See Basile and Marro (1992, Section 5.2) and Willems and Commault (1981).

QED

The above condition is an existence condition and it is not convenient for testing. The following theorem (see Theorem 5.2–2 in Basile and Marro, 1992) gives constructive conditions and they can be readily tested.

Theorem 5.16:

Assume that (A, B) is stabilizable and (A, C_{meas}) is detectable. The disturbance localization problem with stability by dynamic compensator has a solution if and only if the following conditions hold:

i.

$$\mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C), \quad (5.70)$$

- ii. $\mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) + \mathcal{V}_{\max}(A, \text{im } D, \ker C \cap \ker C_{meas})$ is an externally stabilizable $(A, \ker C_{meas})$ -conditioned invariant
- iii. $\mathcal{V}_{sb, \min}(A, \text{im } B + \text{im } D, \ker C) + \mathcal{V}_{\max}(A, \text{im } D, \ker C \cap \ker C_{meas})$ is an internally stabilizable $(A, \text{im } B)$ -controlled invariant.

Remark

The subspaces $\mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) + \mathcal{V}_{\max}(A, \text{im } D, \ker C \cap \ker C_{meas})$ and $\mathcal{V}_{sb, \min}(A, \text{im } B + \text{im } D, \ker C) + \mathcal{V}_{\max}(A, \text{im } D, \ker C \cap \ker C_{meas})$ defined above are, respectively, an $(A, \ker C_{meas})$ -conditioned invariant and an $(A, \text{im } B)$ -controlled invariant. (See Lemma 5.18 at the end of this section for the proof the above remark.)

Proof of Necessity of Theorem 5.16. See Basile and Marro (1992, Section 5.2) and Basile et al. (1986).

QED

Proof of Sufficiency for Theorem 5.16. Let

$$\mathcal{S} := \mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) + \mathcal{V}_{\max}(A, \text{im } D, \ker C \cap \ker C_{meas}), \quad (5.71)$$

$$\mathcal{V} := \mathcal{V}_{sb, \min}(A, \text{im } B + \text{im } D, \ker C) + \mathcal{V}_{\max}(A, \text{im } D, \ker C \cap \ker C_{meas}). \quad (5.72)$$

We will show that the above \mathcal{S} and \mathcal{V} satisfy the conditions of Theorem 5.15. By assumptions (ii) and (iii), \mathcal{S} is externally stabilizable and \mathcal{V} is internally stabilizable. By Inclusion 5.70 and Equation 5.71, trivially $\text{im } D \subset \mathcal{S}$. By Equation 5.72, $\mathcal{V} \subset \ker C$ trivially also. To see the validity of the middle inclusion of Inclusion 5.69, that is, $\mathcal{S} \subset \mathcal{V}$, it suffices to show $\mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) \subset \mathcal{V}_{sb, \min}(A, \text{im } B + \text{im } D, \ker C)$. For this, first observe that, by Inclusion 5.70, we have $\text{im } D \subset \mathcal{V}_{\max}(A, \text{im } B, \ker C)$, which implies $\mathcal{V}_{\max}(A, \text{im } B + \text{im } D, \ker C) = \mathcal{V}_{\max}(A, \text{im } B, \ker C)$ since trivially $\mathcal{V}_{\max}(A, \text{im } B + \text{im } D, \ker C) \supset \mathcal{V}_{\max}(A, \text{im } B, \ker C)$ and $A\mathcal{V}_{\max}(A, \text{im } B + \text{im } D, \ker C) \subset \mathcal{V}_{\max}(A, \text{im } B + \text{im } D, \ker C) + \text{im } B + \text{im } D = \mathcal{V}_{\max}(A, \text{im } B + \text{im } D, \ker C) + \text{im } B$. In addition, Inclusion 5.70 implies $\mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) \subset \ker C$, which leads to $\mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) = \mathcal{S}_{\min}(A, \ker C_{meas} \cap \ker C, \text{im } D) \subset \mathcal{S}_{\min}(A, \ker C, \text{im } D) \subset \mathcal{S}_{\min}(A, \ker C, \text{im } B + \text{im } D)$.

By using Inclusion 5.70, the above facts, and Theorem 5.7, we have

$$\begin{aligned} \mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) &\subset \mathcal{V}_{\max}(A, \text{im } B, \ker C) \cap \mathcal{S}_{\min}(A, \ker C, \text{im } B + \text{im } D) \\ &= \mathcal{V}_{\max}(A, \text{im } B + \text{im } D, \ker C) \cap \mathcal{S}_{\min}(A, \ker C, \text{im } B + \text{im } D) \\ &= \mathcal{V}_{sb, \min}(A, \text{im } B + \text{im } D, \ker C). \end{aligned} \quad (5.73)$$

Thus, Inclusion 5.69 holds. QED

Procedure for Finding A_c , B_c , C_c , and K_c

Define \mathcal{S} and \mathcal{V} by Equations 5.71 and 5.72. Let \mathcal{L} be a subspace of R^n satisfying

$$\mathcal{L} \oplus (\mathcal{S} \cap \ker C_{meas}) = \mathcal{S}. \quad (5.74)$$

Clearly,

$$\mathcal{L} \cap \ker C_{meas} = \{0\}. \quad (5.75)$$

Now let \mathcal{L}_{comp} be a subspace satisfying $\mathcal{L} \oplus \mathcal{L}_{comp} = R^n$ and $\mathcal{L}_{comp} \supset \ker C_{meas}$, and define the projection L_2 on \mathcal{L}_{comp} along \mathcal{L} . Select L_1 such that

$$L_1 C_{meas} = I_n - L_2. \quad (5.76)$$

Such an L_1 exists since $\ker(I_n - L_2) = \mathcal{L}_{comp} \supset \ker C_{meas}$.

Choose real matrices F and G so that

$$(A + BF)\mathcal{V} \subset \mathcal{V}, \quad (5.77)$$

$$(A + GC_{meas})\mathcal{S} \subset \mathcal{S}, \quad (5.78)$$

and $A + BF$ and $A + GC_{meas}$ are stable. Then, use Equations 5.60 through 5.62 as a dynamic compensator, or equivalently, set $A_c := A + BFL_2 + GC_{meas}$, $B_c := BFL_1 - G$, $C_c := FL_2$ and $K_c := FL_1$ in Equations 5.52 and 5.53. From Equation 5.65, the overall system is clearly stable (and so is \hat{A}). It can also be shown (see Basile and Marro, 1992; Lemmas 5.1.1 and 5.1.2, and Section 5.2.1) that

$$\hat{\mathcal{V}} := \left\{ \begin{bmatrix} v \\ v - s \end{bmatrix} : v \in \mathcal{V}, s \in \mathcal{S} \right\}$$

is \hat{A} -invariant and satisfies Equation 5.68.

Lemma 5.18:

The subspaces \mathcal{S} defined by Equations 5.71 is an $(A, \ker C_{meas})$ -conditioned invariant; and, if Inclusion 5.70 holds, then \mathcal{V} defined by Equation 5.72 is an $(A, \text{im } B)$ -controlled invariant.

Proof. Since $\mathcal{V}_{\max}(A, \text{im } D, \ker C \cap \ker C_{meas}) \subset \ker C_{meas}$, by the last equality of Lemma 5.2 we have $\mathcal{S} \cap \ker C_{meas} = \mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) \cap \ker C_{meas} + \mathcal{V}_{\max}(A, \text{im } D, \ker C \cap \ker C_{meas})$. Then, it is easy to see $A(\mathcal{S} \cap \ker C_{meas}) \subset \mathcal{S} + \text{im } D$. But, $\text{im } D \subset \mathcal{S}_{\min}(A, \ker C_{meas}, \text{im } D) \subset \mathcal{S}$. Thus, $A(\mathcal{S} \cap \ker C_{meas}) \subset \mathcal{S}$. To prove that \mathcal{V} is an $(A, \text{im } B)$ -controlled invariant, first it is easy to show $A\mathcal{V} \subset \mathcal{V} + \text{im } B + \text{im } D$. But, by Inclusion 5.73, $\text{im } D \subset \mathcal{V}_{sb, \min}(A, \text{im } B + \text{im } D, \ker C) \subset \mathcal{V}$. Thus, $A\mathcal{V} \subset \mathcal{V} + \text{im } B$. QED

5.11 Conclusion

An introduction to the geometric method (often called geometric approach) has been provided. The basic tools have been described and applied to the disturbance localization (also called disturbance decoupling) problems to demonstrate the use of the tools. Numerous research articles were published on the subject for the last 40 years. Some are included in the list of references in this chapter and a great many others can be found in the books and articles already referenced in this chapter. Reports for practical applications can also be found in the literature, for example, Takamatsu et al. (1979); Massoumnia et al. (1989); Prattichizzott et al. (1997); Barbagli et al. (1998); and Marro and Zattoni (2004). This chapter has dealt with continuous-time systems. Many articles in the literature treat discrete-time systems, for example, Akashi and Imai (1979), Hamano and Basile (1983), and Marro and Zattoni (2006).

The notion of controlled invariant subspaces has been extended to “almost” controlled invariant subspaces, to which the state trajectory can stay arbitrary close by a suitable choice of inputs, possibly with high-gain feedback (Willems, 1981). The theory involves use of distributions for inputs. The dual notion of “almost” conditionally invariant subspaces has also been introduced (Willems, 1982). The geometric approach has also been extended to more general or different classes of linear systems, for example, 2D systems (Conte and Perdon, 1988), systems over a ring including delay differential systems (Conte and Perdon, 1998), and periodic systems (Longhi and Monteriù, 2007). The geometric notions for linear systems have been extended to nonlinear systems (controlled invariant distributions, in particular) using differential geometric tools and problems such as disturbance localization and output decoupling have been studied in the literature (see Nijmeijer and van der Schaft (1990), Isidori (1995), and Mattone and De Luca (2006), for instance). A 40-year historical perspective of the development of geometric methods for linear and nonlinear systems with an insight into the future can be found in Marro (2008).

6.1 Introduction

For control system design, it is useful to characterize multi-input, multi-output, time-invariant linear systems in terms of their transfer function matrices. The transfer function matrix of a real m -input, p -output continuous-time system is a $(p \times m)$ matrix-valued function $G(s)$, where s is the Laplace transform variable; the corresponding object in discrete time is a $(p \times m)$ matrix-valued function $G(z)$, where z is the z -transform variable. Things are particularly interesting when $G(s)$ or $G(z)$ is a *proper rational matrix* function of s or z , that is, when every entry in $G(s)$ or $G(z)$ is a ratio of two real polynomials in s or z whose denominator's degree is at least as large as its numerator's degree. In this case, the system has state space realizations of the form

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t)\end{aligned}$$

or

$$\begin{aligned}x(k+1) &= Ax(k) + Bu(k) \\ y(k) &= Cx(k) + Du(k),\end{aligned}$$

where the state vector x takes values in \mathbf{R}^n . Any such realization defines a decomposition $G(s) = C(sI_n - A)^{-1}B + D$ or $G(z) = C(zI_n - A)^{-1}B + D$ for the system's transfer function matrix. A realization is minimal when the state vector dimension n is as small as it can be; the *MacMillan degree* $\delta_M(G(s))$ or $\delta_M(G(z))$ is the value of n in a minimal realization. A system's MacMillan degree is a natural candidate for the "order of the system."

It is not easy to construct minimal realizations for a multi-input, multi-output system with an arbitrary proper rational transfer function matrix; even determining such a system's MacMillan degree requires some effort. Circumstances are simpler for single-input, single-output (SISO) systems. Consider, for example, a real SISO continuous-time system with proper rational transfer function $g(s)$. We can express

$g(s)$ as a ratio

$$g(s) = \frac{p(s)}{q(s)}, \quad (6.1)$$

where $q(s)$ is a polynomial of degree n , $p(s)$ is a polynomial of degree at most n , and $p(s)$ and $q(s)$ are coprime, which is to say that their only common factors are nonzero real numbers. The coprimeness of $p(s)$ and $q(s)$ endows the fractional representation Equation 6.1 with a kind of irreducibility; furthermore, Equation 6.1 is “minimal” in the sense that any other factorization $g(s) = \hat{p}(s)/\hat{q}(s)$ features a denominator polynomial $\hat{q}(s)$ whose degree is at least n .

The MacMillan degree $\delta_M(g(s))$ is precisely n , the degree of $q(s)$ in Equation 6.1. To see that $n \leq \delta_M(g(s))$, suppose (A, B, C, D) are the matrices in a minimal realization for $g(s)$. Set $\hat{n} = \delta_M(g(s))$, so A is $(\hat{n} \times \hat{n})$. The matrix $(sI_{\hat{n}} - A)^{-1}$ has rational entries whose denominator polynomials have degrees at most \hat{n} . Multiplying on the left by \hat{C} and on the right by \hat{B} and finally adding \hat{D} results in a rational function whose denominator degree in lowest terms is at most \hat{n} . This rational function, however, is $g(s)$, whose lowest-terms denominator degree is n , whence it follows that $n \leq \hat{n}$.

To finish showing that $\delta_M(g(s)) = n$, it suffices to construct a realization whose A -matrix is $(n \times n)$. There are many ways to do this; here is one. Begin by setting $d = \lim_{|s| \rightarrow \infty} g(s)$; d is well-defined because $g(s)$ is proper. Then

$$g(s) = \frac{\tilde{p}(s)}{q(s)} + d,$$

where the degree of $\tilde{p}(s)$ is at most $n - 1$. Cancel the coefficient of s^n from $q(s)$ and $\tilde{p}(s)$ so that

$$q(s) = s^n + q_1 s^{n-1} + \cdots + q_{n-1} s + q_n$$

and

$$\tilde{p}(s) = \gamma_1 s^{n-1} + \gamma_2 s^{n-2} + \cdots + \gamma_{n-1} s + \gamma_n.$$

It is not hard to verify that $g(s) = C(sI_n - A)^{-1}B + D$ when

$$A = \begin{bmatrix} 0 & 1 & 0 & \cdot & \cdot & \cdot & 0 \\ 0 & 0 & 1 & 0 & \cdot & \cdot & 0 \\ 0 & 0 & 0 & 1 & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 1 & 0 \\ 0 & 0 & \cdot & \cdot & \cdot & 0 & 1 \\ -q_n & -q_{n-1} & \cdot & \cdot & \cdot & -q_2 & -q_1 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 0 \\ \cdot \\ \cdot \\ \cdot \\ 0 \\ 1 \end{bmatrix}, \quad (6.2)$$

and

$$C = [\gamma_n \quad \gamma_{n-1} \quad \cdot \quad \cdot \quad \cdot \quad \gamma_1], \quad D = d. \quad (6.3)$$

To summarize the foregoing discussion, if $g(s)$ is the transfer function of a real time-invariant continuous-time SISO linear system, and $g(s)$ is proper rational, then $g(s)$ possesses a fractional representation Equation 6.1 that

- is irreducible because $p(s)$ and $q(s)$ are coprime, or, equivalently.
- is minimal because the degree of $q(s)$ is as small as it can be in such a representation.

Moreover,

- the degree of $q(s)$ in any minimal and irreducible representation Equation 6.1 is equal to the MacMillan degree of $g(s)$.

Replacing s with z results in identical assertions about discrete-time SISO systems.

Our goal in what follows will be to generalize these results to cover continuous-time, multi-input, multi-output (MIMO) systems with $(p \times m)$ proper rational transfer function matrices $G(s)$. The development is purely algebraic and applies equally well to discrete-time MIMO systems with proper rational transfer function matrices $G(z)$; simply replace s with z throughout. In Section 6.2, we present MIMO versions of the fractional representation Equation 6.1, complete with appropriate matrix analogues of irreducibility and minimality. In Section 6.3, we relate the results of Section 6.2 to the MacMillan degree of $G(s)$. We obtain as a bonus a minimal realization of $G(s)$ that turns out to be the MIMO analogue of the realization in Equations 6.2 and 6.3. In Section 6.4 we prove a well-known formula for the MacMillan degree of $G(s)$ and discuss briefly some connections between the material in Section 6.2 and the theory of ARMA models for MIMO systems, with a nod toward some modern results about stable coprime factorization and robust control. The algebra we will be employing throughout, while tedious at times, is never terribly abstract, and much of it is interesting in its own right.

6.2 Polynomial Matrix Fraction Descriptions

We begin by establishing some basic terminology. A *real polynomial matrix* is a matrix each of whose entries is a polynomial in s with real coefficients. We often omit the adjective “real” but assume, unless stated otherwise, that all polynomial matrices are real. One can perform elementary operations on polynomial matrices such as addition and multiplication using the rules of polynomial algebra along with the standard formulas that apply to matrices of numbers. Likewise, one can compute the determinant $\det F(s)$ of a square polynomial matrix $F(s)$ by any of the usual formulas or procedures. All the familiar properties of the determinant hold for polynomial matrices, for example, the product rule

$$\det[F_1(s)F_2(s)] = [\det F_1(s)][\det F_2(s)], \quad (6.4)$$

which applies when $F_1(s)$ and $F_2(s)$ are the same size.

There are two shades of invertibility for square polynomial matrices.

Definition 6.1:

A square polynomial matrix $F(s)$ is said to be *nonsingular* if, and only if, $\det F(s)$ is a nonzero polynomial and *unimodular* if, and only if, $\det F(s)$ is a nonzero real number.

Thus if $F(s)$ is *nonsingular*, we are free to compute $F^{-1}(s)$ using the adjugate-determinant formula for the inverse [12], namely,

$$F^{-1}(s) = \frac{1}{\det F(s)} \text{adj}F(s).$$

The (i, j) entry of $\text{adj}F(s)$ is $(-1)^{i+j}$ times the determinant of the matrix obtained from $F(s)$ by eliminating its j th row and i th column. $F^{-1}(s)$ is in general a rational matrix function of s . If $F(s)$ is not just nonsingular but also *unimodular*, then $F^{-1}(s)$ is actually a polynomial matrix; thus unimodular polynomial matrices are “polynomially invertible.”

From Definition 6.1 along with the product rule Equation 6.4, the product of two nonsingular polynomial matrices is nonsingular and the product of two unimodular polynomial matrices is unimodular. Furthermore, we have the following “pointwise” characterization of unimodularity: a square polynomial matrix $F(s)$ is unimodular precisely when $F(s_0)$ is an invertible matrix of complex numbers for every

complex number s_0 . This statement follows from the fundamental theorem of algebra, which implies that if $\det F(s)$ is a polynomial of nonzero degree, then $\det F(s_0) = 0$ for at least one complex number s_0 .

As an example, consider the two polynomial matrices

$$F_1(s) = \begin{bmatrix} s+2 & s+2 \\ s+1 & s+2 \end{bmatrix} \quad \text{and} \quad F_2(s) = \begin{bmatrix} s+2 & s+4 \\ s & s+2 \end{bmatrix}.$$

$F_2(s)$ is unimodular and $F_1(s)$ is merely nonsingular; in fact,

$$F_1^{-1}(s) = \begin{bmatrix} 1 & -1 \\ -\frac{s+1}{s+2} & 1 \end{bmatrix} \quad \text{and} \quad F_2^{-1}(s) = \frac{1}{4} \begin{bmatrix} s+2 & -s-2 \\ -s & s+2 \end{bmatrix}.$$

We are ready to define the matrix generalization(s) of the fractional representation Equation 6.1.

Definition 6.2:

Let $G(s)$ be a real $(p \times m)$ proper rational matrix function of s .

- A right matrix fraction description, or right MFD, of $G(s)$ is a factorization of the form $G(s) = P(s)Q^{-1}(s)$, where $P(s)$ is a real $(p \times m)$ polynomial matrix and $Q(s)$ is a real $(m \times m)$ nonsingular polynomial matrix.
- A left matrix fraction description, or left MFD, of $G(s)$ is a factorization of the form $G(s) = Q_L^{-1}(s)P_L(s)$, where $P_L(s)$ is a real $(p \times m)$ polynomial matrix and $Q_L(s)$ is a real $(p \times p)$ nonsingular polynomial matrix.

It is easy to construct left and right matrix fraction descriptions for a given $(p \times m)$ proper rational matrix $G(s)$. For instance, let $q(s)$ be the lowest common denominator of the entries in $G(s)$. Set $P(s) = q(s)G(s)$; then $P(s)$ is a polynomial matrix. Setting $Q(s) = q(s)I_m$ makes $P(s)Q^{-1}(s)$ a right MFD for $G(s)$; setting $Q_L(s) = q(s)I_p$ makes $Q_L^{-1}(s)P(s)$ a left MFD of $G(s)$.

Next we introduce matrix versions of the notions of irreducibility and minimality associated with the fractional representation Equation 6.1. First consider minimality. Associated with each right (or left) MFD of $G(s)$ is the “denominator matrix” $Q(s)$ (or $Q_L(s)$); the degree of the nonzero polynomial $\det Q(s)$ (or $\det Q_L(s)$) plays a role analogous to that of the degree of the polynomial $q(s)$ in Equation 6.1.

Definition 6.3:

Let $G(s)$ be a real $(p \times m)$ proper rational matrix.

- A right MFD $P(s)Q^{-1}(s)$ of $G(s)$ is minimal if, and only if, the degree of $\det \hat{Q}(s)$ in any other right MFD $\hat{P}(s)\hat{Q}^{-1}(s)$ of $G(s)$ is at least as large as the degree of $\det Q(s)$.
- A left MFD $Q_L^{-1}(s)P_L(s)$ of $G(s)$ is minimal if, and only if, the degree of $\det \hat{Q}_L(s)$ in any other left MFD $\hat{Q}_L^{-1}(s)\hat{P}_L(s)$ of $G(s)$ is at least as large as the degree of $\det Q_L(s)$.

To formulate the matrix version of irreducibility, we require the following analogues of the coprimeness condition on the polynomials $p(s)$ and $q(s)$ appearing in Equation 6.1.

Definition 6.4:

- Two polynomial matrices $P(s)$ and $Q(s)$ possessing m columns are said to be right coprime if, and only if, the following condition holds: If $F(s)$ is an $(m \times m)$ polynomial matrix so that for some polynomial matrices $\hat{P}(s)$ and $\hat{Q}(s)$, $P(s) = \hat{P}(s)F(s)$ and $Q(s) = \hat{Q}(s)F(s)$, then $F(s)$ is unimodular.
- Two polynomial matrices $P_L(s)$ and $Q_L(s)$ possessing p rows are said to be left coprime if, and only if, the following condition holds: If $F(s)$ is a $(p \times p)$ polynomial matrix so that for some polynomial matrices $\hat{P}_L(s)$ and $\hat{Q}_L(s)$, $P(s) = F(s)\hat{P}_L(s)$ and $Q_L(s) = F(s)\hat{Q}_L(s)$, then $F(s)$ is unimodular.

Saying that two polynomial matrices are right (or left) coprime is the same as saying that they have no right (or left) common square polynomial matrix factors other than unimodular matrices. In this way, unimodular matrices play a role similar to that of nonzero real numbers in the definition of coprimeness for scalar polynomials. Any two unimodular matrices of the same size are trivially right and left coprime. Similarly, any $(r \times r)$ unimodular matrix is right coprime with any polynomial matrix that has r columns and left coprime with any polynomial matrix that has r rows. Equipped with Definition 6.4, we can explain what it means for a right or left MFD to be irreducible.

Definition 6.5:

Let $G(s)$ be a real $(p \times m)$ proper rational matrix.

- A right MFD $P(s)Q^{-1}(s)$ of $G(s)$ is irreducible if, and only if, $P(s)$ and $Q(s)$ are right coprime.
- A left MFD $Q_L^{-1}(s)P_L(s)$ of $G(s)$ is irreducible if, and only if, $P_L(s)$ and $Q_L(s)$ are left coprime.

It is time to begin reconciling Definition 6.3, Definition 6.5, and the scalar intuition surrounding irreducibility and minimality of the fractional representation Equation 6.1. The proof of the following central result will occupy most of the remainder of this section; the finishing touches appear after Lemmas 6.1 and 6.2 below.

Theorem 6.1:

Let $G(s)$ be a real $(p \times m)$ proper rational matrix.

- A right MFD $P(s)Q^{-1}(s)$ of $G(s)$ is minimal if, and only if, it is irreducible. Furthermore, if $P(s)Q^{-1}(s)$ and $\hat{P}(s)\hat{Q}^{-1}(s)$ are two minimal right MFDs of $G(s)$, then an $(m \times m)$ unimodular matrix $V(s)$ exists so that $\hat{P}(s) = P(s)V(s)$ and $\hat{Q}(s) = Q(s)V(s)$.
- A left MFD $Q_L^{-1}(s)P_L(s)$ of $G(s)$ is minimal if, and only if, it is irreducible. Furthermore, if $Q_L^{-1}(s)P_L(s)$ and $\hat{Q}_L^{-1}(s)\hat{P}_L(s)$ are two minimal left MFDs of $G(s)$, then a $(p \times p)$ unimodular matrix $V(s)$ exists so that $\hat{P}_L(s) = V(s)P_L(s)$ and $\hat{Q}_L(s) = V(s)Q_L(s)$.

Some parts of Theorem 6.1 are easier to prove than others. In particular, it is straightforward to show that a minimal right or left MFD is irreducible. To see this, suppose $G(s) = P(s)Q^{-1}(s)$ is a right MFD that is not irreducible. Since $P(s)$ and $Q(s)$ are not right coprime, factorizations $P(s) = \hat{P}(s)F(s)$ and $Q(s) = \hat{Q}(s)F(s)$ exist with $F(s)$ not unimodular. $F(s)$ and $\hat{Q}(s)$ are evidently nonsingular because $Q(s)$ is.

Furthermore,

$$G(s) = P(s)Q^{-1}(s) = \hat{P}(s)F(s)F^{-1}(s)\hat{Q}^{-1}(s) = \hat{P}(s)\hat{Q}^{-1}(s),$$

which shows how to “reduce” the original MFD $P(s)Q^{-1}(s)$ by “canceling” the right common polynomial matrix factor $F(s)$ from $P(s)$ and $Q(s)$. Because $F(s)$ is not unimodular, $\det F(s)$ is a polynomial of positive degree, and the degree of $\det \hat{Q}(s)$ is therefore strictly less than the degree of $\det Q(s)$. Consequently, the original right MFD $P(s)Q^{-1}(s)$ is not minimal. The argument demonstrating that minimality implies irreducibility for left MFDs is essentially identical.

Proving the converse parts of the assertions in Theorem 6.1 is substantially more difficult. The approach we adopt, based on the so-called Smith form for polynomial matrices, is by no means the only one. Rugh [10] follows a quite different route, as does Vidyasagar [13]. We have elected to center our discussion on the Smith form partly because the manipulations we will be performing are similar to the things one does to obtain LDU decompositions [12] for matrices of numbers via Gauss elimination.

We will be employing a famous result from algebra known as the *Euclidean algorithm*. It says that if $f(s)$ is a real polynomial and $g(s)$ is another real polynomial of lower degree, then unique real polynomials $\kappa(s)$ and $\rho(s)$ exist, where $\rho(s)$ has lower degree than $g(s)$, for which

$$f(s) = g(s)\kappa(s) + \rho(s).$$

It is customary to regard the zero polynomial as having degree $-\infty$ and nonzero constant polynomials as having degree zero. If $g(s)$ divides $f(s)$, then $\rho(s) = 0$; otherwise, one can interpret $\kappa(s)$ and $\rho(s)$ respectively as the quotient and remainder obtained from dividing $f(s)$ by $g(s)$.

The Smith form of a real $(k \times r)$ polynomial matrix $F(s)$ is a matrix obtained by performing elementary row and column operations on $F(s)$. The row and column operations are of three kinds:

- Interchanging the i th and j th rows (or the i th and j th columns).
- Replacing row i with the difference (row i) $-\kappa(s) \times$ (row j), where $\kappa(s)$ is a polynomial (or replacing column j with the difference (column j) $-\kappa(s) \times$ (column i)).
- Replacing row (or column) i with its multiple by a nonzero real number γ .

One can view each of these operations as the result of multiplying $F(s)$ on the left or the right by a unimodular matrix. To interchange the i th and j th rows of $F(s)$, multiply on the left by the permutation matrix Π^{ij} ; Π^{ij} is a $(k \times k)$ identity matrix with the i th and j th rows interchanged. To replace row i with itself minus $\kappa(s)$ times row j , multiply on the left by the matrix $E^{ij}[-\kappa(s)]$, a $(k \times k)$ identity matrix except with $-\kappa(s)$ in the ij position. Because $\det \Pi^{ij} = -1$ and $\det E^{ij}[-\kappa(s)] = 1$, both matrices are unimodular. To multiply row i by γ , multiply $F(s)$ on the left by the $(k \times k)$ diagonal matrix with γ in the i th diagonal position and ones in all the others; this matrix is also unimodular, because its determinant is γ . The column operations listed above result from multiplying on the right by $(r \times r)$ unimodular matrices of the types just described.

The following result defines the Smith form of a polynomial matrix. It is a special case of a more general theorem [6, pp. 175–180].

Theorem 6.2: Smith Form

Let $F(s)$ be a real $(k \times r)$ polynomial matrix with $k \geq r$. A $(k \times k)$ unimodular matrix $U(s)$ and an $(r \times r)$

unimodular matrix $R(s)$ exist so that $U(s)F(s)R(s)$ takes the form

$$\Lambda(s) = \begin{bmatrix} d_1(s) & 0 & 0 & \cdot & \cdot & 0 \\ 0 & d_2(s) & 0 & \cdot & \cdot & 0 \\ 0 & 0 & d_3(s) & 0 & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & \cdot & \cdot & \cdot & 0 & d_r(s) \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \end{bmatrix}. \tag{6.5}$$

Furthermore, each nonzero $d_j(s)$ is monic, and $d_j(s)$ divides $d_{j+1}(s)$ for all $j, 1 \leq j \leq r - 1$.

Proof 6.1. Let δ_{\min} be the smallest of the degrees of the nonzero polynomials in $F(s)$. Now invoke the following procedure:

Reduction Step

Pick an entry in $F(s)$ whose degree is δ_{\min} and use row and column exchanges to bring it to the $(1, 1)$ position; denote the resulting matrix by $G(s)$. For each $i, 2 \leq i \leq k$, use the Euclidean algorithm to find $\kappa_i(s)$ so that $\rho_i(s) = [G(s)]_{i1} - \kappa_i(s)[G(s)]_{11}$ has strictly lower degree than $[G(s)]_{11}$, which has degree δ_{\min} . Observe that $\rho_i(s) = 0$ if $[G(s)]_{11}$ divides $[G(s)]_{i1}$. Multiply $G(s)$ on the left by the sequence of matrices $E^{i1}[-\kappa_i(s)]$; this has the effect of replacing each $[G(s)]_{i1}$ with $\rho_i(s)$. Multiplying on the right by a similar sequence of E^{1j} -matrices replaces each $[G(s)]_{1j}$ with a polynomial whose degree is lower than δ_{\min} .

The net result is a new matrix whose δ_{\min} is lower than the δ_{\min} of $F(s)$. Repeating the reduction step on this new matrix results in a matrix whose δ_{\min} is still lower. Because we cannot continue reducing δ_{\min} forever, iterating the reduction step on the successor matrices of $F(s)$ leads eventually to a matrix of the form

$$F_1(s) = \begin{bmatrix} d_1(s) & 0 & 0 & \cdot & \cdot & 0 \\ 0 & \pi & \pi & \cdot & \cdot & \pi \\ 0 & \pi & \pi & \cdot & \cdot & \pi \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & \pi & \cdot & \cdot & \cdot & \pi \end{bmatrix}, \tag{6.6}$$

where each of the π s is a polynomial.

Divisibility Check

If $d_1(s)$ does not divide all the π s in Equation 6.6, find a π that $d_1(s)$ does not divide and multiply $F_1(s)$ on the left by an E^{11} -matrix so as to add the row containing the offending π to the first row of $F_1(s)$. Now repeat the reduction step on this new matrix. What results is a matrix of the form Equation 6.6 with a lower δ_{\min} .

Repeat the divisibility check on this new matrix. The process terminates eventually in a matrix of the form Equation 6.6 whose $d_1(s)$ divides all the polynomials π . Note that this newest $F_1(s)$ can be written in the form $U_1(s)F(s)R_1(s)$ for some unimodular matrices $U_1(s)$ and $R_1(s)$. The next phase of the Smith form computation entails performing the reduction step and divisibility check on the $(k - 1 \times r - 1)$ matrix of

π s in $F_1(s)$. What results is a matrix

$$F_2(s) = \begin{bmatrix} d_1(s) & 0 & 0 & \dots & 0 \\ 0 & d_2(s) & 0 & \dots & 0 \\ 0 & 0 & \pi & \dots & \pi \\ 0 & 0 & \pi & \dots & \pi \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \pi & \dots & \pi \end{bmatrix}$$

in which $d_2(s)$ divides all of the π s. Moreover, $d_1(s)$ divides $d_2(s)$ because $d_2(s)$ is a polynomial linear combination of the π s in $F_1(s)$. Furthermore, there are unimodular matrices $U_2(s)$ and $R_2(s)$ so that $F_2(s) = U_2(s)F_1(s)R_2(s)$, whereby $F_2(s) = U_2(s)U_1(s)F(s)R_1(s)R_2(s)$.

Continuing in this fashion leads successively to $F_3(s), \dots$, and finally $F_r(s)$, which has the same form as $\Lambda(s)$. To get $\Lambda(s)$, modify $F_r(s)$ by scaling all of the rows of $F_r(s)$ so that the nonzero $d_j(s)$ -polynomials are monic. It is evident that there are unimodular matrices $U(s)$ and $R(s)$ so that $\Lambda(s) = U(s)F(s)R(s)$.

A few comments are in order. First, if $F(s)$ is a real $(k \times r)$ polynomial matrix with $k \leq r$, then applying Theorem 6.2 to $F^T(s)$ and transposing the result yields unimodular matrices $U(s)$ and $R(s)$ so that $U(s)F(s)R(s)$ takes the form

$$\Lambda(s) = \begin{bmatrix} d_1(s) & 0 & 0 & \dots & 0 & 0 & \dots & 0 \\ 0 & d_2(s) & 0 & \dots & \dots & \dots & \dots & 0 \\ 0 & 0 & d_3(s) & 0 & \dots & \dots & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & 0 \\ 0 & \dots & \dots & \dots & 0 & d_k(s) & 0 & \dots \end{bmatrix}; \quad (6.7)$$

this is the Smith form of an $F(s)$ with more columns than rows. Next, consider the polynomials $\{d_j(s)\}$ in Equation 6.5; these are called the *elementary divisors* of $F(s)$. It might not appear *prima facie* as if the proof of Theorem 6.2 specified them uniquely, but it does. In fact, we have the following explicit characterization.

Fact 6.1:

For each $j, 1 \leq j \leq \min(k, r)$, the product $d_1(s) \dots d_j(s)$ is the monic greatest common divisor of all of the $(j \times j)$ minors in $F(s)$.

Proof 6.2. The divisibility conditions on the $\{d_j(s)\}$ make it obvious that $d_1(s) \dots d_j(s)$ is the monic greatest common divisor of the $(j \times j)$ minors in $\Lambda(s)$. Fact 6.1 follows immediately from the observation that the reduction procedure leading from $F(s)$ to $\Lambda(s)$ is such that for each i , the set of $(j \times j)$ minors of $F_i(s)$ has the same family of common divisors as the set of $(j \times j)$ minors of $F_{i+1}(s)$. (See also the proof of Corollary 6.1 below.) As a result, the monic greatest common divisor of the $(j \times j)$ minors does not change over the course of the procedure.

One final comment: the sequence of elementary divisors, in general, might start out with one or more 1s and terminate with one or more 0s. In fact, because every nonzero elementary divisor is a monic polynomial, each constant elementary divisor is either a 1 or a 0. If $F(s)$ is a square matrix, then $\det F(s)$ is a nonzero real multiple of the product of its elementary divisors; this follows from the unimodularity of $U(s)$ and $R(s)$ in Theorem 6.2. Hence if $F(s)$ is nonsingular, none of its elementary divisors is zero.

If $F(s)$ is unimodular, then all of its elementary divisors are equal to 1. In other words, the Smith form of a $(k \times k)$ unimodular matrix is simply the $(k \times k)$ identity matrix I_k .

The Smith form is the key to finishing the proof of Theorem 6.1. The following lemma, which offers useful alternative characterizations of coprimeness, is the first step in that direction.

Lemma 6.1:

Let $P(s)$ and $Q(s)$ be real polynomial matrices having respective sizes $(p \times m)$ and $(m \times m)$. The following three conditions are equivalent:

1. $P(s)$ and $Q(s)$ are right coprime.
2. There exist real polynomial matrices $X(s)$ and $Y(s)$ with respective sizes $(m \times m)$ and $(m \times p)$ so that $X(s)Q(s) + Y(s)P(s) = I_m$.
3. The $(m + p \times m)$ matrix

$$\begin{bmatrix} Q(s_0) \\ P(s_0) \end{bmatrix}$$

has full rank m for every complex number s_0 .

Proof 6.3. We show that (1) \implies (2) \implies (3) \implies (1). Set

$$F(s) = \begin{bmatrix} Q(s) \\ P(s) \end{bmatrix}$$

and, using the notation of Theorem 6.2, let $\Lambda(s) = U(s)F(s)R(s)$ be the Smith form of $F(s)$. Denote by $\Delta(s)$ the $(m \times m)$ matrix comprising the first m rows of $\Lambda(s)$; the diagonal elements of $\Delta(s)$ are the elementary divisors of $F(s)$.

If (1) holds, we need $\Delta(s) = I_m$. To see this, partition $U^{-1}(s)$ as

$$U^{-1}(s) = W(s) = \begin{bmatrix} W_1(s) & W_2(s) \\ W_3(s) & W_4(s) \end{bmatrix};$$

then

$$F(s) = \begin{bmatrix} Q(s) \\ P(s) \end{bmatrix} = \begin{bmatrix} W_1(s) \\ W_3(s) \end{bmatrix} \Delta(s) R^{-1}(s),$$

so that $P(s)$ and $Q(s)$ have $\Delta(s)R^{-1}(s)$ as an $(m \times m)$ as a right common polynomial matrix factor. For (1) to hold, this last matrix must be unimodular, and that happens when $\Delta(s) = I_m$.

Hence, right coprimeness of $P(s)$ and $Q(s)$ implies that $\Delta(s) = I_m$. It follows immediately in this case that if we partition the first m rows of $U(s)$ as $\begin{bmatrix} U_1(s) & U_2(s) \end{bmatrix}$, then (2) holds with $X(s) = R(s)U_1(s)$ and $Y(s) = R(s)U_2(s)$. (3) is a straightforward consequence of (2) because, if $F(s_0)$ were rank-deficient for some s_0 , then $X(s_0)Q(s_0) + Y(s_0)P(s_0)$ could not be I_m . Finally, (3) implies (1) because, if (3) holds and

$$F(s) = \begin{bmatrix} \hat{P}(s) \\ \hat{Q}(s) \end{bmatrix} \hat{R}(s)$$

is a factorization with $\hat{R}(s)$ $(m \times m)$ but not unimodular, then $\det \hat{R}(s_0) = 0$ for at least one complex number s_0 , which contradicts (3).

Not surprisingly, Lemma 6.1 has the following left-handed analogue.

Lemma 6.2:

Let $P_L(s)$ and $Q_L(s)$ be real polynomial matrices with respective sizes $(p \times m)$ and $(p \times p)$. The following three conditions are equivalent:

1. $P_L(s)$ and $Q_L(s)$ are left coprime.
2. Real polynomial matrices $X(s)$ and $Y(s)$ exist with respective sizes $(p \times p)$ and $(m \times p)$ so that $Q_L(s)X(s) + P_L(s)Y(s) = I_p$.
3. The $(p \times p + m)$ matrix

$$\begin{bmatrix} Q_L(s_o) & P_L(s_o) \end{bmatrix}$$

has full rank p for every complex number s_o .

We are ready now to finish proving Theorem 6.1.

Proof of Theorem 6.1: We prove only the assertions about right MFDs. We have shown already that a minimal right MFD of $G(s)$ is irreducible. As for the converse, suppose $G(s) = P(s)Q^{-1}$ is an irreducible right MFD and that $G(s) = \hat{P}(s)\hat{Q}^{-1}(s)$ is a minimal (hence irreducible) right MFD. By Lemma 6.1, there exist $X(s)$, $Y(s)$, $\hat{X}(s)$, and $\hat{Y}(s)$ of appropriate sizes satisfying

$$\begin{aligned} X(s)Q(s) + Y(s)P(s) &= I_m \\ \hat{X}(s)\hat{Q}(s) + \hat{Y}(s)\hat{P}(s) &= I_m. \end{aligned}$$

Invoke the fact that $P(s)Q^{-1}(s) = \hat{P}(s)\hat{Q}^{-1}(s)$; a straightforward manipulation yields

$$\begin{aligned} X(s)\hat{Q}(s) + Y(s)\hat{P}(s) &= Q^{-1}(s)\hat{Q}(s), \\ \hat{X}(s)Q(s) + \hat{Y}(s)P(s) &= \hat{Q}^{-1}(s)Q(s). \end{aligned}$$

The matrices on the right-hand sides are inverses of each other and are polynomial matrices; hence they must be unimodular. This implies, in particular, that the degrees of the determinants of $Q(s)$ and $\hat{Q}(s)$ are the same, and $P(s)Q^{-1}(s)$ is, therefore, also a minimal right MFD.

Finally, setting $V(s) = Q^{-1}(s)\hat{Q}(s)$ reveals that $\hat{P}(s) = P(s)V(s)$ and $\hat{Q}(s) = Q(s)V(s)$, proving that the two minimal right MFDs are related as in the theorem statement.

Theorem 6.1 establishes the equivalence of minimality and irreducibility for MFDs. It is worth remarking that its proof furnishes a means for reducing a nonminimal MFD to a minimal one. The argument supporting Lemma 6.1 provides the key. Let $G(s) = P(s)Q^{-1}(s)$ be a nonminimal right MFD. Employing the same notation as in the proof of Lemma 6.1,

$$F(s) = \begin{bmatrix} Q(s) \\ P(s) \end{bmatrix} = \begin{bmatrix} W_1(s) \\ W_3(s) \end{bmatrix} \times \Delta(s)R^{-1}(s) \stackrel{\text{def}}{=} \hat{F}(s)\Delta(s)R^{-1}(s).$$

Setting $\hat{Q}(s) = W_1(s)$ and $\hat{P}(s) = W_3(s)$ makes $\hat{P}(s)\hat{Q}^{-1}(s)$ a right MFD of $G(s)$. By definition of $W(s)$ and $U(s)$,

$$U(s)\hat{F}(s) = \begin{bmatrix} I_m \\ 0 \end{bmatrix};$$

taken in conjunction with Theorem 6.2, this implies that $\hat{F}(s)$ has ones as its elementary divisors. As in the proof of Lemma 6.1, we conclude that $\hat{P}(s)\hat{Q}^{-1}(s)$ is an irreducible (hence minimal) right MFD.

Theorem 6.1 also makes an important assertion about the “denominator matrices” appearing in minimal MFDs. The theorem states that if $Q(s)$ and $\hat{Q}(s)$ are denominator matrices in two minimal right MFDs of a proper rational $G(s)$, then $Q(s)$ and $\hat{Q}(s)$ differ by a right unimodular matrix factor. It follows that the determinants of $Q(s)$ and $\hat{Q}(s)$ are identical up to a nonzero real multiple; in particular, $\det Q(s)$ and $\det \hat{Q}(s)$ have the same roots including multiplicities. The same is true about the determinants of the denominator matrices $Q_L(s)$ and $\hat{Q}_L(s)$ from two minimal left MFDs. It is clear that the poles of $G(s)$ must lie among the roots of $\det Q(s)$ and $\det Q_L(s)$. What is not so obvious is the fact, whose proof we postpone until the next section, that these last two polynomials are actually nonzero real multiples of each other.

6.3 Fractional Degree and MacMillan Degree

Conspicuously absent from Section 6.2 is any substantive discussion of relationships between right and left MFDs for a proper rational matrix $G(s)$. The most important connection enables us to close the circle of ideas encompassing the minimal MFDs of Section 6.2 and the irreducible fractional representation Equation 6.1 for a scalar rational function. A crucial feature of Equation 6.1 is that the degree of $q(s)$ is the same as the MacMillan degree of $g(s)$. Our principal goal in what follows is to prove a similar assertion about the MacMillan degree of $G(s)$ and the degrees of the determinants of the denominator matrices appearing in minimal right and left MFDs of $G(s)$.

Our first task is to demonstrate that, when $P(s)Q^{-1}(s)$ and $Q_L^{-1}(s)P_L(s)$ are right and left MFDs of a proper rational matrix $G(s)$, the degrees of the polynomials $\det Q(s)$ and $\det Q_L(s)$ are the same. To that end, we need the following technical lemma.

Lemma 6.3:

Suppose that the $(m + p \times m + p)$ polynomial matrix $W(s)$ is nonsingular and that the $(m \times m)$ submatrix $W_1(s)$ is also nonsingular, where

$$W(s) = \begin{bmatrix} W_1(s) & W_2(s) \\ W_3(s) & W_4(s) \end{bmatrix}.$$

Then,

1. $H(s) = W_4(s) - W_3(s)W_1^{-1}(s)W_2(s)$ is also nonsingular
2. $\det W(s) = \det W_1(s) \det H(s)$
3. $W^{-1}(s)$ is given by

$$\begin{bmatrix} W_1^{-1}(s) + W_1^{-1}(s)W_2(s)H^{-1}(s)W_3(s)W_1^{-1}(s) & -W_1^{-1}(s)W_2(s)H^{-1}(s) \\ -H^{-1}(s)W_3(s)W_1^{-1}(s) & H^{-1}(s) \end{bmatrix}$$

Proof 6.4. Statements (1) and (2) follow from the identity

$$\begin{bmatrix} I_m & 0 \\ -W_3(s)W_1^{-1}(s) & I_p \end{bmatrix} W(s) = \begin{bmatrix} W_1(s) & W_2(s) \\ 0 & H(s) \end{bmatrix},$$

because the matrix multiplying $W(s)$ has determinant 1. Multiplying the last equation on the left by

$$\begin{bmatrix} W_1^{-1}(s) & 0 \\ 0 & H^{-1}(s) \end{bmatrix} \begin{bmatrix} I_m & -W_2(s)H^{-1}(s) \\ 0 & I_p \end{bmatrix}$$

yields statement (3).

A direct consequence of Lemma 6.3 is the advertised relationship between determinants of the denominator matrices in right and left MFDs.

Theorem 6.3:

Let $P(s)Q^{-1}(s)$ and $Q_L^{-1}(s)P_L(s)$, respectively, be minimal right and left MFDs of a real $(p \times m)$ proper rational matrix $G(s)$. Then $\det Q_L(s)$ is a nonzero real multiple of $\det Q(s)$; in particular, the two polynomials have the same degree and the same roots.

Proof 6.5. We learned in the proof of Lemma 6.1 that unimodular matrices $U(s)$ and $R(s)$ exist so that

$$U(s) \begin{bmatrix} Q(s) \\ P(s) \end{bmatrix} R(s) = \begin{bmatrix} I_m \\ 0 \end{bmatrix}.$$

Set

$$M(s) = \begin{bmatrix} R(s) & 0 \\ 0 & I_p \end{bmatrix} U(s)$$

and define $W(s) = M^{-1}(s)$; observe that $M(s)$ and $W(s)$ are unimodular. Partition $M(s)$ and $W(s)$ conformably as follows:

$$M(s) = \begin{bmatrix} M_1(s) & M_2(s) \\ M_3(s) & M_4(s) \end{bmatrix}; \quad W(s) = \begin{bmatrix} W_1(s) & W_2(s) \\ W_3(s) & W_4(s) \end{bmatrix}.$$

It follows that $W_1(s) = Q(s)$ and $W_3(s) = P(s)$. In particular, $W_1(s)$ is nonsingular. By Lemma 6.3, $M_4(s)$ is nonsingular and equals $H^{-1}(s)$, where $H(s) = W_4(s) - W_3(s)W_1^{-1}(s)W_2(s)$. Because $M(s)W(s) = I_{m+p}$,

$$M_3(s)W_2(s) + M_4(s)W_4(s) = I_p;$$

hence $M_3(s)$ and $M_4(s)$ are left coprime by Lemma 6.1. Furthermore,

$$M_3(s)W_1(s) + M_4(s)W_3(s) = 0;$$

the fact that $G(s) = P(s)Q^{-1}(s) = W_3(s)W_1^{-1}(s)$ makes

$$G(s) = M_4^{-1}(s)[-M_3(s)]$$

a minimal left MFD of $G(s)$. By Theorem 6.1, $\det M_4(s)$ is a nonzero real multiple of the determinant of the matrix $Q_L(s)$ appearing in any minimal left MFD $Q_L^{-1}(s)P_L(s)$ of $G(s)$.

By item (2) in Lemma 6.3, $\det W(s) = \det W_1(s) \det H(s)$. Because $W_1(s) = Q(s)$ and $M_4(s) = H^{-1}(s)$,

$$\det Q(s) = \det W(s) \det M_4(s).$$

Unimodularity of $W(s)$ implies that $\det Q(s)$ and $\det M_4(s)$ differ by a nonzero real multiple.

Theorem 6.3 makes possible the following definition.

Definition 6.6:

The fractional degree $\delta_F[G(s)]$ of a real $(p \times m)$ proper rational matrix $G(s)$ is the degree of $\det Q(s)$ (or of $\det Q_L(s)$), where $Q(s)$ (or $Q_L(s)$) comes from a minimal right (or left) MFD $P(s)Q^{-1}(s)$ (or $Q_L^{-1}(s)P_L(s)$) of $G(s)$.

As promised, we will demonstrate below that the fractional degree of a proper rational matrix $G(s)$ is the same as its MacMillan degree $\delta_M[G(s)]$. Our approach will be first to show that $\delta_F \leq \delta_M$ and then to construct a state space realization for $G(s)$ with state vector dimension $\delta_F[G(s)]$. The existence of such a realization guarantees that $\delta_F \geq \delta_M$, from which it follows that the two degrees are equal.

Accordingly, let $G(s)$ be a given real $(p \times m)$ proper rational matrix. Let $D = \lim_{s \rightarrow \infty} G(s)$; set $Z(s) = G(s) - D$. If $P(s)Q^{-1}(s)$ is a minimal right MFD of $G(s)$, then $\tilde{P}(s)Q^{-1}(s)$ is a minimal right MFD for $Z(s)$, where $\tilde{P}(s) = P(s) - DQ(s)$. To see why $\tilde{P}(s)Q^{-1}(s)$ is minimal, note that the two matrices

$$F(s_0) = \begin{bmatrix} Q(s_0) \\ P(s_0) \end{bmatrix}, \quad \tilde{F}(s_0) = \begin{bmatrix} Q(s_0) \\ P(s_0) - DQ(s_0) \end{bmatrix}$$

have the same nullspace (and hence the same rank) for every complex number s_0 . It follows from item 3 in Lemma 6.1 that $\tilde{P}(s)Q^{-1}(s)$ is irreducible and hence minimal. In addition, we can conclude that the fractional degrees of $G(s)$ and $Z(s)$ are the same.

Suppose that $n = \delta_M(G(s))$ and that (A, B, C, D) is a minimal realization of $G(s)$. The Popov-Belevitch-Hautus test for reachability [11] implies that the $(n \times n + m)$ matrix,

$$K(s_0) = \begin{bmatrix} (s_0 I_n - A) & B \end{bmatrix}$$

has full rank n for every complex number s_0 . By Lemma 6.1, $(sI_n - A)^{-1}B$ is an irreducible (hence minimal) left MFD of $K(s)$. Thus $K(s)$ has fractional degree n . Now,

$$Z(s) = C(sI_n - A)^{-1}B = CF(s);$$

it follows that the fractional degree of $Z(s)$ is at most equal to n . To see this, suppose $K(s) = P(s)Q^{-1}(s)$ is a minimal right MFD of $K(s)$; then $Z(s) = [CP(s)]Q^{-1}(s)$ is a right MFD of $Z(s)$, and this MFD need not be minimal. Hence $\delta_F(Z) \leq \delta_F(K) = n$. The upshot is that the fractional degree of $G(s)$, which is the same as the fractional degree of $Z(s)$, is bounded from above by the MacMillan degree of $G(s)$. In other words,

$$\delta_F[G(s)] \leq \delta_M[G(s)].$$

Proving the reverse inequality requires a bit more effort. Suppose we have a minimal right MFD $G(s) = P(s)Q^{-1}(s)$ and corresponding right MFD $Z(s) = \tilde{P}(s)Q^{-1}(s)$. The fractional degree of $G(s)$ is the same as the degree of $\det Q(s)$. To show how the entries in $Q(s)$ combine to determine the degree of $\det Q(s)$, we need the following definition.

Definition 6.7:

Let $Q(s)$ be a real nonsingular $(m \times m)$ polynomial matrix. The j th column degree of $Q(s)$, $\delta_j[Q(s)]$, is the highest of the degrees of the polynomials in the j th column of $Q(s)$, $1 \leq j \leq m$. The high-order coefficient matrix of $Q(s)$, Q_H , is the real $(m \times m)$ matrix whose (i, j) entry is the coefficient of $s^{\delta_j[Q(s)]}$ in $[Q(s)]_{ij}$.

The nonsingularity of $Q(s)$ guarantees that all of the column degrees are nonnegative integers. The classic expansion for the determinant [12, page 157] reveals $\det Q(s)$ as the sum of m -fold products each of which contains precisely one element from each column of $Q(s)$. It follows that the degree of $\det Q(s)$ is bounded from above by the sum of all the column degrees of $Q(s)$. In fact, if $\delta_1, \dots, \delta_m$ are the column degrees of $Q(s)$, then the coefficient of the $s^{(\delta_1 + \dots + \delta_m)}$ in the expansion for $\det Q(s)$ is exactly $\det Q_H$, the determinant of the high-order coefficient matrix. In other words, $\det Q(s)$ has degree equal to the sum of the column degrees when $\det Q_H \neq 0$, which is the same as saying that the high-order coefficient matrix is invertible.

Our method for constructing for $G(s)$ a realization whose state dimension is $\delta_F[G(s)]$ hinges crucially on having a minimal right MFD $P(s)Q^{-1}(s)$ of $G(s)$ whose $Q(s)$ has an invertible high-order coefficient matrix. It turns out that such an MFD always exists. The idea is to start with an arbitrary minimal right MFD $\hat{P}(s)\hat{Q}^{-1}(s)$ and “operate on it” with a unimodular $V(s)$ via

$$P(s) = \hat{P}(s)V(s), \quad Q(s) = \hat{Q}(s)V(s)$$

to get another minimal right MFD $P(s)Q^{-1}(s)$ with an invertible Q_H . We construct $V(s)$ by looking at $\hat{Q}(s)$ only. Specifically, we prove the following assertion.

Lemma 6.4:

If $\hat{Q}(s)$ is a real nonsingular $(m \times m)$ polynomial matrix, a unimodular matrix $V(s)$ exists so that

- $Q(s) = \hat{Q}(s)V(s)$ has an invertible high-order coefficient matrix Q_H
- The column degrees $\{\delta_j(Q(s))\}$ are in decreasing order, i.e.,

$$\delta_1(Q(s)) \geq \delta_2(Q(s)) \cdots \geq \delta_m(Q(s)). \quad (6.8)$$

Proof 6.6. If \hat{Q}_H is already invertible, let $V(s)$ be a permutation matrix Π so that the columns of $\hat{Q}(s)\Pi$ are lined up in decreasing order of column degree. If \hat{Q}_H is not invertible, after finding Π as above, choose a nonzero $w \in \mathbf{R}^m$ satisfying $\hat{Q}_H \Pi w = 0$. Assume without loss of generality that the first nonzero element in w is a 1 and occurs in the k th position. Let $E(s)$ be the $(m \times m)$ polynomial matrix all of whose columns except the k th are the same as those in the $(m \times m)$ identity matrix I_m ; as for the k th column, let $[E(s)]_{ik}$ be 0 when $i < k$ and $w_i s^{\delta_k - \delta_i}$ when $i > k$, where δ_j denotes the j th column degree of $\hat{Q}(s)\Pi$. $E(s)$ has determinant 1 and is therefore unimodular; furthermore, $\hat{Q}(s)\Pi E(s)$ has the same columns as $\hat{Q}(s)\Pi$ except for the k th column, and the choice of $E(s)$ guarantees that the k th column degree of $\hat{Q}(s)\Pi E(s)$ is lower than the k th column degree of $\hat{Q}(s)\Pi$.

The preceding paragraph describes a technique for taking a $\hat{Q}(s)$ with singular \hat{Q}_H and finding a unimodular matrix $\Pi E(s)$ so that $\hat{Q}(s)\Pi E(s)$ has a set of column degrees whose sum is less than the sum of the column degrees of $\hat{Q}(s)$. If $Q(s) = \hat{Q}(s)\Pi E(s)$ still fails to have an invertible high-order coefficient matrix, we can repeat the column-permutation-and-reduction procedure on $\hat{Q}(s)\Pi E(s)$, and so on. This iteration must terminate after a finite number of steps because we cannot reduce the sum of the column degrees forever. When all is said and done, we will have a unimodular matrix $V(s)$ so that $Q(s) = \hat{Q}(s)V(s)$ has an invertible high-order coefficient matrix Q_H with columns arrayed in decreasing order of column degree, so that the column degrees of $Q(s)$ satisfy Equation 6.8.

Thus we can take an arbitrary minimal right MFD $G(s) = \hat{P}(s)\hat{Q}^{-1}(s)$ and form a new minimal right MFD $P(s)Q^{-1}(s)$ using $P(s) = \hat{P}(s)V(s)$ and $Q(s) = \hat{Q}(s)V(s)$; choosing $V(s)$ appropriately, using Lemma 6.4, makes Q_H invertible, ensuring in turn that

$$\delta_F[G(s)] = \text{degree}[\det Q(s)] = \delta_1[Q(s)] + \cdots + \delta_m[Q(s)].$$

Furthermore, we can assume that the column degrees of $Q(s)$ satisfy the ordering of Equation 6.8.

Our final step is to produce a realization (A, B, C, D) of $G(s)$ where A is $(\delta_F \times \delta_F)$. This will confirm that $\delta_F(G(s)) \geq \delta_M(G(s))$ and, hence, that the two degrees are equal. First define D and $Z(s) = G(s) - D$ as before, and let $Z(s) = \tilde{P}(s)Q^{-1}(s)$ be the corresponding minimal right MFD for $Z(s)$. Because

$$[\tilde{P}(s)]_{ij} = \sum_{k=1}^m [Z(s)]_{ik} [Q(s)]_{kj},$$

and because $Z(s)$ is strictly proper, the degree of $[\tilde{P}(s)]_{ij}$ is strictly less than δ_j for all i and j . In particular, if $\delta_j = 0$, then $[\tilde{P}(s)]_{ij} = 0$ for all i , $1 \leq i \leq p$ (as usual, the zero polynomial has degree $-\infty$).

Next define, for each $k > 0$, the polynomial k -vector \mathbf{s}_k by

$$\mathbf{s}_k = \begin{bmatrix} 1 \\ s \\ s^2 \\ \vdots \\ s^{k-1} \end{bmatrix}.$$

We now form a matrix \mathbf{S} that has m columns and number of rows equal to δ_F , which is equal in turn to the sum of the column degrees $\{\delta_j\}$. The j th column of \mathbf{S} has $\delta_1 + \dots + \delta_{j-1}$ 0s at the top, the vector \mathbf{s}_{δ_j} in the next δ_j positions, and 0s in the remaining positions. For example, if $m = 3$ and $\delta_1 = 3, \delta_2 = 2$, and $\delta_3 = 0$, then

$$\mathbf{S} = \begin{bmatrix} 1 & 0 & 0 \\ s & 0 & 0 \\ s^2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & s & 0 \end{bmatrix}.$$

Our observation above concerning the degrees of the entries in $\tilde{P}(s)$ ensures that a real $(p \times \delta_F)$ matrix C exists so that $\tilde{P}(s) = CS$. This C will be the C -matrix in our realization of $G(s)$. Since we want

$$Z(s) = \tilde{P}(s)Q^{-1}(s) = CSQ^{-1}(s)B = C(sI_{\delta_F} - A)^{-1}B,$$

we will construct A and B so that

$$\mathbf{S}Q^{-1}(s) = (sI_{\delta_F} - A)^{-1}B,$$

or, equivalently,

$$s\mathbf{S} = \mathbf{A}\mathbf{S} + BQ(s). \tag{6.9}$$

Recall first that Q_H , the high-order coefficient matrix of $Q(s)$, is invertible; by definition of Q_H and the column degrees $\{\delta_j\}$,

$$Q(s) = Q_H \begin{bmatrix} s^{\delta_1} & 0 & \cdot & \cdot & \cdot & 0 \\ 0 & s^{\delta_2} & 0 & \cdot & \cdot & \cdot \\ \cdot & 0 & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & 0 & \cdot \\ \cdot & \cdot & \cdot & 0 & s^{\delta_{m-1}} & 0 \\ \cdot & \cdot & \cdot & \cdot & 0 & s^{\delta_m} \end{bmatrix} + \tilde{Q}(s), \tag{6.10}$$

where $\tilde{Q}(s)$ satisfies the same constraints as $\tilde{P}(s)$ on the degrees of its entries. We may write $\tilde{Q}(s) = GS$ for some real $(m \times \delta_F)$ matrix G . Denote by $\Sigma(s)$ the diagonal matrix on the right-hand side of Equation 6.10. Then A and B satisfy Equation 6.9 when

$$s\mathbf{S} = (\mathbf{A} + BQ_HG)\mathbf{S} + BQ_H\Sigma(s). \tag{6.11}$$

Define B as follows: $B = \tilde{B}Q_H^{-1}$, where \tilde{B} is the real $(\delta_F \times m)$ matrix whose j th column is zero when $\delta_j = 0$ and contains a single 1 at the $\delta_1 + \dots + \delta_j$ position if $\delta_j \neq 0$. Observe that if $i = \delta_1 + \dots + \delta_j$ for some j , then the i th row of BQ_HG is the same as the j th row of G ; for all other values of i , the i th row of BQ_HG is zero.

Finally, define A . If $i = \delta_1 + \dots + \delta_j$ for some j , then the i th row of A is the negative of the i th row of $BQ_H G$. For other values of i , the i th row of A contains a 1 in the $(i, i + 1)$ position (just above the diagonal) and 0s elsewhere.

Verifying that A and B so defined satisfy the required relationship Equation 6.11 is straightforward. The important consequence of the construction is that $Z(s) = C(sI_{\delta_F} - A)^{-1}B$, so that (A, B, C, D) is a realization of $G(s)$ whose A -matrix has size $(\delta_F \times \delta_F)$. The following theorem summarizes the results of this section so far.

Theorem 6.4:

If $G(s)$ is a real $(p \times m)$ proper rational matrix, then the MacMillan degree of $G(s)$ is the same as the fractional degree of $G(s)$. The procedure outlined above yields a minimal realization (A, B, C, D) of $G(s)$.

The central role of Lemma 6.4 in the proof of Theorem 6.4 merits a closer look. In essence, Lemma 6.4 guarantees the existence of a minimal right MFD $G(s) = P(s)Q^{-1}(s)$ wherein the column degrees of $Q(s)$ sum to the degree of the determinant of $Q(s)$. The crucial enabling feature of $Q(s)$ is the invertibility of its high-order coefficient matrix Q_H . We will see presently that any minimal right MFD whose denominator matrix possesses this last property will have the same column degrees as $Q(s)$ up to a reordering. As a result, these special column degrees are a feature of certain right MFDs and of the transfer function matrix $G(s)$ itself.

Definition 6.8:

The ordered column indices $l_1[Q(s)], \dots, l_m[Q(s)]$ of a real nonsingular $(m \times m)$ polynomial matrix $Q(s)$ are the column degrees of $Q(s)$ arranged in decreasing order.

Theorem 6.5:

Let $Q(s)$ and $\hat{Q}(s)$ be real nonsingular $(m \times m)$ polynomial matrices appearing in minimal right MFDs $P(s)Q^{-1}(s)$ and $\hat{P}(s)\hat{Q}^{-1}(s)$ of a real $(p \times m)$ proper rational matrix $G(s)$. If the high-order coefficient matrices Q_H and \hat{Q}_H are both invertible, then the ordered column indices of $Q(s)$ and $\hat{Q}(s)$ are identical.

Proof 6.7. Assume first that $Q(s)$ and $\hat{Q}(s)$ satisfy the second item in Lemma 6.4, i.e., have respective column degrees $\{\delta_j\}$ and $\{\hat{\delta}_j\}$ that are decreasing in j . Write Equation 6.10 along with a similar equation for $\hat{Q}(s)$ as follows:

$$\begin{aligned} Q(s) &= Q_H \Sigma(s) + \tilde{Q}(s) \\ \hat{Q}(s) &= \hat{Q}_H \hat{\Sigma}(s) + \tilde{\hat{Q}}(s). \end{aligned}$$

By construction,

$$\begin{aligned} \lim_{|s| \rightarrow \infty} \tilde{Q}(s) \Sigma^{-1}(s) &\stackrel{\text{def}}{=} \lim_{|s| \rightarrow \infty} \Delta(s) = 0, \\ \lim_{|s| \rightarrow \infty} \tilde{\hat{Q}}(s) \hat{\Sigma}^{-1}(s) &\stackrel{\text{def}}{=} \lim_{|s| \rightarrow \infty} \hat{\Delta}(s) = 0. \end{aligned}$$

Because $Q(s)$ and $\hat{Q}(s)$ both come from minimal right MFDs of $G(s)$, by Theorem 6.1 an $(m \times m)$ unimodular matrix $V(s)$ exists so that $\hat{Q}(s) = Q(s)V(s)$. Manipulation yields

$$\Sigma(s)U(s)\hat{\Sigma}^{-1}(s) = [I_m + \Delta(s)]^{-1}Q_H^{-1}\hat{Q}_H[I_m + \hat{\Delta}(s)]. \tag{6.12}$$

The right-hand side of Equation 6.12 approaches a constant limit as $|s| \rightarrow \infty$; note, in particular, that $I_m + \Delta(s)$ is nonsingular for $|s|$ large enough. Meanwhile, the (i, j) entry of the matrix on the left-hand side of Equation 6.12 is simply $s^{\delta_i - \hat{\delta}_j}[U(s)]_{ij}$. Hence we need $[U(s)]_{ij} = 0$ whenever $\delta_i > \hat{\delta}_j$. One by one we will show that $\delta_j \leq \hat{\delta}_j$. If $\delta_1 > \hat{\delta}_1$, then, by the ordering on the $\hat{\delta}$ s, $\delta_1 > \hat{\delta}_j$ for all j , and the entire first row of $U(s)$ must be zero, contradicting nonsingularity and, a fortiori, unimodularity of $U(s)$. Assume inductively that $\delta_j \leq \hat{\delta}_j$ for $j < k$ but that $\delta_k > \hat{\delta}_k$. In this case, the orderings on the δ s and $\hat{\delta}$ s imply that $\delta_i > \hat{\delta}_k \geq \hat{\delta}_j$ for all $i \leq k$ and all $j \geq k$; hence the entire upper right-hand $(k \times m - k)$ corner of $U(s)$ must be zero, which contradicts unimodularity of $U(s)$ once again.

Thus $\delta_j \leq \hat{\delta}_j$ for all $j, 1 \leq j \leq m$. It follows that $\delta_j = \hat{\delta}_j$ for every j because the sum of the δ s and the sum of the $\hat{\delta}$ s must both equal the fractional degree of $G(s)$, which is the common degree of the determinants of $Q(s)$ and $\hat{Q}(s)$. Our initial assumption that the columns of $Q(s)$ and $\hat{Q}(s)$ were arrayed in decreasing order of column degree means, in terms of Definition 6.8, that $Q(s)$ and $\hat{Q}(s)$ have the same ordered column indices. Finally, it is easy to eliminate this initial assumption; simply precede the argument with right multiplications by permutation matrices Π and $\hat{\Pi}$ that reorder the matrices' columns appropriately. In any event, the ordered column indices of $Q(s)$ and $\hat{Q}(s)$ are identical.

The principal consequence of Theorem 6.5 is that any two $Q(s)$ -matrices with invertible Q_H s appearing in minimal right MFDs of $G(s)$ have the same set of ordered column indices. These special ordered column indices are sometimes called the *Kronecker controllability indices* of $G(s)$. They have other names, as well; Forney [4], for example, calls them *invariant dynamical indices*. They relate to controllability because the realization (A, B, C, D) we constructed *en route* to Theorem 6.4 is precisely the MIMO analogue to the SISO realization given in Equations 6.2 and 6.3. The realizations are called *controllable canonical forms* [2,7,10]. Interested readers can verify that applying the realization procedure following Lemma 6.4 to a scalar irreducible fractional representation Equation 6.1 leads exactly to Equations 6.2 and 6.3.

It is worth making one final observation. Our proof of Theorem 6.4 relied on constructing a minimal realization of a proper rational transfer matrix $G(s)$ starting from a minimal right MFD $P(s)Q^{-1}(s)$ of $G(s)$. We could have worked instead with a minimal left MFD $G(s) = Q_L^{-1}(s)P_L(s)$, in which case we would have considered the *row degrees* and high-order coefficient matrix of $Q_L(s)$. Perhaps the simplest way to view this is to realize $G^T(s)$ by following the route we have already laid out beginning with the right MFD $P_L^T(s)(Q_L^T(s))^{-1}$ of $G^T(s)$ and subsequently transposing the end result.

6.4 Smith–MacMillan Form, ARMA Models, and Stable Coprime Factorization

The aim of this section is to tie up some loose ends and to point the reader toward some important modern control theoretic developments that rest heavily on the theory of polynomial MFDs described in the foregoing sections. First we discuss the so-called Smith–MacMillan form for proper rational matrices; many of the results detailed in Sections 6.2 and 6.3 have alternative derivations based on the Smith–MacMillan form. Next, we describe briefly the connection between MFDs and ARMA models for MIMO linear systems. We close with a quick introduction to stable coprime factorization and mention briefly its generalizations and applications in robust control theory.

The Smith–MacMillan form of a real $(p \times m)$ proper rational matrix $G(s)$ is basically a rational version of the Smith form of a polynomial matrix $F(s)$. It was introduced originally by MacMillan [9] and later exploited by Kalman in an important paper [8] that demonstrated correspondences between several

notions of rational matrix degree. Given $G(s)$, begin by letting $q(s)$ be the monic lowest common denominator of its entries. Set $F(s) = q(s)G(s)$; by Theorem 6.2, we can find unimodular matrices $U(s)$ and $R(s)$ of respective sizes $(p \times p)$ and $(m \times m)$ so that $\Lambda(s) = U(s)F(s)R(s)$ has the form of Equation 6.5 or 6.7 depending on whether $p \geq m$ or $p \leq m$, respectively.

Assuming temporarily that $p \geq m$, the matrix $U(s)G(s)R(s) = \frac{1}{q(s)}F(s) \stackrel{\text{def}}{=} \Lambda_{SM}(s)$ takes the form

$$\begin{bmatrix} \gamma_1(s)/\phi_1(s) & 0 & 0 & \cdot & \cdot & 0 \\ 0 & \gamma_2(s)/\phi_2(s) & 0 & \cdot & \cdot & 0 \\ 0 & 0 & \gamma_3(s)/\phi_3(s) & 0 & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & \cdot & \cdot & \cdot & 0 & \gamma_m(s)/\phi_m(s) \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \end{bmatrix}, \quad (6.13)$$

where $\gamma_k(s)/\phi_k(s)$ is the fraction $d_k(s)/q(s)$ expressed in lowest terms. If $d_k(s) = 0$, set $\phi_k(s) = 1$. The divisibility conditions on $\{d_k(s)\}$ guaranteed by Theorem 6.2 ensure that $\gamma_k(s)$ divides $\gamma_{k+1}(s)$ and $\phi_{k+1}(s)$ divides $\phi_k(s)$ for all $k, 1 \leq k < m$.

Furthermore, if we set

$$P(s) = U^{-1}(s) \begin{bmatrix} \gamma_1(s) & 0 & 0 & \cdot & \cdot & 0 \\ 0 & \gamma_2(s) & 0 & \cdot & \cdot & 0 \\ 0 & 0 & \gamma_3(s) & 0 & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & \cdot & \cdot & \cdot & 0 & \gamma_m(s) \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \end{bmatrix} \\ \stackrel{\text{def}}{=} U^{-1}(s)\Gamma(s)$$

and

$$Q(s) = R(s) \begin{bmatrix} \phi_1(s) & 0 & 0 & \cdot & \cdot & 0 \\ 0 & \phi_2(s) & 0 & \cdot & \cdot & 0 \\ 0 & 0 & \phi_3(s) & 0 & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 0 \\ 0 & \cdot & \cdot & \cdot & 0 & \phi_m(s) \end{bmatrix} \\ \stackrel{\text{def}}{=} R(s)\Phi(s),$$

then $P(s)Q^{-1}(s)$ is a right MFD of $G(s)$.

$P(s)Q^{-1}(s)$ is minimal because of the divisibility conditions on the $\{\gamma_j\}$ and $\{\phi_j\}$. The easiest way to see this is by checking that the $(m+p \times m)$ matrix

$$\begin{bmatrix} Q(s_0) \\ P(s_0) \end{bmatrix} = \begin{bmatrix} R(s_0) & 0 \\ 0 & U^{-1}(s_0) \end{bmatrix} \begin{bmatrix} \Phi(s_0) \\ \Gamma(s_0) \end{bmatrix}$$

has full rank m for every complex number s_0 . The idea is that if, for example, $\gamma_k(s_0) = 0$ for some smallest value of k , then $\gamma_j(s_0) = 0$ for all $j \geq k$; hence $\phi_j(s_0) \neq 0$ for $j \geq k$ which, coupled with $\gamma_j(s_0) \neq 0$ for $j < k$,

means that m of the $\{\gamma_j(s_0)\}$ and $\{\phi_j(s_0)\}$ are nonzero. Because $P(s)Q^{-1}(s)$ is a minimal right MFD of $G(s)$, it follows from Theorem 6.4 that the MacMillan degree of $G(s)$ is the degree of $\det Q(s)$, which is the sum of the degrees of the polynomials $\{\phi_j(s)\}$.

The same sort of analysis works when $p \leq m$; in that case, $\Lambda_{SM}(s) = U(s)G(s)R(s)$ looks like a rational version of the matrix in Equation 6.7. In either case, $\Lambda_{SM}(s)$ is called the Smith–MacMillan form of $G(s)$. To summarize,

Theorem 6.6: Smith–MacMillan Form

Let $G(s)$ be a real $(p \times m)$ proper rational matrix and let $m \wedge p$ be the minimum of m and p . Unimodular matrices $U(s)$ and $R(s)$ exist so that $\Lambda_{SM}(s) = U(s)G(s)R(s)$, where

- $[\Lambda_{SM}(s)]_{ij} = 0$, except when $i = j$ and $[\Lambda_{SM}(s)]_{jj}(s) = \gamma_j(s)/\phi_j(s)$, $1 \leq j \leq m \wedge p$, where the $\{\gamma_j(s)/\phi_j(s)\}$ are ratios of coprime monic polynomials,
- $\gamma_j(s)$ divides $\gamma_{j+1}(s)$ and $\phi_{j+1}(s)$ divides $\phi_j(s)$, $1 \leq j < m \wedge p$,
- The MacMillan degree of $G(s)$ is the sum of the degrees of the $\{\phi_j(s)\}$.

An interesting consequence of Theorem 6.6 is the following characterization of MacMillan degree [9].

Corollary 6.1:

The MacMillan degree of a real $(p \times m)$ proper rational matrix $G(s)$ is the degree of the lowest common denominator of all of the minor subdeterminants of $G(s)$.

Proof 6.8. Assume $p \geq m$; the argument is similar when $p \leq m$. A glance at $\Lambda_{SM}(s)$ in Equation 6.13 and the divisibility conditions on the $\{\phi_j(s)\}$ in Theorem 6.6 reveals that for each k , $1 \leq k \leq m$, the product $\phi_1(s) \cdots \phi_k(s)$ is the monic lowest common denominator of all of the $(j \times j)$ minors in $\Lambda_{SM}(s)$ of order $j \leq k$. Hence the product of all of the $\phi_j(s)$ is the monic lowest common denominator of all of the minors of $\Lambda_{SM}(s)$. Now, $G(s)$ and $\Lambda_{SM}(s)$ are related via pre- and postmultiplication by unimodular matrices; hence the $(j \times j)$ minor determinants of each matrix are polynomial linear combinations of the $(j \times j)$ minors of the other matrix. It follows that any common denominator for one set of minors is a common denominator for the other set, and the proof is complete.

Observe that we could have generated many of the results in Sections 6.2 and 6.4 by appealing to the Smith–MacMillan form. A disadvantage of this approach is that Theorem 6.6 produces only right MFDs for $(p \times m)$ rational matrices when $p > m$ and only left MFDs when $p < m$.

We consider next some relationships between MFDs and some well-known time-domain representations of input–output linear systems. Let $G(s)$ be a real $(p \times m)$ proper rational matrix that is the transfer function of a real m -input, p -output, time-invariant linear system with input $u : \mathbf{R} \rightarrow \mathbf{R}^m$ and output $y : \mathbf{R} \rightarrow \mathbf{R}^p$. Let $\mathcal{L}\{y\}(s)$ and $\mathcal{L}\{u\}(s)$ be the Laplace transforms of y and u , so $\mathcal{L}\{y\}(s) = G(s)\mathcal{L}\{u\}(s)$. If $G(s) = Q_L^{-1}(s)P_L(s)$ is a left MFD of $G(s)$, then

$$Q_L(s)\mathcal{L}\{y\}(s) = P_L(s)\mathcal{L}\{u\}(s);$$

in the time domain, this last equation corresponds with the vector differential equation

$$Q_L(D)y(t) = P_L(D)u(t), \tag{6.14}$$

where D is the differential operator $\frac{d}{dt}$. Equation 6.14 is an ARMA (autoregressive moving-average) representation for the system’s input–output relationship.

Similarly, if $G(s) = P(s)Q^{-1}(s)$ is a right MFD of $G(s)$, we can define $w : \mathbf{R} \rightarrow \mathbf{R}^m$ by means of the autoregressive (AR) differential equation

$$Q(D)w(t) = u(t) \quad (6.15)$$

and use w as the input to a moving-average (MA) specification of y , namely,

$$y(t) = P(D)w(t). \quad (6.16)$$

Because

$$\begin{aligned} \mathcal{L}\{y\}(s) &= P(s)\mathcal{L}\{w\}(s) \text{ and } \mathcal{L}\{w\}(s) = Q^{-1}(s)\mathcal{L}\{u\}(s), \\ \mathcal{L}\{y\}(s) &= P(s)Q^{-1}(s)\mathcal{L}\{u\}(s) = G(s)\mathcal{L}\{u\}(s), \end{aligned}$$

so Equations 6.15 and 6.16 together constitute another time-domain description of the input–output behavior of the system. Whereas Equation 6.14 gives an ARMA description for the system, Equations 6.15 and 6.16 split the input–output relation into autoregressive and moving-average parts. For a SISO system, any fractional representation of the form Equation 6.1 acts as a left and right “MFD,” so that the two time-domain characterizations are identical.

We close by presenting a very brief introduction to some of the ideas underlying stable coprime factorization, which is the single most important off-shoot of the theory of MFDs for input–output systems. We call a rational matrix $H(s)$ *stable* if, and only if, the poles of the entries in $H(s)$ lie in the open left half-plane $\text{Re}\{s\} < 0$. As usual, let $G(s)$ be a real $(p \times m)$ proper rational matrix. It turns out to be possible to write $G(s)$ in the form $G(s) = H_1(s)H_2^{-1}(s)$, where

- $H_1(s)$ and $H_2(s)$ are stable proper rational matrices of respective sizes $(p \times m)$ and $(m \times m)$,
- $H_1(s)$ and $H_2(s)$ are *right coprime over the ring of stable rational functions*, that is, the only common right stable $(m \times m)$ proper rational matrix factors of $H_1(s)$ and $H_2(s)$ have inverses that are also stable and proper.

Any such representation $G(s) = H_1(s)H_2^{-1}(s)$ is called a *stable right coprime factorization* of $G(s)$. One can define stable left coprime factorizations similarly.

It is not difficult to show that stable coprime factorizations exist. One approach, patterned after a technique due originally to Vidyasagar [14], goes as follows. Given $G(s)$, choose $\alpha > 0$ so that $-\alpha$ is not a pole of any entry in $G(s)$. Let $\sigma = 1/(s + \alpha)$, so that $s = (1 - \alpha\sigma)/\sigma$. Define $\tilde{G}(\sigma) = G((1 - \alpha\sigma)/\sigma)$. It follows that $\tilde{G}(\sigma)$ is a proper rational matrix function of σ . To see why it is proper, observe that the condition $\sigma \rightarrow \infty$ is the same as $s \rightarrow -\alpha$, and $-\alpha$ is not a pole of $G(s)$.

Now invoke the theory of Section 6.2 and find a minimal right MFD $\tilde{G}(\sigma) = P(\sigma)Q^{-1}(\sigma)$ of $\tilde{G}(\sigma)$. Finally, set $H_1(s) = P[1/(s + \alpha)]$ and $H_2(s) = Q[1/(s + \alpha)]$. Then

$$G(s) = \tilde{G}\left(\frac{1}{s + \alpha}\right) = H_1(s)H_2^{-1}(s).$$

Because $P(\sigma)$ and $Q(\sigma)$ are polynomial in σ , $H_1(s)$ and $H_2(s)$ are proper rational matrix functions of s . Moreover, all of the poles of $H_1(s)$ and $H_2(s)$ are at $-\alpha$, which means that $H_1(s)$ and $H_2(s)$ are stable. Furthermore, any stable $(m \times m)$ proper rational right common factor $H(s)$ of $H_1(s)$ and $H_2(s)$ defines, via $V(s) = H((1 - \alpha\sigma)/\sigma)$, a polynomial right common factor of $P(\sigma)$ and $Q(\sigma)$, which must have a polynomial inverse by minimality of $P(\sigma)Q^{-1}(\sigma)$. It follows that $H^{-1}(s) = V^{-1}[1/(s + \alpha)]$ is stable and proper, implying that $H_1(s)$ and $H_2(s)$ are right coprime over the ring of stable proper rational functions.

The principal application of stable coprime factorizations is to robust control system design. At the heart of such applications is the notion of the H^∞ norm of a stable proper rational matrix $H(s)$. Given such an $H(s)$, the H^∞ norm of $H(s)$ is the supremum over $\omega \in \mathbf{R}$ of the largest singular value of $H(i\omega)$. Given

two possibly unstable ($p \times m$) transfer function matrices $G_a(s)$ and $G_b(s)$, one can define the distance between $G_a(s)$ and $G_b(s)$ in terms of the H^∞ norm of the *stable* rational matrix

$$\begin{bmatrix} H_{a1}(s) \\ H_{a2}(s) \end{bmatrix} - \begin{bmatrix} H_{b1}(s) \\ H_{b2}(s) \end{bmatrix},$$

where $G_a(s) = H_{a1}(s)H_{a2}^{-1}(s)$ and $G_b(s) = H_{b1}(s)H_{b2}^{-1}(s)$ are stable coprime factorizations of $G_a(s)$ and $G_b(s)$.

Interested readers can consult [1,3,5,13], and the references therein for a through development of the ideas underlying robust control system design and their dependence on the theory of stable coprime factorization. A by-product of Vidyasagar's approach [13] is a framework for understanding MFDs and stable coprime factorizations in terms of more general themes from abstract algebra, notably ring theory. This framework reveals that many of our results possess natural generalizations that apply in contexts broader than those considered here.

6.5 Defining Terms

Proper rational matrix: A matrix whose entries are proper rational functions, i.e., ratios of polynomials each of whose numerator degrees is less than or equal to its denominator degree.

MacMillan degree: The dimension of the state in a minimal realization of a proper rational transfer function matrix.

Real polynomial matrix: A matrix whose entries are polynomials with real coefficients.

Nonsingular: A real square polynomial matrix is nonsingular if its determinant is a nonzero polynomial.

Unimodular: A real square polynomial matrix is unimodular if its determinant is a nonzero real number.

7.1 Motivations and Preliminaries

Over the last decades, stability and performance of control systems affected by bounded perturbations have been studied in depth. The attention of researchers and control engineers concentrated on robustness tools in the areas H_∞ , Kharitonov (or real parametric uncertainty), L_1 , Lyapunov, μ , and quantitative feedback control (QFT). For further discussions on these topics and on the exposition of the main technical results, the reader may consult different sections of this volume and the special issue on robust control of *Automatica* (1993).

One of the key features of this chapter is the concept of *robustness*. To explain, instead of a single (nominal) system, we study a family of systems and we say that a certain property (e.g., stability or performance) is robustly satisfied if it is satisfied for all members of the family. In particular, we focus on linear, time-invariant, single-input, single-output systems affected by real parametric uncertainty. Stability of

interval polynomials (i.e., polynomials whose coefficients lie within given intervals) and the well-known *Theorem of Kharitonov* (Kharitonov, 1978) are at the core of this research area. This theorem states that an interval polynomial has all its roots in the open left half-plane if and only if four specially constructed polynomials have roots in the open left half-plane. Subsequently, the *Edge Theorem* (Bartlett et al., 1988) studied the problem of affine dependence between coefficients and uncertain parameters, and more general regions than the open left half-plane. This result provides an elegant solution proving that it suffices to check stability of the so-called one-dimensional exposed edges. We refer to the books (Ackermann, 1993; Barmish, 1994; Bhattacharyya et al., 1995; Djaferis, 1995; Kogan, 1995) for a discussion of the extensive literature on this subject.

To explain robustness analysis more precisely with real parametric uncertainty, we consider a family of polynomials $p(s, q)$ of degree n whose real coefficients $a_i(q)$ are continuous functions of an ℓ -dimensional vector of real uncertain parameters q , each bounded in the interval $[q_i^-, q_i^+]$. More formally, we define

$$p(s, q) \doteq a_0(q) + a_1(q)s + a_2(q)s^2 + \cdots + a_n(q)s^n, \\ q \doteq [q_1, q_2, \dots, q_\ell],$$

and the set

$$Q \doteq \{q : q_i^- \leq q_i \leq q_i^+, i = 1, 2, \dots, \ell\}.$$

We assume that $p(s, q)$ is of degree n for all $q \in Q$ —that is, we assume that $a_n(q) \neq 0$ for all $q \in Q$. Whenever the relations between the polynomial coefficients $a_i(q)$ and the vector q are specified, we study the root location of $p(s, q)$ for all $q \in Q$. Within this framework, the basic property we need to guarantee is robust stability. In particular, we say that $p(s, q)$ is robustly stable if $p(s, q)$ has roots in the open left half-plane for all $q \in Q$.

The real parametric approach can be also formulated for control systems. In this case, we deal with a family of plants denoted by $P(s, q)$. More precisely, we concentrate on robust stability or performance of a proper plant

$$P(s, q) \doteq \frac{N_P(s, q)}{D_P(s, q)},$$

where $N_P(s, q)$ and $D_P(s, q)$ are the numerator and denominator polynomials whose real coefficients are continuous functions of q . We assume that $D_P(s, q)$ has invariant degree for all $q \in Q$. We also assume that there is no unstable pole-zero cancellation for all $q \in Q$; the reader may refer to Chockalingam and Dasgupta (1993) for further discussions.

Robustness analysis is clearly of interest when the plant requires compensation. In practice, if the compensator is designed on the basis of the nominal plant, then, robustness analysis can be performed by means of the closed-loop polynomial. That is, given a compensator transfer function

$$C(s) \doteq \frac{N_C(s)}{D_C(s)}$$

connected in a feedback loop with $P(s, q)$, we immediately write the closed-loop polynomial

$$p(s, q) = N_P(s, q)N_C(s) + D_P(s, q)D_C(s)$$

whose root location determines closed-loop stability.

To conclude this preliminary discussion, we remark that one of the main technical tools described here is the so-called value set (or template in the QFT jargon, see Horowitz, 1991; see Barmish, 1994 for a detailed exposition of its properties). In particular, we show that if the polynomial or plant coefficients are affine functions of q , the value set can be easily constructed with 2D graphics. Consequently, robustness tests in the frequency domain can be readily performed. Finally, in this chapter, since the main goal is to introduce the basic concepts and tools available for robustness analysis with real parametric uncertainty, we do not provide formal proofs but we make reference to the specific literature on the subject.

7.1.1 Motivating Example: DC Electric Motor with Uncertain Parameters

For the sake of illustrative purposes, an example of a DC electric motor is formulated and carried out throughout this chapter in various forms. Consider the system represented in Figure 7.1 of an armature-controlled DC electric motor with independent excitation. The voltage to angle transfer function $P(s) = \Theta(s)/V(s)$ is given by

$$P(s) = \frac{K}{LJs^3 + (RJ + BL)s^2 + (K^2 + RB)s},$$

where L is the armature inductance, R the armature resistance, K the motor electromotive force-speed constant, J the moment of inertia, and B the mechanical friction. Clearly, the values of some of these parameters may be uncertain. For example, the moment of inertia and the mechanical friction are functions of the load. Therefore, depending on the specific application, if the load is not fixed, the values of J and B are not precisely known. Similarly, the armature resistance R is a parameter that can be measured very accurately but is subject to temperature variations, and the motor constant K is a function of the field magnetic flow which may vary.

To summarize, it is reasonable to say that the motor parameters, or a subset of them, may be unknown but bounded within given intervals. More precisely, we can identify

$$q_1 = L; \quad q_2 = R; \quad q_3 = K; \quad q_4 = J; \quad q_5 = B$$

and specify a given interval $[q_i^-, q_i^+]$ for each $q_i, i = 1, 2, \dots, 5$. Then, instead of $P(s)$, we write

$$P(s, q) = \frac{q_3}{q_1 q_4 s^3 + (q_2 q_4 + q_1 q_5) s^2 + (q_3^2 + q_2 q_5) s}.$$

7.2 Description of the Uncertainty Structures

As discussed in the preliminaries in Section 7.1, we consider a proper plant $P(s, q)$ whose coefficients are continuous functions of the uncertainty q which is confined to the set Q . Depending on the specific problem under consideration, the coefficients of $N_P(s, q)$ and $D_P(s, q)$ may be linear or nonlinear functions of q . To explain more precisely, we consider the example of Section 7.1.1. Assume that the armature

FIGURE 7.1 DC electric motor.

inductance L , the armature resistance R , and the constant K are fixed while the moment of inertia J and the mechanical friction B are unknown. Then, we take $q_1 = J$ and $q_2 = B$ as uncertain parameters; the resulting set Q is a two-dimensional rectangle. In this case, the plant coefficients are *affine** functions of q_1 and q_2

$$\begin{aligned} N_P(s, q) &= K; \\ D_P(s, q) &= Lq_1s^3 + (Rq_1 + Lq_2)s^2 + (K^2 + Rq_2)s \end{aligned}$$

and we say that the plant has an affine uncertainty structure. This situation arises in practice whenever, for example, the load conditions are not known. Other cases, however, may be quite different from the point of view of the uncertainty description. For example, if L , K , and B are fixed and R and J are uncertain, we identify q_1 and q_2 with R and J , respectively. We observe that the denominator coefficient of s^2 contains the product of the two uncertain parameters q_1 and q_2

$$\begin{aligned} N_P(s, q) &= K; \\ D_P(s, q) &= Lq_2s^3 + (q_1q_2 + BL)s^2 + (K^2 + Bq_1)s. \end{aligned}$$

In this case, the plant coefficients are no longer affine functions of the uncertainties but they are *multiaffine* functions† of q . This discussion can be further generalized. It is well known that the motor constant K is proportional to the magnetic flow. In an ideal machine with independent excitation, such a flow is constant, but in a real machine, the armature reaction phenomenon causes magnetic saturation with the consequence that the constant K drops when the armature current exceeds a certain value. Hence, we consider K as an uncertain parameter and we set $q_1 = K$. In turn, this implies that the plant coefficients are *polynomial* functions of the uncertainties. In addition, since q_1 enters in $N_P(s, q)$ and $D_P(s, q)$, we observe that there is coupling between numerator and denominator coefficients. In different situations when this coupling is not present, we say that the numerator and denominator uncertainties are *independent*. An important class of independent uncertainties, in which all the coefficients of the numerator and denominator change independently within given intervals, is the so-called interval plant; for example, see Barmish et al. (1992). In other words, an interval plant is the ratio of two independent interval polynomials; recall that an interval polynomial

$$p(s, q) = q_0 + q_1s + q_2s^2 + \cdots + q_ns^n$$

has independent coefficients bounded in given intervals $q_i^- \leq q_i \leq q_i^+$ for $i = 0, 1, 2, \dots, n$.

The choice of the uncertain parameters for a control system is a modeling problem, but robustness analysis is of increasing difficulty for more general uncertainty structures. In the following sections, we show that this analysis can be easily performed if the structure is affine and we demonstrate that a “tight” approximate solution can be readily computed in the multiaffine case.

7.3 Uncertainty Structure Preservation with Feedback

In the previous sections, we described the classes of uncertainty structures entering into the open-loop plant. From the control system point of view, an important and closely related question arises: what are the conditions under which a certain uncertainty structure is preserved with feedback? To answer this question, we consider a plant $P(s, q)$ and a compensator $C(s)$ connected with the feedback structure shown in Figure 7.2.

* An affine function $f : Q \rightarrow \mathbf{R}$ is the sum of a linear function and a constant. For example, $f(q) = 3q_1 + 2q_2 - 4$ is affine.

† A function $f : Q \rightarrow \mathbf{R}$ is said to be multiaffine if the following condition holds: If all components q_1, \dots, q_ℓ except for one are fixed, then f is affine. For example, $f(q) = 3q_1q_2q_3 - 6q_1q_3 + 4q_2q_3 + 2q_1 - 2q_2 + q_3 - 1$ is multiaffine.

FIGURE 7.2 Closed-loop system.

Depending on the specific problem under consideration (e.g., disturbance attenuation or tracking), we study sensitivity, complementary sensitivity, and output-disturbance transfer functions (e.g., see Doyle et al., 1992)

$$S(s, q) \doteq \frac{1}{1 + P(s, q)C(s)}; \quad T(s, q) \doteq \frac{P(s, q)C(s)}{1 + P(s, q)C(s)}; \quad R(s, q) \doteq \frac{P(s, q)}{1 + P(s, q)C(s)}.$$

For example, it is immediate to show that the sensitivity function $S(s, q)$ takes the form

$$S(s, q) = \frac{D_P(s, q)D_C(s)}{N_P(s, q)N_C(s) + D_P(s, q)D_C(s)}.$$

If the uncertainty q enters affinely into the plant numerator and denominator, q also enters affinely into $S(s, q)$. We conclude that the affine structure is preserved with feedback. The same fact also holds for $T(s, q)$ and $R(s, q)$. Next, we consider the interval plant structure; recall that an interval plant has independent coefficients bounded in given intervals. It is easy to see that, in general, this structure is not preserved with compensation. Moreover, if the plant is affected by uncertainty entering independently into numerator and denominator coefficients, this decoupling is destroyed for all transfer functions $S(s, q)$, $T(s, q)$, and $R(s, q)$. Finally, it is important to note that the multiaffine and polynomial uncertainty structures are preserved with feedback. Table 7.1 summarizes this discussion. In each entry of the first row of the table we specify the structure of the uncertain plant $P(s, q)$ and in the entry below the corresponding structure of $S(s, q)$, $T(s, q)$, and $R(s, q)$.

7.4 Overbounding with Affine Uncertainty: The Issue of Conservatism

As briefly mentioned at the end of Section 7.3, the affine structure is very convenient for performing robustness analysis. However, in several real applications, the plant does not have this form; for example, see Abate et al. (1994). In such cases, the nonlinear uncertainty structure can always be embedded into an affine structure by replacing the original family by a “larger” one. Even though this process has the advantage that it handles much more general robustness problems, it has the obvious drawback that it gives only an approximate but guaranteed solution. Clearly, the goodness of the approximation depends on the

TABLE 7.1 Uncertainty Structure with Feedback

$P(s, q)$	Independent	Interval	Affine	Multiaffine	Polynomial
$S(s, q), T(s, q), R(s, q)$	Dependent	Affine	Affine	Multiaffine	Polynomial

specific problem under consideration. To illustrate this simple overbounding methodology, we consider the DC-electric motor transfer function with two uncertain parameters and take $q_1 = R$ and $q_2 = J$. As previously discussed, with this specific choice, the plant has a multiaffine uncertainty structure. That is,

$$P(s, q) = \frac{K}{Lq_2s^3 + (q_1q_2 + BL)s^2 + (K^2 + Bq_1)s}$$

To overbound $P(s, q)$ with an affine structure, we set $q_3 = q_1q_2$. Given bounds $[q_1^-, q_1^+]$ and $[q_2^-, q_2^+]$ for q_1 and q_2 , the range of variation $[q_3^-, q_3^+]$ for q_3 can be easily computed:

$$\begin{aligned} q_3^- &= \min\{q_1^- q_2^-, q_1^- q_2^+, q_1^+ q_2^-, q_1^+ q_2^+\}; \\ q_3^+ &= \max\{q_1^- q_2^-, q_1^- q_2^+, q_1^+ q_2^-, q_1^+ q_2^+\}. \end{aligned}$$

Clearly, the new uncertain plant

$$P(s, \tilde{q}) = \frac{K}{Lq_2s^3 + (q_3 + BL)s^2 + (K^2 + Bq_1)s}$$

has three uncertain parameters $\tilde{q} = (q_1, q_2, q_3)$ entering affinely into $P(s, \tilde{q})$. This new parameter is not independent, because $q_3 = q_1q_2$ and not all values of $[q_3^-, q_3^+]$ are physically realizable. However, since we assume that the coefficients q_i are independent, this technique leads to an affine overbounding of $P(s, q)$ with $P(s, \tilde{q})$. We conclude that if a certain property is guaranteed for $P(s, \tilde{q})$, then, this same property is also guaranteed for $P(s, q)$. Unfortunately, the converse is not true. The control systems interpretation of this fact is immediate: Suppose that a certain compensator $C(s)$ does not stabilize $P(s, \tilde{q})$. It may turn out that this same compensator does stabilize the family $P(s, q)$. Figure 7.3 illustrates the overbounding procedure for $q_1^- = 1.2, q_1^+ = 1.7, q_2^- = 1.7, q_2^+ = 2.2, q_3^- = 2.04$ and $q_3^+ = 3.74$.

To generalize this discussion, we restate the overbounding problem as follows: Given a plant $P(s, q)$ having nonlinear uncertainty structure and a set Q , find a new uncertain plant $P(s, \tilde{q})$ with affine uncertainty structure and a new set \tilde{Q} . In general, there is no unique solution and there is no systematic procedure to construct an “optimal” overbounding. In practice, however, the control engineer may find via heuristic considerations a reasonably good method to perform it. The most natural way to obtain this bound may be to compute an interval overbounding for each coefficient of the numerator and denominator coefficients—that is, an interval plant overbounding. To illustrate, letting $a_i(q)$ and $b_i(q)$

FIGURE 7.3 Overbounding procedure.

denote the numerator and denominator coefficients of $P(s, q)$, lower and upper bounds are given by

$$a_i^- = \min_{q \in Q} a_i(q); \quad a_i^+ = \max_{q \in Q} a_i(q)$$

and

$$b_i^- = \min_{q \in Q} b_i(q); \quad b_i^+ = \max_{q \in Q} b_i(q).$$

If $a_i(q)$ and $b_i(q)$ are affine or multiaffine functions and q lies in a rectangular set Q , these minimizations and maximizations can be easily performed. That is, if we denote by $q^1, q^2, \dots, q^L \doteq q^{2^L}$ the vertices of Q , then

$$a_i^- = \min_{q \in Q} a_i(q) = \min_{k=1,2,\dots,L} a_i(q^k); \quad a_i^+ = \max_{q \in Q} a_i(q) = \max_{k=1,2,\dots,L} a_i(q^k)$$

and

$$b_i^- = \min_{q \in Q} b_i(q) = \min_{k=1,2,\dots,L} b_i(q^k); \quad b_i^+ = \max_{q \in Q} b_i(q) = \max_{k=1,2,\dots,L} b_i(q^k).$$

To conclude this section, we remark that for more general uncertainty structures than multiaffine, a tight interval plant overbounding may be difficult to construct.

7.5 Robustness Analysis for Affine Plants

In this section, we study robustness analysis of a plant $P(s, q)$ affected by affine uncertainty $q \in Q$. The approach taken here is an extension of the classical Nyquist criterion and requires the notion of *value set*.

For fixed frequency $s = j\omega$, we define the value set $P(j\omega, Q) \subset \mathbf{C}$ as

$$P(j\omega, Q) \doteq \{P(j\omega, q) : D_P(j\omega, q) \neq 0, q \in Q\}.$$

Roughly speaking, $P(j\omega, Q)$ is a set in the complex plane which graphically represents the uncertain plant. Without uncertainty, $P(j\omega)$ is a singleton and its plot for a range of frequencies is the Nyquist diagram. The nice feature is that this set is two-dimensional even if the number of uncertain parameters is large. Besides the issue of the value set construction (which is relegated to the next subsection for the specific case of affine plants), we now formally state a robustness criterion. This is an extension of the classical Nyquist criterion and holds for more general uncertainty structures than affine—continuity of the plant coefficients with respect to the uncertain parameters suffices. However, for more general classes of plants than affine, the construction of the value set is a hard problem.

Criterion 7.1: Robustness Criterion for Uncertain Plants

The plant $P(s, q)$ is robustly stable for all $q \in Q$ if and only if the Nyquist stability criterion is satisfied for some $q \in Q$ and $-1 + j0 \notin P(j\omega, Q)$ for all $\omega \in \mathbf{R}$.

This criterion can be proved using continuity arguments; see Fu (1990). To detect robustness, one should check if the Nyquist stability criterion holds for some $q \in Q$; without loss of generality, this check can be performed for the nominal plant. Second, it should be verified that the value set does not go through the point $-1 + j0$ for all $\omega \in \mathbf{R}$. In practice, however, one can discretize a bounded interval $\Omega \subset \mathbf{R}$ with a “sufficiently” large number of samples—continuity considerations guarantee that the intersampling is not a critical issue. Finally, by drawing the value set, the gain and phase margins can be graphically evaluated; similarly, the resonance peak of the closed-loop system can be computed using the well-known constant M-circles.

7.5.1 Value Set Construction for Affine Plants

In this section, we discuss the generation of the value set $P(j\omega, Q)$ in the case of affine plants. The reader familiar with Nyquist-type analysis and design is aware of the fact that a certain range of frequencies, generally close to the crossover frequencies, can be specified *a priori*. That is, a range $\Omega = [\omega^-, \omega^+]$ may be imposed by design specifications or estimated by performing a frequency analysis of the nominal system under consideration. In this section, we assume that $D_P(j\omega, q) \neq 0$ for all $q \in Q$ and $\omega \in \Omega$. We remark that if the frequency $\omega = 0$ lies in the interval Ω , this assumption is not satisfied for type 1 or 2 systems—however, these systems can be easily handled with contour indentation techniques as in the classical Nyquist analysis. We also observe that the assumption that $P(s, q)$ does not have poles in the interval $[\omega^-, \omega^+]$ simply implies that $P(j\omega, Q)$ is bounded.

To proceed with the value set construction, we first need a preliminary definition. The one-dimensional *exposed edge* e^{ik} is a convex combination of the adjacent vertices* q^i and q^k of Q

$$e^{ik} \doteq \lambda q^i + (1 - \lambda)q^k$$

for $\lambda \in [0, 1]$. Denote by E the set of all $q \in e^{ik}$ for some i, k , and $\lambda \in [0, 1]$. This set is the collection of all one-dimensional exposed edges of Q .

Under our assumption $\partial P(j\omega, Q) \neq 0$, for $q \in Q$ and all ω , the set $P(j\omega, Q)$ is compact. Then, for fixed $\omega \in \Omega$, it can be shown (see Fu, 1990) that

$$\partial P(j\omega, Q) \subseteq P(j\omega, E) \doteq \{P(j\omega, q) : q \in E\}$$

where $\partial P(j\omega, Q)$ denotes the boundary of the value set and $P(j\omega, E)$ is the image in the complex plane of the exposed edges (remember that we assumed $\partial P(j\omega, Q) \neq 0$, for $q \in Q$ and all ω). This says that the construction of the value set only requires computations involving the one-dimensional exposed edges. The second important fact observed in Fu (1990) is that the image of the edge e^{ik} in the complex plane is an arc of a circle or a line segment. To explain this claim, in view of the affine dependence of both $N(s, q)$ and $D(s, q)$ versus q , we write the uncertain plant corresponding to the edge e^{ik} in the form

$$P(s, e^{ik}) = \frac{N_P(s, \lambda q^i + (1 - \lambda)q^k)}{D_P(s, \lambda q^i + (1 - \lambda)q^k)} = \frac{N_P(s, q^k) + \lambda N_P(s, (q^i - q^k))}{D_P(s, q^k) + \lambda N_P(s, (q^i - q^k))}$$

for $\lambda \in [0, 1]$. For fixed $s = j\omega$, it follows that the mapping from the edge e^{ik} to the complex plane is bilinear. Then, it is immediate to conclude that the image of each edge is an arc of a circle or a line segment; the center and the radius of the circle and the extreme points of the segment can be also computed. Even though the number of one-dimensional exposed edges of the set Q is $\ell 2^{\ell-1}$, the set E is one dimensional. Therefore, a fast computation of $P(j\omega, E)$ can be easily performed and the boundary of the value set $P(j\omega, Q)$ can be efficiently generated.

Finally, an important extension of this approach is robustness analysis of systems with time delay. That is, instead of $P(s, q)$, we consider

$$P_\tau(s, q) \doteq \frac{N(s, q)}{D(s, q)} e^{-\tau s}$$

where $\tau \geq 0$ is a delay. It is immediate to see that the value set of $P_\tau(s, q)$ at frequency $s = j\omega$ is given by the value set of the plant $N(s, q)/D(s, q)$ rotated with respect to the origin of the complex plane of an angle $\tau\omega$ in clockwise direction. Therefore, Criterion 7.1 still applies; see Barmish and Shi (1990) for further details.

* Two vertices are adjacent if they differ for only one component. For example, in Figure 7.3 the vertices $q^1 = (1.2, 2.2, 2.04)$ and $q^2 = (1.2, 2.2, 3.74)$ are adjacent.

7.5.2 The DC-Electric Motor Example Revisited

To illustrate the concepts discussed in this section, we revisit the DC-electric motor example. We take two uncertain parameters

$$q_1 = J; \quad q_2 = B,$$

where $q_1 \in [0.03, 0.15]$ and $q_2 \in [0.001, 0.03]$ with nominal values $J = 0.042 \text{ kg m}^2$ and $B = 0.01625 \text{ N m/rps}$. The remaining parameters take values $K = 0.9 \text{ V/rps}$, $L = 0.025 \text{ H}$, and $R = 5\Omega$. The voltage to angle uncertain plant is

$$P(s, q) = \frac{0.9}{0.025q_1s^3 + (5q_1 + 0.025q_2)s^2 + (0.81 + 5q_2)s}$$

To proceed with robustness analysis, we first estimate the critical range of frequencies obtaining $\Omega = [10, 100]$. We note that the denominator of $P(s, q)$ is nonvanishing for all $q \in Q$ in this range. Then, we study robust stability of the plant connected in a feedback loop with a PID compensator

$$C(s) = K_P + \frac{K_I}{s} + K_Ds.$$

For closed-loop stability, we recall that the Nyquist criterion requires that the Nyquist plot of the open-loop system does not go through the point $-1 + j0$ and that it does encircle this point (in counter-clockwise direction) a number of times equal to the number of unstable poles; for example, see Horowitz (1963). In this specific case, setting $K_P = 200$, $K_I = 5120$, and $K_D = 20$, we see that the closed-loop nominal system is stable with a phase margin $\phi \approx 63.7^\circ$ and a crossover frequency $\omega_c \approx 78.8 \text{ rad/s}$. As a result of the analysis carried out by sweeping the frequency, it turns out that the closed-loop system is not robustly stable, since at the frequency $\omega \approx 16 \text{ rad/s}$ the value set includes the point $-1 + j0$. Figure 7.4 shows the Nyquist plot of the nominal plant and the value set for 12 equispaced frequencies in the range (12,34).

FIGURE 7.4 Nyquist plot and value set.

FIGURE 7.5 Nyquist plot and value set.

To robustly stabilize $P(s, q)$, we take $K_I = 2000$ and the same values of K_P and K_D as before. The reasons for choosing this value of K_I can be explained as follows: The compensator transfer function has phase zero at the frequency $\bar{\omega} = \sqrt{K_I/K_D}$. Thus, reducing K_I from 5120 to 2000 causes a drop of $\bar{\omega}$ from 16 to 10 rad/s. This implies that the phase lead effect begins at lower frequencies “pushing” the value set out of the critical point $-1 + j0$. Since the nominal system is stable with a phase margin $\phi \approx 63.7^\circ$ and a crossover frequency $\omega_c \approx 80.8$ rad/s, this new control system has nominal performance very close to the previous one. However, with this new PID compensator, the system becomes robustly stable. To see this, we generated the value sets for the same frequencies as before; see Figure 7.5.

From this figure, we observe that $P(j\omega, q)$ does not include the point $-1 + j0$. We conclude that the closed-loop system is now robustly stable; the worst-case phase margin is $\phi \approx 57.9^\circ$.

7.6 Robustness Analysis for Affine Polynomials

In this section, we study robustness analysis of the closed-loop polynomial

$$p(s, q) = N_P(s, q)N_C(s) + D_P(s, q)D_C(s)$$

when the coefficients of $N_P(s, q)$ and $D_P(s, q)$ are affine functions of q . The main goal is to provide an alternative criterion for polynomials instead of plants. With this approach, we do not need the nonvanishing condition about $D_P(s, q)$; furthermore, unstable pole-zero cancellations are not an issue. In this case, however, we lose the crucial insight given by the Nyquist plot. For fixed frequency $s = j\omega$, we define

the value set $p(j\omega, Q) \subset \mathbf{C}$ as

$$p(j\omega, Q) \doteq \{p(j\omega, q) : q \in Q\}.$$

As in the plant case, $p(j\omega, Q)$ is a set in the complex plane which moves with frequency and which graphically represents the uncertain polynomial.

Criterion 7.2: Zero-Exclusion Condition for Uncertain Polynomials

The polynomial $p(s, q)$ is robustly stable for all $q \in Q$ if and only if $p(s, q)$ is stable for some $q \in Q$ and $0 \notin p(j\omega, Q)$ for all $\omega \in \mathbf{R}$.

The proof of this criterion requires elementary facts and, in particular, continuity of the roots of $p(s, q)$ versus its coefficients; see Frazer and Duncan (1929). Similar to the discussion in Section 7.5, we note that Criterion 7.2 is easily implementable—at least whenever the value set can be efficiently generated. That is, given an affine polynomial family, we take any element in this family and we check its stability. This step is straightforward using the Routh table or any root finding routine. Then, we sweep the frequency ω over a selected range of critical frequencies $\Omega = [\omega^-, \omega^+]$. This interval can be estimated, for example, using some *a priori* information on the specific problem or by means of one of the bounds given in Marden (1966). If there is no intersection of $p(j\omega, Q)$ with the origin of the complex plane for all $\omega \in \Omega$, then $p(s, q)$ is robustly stable.

Remark 7.1

A very similar zero exclusion condition can be stated for more general regions \mathcal{D} than the open left half-plane. Meaningful examples of \mathcal{D} regions are the open unit disk, a shifted left half-plane and a damping cone*. In this case, instead of sweeping the imaginary axis, we need to discretize the boundary of \mathcal{D} .

7.6.1 Value Set Construction for Affine Polynomials

In this section, we discuss the generation of the value set $p(j\omega, Q)$. Whenever the polynomial coefficients are affine functions of the uncertain parameters, the value set can be easily constructed. To this end, two key facts are very useful. First, for fixed frequency, we note that $p(j\omega, Q)$ is a two-dimensional convex polygon. Second, letting q^1, q^2, \dots, q^L denote the vertices of Q as in Section 7.4, we note that the vertices of the value set are a subset of the complex numbers $p(j\omega, q^1), p(j\omega, q^2), \dots, p(j\omega, q^L)$. These two observations follow from the fact that, for fixed frequency, real and imaginary parts of $p(s, q)$ are both affine functions of q . Then, the value set is a two-dimensional affine mapping of the set Q and its vertices are generated by vertices of Q . Thus, for fixed ω , it follows that

$$p(j\omega, Q) = \text{conv} \{p(j\omega, q^1), p(j\omega, q^2), \dots, p(j\omega, q^L)\}$$

where conv denotes the convex hull[†]. The conclusion is then immediate: For fixed frequency, one can generate the points $p(j\omega, q^1), p(j\omega, q^2), \dots, p(j\omega, q^L)$ in the complex plane. The value set can be constructed by taking the convex hull of these points—this can be readily done with 2D graphics. From the computational point of view, we observe that the number of edges of the polygon is at most 2ℓ at each frequency. This follows from the observations that any edge of the value set is the image of an exposed edge of Q . In addition, parallel edges of Q are mapped into parallel edges in the complex plane and the edges of Q have only ℓ distinct directions. These facts can be used to efficiently compute $p(j\omega, Q)$. We now provide an example which illustrates the value set generation.

* A damping cone is a subset of the complex plane defined as $\{s : \text{Re}(s) \leq -\alpha|\text{Im}(s)|\}$ for $\alpha > 0$.

† The convex hull $\text{conv } S$ of a set S is the smallest convex set containing S .

7.6.2 Example of Value Set Generation

Using the same data as in the example of Section 7.5.2 and a PID controller with gains $K_P = 200$, $K_I = 5120$, and $K_D = 20$, we study the closed-loop polynomial

$$p(s, q) = 0.025q_1s^4 + s^3(5q_1 + 0.025q_2) + s^2(5q_2 + 18.81) + 180s + 4608.$$

Robustness analysis is performed for 29 equispaced frequencies in the range (2,30). Figure 7.6 shows the polygonality of the value set and zero inclusion for $\omega \approx 16$ rad/s which demonstrates instability. This conclusion is in agreement with that previously obtained in Section 7.5.2.

7.6.3 Interval Polynomials: Kharitonov's Theorem and Value Set Geometry

In the special case of interval polynomials, robustness analysis can be greatly facilitated via Kharitonov's Theorem (Kharitonov, 1978). We now recall this result. Given an interval polynomial

$$p(s, q) = q_0 + q_1s + q_2s^2 + \dots + q_ns^n$$

of order n (i.e., $q_n \neq 0$) and bounds $[q_i^-, q_i^+]$ for each coefficient q_i , define the following four polynomials:

$$\begin{aligned} p_1(s) &\doteq q_0^+ + q_1^+s + q_2^-s^2 + q_3^-s^3 + q_4^+s^4 + q_5^+s^5 + q_6^-s^6 + q_7^-s^7 + \dots; \\ p_2(s) &\doteq q_0^- + q_1^-s + q_2^+s^2 + q_3^+s^3 + q_4^-s^4 + q_5^-s^5 + q_6^+s^6 + q_7^+s^7 + \dots; \\ p_3(s) &\doteq q_0^+ + q_1^-s + q_2^-s^2 + q_3^+s^3 + q_4^+s^4 + q_5^-s^5 + q_6^-s^6 + q_7^+s^7 + \dots; \\ p_4(s) &\doteq q_0^- + q_1^+s + q_2^+s^2 + q_3^-s^3 + q_4^-s^4 + q_5^+s^5 + q_6^+s^6 + q_7^-s^7 + \dots. \end{aligned}$$

FIGURE 7.6 Value set plot.

Then, $p(s, q)$ is stable for all $q \in Q$ if and only if the four Kharitonov polynomials $p_1(s), p_2(s), p_3(s)$ and $p_4(s)$ are stable. To provide a geometrical interpretation of this result, we observe that the value set for fixed frequency $s = j\omega$ is a rectangle with level edges parallel to real and imaginary axis. The four vertices of this set are the complex numbers $p_1(j\omega), p_2(j\omega), p_3(j\omega)$, and $p_4(j\omega)$; see Dasgupta (1988). If the four Kharitonov polynomials are stable, due to the classical Mikhailov's criterion (Mikhailov, 1938), their phase is strictly increasing for ω increasing. In turn, this implies that the level rectangular value set moves in a counterclockwise direction around the origin of the complex plane. Next, we argue that the strictly increasing phase of the vertices and the parallelism of the four edges of the value set with real or imaginary axis guarantee that the origin does not lie on the boundary of the value set. By continuity, we conclude that the origin is outside the value set and the zero exclusion condition is satisfied; see Minnichelli et al. (1989).

7.6.4 From Robust Stability to Robust Performance

In this section, we point out the important fact that the polynomial approach discussed in this chapter can be also used for robust performance. To explain, we take an uncertain plant with affine uncertainty and we show how to compute the largest peak of the Bode plot magnitude for all $q \in Q$ —that is, the worst-case H_∞ norm. Formally, for a stable strictly proper plant $P(s, q)$, we define

$$\max_{q \in Q} \|P(s, q)\|_\infty \doteq \max_{q \in Q} \sup_{\omega} |P(j\omega, q)|.$$

Given a performance level $\gamma > 0$, then

$$\max_{q \in Q} \|P(s, q)\|_\infty < \gamma$$

if and only if

$$\left| \frac{N_P(j\omega, q)}{D_P(j\omega, q)} \right| < \gamma$$

for all $\omega \geq 0$ and $q \in Q$. Since $P(j\omega, q) \rightarrow 0$ for $\omega \rightarrow \infty$, this is equivalent to check if the zero-exclusion condition

$$N_P(j\omega, q) - \gamma D_P(j\omega, q) e^{j\phi} \neq 0$$

is satisfied for all $\omega \in \mathbf{R}, q \in Q$ and $\phi \in [0, 2\pi]$. In turn, this implies that the polynomial with complex coefficients

$$p_\phi(s, q) = N_P(s, q) - \gamma D_P(s, q) e^{j\phi}$$

has roots in the open left half-plane for all $q \in Q$ and $\phi \in [0, 2\pi]$. Clearly, for fixed $\phi \in [0, 2\pi]$, Criterion 7.2 can be readily used; however, since $p_\phi(s, q)$ has complex coefficients, it should be necessarily checked for all $\omega \in \mathbf{R}$, including negative frequencies.

7.6.5 Algebraic Criteria for Robust Stability

If the uncertain polynomial under consideration is affine, the well-known Edge Theorem applies (Bartlett et al., 1988). This algebraic criterion is alternative to the frequency domain approach studied in this section. Roughly speaking, this result says that an affine polynomial family is robustly stable if and only if all the polynomials associated with the one-dimensional exposed edges of the set Q are stable. Even though this result is of algebraic nature, it can be explained by means of value set arguments. For affine polynomials and for fixed ω , we have already observed in Section 7.6.3 that the boundary of the value set $p(j\omega, Q)$ is the image of the one-dimensional exposed edges of Q . Thus, to guarantee the zero-exclusion

condition, we need to guarantee that all edge polynomials are nonvanishing for all $\omega \in \mathbf{R}$ —otherwise an instability occurs. We conclude that stability detection for affine polynomials requires the solution of a number of one-dimensional stability problems. Each of these problems can be stated as follows: Given polynomials $p_0(s)$ and $p_1(s)$ of order n and $m < n$, respectively, we need to study the stability of

$$p(s, \lambda) = p_0(s) + \lambda p_1(s)$$

for all $\lambda \in [0, 1]$. A problem of great interest is to ascertain when the robust stability of $p(s, \lambda)$ can be deduced from the stability of the extreme polynomials $p(s, 0)$ and $p(s, 1)$. This problem can be formulated in more general terms: To construct classes of uncertain polynomials for which the stability of the vertex polynomials (or a subset of them) implies stability of the family. Clearly, the edges associated with an interval polynomial is one such class. Another important example is given by the edges of the closed-loop polynomial of a control system consisting of a first-order compensator and an interval plant; see Barmish et al. (1992). Finally, see Rantzer (1992) for generalizations and for the concept of convex directions polynomials.

7.6.6 Further Extensions: The Spectral Set

In some cases, it is of interest to generate the entire root location of a family of polynomials. This leads to the concept of *spectral set*; see Barmish and Tempo (1991). Given a polynomial $p(s, q)$, we define the spectral set as

$$\sigma \doteq \{s \in \mathbf{C} : p(s, q) = 0 \text{ for some } q \in Q\}.$$

The construction of this set is quite easy for affine polynomials. Basically, the key idea can be explained as follows: For fixed $s \in \mathbf{C}$, checking if s is a member of the spectral set can be accomplished by means of the zero-exclusion condition; see also Remark 7.6.2. Next, it is easy to compute a bounded root confinement region $\bar{\sigma} \supseteq \sigma$; for example, see Marden (1966). Then, the construction of the spectral set σ amounts to a two-dimensional gridding of $\bar{\sigma}$ and, for each grid point, checking zero exclusion.

The spectral set concept can be further extended to control systems consisting of a plant $P(s, q)$ with a feedback gain K_P which needs tuning. In this case, we deal with the so-called robust root locus (Barmish and Tempo, 1990)—that is, the generation of all the roots of the closed-loop polynomial when K_P ranges in a given interval. To illustrate, we consider the same data as in Section 7.6.3 and a feedback gain K_P , thus obtaining the closed loop polynomial

$$p(s, q) = 0.025q_1s^3 + (5q_1 + 0.025q_2)s^2 + (0.81 + 5q_2)s + 0.9K_P,$$

where $q_1 \in [0.03, 0.15]$ and $q_2 \in [0.001, 0.03]$. In Figure 7.7, we show the spectral set for $K_P = 200$. Actually, only the portion associated with the dominant roots is visible since the spectral set, obviously, includes a real root in the interval $[-200.58, -200.12]$ which is out of the plot.

7.7 Multiaffine Uncertainty Structures

In this section, we discuss the generation of the value set for polynomials with more general uncertainty structures than affine. In particular, we study the case when the polynomial coefficients are multiaffine functions of the uncertain parameters. Besides the motivations provided in Section 7.3, we recall that this uncertainty structure is quite important for a number of reasons. For example, consider a linear state-space system of the form $\dot{x}(t) = A(q)x(t)$ where each entry of the matrix $A(q) \in \mathbf{R}^{m \times m}$ lies in a bounded interval, that is, it is an interval matrix. Then, the characteristic polynomial required for stability considerations has a multiaffine uncertainty structure.

In the case of multiaffine uncertainty, the value set is generally not convex and its construction cannot be easily performed. However, we can easily generate a “tight” convex approximation of $p(j\omega, Q)$ —this approximation being its convex hull $\text{conv } p(j\omega, Q)$. More precisely, the following fact, called the Mapping

FIGURE 7.7 Spectral set.

Theorem, holds: The convex hull of the value set $\text{conv } p(j\omega, Q)$ is given by the convex hull of the vertex polynomials $p(j\omega, q^1), p(j\omega, q^2), \dots, p(j\omega, q^L)$. In other words, the parts of the boundary of $p(j\omega, Q)$ which are not line segments are always contained inside this convex hull. Clearly, if $\text{conv } p(j\omega, Q)$ is used instead of $p(j\omega, Q)$ for robustness analysis through zero exclusion, only a sufficient condition is obtained. That is, if the origin of the complex plane lies inside the convex hull, we do not know if it is also inside the value set. We now formally state the Mapping Theorem; see Zadeh and Desoer (1963).

Theorem 7.1: Mapping Theorem

For fixed frequency $\omega \in \mathbf{R}$,

$$\text{conv } p(j\omega, Q) = \text{conv } \{p(j\omega, q^1), p(j\omega, q^2), \dots, p(j\omega, q^L)\}.$$

With regard to applicability and usefulness of this result, comments very similar to those made in Section 7.7 about the construction of the value set for affine polynomials can be stated. Figure 7.8 illustrates the Mapping Theorem for the polynomial

$$p(s, q) = s^3 + (q_2 + 4q_3 + 2q_1q_2)s^2 + (4q_2q_3 + q_1q_2q_4)s + q_3 + 2q_1q_3 - q_1q_2(q_4 - 0.5)$$

with four uncertain parameters q_1, q_2, q_3 , and q_4 each bounded in the interval $[0, 1]$ and frequency $\omega = 1$ rad/s. The “true” value set shown in this figure is obtained via random generation of 10,000 samples uniformly distributed in the set Q .

FIGURE 7.8 Value set and its convex hull.

7.8 General Uncertainty Structures and Controller Synthesis

For general uncertainty structures there is no analytical tool that enables us to construct the value set. For systems with a very limited number of uncertain parameters, a brute force approach, as in the example of Theorem 7.1, can be taken by simply gridding the set Q with a sufficient number of points. With this procedure, one can easily obtain a “cloud” in the complex plane which approximates the value set. Obviously, this method is not practical for a large number of uncertain parameters and provides no guarantee that robustness is satisfied outside the grid points.

Several attempts in the literature aimed at solving this general problem. Among the pioneering contributions along this line we recall the parameter space approach (Ackermann, 1980), techniques for the multivariable gain margin computation (de Gaston and Safonov, 1988) and (Sideris and Sanchez Pena, 1989) and the geometric programming approach (Vicino et al., 1990).

As far as the robust synthesis problem is concerned, it is worth mentioning that the methods described in this chapter are suitable for synthesis in a trial-and-error fashion. A practical use of the techniques can be summarized in the following two steps (as illustrated in Section 7.5.2):

- Synthesize a controller for the nominal plant with any proper technique.
- Perform robustness analysis taking into account the uncertainties and go back to the previous step if necessary.

In the special case of low complexity compensators, the two steps can be combined. This is the case of PID synthesis for which efficient robust design tools have been proposed (Ho et al., 2000).

To facilitate robustness analysis for general parametric uncertainty structures and for nonparametric uncertainty, different approaches have been proposed in the literature. Among the others, we recall the μ approach (Zhou et al., 1996; Sanchez Pena and Sznaier, 1998) and the probabilistic methods (Tempo et al., 2005). These approaches can be also used for designing a controller, but μ -synthesis is based on a

procedure which is not guaranteed to converge to a global solution and probabilistic methods provide a controller which satisfies the required specification only with a given probability. However, both methods are useful tools for many robust control problems.

As a final remark, we emphasize that in this chapter we considered only uncertainties which are constant in time. It is known that parameter variations or, even worse, switching, may have a destabilizing effect. There are, indeed, examples of very simple systems that are (Hurwitz) stable for any fixed value of the parameters but can be destabilized by parameter variations. A class of systems which has been investigated is that of Linear Parameter-Varying (LPV) systems. For these systems, it has been established that the Lyapunov approach is crucial. For an overview of the problem of robustness of LPV systems and the link with switching systems, the reader is referred to Blanchini and Miani (2008).

8.1 Modeling MIMO Linear Time-Invariant Systems in Terms of Transfer Function Matrices

Any multivariable linear time invariant (LTI) system is uniquely described by its impulse response matrix. The Laplace transform of this matrix function of time gives rise to the system's transfer function matrix (TFM). We assume that all systems in the sequel have TFM representations; frequency response analysis is always applied to TFM descriptions of systems. For the case of finite dimensional LTI systems, when we have a state-space description of the system, closed-form evaluation of the TFM is particularly easy. This is discussed in Example 8.1. More generally, *infinite*-dimensional LTI systems also have TFM representations, although closed-form evaluation of the TFM of these systems is less straightforward. Stability (in whatever sense) is *presumed*; without stability we cannot talk about the steady-state response of a system to sinusoidal inputs. For such systems, the TFM can be measured by means of sinusoidal inputs. We will not discuss the use of frequency-domain techniques in robustness analysis.

Example 8.1: Finite-Dimensional LTI Systems

Suppose that we have a finite-dimensional LTI system G , with the following state equations

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t).\end{aligned}$$

Taking the Laplace transform of the state equation, we see that,

$$x(s) = (sI - A)^{-1}Bu(s)$$

where we have abused notation slightly with $x(s)$ and $u(s)$ representing the Laplace transforms of $x(t)$ and $u(t)$, respectively. Similarly,

$$y(s) = [C(sI - A)^{-1}B + D]u(s) \equiv G(s)u(s).$$

The matrix quantity $G(s)$ is the transfer function matrix associated with the system G .

As a matter of convention, we will refer to the input of the system generically as u . The more specific notation $u(t)$ and $u(s)$ will be used in reference to u represented as time-domain and frequency-domain (Laplace-transform) signals, respectively. A similar convention applies to the output, y . We will assume that u is a vector with m components and that the output y is a vector with p components. This makes the TFM a $p \times m$ matrix. To make this explicit,

$$G(s) = \begin{bmatrix} g_{11}(s) & \cdots & g_{1m}(s) \\ \vdots & & \vdots \\ g_{p1}(s) & \cdots & g_{pm}(s) \end{bmatrix} \quad (8.1)$$

$$u(s) = [u_1(s), \dots, u_m(s)]^T \quad (8.2)$$

$$y(s) = [y_1(s), \dots, y_p(s)]^T \quad (8.3)$$

Componentwise,

$$y_k(s) = \sum_{j=1}^m g_{kj}(s)u_j(s), \quad k = 1, \dots, p. \quad (8.4)$$

As Laplace transforms, $u(s)$, $y(s)$, and $G(s)$ are generally complex-valued quantities. In more formal mathematical notation, $u(s) \in C^m$, $y(s) \in C^p$, and $G(s) \in C^{p \times m}$.

8.2 Frequency Response for MIMO Plants

In discussing the frequency response of LTI systems, we focus our attention on systems which are *strictly* stable. This allows us to envision applying sinusoidal inputs to the system and measuring steady-state output signals which are appropriately scaled and phase-shifted sinusoids of the same frequency. Because we are dealing with MIMO systems, there are now additional factors which affect the nature of the frequency response, particularly the relative magnitude and phase of each of the components of the input vector u . These considerations will be discussed in detail below.

Suppose that we have in mind a complex exponential input, as below,

$$u(t) = \tilde{u}e^{j\omega t} \quad (8.5)$$

where $\tilde{u} = (\tilde{u}_1, \dots, \tilde{u}_m)^T$ is a fixed (complex) vector in C^m . Note that by allowing \tilde{u} to be complex, the individual components of $u(t)$ can have different phases relative to one another.

Example 8.2:

Suppose that $m = 2$ and that $\tilde{u} = ((1 + j1), (1 - j1))^T$, then,

$$u(t) = \begin{pmatrix} (1 + j1) \\ (1 - j1) \end{pmatrix} e^{j\omega t} = \begin{pmatrix} \sqrt{2}e^{j\pi/4} \\ \sqrt{2}e^{-j\pi/4} \end{pmatrix} e^{j\omega t} = \begin{pmatrix} \sqrt{2}e^{j(\omega t + \pi/4)} \\ \sqrt{2}e^{j(\omega t - \pi/4)} \end{pmatrix}$$

Thus, the two components of $u(t)$ are phase shifted by $\pi/2$ radians (or 90 degrees).

Suppose that this input is applied to our stable LTI system G (of compatible dimension). We know from elementary linear systems theory that each component of the output of G can be expressed in terms of G 's frequency response $G(j\omega)$. (We obtain the frequency response from $G(s)$, literally, by setting $s = j\omega$.) Thus, at steady state,

$$y_k(t) = \sum_{j=1}^m g_{kj}(j\omega) \tilde{u}_j e^{j\omega t}; \quad k = 1, \dots, p. \quad (8.6)$$

We may now express the vector output $y(t)$ at steady state as follows:

$$y(t) = \tilde{y} e^{j\omega t}, \quad \tilde{y} = (\tilde{y}_1, \dots, \tilde{y}_p)^T \in C^p, \quad (8.7)$$

where

$$\tilde{y}_k = \sum_{j=1}^m g_{kj}(j\omega) \tilde{u}_j, \quad k = 1, \dots, p. \quad (8.8)$$

Putting all of this together,

$$\tilde{y} = G(j\omega) \tilde{u}. \quad (8.9)$$

Just as in the SISO case, the MIMO frequency response $G(j\omega)$ provides a convenient means of computing the output of an LTI system driven by a complex exponential input. *Analysis* of the frequency response, however, is now complicated by the fact that $G(j\omega)$ is a matrix quantity. A simple way is needed to characterize the “size” of the frequency response as a function of ω . The effect of $G(j\omega)$ on complex exponential input signals depends on the direction of $\tilde{u} \in C^m$, including the relative phase of the components. In fact, a whole range of “sizes” of $G(j\omega)$ exists, depending on the directional nature of \tilde{u} . Our characterization of size should thus provide both upper and lower bounds on the magnitude gain of the frequency response matrix. The mathematical tool we need here is the Singular Value Decomposition (SVD) discussed briefly in the following section.

8.3 Mathematical Detour

We present here some mathematical definitions and basic results from linear algebra germane to our discussion of MIMO frequency response analysis. An excellent reference for this material can be found in [5].

8.3.1 Introduction to Complex Vectors and Complex Matrices

Given a complex-valued column vector $x \in C^n$, we may express x in terms of its real and imaginary components,

$$x = \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} = \begin{pmatrix} a_1 + jb_1 \\ \vdots \\ a_n + jb_n \end{pmatrix} = a + jb$$

where a and b are both purely real-valued vectors in C^n . We define the row vector x^H as the complex-conjugate transpose of x , i.e.,

$$x^H = (x_1^*, \dots, x_n^*) = a^T - jb^T.$$

The superscript asterisk above denotes the complex-conjugate operation.

If we have two vectors x and y , both elements of C^n , then the *inner product of x and y* is given by the (complex) scalar $x^H y$. Two vectors x and y in C^n , which satisfy $x^H y = 0$, are said to be *orthogonal*.

The *Euclidean norm* of x , denoted by $\|x\|_2$, is given by the square root of the inner product of x with itself,

$$\|x\|_2 = \sqrt{x^H x} = \sqrt{a^T a + b^T b} = \sqrt{\sum_{i=1}^n (a_i^2 + b_i^2)}.$$

It is important to note that $\|\cdot\|_2$ is a real scalar function chosen arbitrarily to reflect the “size” of vectors in C^n . (It is true that, as a norm, $\|\cdot\|_2$ has to satisfy certain mathematical requirements, particularly positivity, scaling, and the triangle inequality. Aside from this, our definition of $\|\cdot\|_2$ is arbitrary.) Because all of the components of x are taken into account simultaneously, the value (and interpretation) of $\|x\|_2$ will depend on the *units* in which the components of x are expressed.

Example 8.3:

Suppose that we are dealing with a high-power (AC) electronic device and that the state of the device is determined by a vector $x \in C^2$ made up of phased voltages at two distinct points in the circuitry. Suppose first that both quantities are expressed in terms of kilovolts (kV). For example,

$$x = (1 + j2, 2 - j3)^T \text{ kV}$$

then,

$$\begin{aligned} \|x\|_2^2 &= [(1 - j2), (2 + j3)][(1 + j2), (2 - j3)]^T \\ &= (1 + 4) + (4 + 9) \\ &= 18 \end{aligned}$$

If, however, the first component is expressed in terms of Volts (V), then

$$\begin{aligned} \|x\|_2^2 &= [(1000 - j2000), (2 + j3)][(1000 + j2000), (2 - j3)]^T, \\ &= (10^6 + 4 \times 10^6) + (4 + 9) \\ &= 5000013, \end{aligned}$$

which is a far cry from what we had before! Note that this is not an entirely unreasonable example. In general, the components of x can consist of entirely different types of physical quantities, such as voltage, current, pressure, concentration, etc. The choice of units is arbitrary and will have an important impact on the “size” of x when measured in terms of the Euclidean norm.

A complex-valued matrix $M \in C^{p \times m}$ is a matrix whose individual components are complex valued. Since M is complex valued, we can express it as the sum of its real and imaginary matrix parts, i.e., $M = A + jB$, where A and B are both purely real-valued matrices in $C^{p \times m}$.

We define the *Hermitian of a complex matrix* M as the complex-conjugate transpose of M , that is, M^H is computed by taking the complex conjugate of the transpose of M . Mathematically,

$$M^H = A^T - jB^T \quad (8.10)$$

The following will play an important role in the next subsection.

8.3.1.1 Important Fact

Both $M^H M$ and MM^H have eigenvalues that are purely real valued and nonnegative. Moreover, their nonzero eigenvalues are identical even though $M^H M \neq MM^H$.

Example 8.4:

Let

$$M = \begin{bmatrix} 1 & 1+j \\ -j & 2+j \end{bmatrix}$$

Then,

$$M^H = \begin{bmatrix} 1 & j \\ 1-j & 2-j \end{bmatrix}$$

$$M^H M = \begin{bmatrix} 2 & j3 \\ -j3 & 7 \end{bmatrix}$$

and

$$MM^H = \begin{bmatrix} 3 & 3+j2 \\ 3-j2 & 6 \end{bmatrix}$$

Although $M^H M$ and MM^H are clearly not equal, a simple calculation easily reveals that both products have the same characteristic polynomial,

$$\det(\lambda I - M^H M) = \det(\lambda I - MM^H) = \lambda^2 - 9\lambda + 5$$

This implies that $M^H M$ and MM^H share the same eigenvalues.

A complex-valued matrix M is called *Hermitian* if $M = M^H$. A nonsingular, complex-valued matrix is called *unitary* if $M^{-1} = M^H$. Stated another way, a complex-valued matrix M is unitary if its column-vectors are mutually orthonormal.

The *spectral norm of a matrix* $M \in C^{p \times m}$, denoted $\|M\|_2$, is defined by

$$\|M\|_2 = \max_{\|x\|_2=1} \|Mx\|_2 \quad (8.11)$$

The best way to interpret this definition is to imagine the vector x rotating on the surface of the unit hypersphere in C^m , generating the vector Mx in C^p . The size of Mx , i.e., its Euclidean norm, will depend on the direction of x . For some direction of x , the vector Mx will attain its maximum value. This value is equal to the spectral norm of M .

8.3.2 The Singular Value Decomposition

In this subsection we give a quick introduction to the singular value decomposition. This will be an essential tool in analyzing MIMO frequency response. For more details, the reader is referred to [5].

8.3.2.1 The Singular Values of a Matrix

Suppose that M is a $p \times m$ matrix, real or complex. Assume that the rank of M is k . We associate with M a total of k positive constants, denoted $\sigma_i(M)$, or simply σ_i , $i = 1, \dots, k$. These are the *singular values* of M , computed as the positive square roots of the nonzero eigenvalues of either $M^H M$ or MM^H , that is,

$$\sigma_i(M) = \sqrt{\lambda_i(M^H M)} = \sqrt{\lambda_i(MM^H)} > 0, \quad i = 1, \dots, k \quad (8.12)$$

where $\lambda_i(\cdot)$ is a shorthand notation for “the i th nonzero eigenvalue of”. Note that the matrices $M^H M$ and MM^H may have one or more zero valued eigenvalues in addition to the ones used to compute the singular values of M . It is common to index and rank the singular values as follows:

$$\sigma_1(M) \geq \sigma_2(M) \geq \dots \geq \sigma_k(M) > 0 \quad (8.13)$$

The largest singular value of M , denoted $\sigma_{\max}(M)$, is thus equal to $\sigma_1(M)$. Similarly, $\sigma_{\min}(M) = \sigma_k(M)$.

While it is tricky, in general, to compute the eigenvalues of a matrix numerically, reliable and efficient techniques for computing singular values are available in commercial software packages, such as MATLAB[®].

8.3.2.2 The Singular Value Decomposition

The SVD is analogous to matrix diagonalization. It allows one to write the matrix M in terms of its singular values and involves the definition of special directions in both the range and domain spaces of M .

To begin the definition of the SVD, we use the k nonzero singular values σ_i of M , computed above. First form a square matrix with the k singular values along the main diagonal. Next, add rows and columns of zeros until the resulting matrix Σ is $p \times m$. Thus,

$$\Sigma = \left[\begin{array}{cccc|cc} \sigma_1 & 0 & \cdots & 0 & & \\ 0 & \sigma_2 & \cdots & 0 & & \\ \cdots & \cdots & \cdots & \cdots & & \\ 0 & 0 & \cdots & \sigma_k & & \\ \hline & & & & 0_{(p-k) \times k} & 0_{(p-k) \times (m-k)} \end{array} \right] \quad (8.14)$$

By convention, assume that

$$\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_k$$

Theorem 8.1: Singular Value Decomposition

A $p \times p$ unitary matrix U (with $U = U^H$) and an $m \times m$ unitary matrix V (with $V = V^H$) exist so that

$$M = U \Sigma V^H \quad \Sigma = U^H M V \quad (8.15)$$

The p -dimensional column vectors u_i , $i = 1, \dots, p$, of the unitary matrix U are called the *left singular vectors* of M . The m -dimensional column vectors v_i , $i = 1, \dots, m$ of V are called the *right singular vectors* of M . Thus, we can visualize,

$$U = [u_1 \ u_2 \ \dots \ u_p], \quad V = [v_1 \ v_2 \ \dots \ v_m]$$

Since U and V are each unitary,

$$\begin{aligned} u_i^H u_k &= \delta_{ik}, \quad i, k = 1, \dots, p \\ v_i^H v_k &= \delta_{ik}, \quad i, k = 1, \dots, m \end{aligned}$$

where δ_{ik} is the Kronecker delta. Because the left and right singular vectors are linearly independent, they can serve as basis vectors for C^p and C^m , respectively. Moreover, the left and right singular vectors

associated with the (nonzero) singular values of M span the range and left-null spaces of the matrix M , respectively. Finally, a simple calculation shows that the left singular vectors of M are the normalized right eigenvectors of the $p \times p$ matrix MM^H . Similarly, the right singular vectors of M are the normalized left eigenvectors of the $p \times p$ matrix $M^H M$.

8.3.2.3 Some Properties of Singular Values

We list here some important properties of singular values. We leave the proofs to the reader. Some of the properties require that the matrix be square and nonsingular.

1. $\sigma_{\max}(M) = \max_{\|x\|_2=1} \|Mx\|_2 = \|M\|_2 = \frac{1}{\sigma_{\min}(M^{-1})}$.
2. $\sigma_{\min}(M) = \min_{\|x\|_2=1} \|Mx\|_2 = \frac{1}{\|M^{-1}\|_2} = \frac{1}{\sigma_{\max}(M^{-1})}$.
3. $\sigma_i(M) - 1 \leq \sigma_i(I + M) \leq \sigma_i(M) + 1$, $i = 1, \dots, k$.
4. $\sigma_i(\alpha M) = |\alpha| \sigma_i(M)$ for all $\alpha \in \mathbb{C}$, $i = 1, \dots, k$.
5. $\sigma_{\max}(M_1 + M_2) \leq \sigma_{\max}(M_1) + \sigma_{\max}(M_2)$.
6. $\sigma_{\max}(M_1 M_2) \leq \sigma_{\max}(M_1) \cdot \sigma_{\max}(M_2)$.

Property 1 indicates that maximum singular value $\sigma_{\max}(M)$ is identical to the spectral norm of M . Thus, Properties 5 and 6 are restatements of the triangle inequality and submultiplicative property, respectively.

8.3.2.4 The SVD and Finite Dimensional Linear Transformations

We shall now present some geometric interpretations of the SVD result. Consider the linear transformation

$$y = Mu, \quad u \in C^m, \quad y \in C^p. \quad (8.16)$$

Let M have the singular value decomposition discussed above, that is, $M = U\Sigma V^H$. It may help the reader to think of u as the input to a static system M with output y . From the SVD of M ,

$$y = Mu = U\Sigma V^H u.$$

Suppose we choose u to be one of the right singular vectors, say v_i , of M . Let y_i denote the resulting “output” vector. Then,

$$y_i = Mv_i = U\Sigma V^H v_i.$$

Because the right singular vectors of M are orthonormal,

$$V^H v_i = (0, \dots, 0, 1, 0, \dots, 0)^T,$$

where the i th component only takes on the value of 1. In view of the special structure of the matrix of singular values Σ ,

$$\Sigma V^H v_i = (0, \dots, 0, \sigma_i, 0, \dots, 0)^T$$

where, again, only the i th component is potentially nonzero. Thus, finally,

$$y_i = U\Sigma V^H v_i = \sigma_i u_i. \quad (8.17)$$

Equation 8.17 interprets the unique relationship between singular values and singular vectors. In the context of M as a “static” system, when the input u is equal to a right singular vector v_i , the output direction is fixed by the corresponding left singular vector u_i . Keeping in mind that both u_i and v_i have unit magnitudes (in the Euclidean sense), the amplification (or attenuation) of the input is measured by the associated singular value σ_i . If we choose $u = v_i$, where $i > k$, then the corresponding output vector is zero because the matrix is not full rank and there are no more (nonzero) singular values.

Because Equation 8.17 holds for $i = 1, \dots, k$, it is true in particular for the maximum and minimum singular values and associated singular vectors. By abuse of notation, we shall refer to these left and right

FIGURE 8.1 Visualization of SVD quantities.

singular vectors as *maximum and minimum singular vectors*, respectively, and use the subscripts “max” and “min” to distinguish them. Within the context of “static” systems, inputs along the *maximum* right singular vector generate the *largest* output along the direction of the *maximum* left singular vector. Similar comments apply to the case where inputs are in the direction of the minimum left singular vector.

Example 8.5: The Case Where M Is Real and 2 x 2

Let us suppose that M is a real-valued, nonsingular matrix mapping $u \in R^2$ to $y = Mu \in R^2$. Let us suppose further that u rotates on the circumference of the unit circle. The image of u under the transformation of M will then trace an ellipse in the (output) plane, as illustrated in Figure 8.1.

Because M is a real, nonsingular, 2×2 matrix, the SVD analysis will give

$$\Sigma = \begin{bmatrix} \sigma_{max} & 0 \\ 0 & \sigma_{min} \end{bmatrix} \quad U = [u_{max} \ u_{min}] \quad V = [v_{max} \ v_{min}]$$

where Σ , U , and V are all real valued.

Suppose that when u equals the vector OA , the output y is the vector OA' . Suppose further that, $y = y_{max} \equiv \sigma_{max}u_{max}$. Thus, the maximum right singular vector v_{max} equals the (unit length) vector OA , and the maximum left singular vector u_{max} equals the (unit length) vector OA'' . Moreover, the maximum singular value, σ_{max} equals the length of the vector OA' .

Similarly, suppose that when u equals the vector OB , the output y is the vector OB' . Suppose further that, $y = y_{min} \equiv \sigma_{min}u_{min}$. Thus, the minimum right singular vector v_{min} equals the (unit length) vector OB , and the minimum left singular vector u_{min} equals the (unit length) vector OB'' . Moreover, the minimum singular value, σ_{min} equals the length of the vector OB' .

Notice in Figure 8.1 that the left singular vectors are normal to each other, as are the right singular vectors.

As the minimum singular value decreases, so does the semiminor axis of the ellipse. As this happens, the ellipse becomes more and more elongated. In the limit, as $\sigma_{min} \rightarrow 0$, the ellipse degenerates into a straight line segment, and the matrix M becomes singular. In this limiting case, there are directions in the output space that we cannot achieve.

If the matrix M were a 3×3 real nonsingular matrix, then we could draw a similar diagram, illustrating the unit sphere mapping into a three-dimensional ellipsoid. Unfortunately, diagrams for higher dimensional matrices are impossible. Similarly, diagrams for *complex* matrices (even 2×2 matrices) are impossible, because we need a plane to represent each complex number.

Using these geometric interpretations of SVD quantities, it is possible to be precise about the meaning of the “size” of a real or complex matrix. From an intuitive point of view, if we consider the “system” $y = Mu$, and if we restrict the input vector u to have unit length, then

1. The matrix M is “large” if $\|y\|_2 \gg 1$, independent of the direction of the unit input vector u .
2. The matrix M is “small” if $\|y\|_2 \ll 1$, independent of the direction of the unit input vector u .

If we accept these definitions, then we can quantify size as follows:

1. The matrix M is “large” if its minimum singular value is large, i.e., $\sigma_{\min}(M) \gg 1$.
2. The matrix M is “small” if its maximum singular value is small, i.e., $\sigma_{\max}(M) \ll 1$.

8.3.2.5 More Analytical Insights

Once we have computed an SVD for a matrix M , in $y = Mu$, then we can compute many other important quantities. In particular, suppose that M is $m \times m$ and nonsingular. It follows that M has m nonzero singular values. We saw earlier (in Equation 8.17) that

$$y_i = \sigma_i u_i$$

when $u = v_i$, $i = 1, \dots, m$. Because the left singular vectors are orthonormal, they form a basis for the m -dimensional input space, so that we can write any (input) vector in C^m as a linear combination of the v_i s. For example, let u be given as follows:

$$u = \gamma_1 v_1 + \gamma_2 v_2 + \dots + \gamma_m v_m$$

where the γ_i are real or complex scalars. From the linearity of the transformation M ,

$$y = Mu = \gamma_1 \sigma_1 u_1 + \gamma_2 \sigma_2 u_2 + \dots + \gamma_m \sigma_m v_m.$$

Using the SVD, we can also gain insight on the inverse transformation $u = M^{-1}y$. From the SVD theorem, we know that $M = U\Sigma V^H$. Using the fact that U and V are unitary, $M^{-1} = V\Sigma^{-1}U^H$. Notice that

$$\Sigma^{-1} = \text{diag} \left\{ \frac{1}{\sigma_1}, \frac{1}{\sigma_2}, \dots, \frac{1}{\sigma_m} \right\}$$

Thus, if

$$y = \delta_1 u_1 + \delta_2 u_2 + \dots + \delta_m u_m$$

then

$$u = M^{-1}y = \delta_1 \frac{1}{\sigma_1} v_1 + \delta_2 \frac{1}{\sigma_2} v_2 + \dots + \delta_m \frac{1}{\sigma_m} v_m$$

This implies that the information in the SVD of M can be used to solve systems of linear equations without computing the inverse of M .

8.4 The SVD and MIMO Frequency Response Analysis

We now return to our discussion of MIMO frequency response with the full power of the SVD at our disposal. Once again, we shall focus our attention on the transfer function matrix (TFM) description of the strictly stable LTI system $G(s)$. As before, we will assume that G has m inputs and p outputs, making $G(s)$ a $p \times m$ matrix. In general we shall assume that $p \geq m$, so that, unless the rank k of $G(s)$ becomes less than m , the response of the system to a non-zero input is always non-zero.

Recall that if the input vector signal $u(t)$ is a complex exponential of the form $u(t) = \tilde{u}e^{j\omega t}$, with \tilde{u} fixed in C^m , then at steady state, the output vector $y(t)$ will also be a complex exponential function,

$y(t) = \tilde{y}e^{j\omega t}$, for some $\tilde{y} \in C^p$. Recall, also, that the complex vectors \tilde{u} and \tilde{y} are related by $G(s)$ evaluated at $s = j\omega$, that is,

$$\tilde{y} = G(j\omega)\tilde{u}.$$

It is important to note that $G(j\omega)$ is a complex matrix that changes with frequency ω . For any given fixed frequency, we can calculate the SVD of $G(j\omega)$:

$$G(j\omega) = U(j\omega)\Sigma(\omega)V^H(j\omega)$$

Note that, in general, all of the factors in the SVD of $G(j\omega)$ are explicitly dependent on omega:

1. The matrix $\Sigma(\omega)$ is a $p \times m$ matrix whose main diagonal is composed of the singular values of $G(j\omega)$,

$$\sigma_{max}(\omega) = \sigma_1(\omega), \sigma_2(\omega), \dots, \sigma_{k_\omega}(\omega) = \sigma_{min}(\omega)$$

where k_ω is the rank of $G(j\omega)$.

2. The matrix $U(j\omega)$ is an $m \times m$ complex-valued matrix whose column vectors $\{u_j(j\omega)\}$ are the left singular vectors of $G(j\omega)$.
3. The matrix $V(j\omega)$ is a $p \times p$ complex-valued matrix whose column vectors $\{v_j(j\omega)\}$ are the right singular vectors of $G(j\omega)$.

8.4.1 Singular Value Plots (SV Plots)

Once we calculate the maximum and minimum singular values of $G(j\omega)$ for a range of frequencies ω , we can plot them together on a Bode plot (decibels versus rad/sec in log-log scale). Figure 8.2 shows a hypothetical SV plot.

With the proper interpretation, the SV plot can provide valuable information about the properties of the MIMO system G . In particular, it quantifies the “gain-band” of the plant at each frequency, and shows how this changes with frequency. It is a natural generalization of the information contained in the classical Bode magnitude plot for SISO plants. One main difference here is that, in the multivariable case, this “gain-band” is described by two curves, not one.

It is crucial to interpret the information contained in the SV plot correctly. At each frequency ω we assume that the input is a *unit* complex exponential, $u(t) = \tilde{u}e^{j\omega t}$. Then, assuming that we have reached steady state, we know that the output is also a complex exponential with the same frequency, $y(t) = \tilde{y}e^{j\omega t}$,

FIGURE 8.2 A hypothetical SV plot.

where $\tilde{y} = G(j\omega)\tilde{u}$. The magnitude $\|\tilde{y}\|_2$ of the output complex exponential thus depends on the direction of the input as well as on the frequency ω . Now, by looking at an SV plot, we can say that, at a given frequency:

1. The largest output size is $\|\tilde{y}\|_{2,max} = \sigma_{max}G(j\omega)$, for $\|\tilde{u}\|_2 = 1$.
2. The smallest output size is $\|\tilde{y}\|_{2,min} = \sigma_{min}G(j\omega)$, for $\|\tilde{u}\|_2 = 1$.

This allows us to discuss qualitatively the size of the plant gain as a function of frequency:

1. The plant has large gain at ω if $\sigma_{min}G(j\omega) \gg 1$.
2. The plant has small gain at ω if $\sigma_{max}G(j\omega) \ll 1$.

8.4.2 Computing Directional Information

In addition to computing system gain as a function of frequency, we can also use the SVD to compute “directional information” about the system. In particular, we can compute the direction of maximum and minimum amplification of the unit, real-valued sinusoidal input. In the following, we present a step-by-step methodology for maximum amplification direction analysis. Minimum amplification direction analysis is completely analogous, and will therefore not be presented explicitly.

8.4.2.1 Maximum Amplification Direction Analysis

1. Select a specific frequency ω .
2. Compute the SVD of $G(j\omega)$, i.e., find $\Sigma(\omega)$, $U(j\omega)$, and $V(j\omega)$ such that $G(j\omega) = U(j\omega)\Sigma(\omega)V^H(j\omega)$ where U and V are unitary and Σ is the matrix of singular values.
3. In particular, find the maximum singular value $\sigma_{max}(\omega)$ of $G(j\omega)$.
4. Find the maximum right singular vector $v_{max}(\omega)$. This is the first column of the matrix $V(j\omega)$ found in the SVD. Note that $v_{max}(\omega)$ is a complex vector with m elements. Write the elements of $v_{max}(\omega)$ in polar form, i.e.,

$$[v_{max}(\omega)]_i = |a_i|e^{j\psi_i}, \quad i = 1, 2, \dots, m.$$

Notice that a_i and ψ_i are really functions of ω ; we suppress this frequency dependence for clarity.

5. Find the maximum left singular vector $u_{max}(\omega)$. This is the first column of the matrix $U(j\omega)$ found in the SVD. Note that $u_{max}(\omega)$ is a complex vector with p elements. Write the elements of $u_{max}(\omega)$ in polar form, i.e.,

$$[u_{max}(\omega)]_i = |b_i|e^{j\phi_i}, \quad i = 1, 2, \dots, p.$$

Notice that b_i and ϕ_i are functions of ω ; we suppress this frequency dependence for clarity.

6. We are now in a position to construct the real sinusoidal input signals that correspond to the direction of maximum amplification and to predict the output sinusoids that are expected at steady state. The input vector $u(t)$ is defined componentwise by

$$u_i(t) = |a_i| \sin(\omega t + \psi_i), \quad i = 1, 2, \dots, m$$

where the parameters a_i and ψ_i are those determined above. Note that the amplitude and phase of each component sinusoid is distinct. We can utilize the implications of the SVD to predict the steady-state output sinusoids as

$$y_i(t) = \sigma_{max}(\omega)|b_i| \sin(\omega t + \phi_i), \quad i = 1, 2, \dots, p.$$

Notice that all parameters needed to specify the output sinusoids are already available from the SVD.

When we talk about the “directions of maximum amplification,” we mean input *sinusoids* of the form described above with very precise magnitude and phase relations to one another. The resulting output sinusoids also have very precise magnitude and phase relations, all as given in the SVD of $G(j\omega)$. Once again, a completely analogous approach can be taken to compute the minimum amplification direction associated with $G(j\omega)$.

It is important to remember that the columns of $U(j\omega)$ and $V(j\omega)$ are orthonormal. This means we can express *any* sinusoidal input vector as a linear combination of the right singular vectors of $G(j\omega)$ at a particular value of ω . The corresponding output sinusoidal vector will be a linear combination of the left singular vectors, after being scaled by the appropriate singular values.

Finally, because we measure system “size” in terms of the ratio of output Euclidean norm to input Euclidean norm, the “size” of the system is heavily dependent on the units of the input and output variables.

8.5 Frequency Response Analysis of MIMO Feedback Systems

In this section, we look at frequency domain-analysis for various control system configurations. We will pay particular attention to the classical unity-feedback configuration, where the variables to be controlled are used as feedback. Next we will look at a broader class of control system configurations relevant for some of the more modern controller design methodologies such as H_∞ and l_1 synthesis, as well as in robustness analysis and synthesis. MIMO frequency-domain analysis as discussed above will be pivotal throughout.

8.5.1 Classical Unity-Feedback Systems

Consider the unity-feedback system in the block diagram of Figure 8.3. Recall that the *loop* transfer function matrix is defined as

$$T(s) = G(s)K(s)$$

The *sensitivity* $S(s)$ and *complementary-sensitivity* $C(s)$ transfer function matrices are, respectively, defined as

$$S(s) = [I + T(s)]^{-1}$$

$$C(s) = [I + T(s)]^{-1}G(s)K(s) = S(s)T(s)$$

With these definitions,

$$e(s) = S(s)[r(s) - d(s)] + C(s)n(s) \tag{8.18}$$

The objective in control system design is to keep the error signal e “small”. This means the *transfer* from the various disturbances to e must be small. Because it is always true that $S(s) + C(s) = I$, there is a

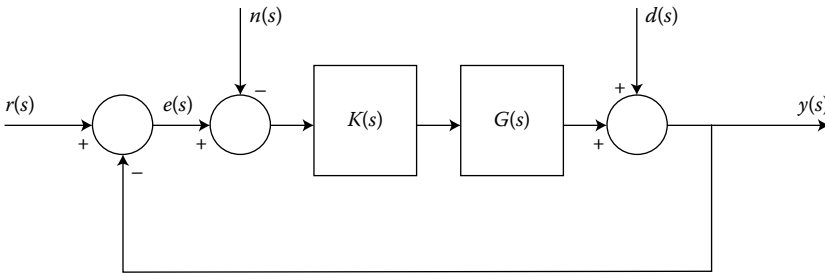

FIGURE 8.3 The unity feedback control system configuration.

trade-off involved. From Equation 8.18, we would like both $S(s)$ and $C(s)$ to be “small” for all s ; but this is impossible because $S(s) + C(s) = I$. SVD analysis of the MIMO frequency response can be important in quantifying these issues.

8.5.1.1 Command Following

Suppose that the reference (command) signal $r(t)$ is sinusoidal, $r(t) = \tilde{r}e^{j\omega t}$. Then, as long as $d(s) = 0$ and $n(s) = 0$,

$$e(t) = \tilde{e}e^{j\omega t}$$

where $\tilde{e} = S(j\omega)\tilde{r}$. Thus,

$$\|\tilde{e}\|_2 \leq \sigma_{\max}[S(j\omega)] \cdot \|\tilde{r}\|_2$$

Now suppose that $r(t)$ is the superposition of more than one sinusoid. Let Ω_r be the range of frequencies at which the input $r(t)$ has its energy. Then, in order to have good command following, we want

$$\sigma_{\max}[S(j\omega)] \ll 1 \quad \forall \omega \in \Omega_r \quad (8.19)$$

Our objective now is to express this prescription for command following in terms of the loop-transfer function $T(s) = G(s)K(s)$. From our earlier discussion

$$\begin{aligned} \sigma_{\max}[S(j\omega)] &= \sigma_{\max}\{[I + T(j\omega)]^{-1}\} \\ &= \frac{1}{\sigma_{\min}[I + T(j\omega)]} \end{aligned}$$

This implies that, for good command following, we must have $\sigma_{\min}[I + T(j\omega)] \gg 1$ for all $\omega \in \Omega_r$. However, as we saw earlier,

$$\sigma_{\min}[I + T(j\omega)] \geq \sigma_{\min}[T(j\omega)] - 1$$

so it is sufficient that, for all $\omega \in \Omega_r$, $\sigma_{\min}[T(j\omega)] \gg 1$ for good command following.

8.5.1.2 Disturbance Rejection

Suppose that the disturbance signal $d(t)$ is sinusoidal, $d(t) = \tilde{d}e^{j\omega t}$. Then, as long as $r(s) = 0$ and $n(s) = 0$,

$$e(t) = \tilde{e}e^{j\omega t}$$

where $\tilde{e} = -S(j\omega)\tilde{d}$. Thus,

$$\|\tilde{e}\|_2 \leq \sigma_{\max}[S(j\omega)] \cdot \|\tilde{d}\|_2$$

Now suppose that $d(t)$ is the superposition of more than one sinusoid. Let Ω_d be the range of frequencies at which the input $d(t)$ has its energy. Then, just as with command following, for good disturbance rejection, we want

$$\sigma_{\max}[S(j\omega)] \ll 1 \quad \forall \omega \in \Omega_d \quad (8.20)$$

Using the same argument given earlier, this prescription for disturbance rejection makes it sufficient that, for all $\omega \in \Omega_d$, $\sigma_{\min}[T(j\omega)] \gg 1$.

8.5.1.3 Relationships to $C(s)$

Here we wish to determine in a precise quantitative way the consequences of obtaining command following and disturbance rejection. As we shall see, a price is paid in constraints on the complementary-sensitivity function $C(s)$.

Theorem 8.2:

Let $\Omega_p = \Omega_r \cup \Omega_d$. (Here “ p ” refers to “performance”.) Consider δ so that $0 < \delta \ll 1$. If

$$\sigma_{\max}[S(j\omega)] \leq \delta \ll 1$$

for all $\omega \in \Omega_p$, then

$$1 \ll \frac{1-\delta}{\delta} \leq \sigma_{\min}[T(j\omega)]$$

and

$$1 - \delta \leq \sigma_{\min}[C(j\omega)] \leq \sigma_{\max}[C(j\omega)] \leq 1 + \delta$$

for all $\omega \in \Omega_p$.

Thus, in obtaining a performance level of δ , it is necessary that all of the singular values of $C(j\omega)$ are within δ of 1. In fact, because $S(s) + C(s) = I$, we must have $C(j\omega) \approx I$. (We shall discuss below why this can be a problem.)

Proof 8.1. We start by using the definition of $S(s)$,

$$\begin{aligned} \sigma_{\max}[S(j\omega)] &= \sigma_{\max}[(I + T(j\omega))^{-1}] \\ &= \frac{1}{\sigma_{\min}[I + T(j\omega)]} \\ &\geq \frac{1}{1 + \sigma_{\min}[T(j\omega)]} \end{aligned}$$

Using the hypothesis that $\sigma_{\max}[S(j\omega)] \leq \delta$,

$$\frac{1}{1 + \sigma_{\min}[T(j\omega)]} \leq \delta$$

which by solving for $\sigma_{\min}[T(j\omega)]$ yields the first inequality. By cross-multiplying, we obtain the following useful expression:

$$\frac{1}{\sigma_{\min}[T(j\omega)]} \leq \frac{\delta}{1 - \delta} \ll 1 \quad (8.21)$$

Now consider the complementary-sensitivity function $C(s)$. $C(s) = [I + T(s)]^{-1}T(s)$. By taking the inverse of both sides, $C^{-1}(s) = T^{-1}(s)[I + T(s)] = I + T^{-1}(s)$. Thus

$$\frac{1}{\sigma_{\min}[C(j\omega)]} = \sigma_{\max}[C^{-1}(j\omega)] = \sigma_{\max}[I + T^{-1}(j\omega)]$$

which implies

$$\begin{aligned} \frac{1}{\sigma_{\min}[C(j\omega)]} &\leq 1 + \sigma_{\max}[T^{-1}(j\omega)] \\ &= 1 + \frac{1}{\sigma_{\min}[T(j\omega)]} \\ &\leq 1 + \frac{\delta}{1 - \delta} = \frac{1}{1 - \delta} \end{aligned}$$

(Notice that the second inequality follows from Equation 8.21.) Now,

$$\begin{aligned} 1 - \delta &\leq \sigma_{\min}[C(j\omega)] \leq \sigma_{\max}[C(j\omega)] \\ &= \sigma_{\max}[I - S(j\omega)] \leq 1 + \sigma_{\max}[S(j\omega)] \leq 1 + \delta \end{aligned}$$

which is the second desired inequality.

8.5.1.4 Measurement Noise Insensitivity: A Conflict!

Suppose that the measurement noise $n(t)$ is sinusoidal, $n(t) = \tilde{n}e^{j\omega t}$. Then, as long as $r(s) = 0$ and $d(s) = 0$,

$$e(t) = \tilde{e}e^{j\omega t}$$

where $\tilde{e} = C(j\omega)\tilde{d}$. Thus,

$$\|\tilde{e}\|_2 \leq \sigma_{\max}[C(j\omega)] \cdot \|\tilde{d}\|_2$$

Now suppose that $n(t)$ is the superposition of more than one sinusoid. Let Ω_n be the range of frequencies at which the input $n(t)$ has its energy. Then, in order to be insensitive to measurement noise, we want

$$\sigma_{\max}[C(j\omega)] \ll 1 \quad \forall \omega \in \Omega_n \quad (8.22)$$

Theorem 8.3:

Let γ be such that $0 < \gamma \ll 1$. If

$$\sigma_{\max}[C(j\omega)] \leq \gamma$$

for all $\omega \in \Omega_n$, then

$$\sigma_{\min}[T(j\omega)] \leq \sigma_{\max}[T(j\omega)] \leq \frac{\gamma}{1-\gamma} \approx \gamma \ll 1$$

and

$$1 \approx 1 - \gamma \leq \sigma_{\min}[S(j\omega)] \leq \sigma_{\max}[S(j\omega)]$$

for all $\omega \in \Omega_n$.

Thus, if the complementary-sensitivity function $C(j\omega)$ has low gain on Ω_n , then so does the loop-transfer function $T(j\omega)$. This in turn implies that the sensitivity transfer function $S(j\omega)$ has nearly unity gain on Ω_n . In other words, wherever (in frequency) we are insensitive to measurement noise we are necessarily prone to poor command following *and* disturbance rejection. This is primarily a consequence of the fact that $C(s) + S(s) = I$.

Proof 8.2. To prove the first relationship we use the fact that $C(s) = [I + T(s)]^{-1}T(s) = [T^{-1}(s) + I]^{-1}$ (proved using a few algebraic manipulations). This gives

$$\begin{aligned} \sigma_{\max}[C(j\omega)] &= \frac{1}{\sigma_{\min}[T^{-1}(j\omega) + I]} \\ &\geq \frac{1}{\sigma_{\min}[T^{-1}(j\omega)] + 1} \\ &= \frac{\sigma_{\max}[T(j\omega)]}{1 + \sigma_{\max}[T(j\omega)]} \end{aligned}$$

Thus,

$$\begin{aligned} \sigma_{\max}[T(j\omega)] &\leq \sigma_{\max}[C(j\omega)] + \sigma_{\max}[C(j\omega)]\sigma_{\max}[T(j\omega)] \\ &\leq \gamma + \gamma\sigma_{\max}[T(j\omega)] \end{aligned}$$

which yields the desired inequality.

To prove the second relationship, observe that

$$\begin{aligned}
 \sigma_{max}[S(j\omega)] &\geq \sigma_{min}[S(j\omega)] \\
 &= \sigma_{min}[(I + T(j\omega))^{-1}] \\
 &= \frac{1}{\sigma_{max}[I + T(j\omega)]} \\
 &\geq \frac{1}{\sigma_{max}[T(j\omega)] + 1} \\
 &\geq 1 - \gamma
 \end{aligned}$$

where the last inequality comes from the first relationship proved above.

8.5.1.5 Design Implications

Achievable control design specifications must have a wide separation (in frequency) between the sets $\Omega_p = \Omega_r \cup \Omega_d$ and Ω_n . We cannot obtain good command following and disturbance rejection when we have sensors that are noisy on Ω_p . Figure 8.4 illustrates a problem that is well-posed in terms of these constraints.

FIGURE 8.4 A well-posed problem: the singular value traces fall within the regions defined by Ω_p and δ (for performance) and Ω_n and γ (for noise insensitivity).

FIGURE 8.5 A generalized plant.

8.5.2 A More General Setting

Recent control design methodologies are convenient for more generalized problem descriptions. Consider the LTI system P shown in Figure 8.5, where u denotes the control vector input to the plant, y represents the measurement vector, w is a generalized disturbance vector, and z is a generalized performance vector. The assignment of physical variables to w and z here is arbitrary and is left to the control system analyst. One illustration is given in Example 8.6. We see that the transfer function matrix for this system can be partitioned as follows:

$$P(s) = \begin{bmatrix} P_{11}(s) & P_{12}(s) \\ P_{21}(s) & P_{22}(s) \end{bmatrix}$$

From this partition,

$$\begin{aligned} z(s) &= P_{11}(s)w(s) + P_{12}(s)u(s) \\ y(s) &= P_{21}(s)w(s) + P_{22}(s)u(s) \end{aligned}$$

Let K be a feedback controller for the system so that $u(s) = K(s)y(s)$. This feedback interconnection is shown in Figure 8.6. It is simple to verify that

$$\begin{aligned} y(s) &= [I - P_{22}(s)K(s)]^{-1}P_{21}(s)w(s), \\ z(s) &= \{P_{11}(s) + P_{12}(s)K(s)[I - P_{22}(s)K(s)]^{-1}P_{21}(s)\}w(s), \\ &\equiv F(P, K)(s)w(s). \end{aligned}$$

FIGURE 8.6 A feedback interconnection.

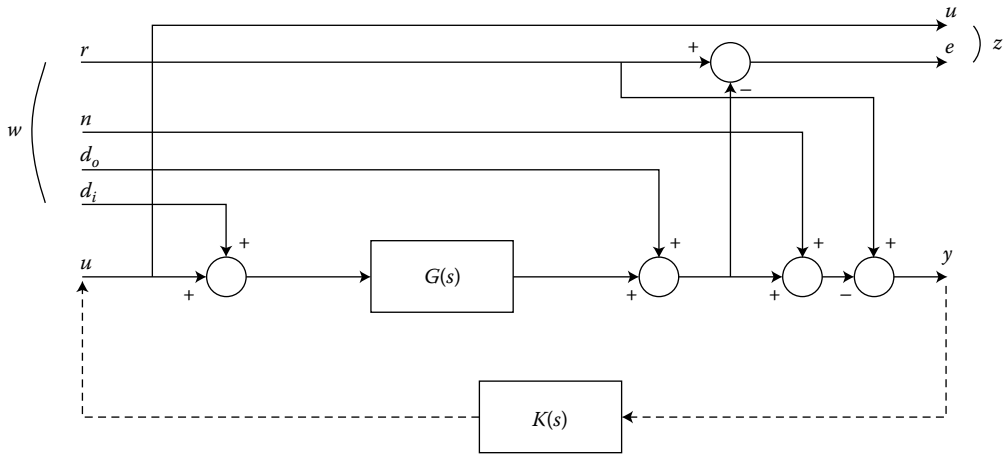

FIGURE 8.7 Unity feedback example.

The closed-loop transfer function from $w(s)$ to $z(s)$, denoted $F(P,K)(s)$, is called the (lower) linear fractional transformation (of the plant P and K). This type of mathematical object is often very useful in describing feedback interconnections.

Example 8.6: Relationships

In this example we show how the classical unity-feedback setup can be mapped into the general formulation of this section. Consider the block diagram shown in Figure 8.7. With four generalized disturbance inputs, a command input r , a sensor noise input n , a system-output disturbance d_o , and a system-input disturbance d_i . (These variables are lumped into the generalized disturbance vector w .) There are two generalized performance variables, control (effort) u and tracking error e . (These are lumped into the generalized performance vector z .) The variables u and y are the control inputs and sensor outputs of the generalized plant P .

8.5.2.1 Frequency Weights

In control design or analysis it is often necessary to incorporate extra information about the plant and its environment into the generalized description P . For example, we may know that system-input disturbances are always low-frequency in nature, and/or we may only care about noise rejection at certain high frequencies. This kind of information can be incorporated as “frequency weights” augmenting the generalized inputs and outputs of the plant P . Such weighting functions $W_d(s)$ and $W_p(s)$ are included in the block diagram of Figure 8.8. Examples are given below.

FIGURE 8.8 Weighting functions and the generalized plant.

With frequency-dependent weightings we can define a new generalized plant P_w . Referring to Figure 8.8 and using the block partition of P discussed earlier,

$$P_w(s) = \begin{bmatrix} W_p(s)P_{11}(s)W_d(s) & W_p(s)P_{12}(s) \\ P_{21}(s)W_d(s) & P_{22}(s) \end{bmatrix}.$$

With the weighting functions augmenting the plant description, P_w is ready (at least conceptually) for control design or analysis. If state-space techniques are being employed, the *dynamics* (i.e., the state variables) for W_d and W_p must be included in the state-space representation of P_w . This can be accomplished by state augmentation.

Typically, weights W_d on the generalized disturbance vector emphasize the frequency regions of most significant disturbance strength. Here $w(s) = W_d(s)w_1(s)$. We choose W_d so that a complete description of the generalized disturbance is obtained with $\|w_1(j\omega)\| = 1$ for all ω . Thus, we may think of W_d as an active filter which emphasizes (or de-emphasizes) certain variables in specific frequency domains consistent with our understanding of the system's environment. Reference inputs and system disturbances are most often low frequency, so these parts of W_d are usually low-pass filters. On the other hand, certain noise inputs are notched (like 60 Hz electrical hum) or high frequency. These parts of $W_d(s)$ should be band-pass or high-pass filters, respectively.

Weights W_p on the generalized performance vector emphasize the *importance* of good performance in different frequency regions. For example, we may be very interested in good tracking at low frequencies (but not at high frequencies), so that the weighting on this part of $W_p(s)$ should be a low-pass filter. On the other hand, we may not want to use control energy at high frequencies, so we would choose this part of $W_p(s)$ as high-pass. The various components of $W_p(s)$ must be consistent with one another in gain. The relative weights on variables in z should make sense as a whole.

It is important to note that we must still operate within constraints to mutually achieve various types of performance, as was the case with the classical unity-feedback formulation. Because we are no longer constrained to that rigid type of feedback interconnection, general results are difficult to state. The basic idea, however, remains that there is an essential conflict between noise-rejection and command-following/disturbance-rejection. In general there must be a separation in frequency between the regions in which the respective types of performance are important.

8.5.2.2 Weighted Sensitivity

We consider here the case of only one generalized input variable, d , a system-output disturbance. We are also interested in only one performance variable y , the disturbed output of the plant. Specifically, we have in mind a weighting function W_p which reflects our specifications for y . The feedback configuration is shown in Figure 8.9.

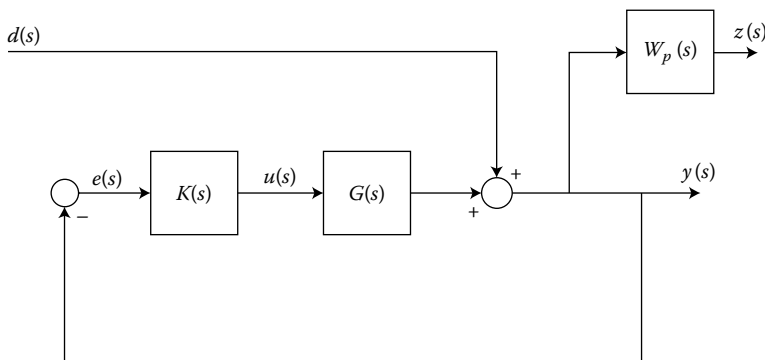

FIGURE 8.9 Feedback interconnection for weighted sensitivity.

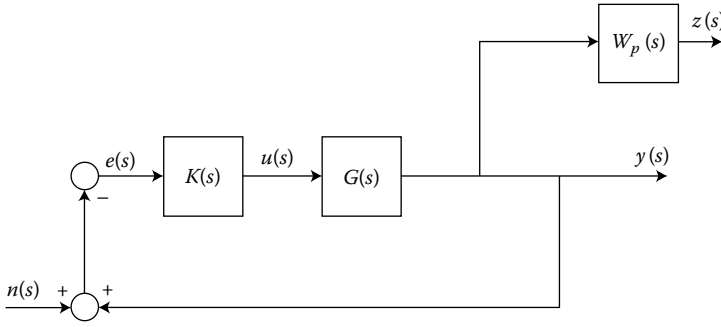

FIGURE 8.10 Feedback interconnection for weighted complementary sensitivity.

It is not hard to see that $y(s) = S(s)d(s)$. Thus, $z(s) = W_p(s)S(s)d(s)$. We refer to $W_p(s)S(s)$ as the “weighted” sensitivity transfer function for the feedback system. If $\sigma_{max}[W_p(j\omega) S(j\omega)] < 1$ for all ω , then,

$$\begin{aligned} \sigma_{max}[S(j\omega)] &= \sigma_{max}[W_p^{-1}(j\omega)W_p(j\omega)S(j\omega)] \\ &\leq \sigma_{max}[W_p^{-1}(j\omega)]\sigma_{max}[W_p(j\omega)S(j\omega)] \\ &< \sigma_{max}[W_p^{-1}(j\omega)] \end{aligned}$$

To interpret this, when $\sigma_{max}[W_p(j\omega)S(j\omega)] < 1$ for all ω , then the largest singular value of the sensitivity transfer function is strictly less than the largest singular value of the inverse of the weighting function.

8.5.2.3 Weighted Complementary Sensitivity

We consider here the case of only one generalized input variable, n , a sensor noise input. We are also only interested in one performance variable y , the output of the plant. Once again, we have in mind a weighting function W_p which reflects our specifications for y . The feedback configuration is shown in Figure 8.10.

It is not hard to see that $y(s) = C(s)d(s)$. Thus, $z(s) = W_p(s)C(s)d(s)$. We refer to $W_p(s)C(s)$ as the “weighted” complementary-sensitivity transfer function for the feedback system. Notice that if $\sigma_{max}[W_p(j\omega)C(j\omega)] < 1$ for all ω then,

$$\begin{aligned} \sigma_{max}[C(j\omega)] &= \sigma_{max}[W_p^{-1}(j\omega)W_p(j\omega)C(j\omega)] \\ &\leq \sigma_{max}[W_p^{-1}(j\omega)]\sigma_{max}[W_p(j\omega)C(j\omega)] \\ &< \sigma_{max}[W_p^{-1}(j\omega)] \end{aligned}$$

To interpret this, when $\sigma_{max}[W_p(j\omega)C(j\omega)] < 1$ for all ω , then the largest singular value of the complementary-sensitivity transfer function is strictly less than the largest singular value of the inverse of the weighting function.

9.1 Introduction

In designing feedback control systems, the stability of the resulting closed-loop system is a primary objective. Given a finite dimensional, linear time-invariant (FDLTI) model of the plant, $G(s)$, the stability of the nominal closed-loop system based on this model, Figure 9.1, can be guaranteed through proper design: in the Nyquist plane for single-input, single-output (SISO) systems or by using well-known design methodologies such as LQG and \mathcal{H}_∞ for multi-input, multi-output (MIMO) systems. In any case, since the mathematical model is FDLTI, this nominal stability can be analyzed by explicitly calculating the closed-loop poles of the system. It is clear, however, that nominal stability is never enough since the model is never a true representation of the actual plant. That is, there are always modeling errors or uncertainty. As a result, the control engineer must ultimately ensure the stability of the actual closed-loop system, Figure 9.2. In other words, the designed controller, $K(s)$, must be robust to the model uncertainty. In this article, we address this topic of stability robustness. We present a methodology to analyze the stability of the actual closed-loop system under nominal stability to a given model and a certain representation of the uncertainty.

FIGURE 9.1 Block diagram of nominal feedback loop.

The outline of the chapter is as follows. We first establish a representation of the uncertainty on which we will base our analysis. We then proceed to derive conditions that guarantee the stability of the actual closed-loop system. First, we concentrate on SISO systems where we use the familiar Nyquist stability criterion to derive the stability robustness condition. We then derive this same condition using the small gain theorem. The purpose of this is to provide a simple extension of our analysis to MIMO systems, which we present next. We then interpret the stability robustness conditions and examine their impact on attainable closed-loop performance, such as disturbance rejection and command following. Finally, we present a discussion on other possible representations of uncertainty and their respective stability robustness conditions. Examples are presented throughout the discussion.

9.2 Representation of Model Uncertainty

9.2.1 Sources of Uncertainty

Before we can analyze the stability of a closed-loop system under uncertainty, we must first understand the causes of uncertainty in the model so as to find a proper mathematical representation for it. Throughout the discussion we will assume that the actual plant, $G_a(s)$, is linear time-invariant (LTI) and that we have a nominal LTI model, $G(s)$. Although this assumption may seem unreasonable since actual physical systems are invariably nonlinear and since a cause of uncertainty is that we model them as LTI systems, we need this assumption to obtain simple, practical results. In practice, these results work remarkably well for a large class of engineering problems, because many systems are designed to be as close to linear time-invariant as possible.

The sources of modeling errors are both intentional and unintentional. Unintentional model errors arise from the underlying complexity of the physical process, the possible lack of laws for dynamic cause and effect relations, and the limited opportunity for physical experimentation. Simply put, many physical processes are so complex that approximations are inevitable in deriving a mathematical model. On the other hand, many modeling errors are intentionally induced. In the interest of reducing the complexity and cost of the control design process, the engineer will often neglect “fast” dynamics in an effort to reduce the order or the dimension of the state-space representation of the model. For example, one may

FIGURE 9.2 Block diagram of actual feedback loop.

neglect “fast” actuator and sensor dynamics, “fast” bending and/or torsional modes, and “small” time delays. In addition, the engineer will often use nominal values for the parameters of his model, such as time constants and damping ratios, even though he knows that the actual values will be different because of environmental and other external effects.

9.2.2 Types of Uncertainty

The resulting modeling errors can be separated into two types. The first type is known as parametric uncertainty. Parametric uncertainty refers to modeling errors, under the assumption that the actual plant is of the same order as the model, where the numerical values of the coefficients to the differential equation, which are related to the physical parameters of the system, between the actual plant and the model are different. The second type of uncertainty is known as unstructured uncertainty. In this case, the modeling errors refer to the difference in the dynamics between the finite dimensional model and the unknown and possibly infinite dimensional actual process.

In this chapter, we limit ourselves to addressing stability robustness with respect to unstructured uncertainty. We do this for two main reasons. First, we can capture the parametric errors in terms of the more general definition of unstructured uncertainty. Second and more importantly, unstructured uncertainty allows us to capture the effects of unmodeled dynamics. From our discussion above, we admit that we often purposely neglect “fast” dynamics in an effort to simplify the model. Furthermore, it can be argued that all physical processes are inherently distributed systems and that the modeling process acts to lump the dynamics of the physical process into a system that can be defined in a finite dimensional state-space. Therefore, unmodeled dynamics are always present and need to be accounted for in terms of stability robustness.

9.2.3 Multiplicative Representation of Unstructured Uncertainty

What we need now is a mathematical representation of unstructured uncertainty. The difficulty is that since the actual plant is never exactly known, we cannot hope to model the uncertainty to obtain this representation, for otherwise, it would not be uncertain. On the other hand, in practice, the engineer is never totally ignorant of the nature and magnitude of the modeling error. For example, from our arguments above, it is clear that unstructured uncertainty cannot be captured by a state-space representation, since the order of the actual plant is unknown, and thus we are forced to find a representation in terms of input–output relationships. In addition, if we choose to neglect “fast” dynamics, then we would expect that the magnitude of the uncertainty will be large at high frequencies in the frequency domain. In any case, the key here is to define a representation that employs the minimal information regarding the modeling errors and that is, in turn, sufficient to address stability robustness.

9.2.3.1 Set Membership Representation for Uncertainty

In this article we adopt a set membership representation of unstructured uncertainty. The idea is to define a bounded set of transfer function matrices, \mathcal{G} , which contains $G_d(s)$. Therefore, if \mathcal{G} is properly defined such that we can show stability for all elements of \mathcal{G} , then we would have shown stability robustness. Towards this end, we define \mathcal{G} as

$$\mathcal{G} = \{\tilde{G}(s) \mid \tilde{G}(s) = (I + w(s)\Delta(s))G(s), \|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1\} \quad (9.1)$$

where

1. $w(s)$ is a fixed, proper, and strictly stable scalar transfer function
2. $\Delta(s)$ is a strictly stable transfer function matrix (TFM)
3. No unstable or imaginary axis poles of $G(s)$ are cancelled in forming $\tilde{G}(s)$

This is known as the multiplicative representation for unstructured uncertainty. Since it is clear that the nominal model $G(s)$ is contained in \mathcal{G} , we view \mathcal{G} as a set of TFMs perturbed from $G(s)$ that covers the actual plant. Our requirements that $w(s)\Delta(s)$ is strictly stable and that there are no unstable or imaginary axis pole-zero cancellations mean that the unstable and imaginary axis poles of our model and any $\tilde{G}(s) \in \mathcal{G}$ coincide. This assumes that the modeling effort is at least adequate enough to capture the unstable dynamics of $G_a(s)$.

In Equation 9.1, the term $w(s)\Delta(s)$ is known as the multiplicative error. We note that since the \mathcal{H}_∞ norm of $\Delta(j\omega)$ varies between 0 and 1 and since the phase and direction of $\Delta(j\omega)$ are allowed to vary arbitrarily, the multiplicative error for any $\tilde{G}(s) \in \mathcal{G}$ is contained in a bounded hypersphere of radius $|w(j\omega)|$ at each frequency. Therefore, our representation of unstructured uncertainty is one in which we admit total lack of knowledge of the phase and direction of the actual plant with respect to the model, but that we have a bound on the magnitude of this multiplicative error. This magnitude-bound information is frequency dependent and is reflected in the fixed transfer function $w(s)$, which we will refer to as the weight. We note that we could have used a TFM $W(s)$ instead of a scalar $w(s)$ in our representation. However, in that case, the multiplicative error will reflect directional information of $W(s)$. Since we have presumed total lack of knowledge regarding directional information of the actual plant relative to the model, it is common in practice to choose $W(s)$ to be scalar.

9.2.3.2 SISO Interpretations for \mathcal{G}

To get a better feel for \mathcal{G} and our representation for unstructured uncertainty, we first specialize to the SISO case in which our definition for \mathcal{G} gives

$$\tilde{g}(s) = (1 + w(s)\Delta(s))g(s) \tag{9.2}$$

where

$$\|\Delta(j\omega)\|_{\mathcal{H}_\infty} = \sup_{\omega} |\Delta(j\omega)| \leq 1 \tag{9.3}$$

Since the phase of $\Delta(j\omega)$ is allowed to vary arbitrarily and its magnitude varies from 0 to 1 at all frequencies, the set \mathcal{G} is the set of transfer functions whose magnitude bode plot lies in an envelope surrounding the magnitude plot of $g(s)$, as shown in Figure 9.3. Therefore, the size of the unstructured uncertainty

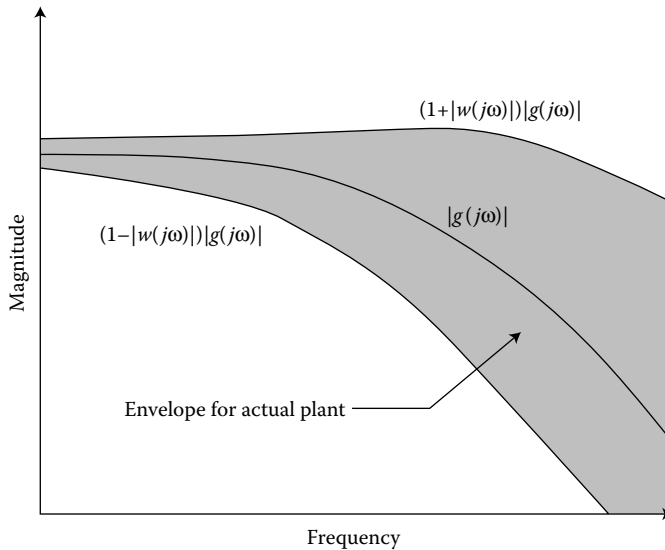

FIGURE 9.3 Bode plot interpretation of multiplicative uncertainty.

is represented by the size of this envelope. From the figure, the upper edge of the envelope corresponds to the plot of $(1 + |w(j\omega)|)|g(j\omega)|$ while the lower edge corresponds to the plot of $(1 - |w(j\omega)|)|g(j\omega)|$. Therefore, $|w(j\omega)|$ is seen as a frequency-dependent magnitude bound on the uncertainty. As mentioned beforehand, the size of the unstructured uncertainty typically increases with increasing frequency. Therefore, we would typically expect the size of the envelope containing \mathcal{G} to increase with increasing frequency and also $|w(j\omega)|$ to increase with increasing frequency, as shown in Figure 9.3. Furthermore, we want to stress that since the phase of $\Delta(j\omega)$ is allowed to vary arbitrarily, the phase difference between any $\tilde{g}(j\omega) \in \mathcal{G}$ and $g(j\omega)$ can be arbitrarily large at any frequency.

For another interpretation, we can look at the multiplicative error $w(s)\Delta(s)$ in the SISO case. Solving for $w(s)\Delta(s)$ in Equation 9.2 gives

$$\frac{\tilde{g}(s) - g(s)}{g(s)} = w(s)\Delta(s) \quad (9.4)$$

which shows that $w(s)\Delta(s)$ is the normalized error in the transfer function of the perturbed system with respect to the nominal model. Using Equation 9.3 and noting that everything is scalar, we take magnitudes on both sides of (Equation 9.4) for $s = j\omega$ to get

$$|\tilde{g}(j\omega) - g(j\omega)| \leq |w(j\omega)||\Delta(j\omega)||g(j\omega)| \leq |w(j\omega)||g(j\omega)| \quad \forall \omega \quad (9.5)$$

As shown in Figure 9.4, for each ω , this inequality describes a closed disk in the complex plane of radius $|w(j\omega)||g(j\omega)|$ centered at $g(j\omega)$ which contains $\tilde{g}(j\omega)$. Since Equation 9.5 is valid for any $\tilde{g}(s) \in \mathcal{G}$, the set \mathcal{G} is contained in that closed disk for each ω . In this interpretation, the unstructured uncertainty is represented by the closed disk, and therefore, we see that the direction and phase of the uncertainty is left arbitrary. However, we note that the radius of the closed disk does not necessarily increase with increasing frequency because it depends also on $|g(j\omega)|$, which typically decreases with increasing frequency at high frequencies due to roll-off.

9.2.3.3 Choosing $w(s)$

From our discussion, it is clear that our representation of the uncertainty only requires a nominal model, $G(s)$, and a scalar weight, $w(s)$, which reflects our knowledge on the magnitude bound of the uncertainty. The next logical question is how to choose $w(s)$ in the modeling process. From the definition

FIGURE 9.4 Interpretation of multiplicative uncertainty in the complex plane.

in Equation 9.1, we know that we must choose $w(s)$ so that the actual plant is contained in \mathcal{G} . In the course of modeling, whether through experimentation, such as frequency response, and/or model reduction, we will arrive at a set of transfer function matrices. It is assumed that our modeling effort is thorough enough to adequately capture the actual process so that this set will cover the TFM of the actual plant. From this set we will choose a nominal model, $G(s)$. We assume that $G(s)$ is square, same number of inputs as outputs, and nonsingular along the $j\omega$ -axis in the s -plane. With this assumption, we can calculate, at each frequency, the multiplicative error for each TFM $G_i(s)$ in our set using

$$w(j\omega)\Delta(j\omega) = G_i(j\omega)G^{-1}(j\omega) - I \quad (9.6)$$

Taking maximum singular values on both sides of the above equation gives

$$\sigma_{\max}[w(j\omega)\Delta(j\omega)] = \sigma_{\max}[G_i(j\omega)G^{-1}(j\omega) - I] \quad (9.7)$$

Since $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$ and $w(j\omega)$ is a scalar, it is clear that we must choose

$$|w(j\omega)| \geq \sigma_{\max}[G_i(j\omega)G^{-1}(j\omega) - I] \quad \forall \omega \geq 0 \quad (9.8)$$

to include the TFM $G_i(s)$ in \mathcal{G} . Therefore, we must choose a stable, proper $w(s)$ such that

$$|w(j\omega)| \geq \max_i \sigma_{\max}[G_i(j\omega)G^{-1}(j\omega) - I] \quad \forall \omega \geq 0 \quad (9.9)$$

to ensure that we include all $G_i(s)$ and, thus, the actual plant in \mathcal{G} . This process is illustrated in the following example.

Example 9.1: Integrator with Time Delay

Consider the set of SISO plants

$$g_\tau(s) = \frac{1}{s} \exp^{-s\tau}, \quad 0 \leq \tau \leq 0.2 \quad (9.10)$$

which is the result of our modeling process on the actual plant. Since we cannot fully incorporate the delay in a state-space model, we choose to ignore it. As a result, our model of the plant is

$$g(s) = \frac{1}{s} \quad (9.11)$$

To choose the appropriate $w(s)$ to cover all $g_\tau(s)$ in \mathcal{G} , we have to satisfy Equation 9.9, which in the SISO case is

$$|w(j\omega)| \geq \max_\tau \left| \frac{g_\tau(j\omega)}{g(j\omega)} - 1 \right| \quad \forall \omega \geq 0 \quad (9.12)$$

Therefore, we need to choose $w(s)$ such that

$$|w(j\omega)| \geq \max_\tau \left| e^{-j\omega\tau} - 1 \right| \quad \forall \omega \geq 0 \quad (9.13)$$

Using $e^{-j\omega\tau} = \cos(\omega\tau) - j \sin(\omega\tau)$ and a few trigonometry identities, the above inequality can be simplified as

$$|w(j\omega)| \geq \max_\tau \left| 2 \sin \left(\frac{\omega\tau}{2} \right) \right| \quad \forall \omega \geq 0 \quad (9.14)$$

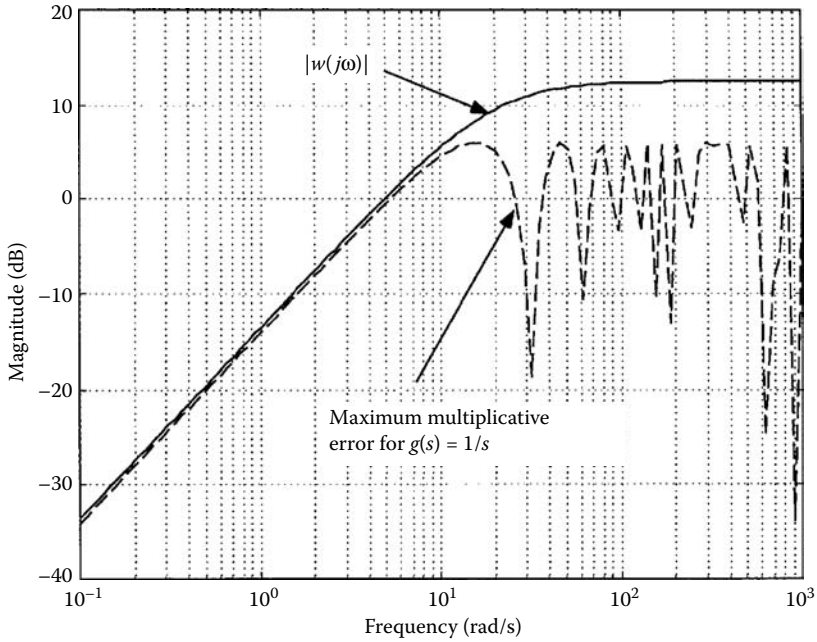

FIGURE 9.5 $w(s)$ for time delay uncertainty.

A simple $w(s)$ that will satisfy Equation 9.14 is

$$w(s) = \frac{0.21s}{0.05s + 1} \tag{9.15}$$

This is shown in Figure 9.5, where $|w(j\omega)|$ and $2|\sin(\frac{\omega\tau}{2})|$ are plotted together on a magnitude bode plot for $\tau = 0.2$, which is the worst-case value. We note that $w(s)$ is proper and strictly stable as required.

Now, let us suppose that we seek a better model by approximating the delay with a first-order Pade approximation

$$e^{-s\tau} \approx \frac{1 - \frac{s\tau}{2}}{1 + \frac{s\tau}{2}} \tag{9.16}$$

Our model becomes

$$g(s) = \frac{1}{s} \left(\frac{1 - \frac{0.1s}{2}}{1 + \frac{0.1s}{2}} \right) \tag{9.17}$$

where we approximate the delay at its midpoint value of 0.1 s. To choose $w(s)$ in this case, we again need to satisfy Equation 9.12 which becomes

$$|w(j\omega)| \geq \max_{\tau} \left| -\frac{e^{-j\omega\tau}(j\omega + 20)}{(j\omega - 20)} - 1 \right| \quad \forall \omega \geq 0 \tag{9.18}$$

A simple $w(s)$ that will satisfy Equation 9.18 is

$$w(s) = \frac{0.11s}{0.025s + 1} \tag{9.19}$$

This is shown in Figure 9.6. We again note that $w(s)$ is proper and strictly stable as required.

FIGURE 9.6 $w(s)$ for time delay uncertainty with Pade approximation.

Comparing the magnitudes of $w(s)$ for the two models in Figure 9.7, we note that, for the model with the Pade approximation, $|w(j\omega)|$ is less than that for the original model for $\omega \leq 100$ rad/s. Since $|w(j\omega)|$ is the magnitude bound on the uncertainty, Figure 9.7 shows that the uncertainty for the model with the Pade approximation is smaller than that for the original model in this frequency range. Physically, this is

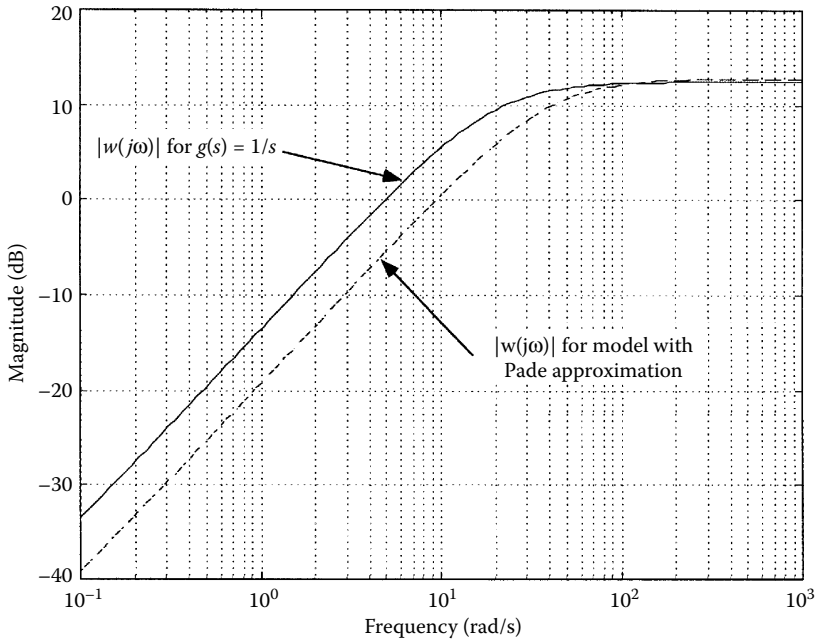

FIGURE 9.7 Comparing $w(s)$ for the two models.

because the model with the Pade approximation is a better model of the actual plant for $\omega \leq 100$ rad/s. As a result, its uncertainty is smaller.

We note that our choice of representing the uncertainty as being bounded in magnitude but arbitrary in phase and direction is, in general, an overbound on the set of TFMs that we obtained from the modeling process. That is, the set of TFMs from the modeling process may only be a small subset of \mathcal{G} . The benefit of using this uncertainty representation is that it allows for simple analysis of the stability robustness problem using minimal information regarding the modeling errors. However, the cost of such a representation is that the stability robustness results obtained may be conservative. This is because these results are obtained by showing stability with respect to the larger set \mathcal{G} instead of the smaller set from our modeling process. Another way of looking at it is that the resulting set of stabilizing controllers for the larger set \mathcal{G} will be smaller. As a result, the achievable performance may be worse. This conservatism will be discussed throughout as we develop our analysis for stability robustness, and the impact of stability robustness and this conservatism on closed-loop performance will be discussed in Section 9.4.

9.2.3.4 Reflecting Modeling Errors to the Input of the Plant

Finally, we note that in our representation of multiplicative unstructured uncertainty, we choose to lump the uncertainty at the plant output. In other words, we assume that the actual plant is of the form $(I + w(s)\Delta(s))G(s)$ where the uncertainty, $(I + w(s)\Delta(s))$ multiplying the model is at the plant output. To be more precise notationally, we should rewrite our definition for \mathcal{G} as

$$\mathcal{G} = \{\tilde{G}(s) \mid \tilde{G}(s) = (I + w_o(s)\Delta(s))G(s), \|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1\} \tag{9.20}$$

where we have added the subscript “o” to $w(s)$ to distinguish it as the weight corresponding to uncertainty at the plant output. Alternatively, we can instead choose to lump the uncertainty at the plant input. In this case, we assume that the actual plant is of the form $G(s)(I + w_i(s)\Delta(s))$ where the uncertainty multiplying the model is at the plant input. As a result, the definition for \mathcal{G} in this case is

$$\mathcal{G} = \{\tilde{G}(s) \mid \tilde{G}(s) = G(s)(I + w_i(s)\Delta(s)), \|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1\} \tag{9.21}$$

where $w_i(s)$ is the weight corresponding to the uncertainty at the plant input. Comparing the two representations reveals that, in general, the two sets defined by Equations 9.20 and 9.21 are not the same because matrix multiplication does not commute. Since $\Delta(s)$ is constrained similarly and we must choose the weight so that \mathcal{G} covers the actual plant in both cases, we note that, in general, $w_o(s)$ is not the same as $w_i(s)$.

Of course, we do not physically lump the modeling errors to the plant input or output. Instead, in the course of modeling, we lump the model so that the modeling errors are reflected either to the input of the model or to the output. To be sure, modeling errors associated with the plant actuators and sensors, such as neglected actuator and sensor dynamics, are reflected more naturally to the model’s input and output, respectively. However, modeling errors associated with internal plant dynamics, such as neglected flexible modes, are not naturally reflected to either the model’s input or output. In this case, we have a choice as to where we wish to reflect these errors. As a final note, for the SISO case, the two representations are equivalent since scalar multiplication does commute. As a result, we can choose $w_o(s) = w_i(s) = w(s)$ so that it does not make a difference where we reflect our modeling errors.

9.3 Conditions for Stability Robustness

Having established a multiplicative representation for unstructured uncertainty, we proceed to use it to analyze the stability robustness problem. As mentioned beforehand, since the actual modeling error and, thus, the actual plant is never known, we cannot hope to simply evaluate the stability of the actual closed-loop system by using the Nyquist stability criterion or by calculating closed-loop poles. Instead, we

must rely on our representation of the uncertainty to arrive at conditions or tests in the frequency domain that guarantee stability robustness. Throughout the discussion, we assume that we have a controller, $K(s)$, that gives us nominal stability for the feedback loop in Figure 9.1 and that we use this controller in the actual feedback loop, Figure 9.2. In addition, since we are interested in internal stability of the feedback loop, we assume throughout that for SISO systems, the transfer function $k(s)g(s)$ is stabilizable and detectable; that is, there are no unstable pole-zero cancellations in forming $k(s)g(s)$. For MIMO systems, the corresponding conditions are that both $K(s)G(s)$ and $G(s)K(s)$ are stabilizable and detectable.

9.3.1 Stability Robustness for SISO Systems

In this section we analyze the stability robustness of SISO feedback systems to multiplicative unstructured uncertainty. We first derive a sufficient condition for stability robustness using the familiar Nyquist stability criterion. We then derive the same condition using another method: the small gain theorem. The goal here is not only to show that one can arrive at the same answer but also to present the small gain approach to analyzing stability robustness, which can be easily extended to MIMO systems. Finally, we compare our notion of stability robustness to more traditional notions of robustness such as gain and phase margins.

9.3.1.1 Stability Robustness Using the Nyquist Stability Criterion

We begin the analysis of stability robustness to unstructured uncertainty for SISO systems with the Nyquist stability criterion. We recall from classical control theory that the Nyquist stability criterion is a graphical representation of the relationship between the number of unstable poles of an open-loop transfer function, $l(s)$, and the unstable zeros of the return difference transfer function, $1 + l(s)$. Since the zeros of $1 + l(s)$ correspond to the closed-loop poles of $l(s)$ under negative unity feedback, the Nyquist stability criterion is used to relate the number of unstable poles of $l(s)$ to the stability of the resulting closed-loop system. Specifically, the Nyquist stability criterion states that the corresponding closed-loop system is stable if and only if the number of positive clockwise encirclements (or negative counterclockwise encirclements) of the point $(-1, 0)$ in the complex plane by the Nyquist plot of $l(s)$ is equal to $-P$, where P is the number of unstable poles of $l(s)$. Here, the Nyquist plot is simply the plot in the complex plane of $l(s)$ evaluated along the closed Nyquist contour D_r , which is defined in the usual way with counterclockwise indentations around the imaginary axis poles of $l(s)$ so that they are excluded from the interior of D_r . Notationally, we express the Nyquist stability criterion as

$$\aleph(-1, l(s), D_r) = -P \quad (9.22)$$

In our analysis we are interested in the stability of the two feedback loops given in Figures 9.1 and 9.2. For the nominal feedback loop, we define the nominal loop transfer function as

$$l(s) = g(s)k(s) \quad (9.23)$$

Since we assume that the nominal closed loop is stable, we have that

$$\aleph(-1, g(s)k(s), D_r) = -P \quad (9.24)$$

where P is the number of unstable poles of $g(s)k(s)$. For the actual feedback loop, we define the actual loop transfer function as

$$l_a(s) = g_a(s)k(s) = (1 + w(s)\Delta(s))g(s)k(s) \quad (9.25)$$

where the second equality holds for some $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$ since we assumed that $g_a(s) \in \mathcal{G}$ in our representation of the unstructured uncertainty. In addition, since we assumed that the unstable poles of $g(s)$ and $g_a(s)$ coincide and since the same $k(s)$ appears in both loop transfer functions, the number of unstable poles of $g_a(s)k(s)$ and thus $l_a(s)$ is also P . Similarly, since we assumed that the imaginary axis

poles of $g(s)$ and $g_a(s)$ coincide, the same Nyquist contour D_r can be used to evaluate the Nyquist plot of $l_a(s)$. Therefore, by the Nyquist stability criterion, the actual closed-loop system is stable if and only if

$$\begin{aligned} \aleph(-1, g_a(s)k(s), D_r) &= \aleph(-1, (1 + w(s)\Delta(s))g(s)k(s), D_r) \\ &= -P \end{aligned} \tag{9.26}$$

Since we do not know $g_a(s)$, we can never hope to use Equation 9.26 to evaluate or show the stability of the actual system. However, we note that Equation 9.26 implies that the actual closed-loop system is stable if and only if the number of counterclockwise encirclements of the critical point, $(-1, 0)$, is the same for the Nyquist plot of $l_a(s)$ as that for $l(s)$. Therefore, if we can show that for the actual loop transfer function, we do not change the number of counterclockwise encirclements from that of the nominal loop transfer function, then we can guarantee that the actual closed-loop system is stable. The idea is to utilize our set membership representation of the uncertainty to ensure that it is impossible to change the number of encirclements of the critical point for any loop transfer function $\tilde{g}(s)k(s)$ with $\tilde{g}(s) \in \mathcal{G}$. This will guarantee that the actual closed-loop system is stable, since our representation is such that $g_a(s) \in \mathcal{G}$. This is the type of sufficient condition for stability robustness that we seek.

To obtain this condition, we need a relationship between the Nyquist plots of $l(s)$ and $l_a(s)$ using our representation of the unstructured uncertainty. To start, we separate the Nyquist plot into three parts corresponding to the following three parts of the Nyquist contour D_r :

1. The nonnegative $j\omega$ axis
2. The negative $j\omega$ axis
3. The part of D_r that encircles the right half s -plane where $|s| \rightarrow \infty$

For the first part, we note from Equations 9.23 and 9.25 that $l_a(s)$ can be expressed as

$$l_a(s) = (1 + w(s)\Delta(s))l(s) \tag{9.27}$$

for some $\|\Delta\|_{\mathcal{H}_\infty} \leq 1$. Therefore, the multiplicative uncertainty representation developed earlier holds equally for $l(s) = g(s)k(s)$ as for $g(s)$. Extending the SISO interpretation of this uncertainty representation in Figure 9.4 through Figure 9.8, we note that for any nonnegative ω , the Nyquist plot of $l_a(s)$ is a point contained in the disk of radius $|w(j\omega)||l(j\omega)|$ centered at the point $l(j\omega)$, which is the Nyquist plot

FIGURE 9.8 Multiplicative uncertainty in the Nyquist plot.

of $l(s)$ at that ω . Figure 9.8, then, gives a relationship between the Nyquist plot of $l(s)$ and $l_a(s)$ at a particular frequency for the part of the Nyquist contour along the positive $j\omega$ axis. For the second part of the Nyquist contour, we note that the Nyquist plot is simply a mirror image, with respect to the real axis, of the Nyquist plot for the first part, and thus this relationship will be identical. For the third part of the Nyquist contour, we note that since the model $g(s)$ represents a physical system, it should be strictly proper, and therefore, $|g(s)| \rightarrow 0$ as $|s| \rightarrow \infty$. In addition, the same holds for $g_a(s)$ since it is a physical system. Since the controller $k(s)$ is proper, it follows that the both the Nyquist plots for $l(s)$ and $l_a(s)$ are at the origin for the part of the Nyquist contour that encircles the right half s -plane.

For stability robustness, we only need to consider the relationship between $l(s)$ and $l_a(s)$ for the first part of the Nyquist contour. This is because for the second part the relationship is identical and thus the conclusions for stability robustness will be identical. Finally, for the third part, since the Nyquist plots for both $l(s)$ and $l_a(s)$ are at the origin, they are identical and cannot impact stability robustness. As a result, we only need to consider the relationship between $l(s)$ and $l_a(s)$ that is presented in Figure 9.8. We illustrate this relationship along a typical Nyquist plot of the nominal $l(s)$, for $\omega \geq 0$, in Figure 9.9 where, for clarity, we only illustrate the uncertainty disk at a few frequencies. Here, we note that the radius of the uncertainty disk changes as a function of frequency since both $w(j\omega)$ and $l(j\omega)$ varies with frequency.

From Figure 9.9, we note that it is impossible for the Nyquist plot of $l_a(s)$ to change the number of encirclements of the critical point $(-1, 0)$ if the disks representing the uncertainty in $l(s)$ do not intersect the critical point for all $\omega \geq 0$. To show this, let us prove the contrapositive. That is, if the Nyquist plot of $l_a(s)$ does change the number of encirclements of the critical point, then by continuity there exists a frequency ω^* where the line connecting $l(j\omega^*)$ and $l_a(j\omega^*)$ must intersect the critical point. Since the uncertainty disk at that frequency is convex, this uncertainty disk must also intersect the critical point.

FIGURE 9.9 Stability robustness using the Nyquist stability criterion.

Graphically, then, we can guarantee stability robustness if the distance between the critical point and the Nyquist plot of $l(s)$ is strictly greater than the radius of the uncertainty disk for all $\omega \geq 0$. From Figure 9.8, the distance between the critical point and the Nyquist plot of the nominal loop transfer function, $l(s)$, is simply $|1 + l(j\omega)|$, which is the magnitude of the return difference. Therefore, a condition for stability robustness is

$$|w(j\omega)||l(j\omega)| < |1 + l(j\omega)| \quad \forall \omega \geq 0 \tag{9.28}$$

or equivalently,

$$|w(j\omega)||g(j\omega)k(j\omega)| < |1 + g(j\omega)k(j\omega)| \quad \forall \omega \geq 0 \tag{9.29}$$

We note that although the Nyquist stability criterion is both a necessary and sufficient condition for stability, the above condition for stability robustness is clearly only sufficient. That is, even if we violate this condition at a particular frequency or at a range of frequencies, the Nyquist plot of the actual system may not change the number of encirclements of the critical point and thus the actual closed-loop system may be stable. This is illustrated in Figure 9.10, where we note that if the Nyquist plot of $l_a(s)$ follows $l_{a2}(s)$, then the actual system is stable. The key here is that since we do not know $l_a(s)$, we cannot say whether or not the actual system is stable when the condition is violated. Therefore, to guarantee actual stability, we need to ensure a safe distance or margin, which may not be necessary, between the nominal Nyquist plot and the critical point. This margin is in terms of the uncertainty disk. We see that this conservatism stems from the fact that we admit total lack of knowledge concerning the phase of the actual plant, which led to the representation of the uncertainty as a disk in the complex plane.

FIGURE 9.10 Sufficiency of the stability robustness condition.

FIGURE 9.11 Standard feedback form.

9.3.1.2 Stability Robustness Using Small Gain Theorem

We now seek to derive an equivalent condition for stability robustness for SISO systems using the small gain theorem, see for example Dahleh and Diaz-Bobillo [1]. The goal here is to introduce another methodology whereby conditions for stability robustness can be derived. As we will see in the sequel, this methodology can be easily extended to MIMO systems. We begin with a statement of the small gain theorem, specialized to LTI systems, which addresses the stability of a closed-loop system in the standard feedback form given in Figure 9.11.

Theorem 9.1: Small Gain Theorem

Under the assumption that $G_1(s)$ and $G_2(s)$ are stable in the feedback system in Figure 9.11, the closed-loop transfer function matrix from (u_1, u_2) to (e_1, e_2) is stable if the small gain condition

$$\|G_1(j\omega)\|_{\mathcal{H}_\infty} \|G_2(j\omega)\|_{\mathcal{H}_\infty} < 1 \tag{9.30}$$

is satisfied.

Proof. We first show that the sensitivity transfer function matrix, $S(s) = (I - G_1(s)G_2(s))^{-1}$ is stable. For this, we need to show that if the small gain condition Equation 9.30 is satisfied, then $S(s) = (I - G_1(s)G_2(s))^{-1}$ is analytic in the closed right-half s -plane. An equivalent statement is that the return difference, $D(s) = I - G_1(s)G_2(s)$ is nonsingular for all s in the closed right-half plane.

For arbitrary input u and for all complex s ,

$$\|D(s)u\| = \|(I - G_1(s)G_2(s))u\| = \|u - G_1(s)G_2(s)u\| \tag{9.31}$$

where $\|\cdot\|$ represents the standard Euclidean norm. From the triangle inequality,

$$\|u - G_1(s)G_2(s)u\| \geq \|u\| - \|G_1(s)G_2(s)u\| \tag{9.32}$$

from the definition of the maximum singular value,

$$\|G_1(s)G_2(s)u\| \leq \sigma_{\max}[G_1(s)G_2(s)]\|u\| \tag{9.33}$$

and from the submultiplicative property of induced norms,

$$\sigma_{\max}[G_1(s)G_2(s)] \leq \sigma_{\max}[G_1(s)]\sigma_{\max}[G_2(s)] \tag{9.34}$$

Substituting Equations 9.32 through 9.34 into Equation 9.31 gives for all complex s ,

$$\begin{aligned}
 \|D(s)u\| &= \|u - G_1(s)G_2(s)u\| \\
 &\geq \|u\| - \|G_1(s)G_2(s)u\| \\
 &\geq \|u\| - \sigma_{\max}[G_1(s)G_2(s)]\|u\| \\
 &\geq \|u\| - \sigma_{\max}[G_1(s)]\sigma_{\max}[G_2(s)]\|u\| \\
 &= (1 - \sigma_{\max}[G_1(s)]\sigma_{\max}[G_2(s)])\|u\|
 \end{aligned} \tag{9.35}$$

Since G_1 and G_2 are stable, they are analytic in the closed right-half plane. Therefore, by the maximum modulus theorem [2],

$$\begin{aligned}
 \sigma_{\max}[G_1(s)] &\leq \sup_{\omega} \sigma_{\max}[G_1(j\omega)] = \|G_1(j\omega)\|_{\mathcal{H}_{\infty}} \\
 \sigma_{\max}[G_2(s)] &\leq \sup_{\omega} \sigma_{\max}[G_2(j\omega)] = \|G_2(j\omega)\|_{\mathcal{H}_{\infty}}
 \end{aligned} \tag{9.36}$$

for all s in the closed right-half plane. Substituting Equation 9.36 into Equation 9.35 gives

$$\|D(s)u\| \geq (1 - \|G_1(j\omega)\|_{\mathcal{H}_{\infty}} \|G_2(j\omega)\|_{\mathcal{H}_{\infty}})\|u\| \tag{9.37}$$

for all s in the closed right-half plane. From the small gain condition, there exists an $\epsilon > 0$ such that

$$\|G_1(j\omega)\|_{\mathcal{H}_{\infty}} \|G_2(j\omega)\|_{\mathcal{H}_{\infty}} < 1 - \epsilon \tag{9.38}$$

Therefore, for all s in the closed right-half plane,

$$\|D(s)u\| \geq \epsilon\|u\| > 0 \tag{9.39}$$

for any arbitrary u , which implies that $D(s)$ is nonsingular in the closed right-half s -plane.

From a similar argument, we can show that $(I - G_2(s)G_1(s))$ is also stable. Therefore, the transfer function matrix relating (u_1, u_2) to (e_1, e_2) , which is given by

$$\begin{bmatrix} (I - G_2(s)G_1(s))^{-1} & -(I - G_2(s)G_1(s))^{-1}G_2(s) \\ (I - G_1(s)G_2(s))^{-1}G_1(s) & (I - G_1(s)G_2(s))^{-1} \end{bmatrix} \tag{9.40}$$

is stable.

We note that the small gain theorem is only a sufficient condition for stability. For example, in the SISO case, the small gain condition (Equation 9.30) can be expressed as

$$|g_1(j\omega)g_2(j\omega)| < 1 \quad \forall \omega \geq 0 \tag{9.41}$$

which implies that the Nyquist plot of the loop transfer function $g_1(s)g_2(s)$ lies strictly inside the unit circle centered at the origin, as shown in Figure 9.12. This is sufficient for stability because $g_1(s)$ and $g_2(s)$ are stable; however, we note that it is clearly not necessary. In addition, we note that the small gain theorem applies equally well to MIMO systems, since the proof was actually done for the MIMO case. In fact, the general form of the small gain theorem applies to nonlinear, time-varying operators over any normed signal space. For a treatment of the general small gain theorem and its proof, the reader is referred to [3].

For stability robustness, we are, as before, interested in the stability of the two feedback loops given in Figures 9.1 and 9.2. From our representation of unstructured uncertainty, we can express the actual plant as

$$g_a(s) = (1 + w(s)\Delta(s))g(s) \tag{9.42}$$

for some $\|\Delta(j\omega)\|_{\mathcal{H}_{\infty}} \leq 1$. Therefore, the actual feedback loop can also be represented by the block diagram in Figure 9.13. In the figure, we note that we choose, merely by convention, to reflect the

FIGURE 9.12 Sufficiency of SISO small gain theorem.

unstructured uncertainty to the output of the plant instead of to the input since for the SISO case the two are equivalent. In addition, we note that Figure 9.13 can also be interpreted as being the feedback loop for all perturbed plants, $\tilde{g}(s)$, belonging to the set \mathcal{G} . The key for stability robustness, then, is to show stability for this feedback loop using the small gain theorem for all $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$ and, therefore, for all $\tilde{g}(s) \in \mathcal{G}$.

To apply the small gain theorem, we first reduce the feedback loop in Figure 9.13 to the standard feedback form in Figure 9.11. To do this, we isolate $\Delta(s)$ and calculate the transfer function from the output of Δ , v , to its input, z . From Figure 9.13,

$$\begin{aligned} z(s) &= -w(s)g(s)k(s)y(s) \\ y(s) &= v(s) - g(s)k(s)y(s) \end{aligned} \tag{9.43}$$

FIGURE 9.13 Actual feedback loop with uncertainty representation.

FIGURE 9.14 Actual feedback loop in standard form.

As a result, the transfer function seen by Δ is given by $m(s)$ where

$$m(s) = \frac{-w(s)g(s)k(s)}{1 + g(s)k(s)} \tag{9.44}$$

and the reduced block diagram is given in Figure 9.14. We note that $m(s)$ is simply the product of the complementary sensitivity transfer function for the nominal feedback loop and the weight $w(s)$. Since we assumed that the nominal closed loop is stable and $w(s)$ is stable, $m(s)$ is stable. Furthermore, since we also assumed that $\Delta(s)$ is stable, the assumption for the small gain theorem is satisfied for the closed-loop system in Figure 9.14. Applying the small gain theorem, this closed-loop system is stable if the small gain condition

$$\left\| \frac{-w(j\omega)g(j\omega)k(j\omega)}{1 + g(j\omega)k(j\omega)} \right\|_{\mathcal{H}_\infty} \|\Delta(j\omega)\| < 1 \tag{9.45}$$

is satisfied. Since $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$, an equivalent condition for stability to all $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$ is

$$\left\| \frac{w(j\omega)g(j\omega)k(j\omega)}{1 + g(j\omega)k(j\omega)} \right\|_{\mathcal{H}_\infty} < 1 \tag{9.46}$$

which is a sufficient condition for the stability of the feedback loop in Figure 9.13 for all $\tilde{g}(s) \in \mathcal{G}$. Since $g_a(s) \in \mathcal{G}$, this is a sufficient condition for stability robustness.

We now proceed to show that the stability robustness condition in Equation 9.46 is equivalent to that derived using the Nyquist stability criterion. From the definition of the \mathcal{H}_∞ norm, an equivalent condition to Equation 9.46 is given by

$$\left| \frac{w(j\omega)g(j\omega)k(j\omega)}{1 + g(j\omega)k(j\omega)} \right| < 1 \quad \forall \omega \geq 0 \tag{9.47}$$

Since everything is scalar, this condition is equivalent to

$$|w(j\omega)g(j\omega)k(j\omega)| < |1 + g(j\omega)k(j\omega)| \quad \forall \omega \geq 0 \tag{9.48}$$

which is exactly the condition for stability robustness derived using the Nyquist stability criterion. This equivalence is not due to the equivalence of the Nyquist stability criterion and the small gain theorem, since the former is a necessary and sufficient condition for stability while the latter is only sufficient. Rather, this equivalence is due to our particular approach in applying the small gain theorem and to our representation of the uncertainty. What this equivalence gives us is an alternative to the more familiar Nyquist stability criterion in analyzing the stability robustness problem. Unlike the Nyquist stability criterion, the small gain theorem applies equally well to MIMO systems. Therefore, our analysis is easily extended to the MIMO case, as we will do in Section 9.3.2.

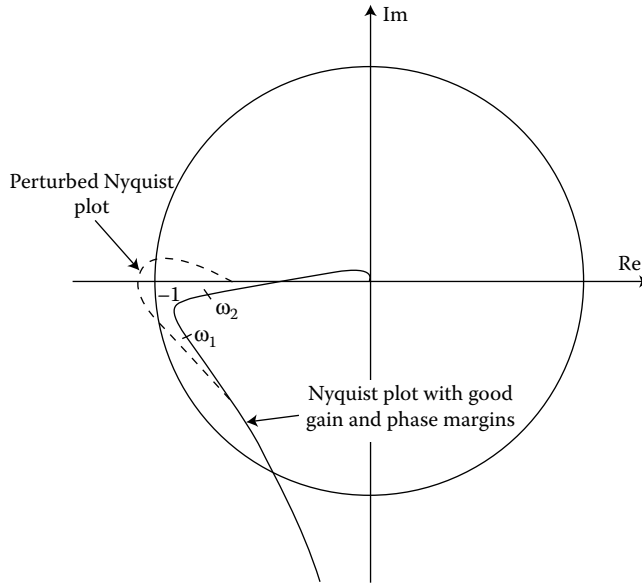

FIGURE 9.15 Insufficiency of gain and phase margins.

9.3.1.3 Comparison to Gain and Phase Margins

In closing this section on stability robustness for SISO systems, we would like to compare our notion of robustness to more traditional notions such as gain and phase margins. As we recall, gain margin is the amount of additional gain that the SISO open-loop transfer function can withstand before the closed loop goes unstable, and phase margin is the amount of additional phase shift or pure delay that the loop transfer function can withstand before the closed loop goes unstable. To be sure, gain and phase margins are measures of robustness for SISO systems, but they are, in general, insufficient in guaranteeing stability in the face of dynamic uncertainty such as those due to unmodeled dynamics. This is because gain and phase margins only deal with uncertainty in terms of pure gain variations or pure phase variations but not a combination of both. That is, the open loop can exhibit large gain and phase margins and yet be close to instability as shown in the Nyquist plot in Figure 9.15. In the figure, we note that for frequencies between ω_1 and ω_2 the Nyquist plot is close to the critical point so that a combination of gain and phase variation along these frequencies such as that in the perturbed Nyquist plot will destabilize the closed loop. This combination of gain and phase variations can be the result of unmodeled dynamics. In such a case, gain and phase margins will give a false sense of stability robustness. In contrast, we could get a true sense of stability robustness by explicitly accounting for the dynamic uncertainty in terms of unstructured uncertainty.

In addition, gain and phase margins are largely SISO measures of stability robustness since they are inadequate in capturing the cross coupling between inputs and outputs of the dynamics of MIMO systems. For MIMO systems, we usually think of gain and phase margins as being independent gain and phase variations that are allowed at each input channel. These variations clearly cannot cover the combined gain, phase, and directional variations due to MIMO dynamic uncertainty. As a result, the utility of our notion of stability robustness over traditional gain and phase margin concepts becomes even more clear in the MIMO case.

9.3.2 Stability Robustness for MIMO Systems

In this section, we analyze the stability robustness of MIMO feedback systems to multiplicative unstructured uncertainty. As mentioned beforehand, we will use the small gain theorem since it offers a natural

extension from the SISO case to the MIMO case. As shown in the SISO case, the general procedure for analyzing stability robustness using the small gain theorem is as follows:

1. Start with the block diagram of the actual feedback loop with the actual plant represented by the nominal model perturbed by the uncertainty. Note that this block diagram also represents the feedback loop for all perturbed plants belonging to the set \mathcal{G} , which contains the actual plant.
2. Reduce the feedback loop to the standard feedback form by isolating the $\Delta(s)$ block and calculating the TFM from the output of Δ to the input of Δ . Denote this TFM as $M(s)$.
3. Apply the small gain theorem. In particular, since $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$, the small gain theorem guarantees stability for the feedback loop for all perturbed plants in the set \mathcal{G} and therefore guarantees robust stability if $\|M(j\omega)\|_{\mathcal{H}_\infty} < 1$.

We will follow this procedure in our analysis of MIMO stability robustness. For MIMO systems, as shown in Section 9.2.3, there is a difference between reflecting the modeling errors to the input and the output of the plant. As a consequence, we separate the two cases and derive a different stability robustness condition for each case. In the end, we will relate these two stability robustness tests and discuss their differences.

9.3.2.1 Uncertainty at Plant Output

We start with the case where the modeling errors are reflected to the plant output. In this case, the actual plant is of the form

$$G_a(s) = (I + w_o(s)\Delta(s))G(s) \quad (9.49)$$

for some $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$. Following step 1 of the procedure, the block diagram of the actual feedback loop given this representation of the uncertainty is depicted in Figure 9.16a. For step 2, we calculate the TFM from the output of Δ , v , to its input, z . From Figure 9.16a,

$$\begin{aligned} z(s) &= -w_o(s)G(s)K(s)y(s) \\ y(s) &= v(s) - G(s)K(s)y(s) \end{aligned} \quad (9.50)$$

As a result, $M(s)$, the TFM seen by $\Delta(s)$, is

$$M(s) = -w_o(s)G(s)K(s)(I + G(s)K(s))^{-1} \quad (9.51)$$

and the reduced block diagram is given in Figure 9.16b. We note that $M(s)$ is simply the product of the complementary sensitivity TFM, $C(s) = G(s)K(s)(I + G(s)K(s))^{-1}$, for the nominal feedback loop and the scalar weight $w_o(s)$. Since we assumed that the nominal closed loop and $w_o(s)$ are both stable, $M(s)$ is stable. Furthermore, since we also assumed that $\Delta(s)$ is stable, the assumption for the small gain theorem is satisfied for the closed loop system in Figure 9.16b. For step 3, we apply the small gain theorem, which gives

$$\|w_o(j\omega)G(j\omega)K(j\omega)(I + G(j\omega)K(j\omega))^{-1}\|_{\mathcal{H}_\infty} < 1 \quad (9.52)$$

as a sufficient condition for stability robustness. Using the definition of the \mathcal{H}_∞ norm, an equivalent condition for stability robustness is

$$\sigma_{\max}[w_o(j\omega)G(j\omega)K(j\omega)(I + G(j\omega)K(j\omega))^{-1}] < 1 \quad \forall \omega \geq 0 \quad (9.53)$$

Since $w_o(s)$ is scalar, another sufficient condition for stability robustness to multiplicative uncertainty at the plant output is

$$\sigma_{\max}[G(j\omega)K(j\omega)(I + G(j\omega)K(j\omega))^{-1}] < \frac{1}{|w_o(j\omega)|} \quad \forall \omega \geq 0 \quad (9.54)$$

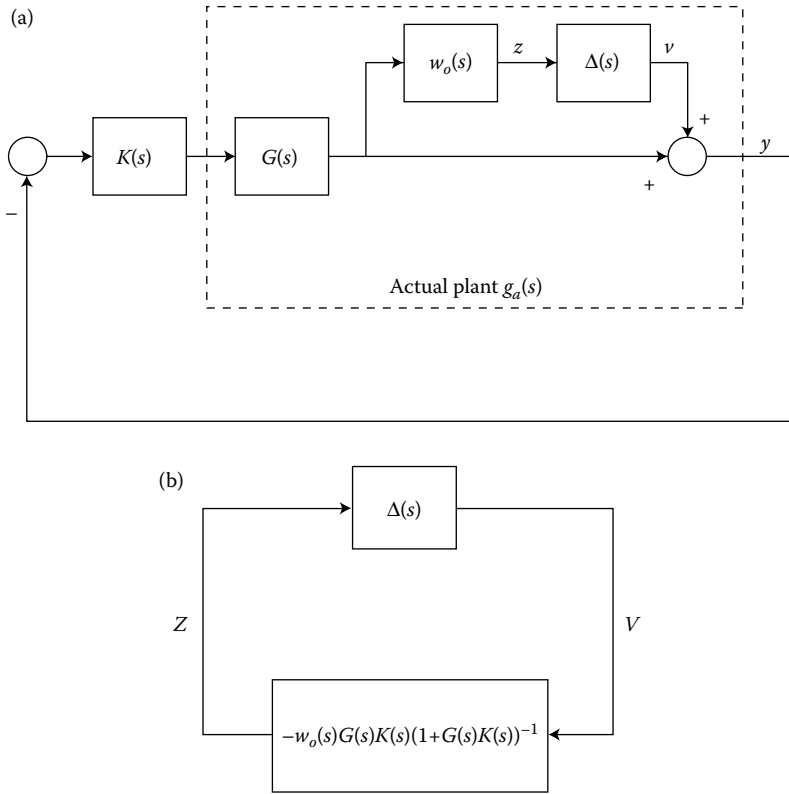

FIGURE 9.16 Stability robustness for multiplicative uncertainty at plant output.

9.3.2.2 Uncertainty at Plant Input

In the case where the modeling errors are reflected to the plant input, the actual plant is of the form

$$G_a(s) = G(s)(I + w_i(s)\Delta(s)) \tag{9.55}$$

for some $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$. Following the procedure in Section 9.3.2, a sufficient condition for stability robustness is given by

$$\|w_i(j\omega)(I + K(j\omega)G(j\omega))^{-1}K(j\omega)G(j\omega)\|_{\mathcal{H}_\infty} < 1 \tag{9.56}$$

Using the definition of the \mathcal{H}_∞ norm and the fact that $w_i(s)$ is scalar, an equivalent condition for stability robustness is

$$\sigma_{\max}[(I + K(j\omega)G(j\omega))^{-1}K(j\omega)G(j\omega)] < \frac{1}{|w_i(j\omega)|} \quad \forall \omega \geq 0 \tag{9.57}$$

Comparison between the sufficient conditions Equations 9.54 and 9.57 reveals that, although the two conditions both address the same stability robustness problem, they are indeed different. When we reflect the modeling errors to the plant output, our stability robustness condition is based on the nominal complementary sensitivity TFM, $C(s)$. This TFM is the closed loop TFM formed from the loop TFM with the loop broken at the plant output. On the other hand, when we reflect the modeling errors to the plant input, our stability robustness condition is based on the nominal input complementary sensitivity TFM, $C_i(s)$. In general, $C_i(s)$ is different from $C(s)$. As mentioned in Section 9.2.3, this difference stems from

the fact that, although the sets \mathcal{G} for the two cases both contain the actual plant, they are different because matrix multiplication does not commute. As a result, the two different conditions can give different results. Since the two conditions are both only sufficient, only one of them needs to be satisfied in order to conclude stability robustness. The fact that we only need to satisfy one of the conditions to achieve stability robustness means that one condition is less conservative than the other. This is indeed true since the sets \mathcal{G} are different, and thus, invariably, one is larger than the other, resulting in a more conservative measure of modeling error. Finally, we note that if $G(s)$ and $K(s)$ are both SISO, then both Equations 9.54 and 9.57 reduce to the sufficient condition derived for the SISO case.

9.4 Impact of Stability Robustness on Closed-Loop Performance

In the previous section, we have established, for both the SISO and MIMO cases, sufficient conditions for stability robustness under the multiplicative representation for unstructured uncertainty. To the control engineer, these conditions will have to be satisfied by design in order to ensure the stability of the actual closed-loop system. These conditions, then, become additional constraints on the design that will invariably impact the performance of the closed-loop system, such as command following and disturbance rejection. As shown in the chapter on MIMO frequency response analysis in this handbook, these performance specifications can be defined in the frequency domain in terms of the maximum singular value of the sensitivity TFM, $S(s) = (I + G(s)K(s))^{-1}$. In particular, we require $\sigma_{\max}[S(j\omega)]$ to be small in the frequency range of the command and/or disturbance signals. In this section, we seek an interpretation of our stability robustness conditions in the frequency domain in order to discuss its impact on command following and disturbance rejection.

We start with the SISO case and the stability robustness condition given in Equation 9.48. Since everything is scalar and positive, this condition is equivalent to

$$\left| \frac{g(j\omega)k(j\omega)}{1 + g(j\omega)k(j\omega)} \right| < \frac{1}{|w(j\omega)|} \quad \forall \omega \geq 0 \tag{9.58}$$

where the left side is the magnitude of the closed-loop or complementary sensitivity transfer function, $c(j\omega)$, of the nominal design. This condition is illustrated in the frequency domain in Figure 9.17. Interpreting from the figure, the stability robustness condition states that the magnitude plot of the nominal closed-loop transfer function must lie strictly below the plot of the inverse of $|w(j\omega)|$. As is typically the case, the inverse of the magnitude of $w(j\omega)$ will be large at low frequencies and small at high frequencies, since modeling errors increase with increasing frequency. Specifically, the modeling errors become significant near and above the frequency ω_m defined by

$$|w(j\omega_m)| = 0 \text{ dB} \tag{9.59}$$

Therefore, the stability robustness condition limits the bandwidth of the nominal closed-loop design. That is, the bandwidth of the nominal closed-loop design, ω_b , is constrained to be less than ω_m , as shown in the figure. Indeed, as indicated in Figure 9.17, the presence of significant modeling errors at frequencies beyond ω_m forces the rapid roll-off of the designed closed-loop transfer function at high frequencies. Physically, this roll-off prevents energy at these frequencies from exciting the unmodeled dynamics and, therefore, prevents the possible loss of stability. In terms of closed-loop performance, we recall from the chapter on MIMO frequency response analysis that a necessary condition for $\sigma_{\max}[S(j\omega)]$ to be small at a certain frequency is that the singular values of the closed-loop or complementary sensitivity TFM, $C(s) = G(s)K(s)(I + G(s)K(s))^{-1}$, must be close to unity (0 dB) at that frequency. For SISO systems, this simply translates to requiring that the magnitude of the closed-loop transfer function be close to unity (0 dB). From Figure 9.17, it is clear that the stability robustness condition limits the range of frequencies over which we can expect to achieve good command following and/or output disturbance rejection

FIGURE 9.17 Interpretation of stability robustness for SISO systems.

to below ω_m . In other words, we should not expect good performance at frequencies where there are significant modeling errors.

For the MIMO case where the modeling errors are reflected to the plant output, the stability robustness condition given in Equation 9.54 can be illustrated in terms of singular value plots, as shown in Figure 9.18. This figure gives a similar interpretation concerning the impact of stability robustness on the nominal closed-loop performance as that for the SISO case. From the figure, the output bandwidth of the nominal closed-loop design, ω_{bo} , is constrained by the stability robustness condition to be less than ω_{mo} , where ω_{mo} is defined as the frequency at and beyond which the modeling error reflected to the plant output

FIGURE 9.18 Interpretation of stability robustness for MIMO systems with uncertainty reflected to plant output.

FIGURE 9.19 Interpretation of stability robustness for MIMO systems with uncertainty reflected to plant input.

becomes significant. In other words, ω_{mo} is defined as

$$|w_o(j\omega_{mo})| = 0 \text{ dB} \tag{9.60}$$

Therefore, as in the SISO case, the stability robustness condition limits the range of frequencies over which we can expect to achieve good command following and/or output disturbance rejection to below ω_{mo} . On the other hand, for the MIMO case where the modeling errors are reflected to the plant input, we do not get a similar interpretation. In this case, the stability robustness condition given in Equation 9.57 can be illustrated in terms of singular value plots, as shown in Figure 9.19. The difference lies in the fact that this condition depends on the input complementary sensitivity TFM, $C_i(s) = (I + K(s)G(s))^{-1}K(s)G(s)$, instead of $C(s)$. Under this stability robustness condition, the input bandwidth of the nominal closed-loop design, ω_{bi} , is constrained to be less than ω_{mi} , where ω_{mi} is defined as the frequency at and beyond which the modeling error reflected to the plant input becomes significant. Here, ω_{mi} is defined as

$$|w_i(j\omega_{mi})| = 0 \text{ dB} \tag{9.61}$$

which may be different than ω_{mo} since $w_i(s)$ is, in general, not the same as $w_o(s)$. Since command following and output disturbance rejection depends on the sensitivity TFM, $S(s) = (I + G(s)K(s))^{-1}$, instead of the input sensitivity TFM, $S_i(s) = (I + K(s)G(s))^{-1}$, we cannot directly ascertain the impact of the stability robustness condition in Equation 9.57 on these performance measures. However, we can obtain insight on the impact of this stability robustness condition on input disturbance rejection because the TFM from the disturbance at the plant input to the plant output is equal to $G(s)(I + K(s)G(s))^{-1}$. Therefore, if the input sensitivity TFM is small then we have good input disturbance rejection. As before, a necessary condition for $\sigma_{\max}[S_i(j\omega)]$ to be small at a certain frequency is that the singular values of $C_i(j\omega)$ are close to unity (0 dB). From Figure 9.19, this stability robustness condition clearly limits the range of frequencies at which we can expect to achieve good input disturbance rejection to below ω_{mi} . This is because we must roll-off $C_i(j\omega)$ above ω_{mi} to satisfy the stability robustness condition.

To illustrate the concept of stability robustness to multiplicative unstructured uncertainty and its impact on closed-loop performance, we present the following example.

Example 9.2: Integrator with Time Delay

Suppose that we wish to control the plant from Example 1 using a simple proportional controller. Our objective is to push the bandwidth of the nominal closed-loop system as high as possible. We use the simple integrator model

$$g(s) = \frac{1}{s} \tag{9.62}$$

for our design. In this case, the nominal loop transfer function is simply $g(s)k$ where k is the proportional gain of our controller, and the nominal closed loop transfer function is simply

$$c(s) = \frac{k}{s + k} \tag{9.63}$$

Since we require stability of the actual closed loop, we need to satisfy the stability robustness condition given in Equation 9.58 where, from Example 1, the weight $w(s)$ of the uncertainty for this model is

$$w(s) = \frac{0.21s}{0.05s + 1} \tag{9.64}$$

As shown in Figure 9.20, the maximum value for k at which the stability robustness condition is satisfied is $k = 5.9$. With this value of k , the bandwidth achieved for the nominal system based on this model is 5.9 rad/s .

Now, consider the case where the time delay can vary up to 0.4 s instead of 0.2 s . In this case, we use the same model as above, but our uncertainty representation must change in order to cover this additional uncertainty. Specifically, we must choose a new weight $w(s)$. As in Example 1, we need to choose $w(s)$

FIGURE 9.20 Stability robustness condition for 0.2 s maximum delay uncertainty.

such that

$$|w(j\omega)| \geq \max_{\tau} \left| 2 \sin\left(\frac{\omega\tau}{2}\right) \right| \quad \forall \omega \geq 0 \tag{9.65}$$

where τ now ranges from 0 to 0.4 s. A simple $w(s)$ that will satisfy Equation 9.65 is

$$w(s) = \frac{0.41s}{0.1s + 1} \tag{9.66}$$

This is shown in Figure 9.21, where $|w(j\omega)|$ and $2 \left| \sin\left(\frac{\omega\tau}{2}\right) \right|$ are plotted together on a magnitude Bode plot for $\tau = 0.4$, which is now the worst case value. We note that $w(s)$ is proper and strictly stable as required.

Since we require stability of the actual closed loop, we again need to satisfy the stability robustness condition given in Equation 9.58. As shown in Figure 9.22, the maximum value for k at which the stability robustness condition is satisfied is now $k = 2.9$. With this value of k , the bandwidth achieved for the nominal system based on this model is 2.9 rad/s.

Comparing the two cases, it is clear that the uncertainty set for the second case is larger because the variation in the unknown time delay is larger. Physically, the larger time delay means larger unmodeled dynamics that we must cover in our uncertainty representation. This results in a larger magnitude for $w(s)$ at low frequencies, as shown in Figure 9.23. In particular, the frequency at which the modeling errors become significant, ω_m , is lower for the second case than the first, and therefore, further limiting the achievable bandwidth of the nominal closed loop. As a result, we are able to push the bandwidth higher for the first case. This results in better achievable performance, such as command following and output disturbance rejection, as shown by the sensitivity bode plots in Figure 9.24.

In summary, the requirement of stability robustness has a definite impact on the achievable nominal performance of the closed loop. This impact is typically a limitation on the nominal closed-loop bandwidth which, in turn, constrains the frequency range at which good command following and output disturbance rejection is achievable. As is evident in the above example, there is a trade-off between stability robustness

FIGURE 9.21 $w(s)$ for 0.4 s maximum delay uncertainty.

FIGURE 9.22 Stability robustness condition for 0.4 s maximum delay uncertainty.

FIGURE 9.23 Comparing $|w(j\omega)|$.

FIGURE 9.24 Comparing sensitivity magnitude plots.

and performance. That is, a controller that is designed to be robust to a larger uncertainty set will result in poorer performance due to the fact that its bandwidth will be further limited. In addition, there is a connection between this trade-off and the conservatism of our stability robustness conditions. In particular, our representation of the uncertainty is one of overbounding the set of TFMs from our modeling process with a larger set. If we choose $w(s)$ where the overbounding is not tight, then this will further limit the amount of achievable performance that we can obtain for the closed loop. Therefore, we see that both the concept of unstructured uncertainty and the way we represent this uncertainty in the stability robustness problem have an impact on achievable nominal performance. As a result, to improve performance we may have to reduce the level of uncertainty by having a better model and/or by obtaining a better representation for the uncertainty. Finally, we wish to point out that only nominal performance or the closed-loop performance of the model without the uncertainty is discussed. The actual performance of the loop will be different. However, for low frequencies where we care about command following and output disturbance rejection, the modeling errors will be typically small. Therefore, the difference between actual performance and nominal performance at these frequencies will be small.

9.5 Other Representations for Model Uncertainty

In this section, we present some alternative set membership representations for unstructured uncertainty. For each representation, we will start with the definition of the set \mathcal{G} . In defining \mathcal{G} , we assume throughout that

1. The weight is a fixed, proper, and strictly stable scalar transfer function
2. $\Delta(s)$ is a strictly stable TFM
3. No unstable or imaginary axis poles of $G(s)$ are cancelled in forming any element $\tilde{G}(s)$ of the set \mathcal{G}

With this definition, the appropriate stability robustness condition is obtained using the procedure outlined in Section 9.3.2. Like those derived for the multiplicative uncertainty representation, these

conditions are all conservative since they are derived using the small gain theorem. The focus here will be primarily on the presentation of results rather than detailed treatments of their derivation. MIMO systems are treated as SISO systems that are simply special cases. Comments on the usefulness of these representations and interpretations of their results are given as appropriate.

9.5.1 Additive Uncertainty

An alternative representation for unstructured uncertainty is additive uncertainty. In this case, the set \mathcal{G} is defined as

$$\mathcal{G} = \{\tilde{G}(s) \mid \tilde{G}(s) = G(s) + w_a(s)\Delta(s), \|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1\} \quad (9.67)$$

Following the procedure in Section 9.3.2, the stability robustness condition for additive uncertainty is

$$\sigma_{\max}[(I + K(j\omega)G(j\omega))^{-1}K(j\omega)] < \frac{1}{|w_a(j\omega)|} \quad \forall \omega \geq 0 \quad (9.68)$$

From Equation 9.67, the additive error is defined as

$$E_a(s) = w_a(s)\Delta(s) = \tilde{G}(s) - G(s) \quad (9.69)$$

which is simply the difference between the perturbed plant and the model. As a result, the additive representation is a more natural representation for differences in the internal dynamics between the actual plant and the model. In particular, it is no longer necessary to reflect these modeling errors to the plant input or output. However, we note that the resulting stability robustness condition is explicitly dependent on the controller TFM, $K(s)$, and the loop TFM, $K(s)G(s)$, instead of simply on $K(s)G(s)$. This is because, unlike multiplicative uncertainty, the uncertainty representation here does not apply equally to the loop TFM as to the model, $G(s)$. The result is that there will be added complexity in designing a $K(s)$ that will satisfy the condition because shaping the TFM, $(I + K(j\omega)G(j\omega))^{-1}K(j\omega)$, to satisfy Equation 9.68 will require shaping both $K(j\omega)$ and $K(j\omega)G(j\omega)$. Due to this complication, the multiplicative uncertainty or another form of cascaded uncertainty representation, where the representation applies equally to $G(s)$ as to $K(s)G(s)$, is often used instead in practice.

9.5.2 Division Uncertainty

Another representation for unstructured uncertainty is the division uncertainty. Like the multiplicative uncertainty representation, the division uncertainty represents the modeling error in a cascade form, and therefore, the modeling error can be reflected either to the plant output or the plant input. In the case where the modeling errors are reflected to the plant output, the set \mathcal{G} is defined as

$$\mathcal{G} = \{\tilde{G}(s) \mid \tilde{G}(s) = (I + w_{do}(s)\Delta(s))^{-1}G(s), \|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1\} \quad (9.70)$$

Following the procedure in Section 9.3.2, the stability robustness condition for division uncertainty at the plant output is given by

$$\sigma_{\max}[(I + G(j\omega)K(j\omega))^{-1}] < \frac{1}{|w_{do}(j\omega)|} \quad \forall \omega \geq 0 \quad (9.71)$$

Similarly, for the case where the modeling errors are reflected to the plant input, the set \mathcal{G} is defined as

$$\mathcal{G} = \{\tilde{G}(s) \mid \tilde{G}(s) = G(s)(I + w_{di}(s)\Delta(s))^{-1}, \|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1\} \quad (9.72)$$

and the resulting stability robustness condition is given by

$$\sigma_{\max}[(I + K(j\omega)G(j\omega))^{-1}] < \frac{1}{|w_{di}(j\omega)|} \quad \forall \omega \geq 0 \quad (9.73)$$

FIGURE 9.25 Interpretation of stability robustness for division uncertainty at plant output.

As shown in Figure 9.25, the stability robustness condition for division uncertainty at the plant output requires the maximum singular value plot for the sensitivity TFM of the nominal system, $\sigma_{\max}[S(j\omega)]$, to lie strictly below the plot of the inverse of $|w_{do}(j\omega)|$. Similarly, for division uncertainty at the plant input, the stability robustness condition requires that the maximum singular value plot for the input sensitivity TFM of the nominal system, $\sigma_{\max}[S_i(j\omega)]$, must lie strictly below the plot of the inverse of $|w_{di}(j\omega)|$. As shown in the figure, the inverse of the magnitude of $w_{do}(s)$ is typically large at low frequencies and approaches unity (0 dB) at high frequencies where the modeling errors become significant. Since the stability robustness condition for division uncertainty at the plant output depends on the nominal sensitivity TFM, its impact on command following and output disturbance rejection is clear from Figure 9.25. In particular, if the modeling error becomes significant at a particular frequency, ω_{mo} such that the plot of the inverse of $|w_{do}(j\omega)|$ is close to 0 dB at that frequency and beyond, the control must be designed such that $\sigma_{\max}[S(j\omega)]$ is below this barrier. That is, $\sigma_{\max}[S(j\omega)]$ is not allowed to be much greater than 0 dB for $\omega \geq \omega_{mo}$. However, we know from the Bode integral theorem [4] that if we suppress the sensitivity at high frequencies then we cannot also suppress it at low frequencies. Therefore, we again see how modeling errors can place a limitation on the range of frequencies over which we can expect to achieve good command following and output disturbance rejection. The same can be said for input disturbance rejection with respect to the stability robustness condition for division uncertainty at the plant input.

9.5.3 Representation for Parametric Uncertainty

Finally, we can also define the set \mathcal{G} as

$$\mathcal{G} = \{\tilde{G}(s) \mid \tilde{G}(s) = (I + w_p(s)G(s)\Delta(s))^{-1}G(s), \|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1\} \quad (9.74)$$

In this case, the stability robustness condition is given by

$$\sigma_{\max}[(I + G(j\omega)K(j\omega))^{-1}G(j\omega)] < \frac{1}{|w_p(j\omega)|} \quad \forall \omega \geq 0 \quad (9.75)$$

As shown in the following example, we can use this representation to handle parametric uncertainty in the A matrix of the nominal model $G(s)$.

FIGURE 9.26 Representation for parametric uncertainty in the A matrix.

Example 9.3: Parametric Uncertainty in the A Matrix

Consider the dynamics of the actual plant in state-space form

$$\begin{aligned} \dot{x} &= Ax + Bu \\ y &= Cx \end{aligned} \tag{9.76}$$

where the parameters of the A matrix are uncertain but are known to be constant and contained in a certain interval. In particular, consider the case where the A matrix is given as

$$A = \bar{A} + \delta A \tag{9.77}$$

where the elements of \bar{A} contain the midpoint values for each corresponding element in A and each element of δA is known to exist in the interval

$$-1 \leq \delta A_{ij} \leq 1 \tag{9.78}$$

We note that since

$$\|\delta A\| \leq n \tag{9.79}$$

for all possible δA satisfying Equation 9.78 where n is the dimension of A, it is clear that the set of possible δA is contained in the set $\{w_p(s)\Delta(s) \mid \|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1, w_p(s) = n\}$. Therefore, we can express the A matrix as

$$A = \bar{A} + w_p(s)\Delta(s) \tag{9.80}$$

for $w_p(s) = n$ and for some $\|\Delta(j\omega)\|_{\mathcal{H}_\infty} \leq 1$. In block diagram form, the state-space equations in Equation 9.76 can then be represented as in Figure 9.26, where the model $G(s)$ is taken to be $(sI - \bar{A})^{-1}$. We note that this is equivalent to the uncertainty representation given in Equation 9.74.

We note that the above representation for parametric uncertainty is, in general, very conservative. This is because the representation allows for complex perturbations of the matrix A since $\Delta(s)$ is complex. Since the parameters are real, the perturbed set of plants is much larger than the set that will actually be realized by the plant, which results in the conservatism.

10.1 Introduction and Motivation

It is well known that feedback may be used in a control design to obtain desirable properties that are not achievable with open-loop control. Among these are the ability to stabilize an unstable system and

to reduce the effects of plant disturbances and modeling errors upon the system output. On the other hand, use of feedback control can also have undesirable consequences: feedback may destabilize a system, introduce measurement noise, amplify the effects of disturbances and modeling errors, and generate large control signals. A satisfactory control design will, if possible, achieve the potential benefits of feedback without incurring excessive costs.

Unfortunately, feedback systems possess limitations that manifest themselves as *design trade-offs* between the benefits and costs of feedback. For example, there exists a well-known trade-off between the response of a feedback system to plant disturbances and to measurement noise. This trade-off is an inherent consequence of feedback system topology; indeed, a plant disturbance cannot be attenuated without a measurement of its effect upon the system output. Other design trade-offs are a consequence of system properties such as unstable poles, nonminimum phase zeros, time delays, and bandwidth limitations.

The study of feedback design limitations and trade-offs dates back at least to the seminal work of Bode [7]. In his classic work, Bode stated the famous gain-phase relation and analyzed its implications for the classical loop-shaping problem. He also derived the Bode sensitivity integral. The importance of the sensitivity integral to feedback control design was emphasized by Horowitz [36]. Connections between the classical loop-shaping problem, including the gain-phase relation, and modern control techniques were developed by Doyle and Stein [22]. Further results pertaining to design limitations were derived by Freudenberg and Looze [28,31], who studied inherent design limitations present when the system to be controlled has unstable poles, nonminimum phase zeros, time delays, and/or bandwidth constraints. A result dual to the Bode sensitivity integral, and applicable to the complementary sensitivity function, was obtained by Middleton and Goodwin [43,45]. In all these works, emphasis is placed upon frequency response properties and, in particular, the insight into feedback design that may be obtained from a Bode plot.

In this chapter, we describe several trade-offs that are present in feedback system design due to the structure of a feedback loop, bandwidth limitations, and plant properties such as unstable poles, nonminimum phase zeros, and time delays. We focus primarily on linear time-invariant single input single output systems (SISOs) and later give a brief description and references to a number of extensions of these results. In Section 10.2, we show how the closed-loop transfer functions of a feedback system may be used to describe signal response, differential sensitivity, and stability robustness properties of the system. In Section 10.3, we describe design trade-offs imposed by the topology of a feedback loop and the relation between feedback properties and open-loop gain and phase. Next, in Section 10.4, we describe design limitations imposed by the Bode gain-phase relation, Bode sensitivity integral, and the dual complementary sensitivity integral. These trade-offs are present due to the fact that the closed-loop system is stable, linear, and time invariant. When the plant has nonminimum phase zeros, unstable poles, and/or time delays, additional design trade-offs are present. As discussed in Section 10.5, these may be described using the Poisson integral. An alternate view of some of the performance limitations using time responses is described in Section 10.6. In Section 10.7, we give a brief summary and references to various extensions of the theory of feedback performance limitations, including discrete-time systems, systems with feedback over a communication channel, limits on optimal cheap control and H_2 performance, multivariable systems, and nonlinear and time-varying systems. We conclude the section with a brief discussion of cases in which performance limitations may be alleviated in tracking problems. A general summary and suggestions for further reading are presented in Section 10.8.

10.2 Quantification of Performance for Feedback Systems

10.2.1 Overview

Throughout this chapter, we consider the single-degree-of-freedom unity feedback system depicted in Figure 10.1. In this figure, $P(s)$ and $C(s)$ denote the transfer functions of the plant and the compensator,

FIGURE 10.1 Linear time-invariant feedback system.

respectively. The system output is denoted $y(t)$, the control signal by $u(t)$, and the command input by $r(t)$. An important goal in many feedback control problems is that of forcing $y(t)$ to track $r(t)$ despite the presence of input and output disturbances $d_i(t)$ and $d_o(t)$. To do so, a measurement of the system output is compared to the command input to form an error signal $e(t)$, and used as an input to the controller. The effects of measurement noise are denoted $n(t)$.

Other feedback architectures are possible, including a two-degree-of-freedom architecture, in which the command input and measured output are processed separately. For example, the command input may be shaped by a precompensator before the error signal is formed. Similarly, any disturbances that are measurable may also be processed separately. Throughout this chapter, we discuss the feedback architecture in Figure 10.1, and assume that any precompensation is absorbed into the definition of the command input $r(t)$.

The ability of the plant output to follow the command input is referred to as tracking. In order that tracking be feasible, the closed-loop system must, at a minimum, be stable. As Figure 10.1 illustrates, exogenous signals can act at various points in the feedback loop to affect the response of the system. Signals that enter the loop between the control action and the output to be controlled are referred to as disturbance signals. The ability of the control system to eliminate the effects of the disturbances is referred to as disturbance rejection. Signals that enter the loop between the system output and the comparison of the measurement with the command input are referred to as measurement noise signals. Measurement noise only affects the output through the action of the compensator.

In addition to the uncertainty caused by the disturbance signals and measurement noise, the behavior of the plant as described by the model will differ from that of the true plant. A feedback system that is stable for the plant model is called nominally stable. A feedback loop that maintains stability when subject to variations in the plant model is robustly stable. Nominal performance is achieved when tracking and disturbance rejection objectives are met for the plant model. Robust performance is achieved if the feedback loop maintains performance (tracking or disturbance rejection) when subject to variations in the plant model.

To proceed with our analysis, we define closed-loop transfer functions from the exogenous input signals in Figure 10.1 to the system output, measured error, and the control signal, and shall quantify performance in terms of the peak in a Bode gain plot of each transfer function. We shall also see that these closed-loop transfer functions describe the sensitivity and robustness properties of a feedback system.

10.2.2 Nominal Signal Response

Consider the linear time-invariant feedback system shown in Figure 10.1. Three transfer functions are essential in studying properties of this system. Define the open-loop transfer function

$$L(s) = P(s)C(s), \quad (10.1)$$

the sensitivity function

$$S(s) = \frac{1}{1 + L(s)}, \quad (10.2)$$

and the complementary sensitivity function

$$T(s) = \frac{L(s)}{1 + L(s)}. \quad (10.3)$$

The response of the system of Figure 10.1 to the exogenous inputs (i.e., the command input, the input disturbance, the output disturbance, and the sensor noise) is governed by the closed-loop transfer functions (Equations 10.2 and 10.3). The output of the system is given by

$$Y(s) = S(s) (D_o(s) + P(s)D_i(s)) + T(s) (R(s) - N(s)). \quad (10.4)$$

The feedback loop error between the measured output and the command input is given by

$$E(s) = S(s) (R(s) - D_o(s) - P(s)D_i(s) - N(s)). \quad (10.5)$$

The performance error between the output and the command input is given by

$$E_p(s) = R(s) - Y(s) = S(s) (R(s) - D_o(s) - P(s)D_i(s)) - T(s)N(s). \quad (10.6)$$

The control input generated by the compensator is given by

$$U(s) = -T(s)D_i(s) + S(s)C(s) (R(s) - N(s) - D_o(s)). \quad (10.7)$$

Because the principal objective for control system performance is to have the plant output track the command input without using too much control energy, it is desirable that the performance error (Equation 10.6) and the plant input (Equation 10.7) be small. It is apparent from Equations 10.6 and 10.7 that each of these signals can be made small by making the sensitivity and complementary sensitivity transfer functions small. In particular, the performance error (Equation 10.6) can be made small at any frequency $s = j\omega$ by making the sensitivity function small relative to the command response and disturbances, and by making the complementary sensitivity small relative to the measurement noise. The plant input can also be kept within a desired range by bounding the magnitude of the complementary sensitivity function relative to the external signals. The presence of the plant transfer function in the denominator of the second term in Equation 10.7 implies that the magnitude of the control signal will increase as the plant magnitude decreases, unless there is a corresponding decrease in the magnitudes of either the complementary sensitivity function or the external command, measurement noise, and output disturbance signals. The presence of high-frequency measurement noise, or disturbances together with a bound on the desired control magnitude thus imposes a bandwidth constraint on the closed-loop system.

10.2.3 Differential Sensitivity

Because the true plant behavior will be somewhat different from the behavior described by the plant model $P(s)$, it is important that performance be maintained for variations in the plant model that correspond to possible differences with reality. Although the precise characterization of robust performance is beyond the scope of this chapter (see [23]), incremental changes in the system response due to model variations can be characterized by the sensitivity function. Assume that the true plant model is given by

$$P'(s) = P(s) + \Delta P(s), \quad (10.8)$$

where $\Delta P(s)$ represents the difference between the true and nominal values of the plant transfer function. Assuming that the disturbance and measurement noise signals are zero, the nominal closed-loop response

(i.e., the response to the command reference for the plant model $P(s)$) is

$$Y(s) = T(s)R(s). \quad (10.9)$$

The response for the feedback system using the true plant is

$$Y'(s) = T'(s)R(s), \quad (10.10)$$

where

$$Y'(s) = Y(s) + \Delta Y(s), \quad (10.11)$$

$$T'(s) = T(s) + \Delta T(s). \quad (10.12)$$

Thus the variation in the command response is proportional to the variation in the true complementary sensitivity function.

Let $S'(s)$ denote the sensitivity function for the feedback system using the true plant transfer function. Then, it can be shown that [20]

$$\frac{\Delta T(s)}{T(s)} = S'(s) \frac{\Delta P(s)}{P(s)}. \quad (10.13)$$

Equation 10.13 shows that the true sensitivity function determines the relative deviation in the command response due to a relative deviation in the plant transfer function. If the true sensitivity function is small, the variation in command response will be small relative to the variation in the plant model.

Although Equation 10.13 provides insight into how the command response varies, it is not useful as a practical analysis and design tool because the relationship is expressed in terms of the unknown true plant transfer function. However, as the plant variation $\Delta P(s)$ becomes small, the true sensitivity function $S'(s)$ approaches the nominal sensitivity function $S(s)$. Thus, for $\Delta P(s) = dP(s)$, Equation 10.13 becomes

$$\frac{dT(s)}{T(s)} = S(s) \frac{dP(s)}{P(s)}. \quad (10.14)$$

Equation 10.14 shows that the sensitivity function $S(s)$ governs the sensitivity of the system output to small variations in the plant transfer function. Hence, the variation in the command response will be small if the sensitivity function is small relative to the plant variation.

10.2.4 Robust Stability

The feedback system in Figure 10.1 will be internally stable if each transfer function $S(s)$, $T(s)$, $S(s)P(s)$, and $C(s)S(s)$ is proper and have no poles in the closed right half-plane (CRHP) [34]. If there are no CRHP pole-zero cancellations between the plant and the controller, then the feedback system will be stable if the sensitivity function is proper and has no CRHP poles. A number of techniques, such as the Routh–Hurwitz and Nyquist criteria [21,27], are available for evaluating whether the system is stable for the nominal plant model. A more challenging problem is to determine whether the feedback system will be robustly stable for the true but unknown plant.

The sensitivity and complementary sensitivity functions each characterize stability robustness of the system against particular classes of plant variations (e.g., see [70], Table 9.1). One of the most significant types of plant modeling error is the high-frequency uncertainty that is present in any model of a physical system. All finite-order transfer function models of physical systems deteriorate at high-frequencies due to neglected dynamics (such as actuator and measurement lags, and flexible modes), the effects of approximating distributed systems with lumped models, and time delays. The result of these neglected physical phenomena is that the uncertainty in the gain of the true plant increases (eventually differing from the assumed plant model by more than 100%) and the phase of the true plant becomes completely uncorrelated with that of the model (i.e., there is $\pm 180^\circ$ uncertainty in the phase).

This type of uncertainty can be represented as a relative deviation from the nominal plant. The true plant transfer function is represented by a multiplicative error model

$$P'(s) = P(s)(1 + \Delta(s)). \quad (10.15)$$

Given a true plant $P'(s)$, the multiplicative error $\Delta(s)$ is the relative plant error

$$\Delta(s) = \frac{P'(s) - P(s)}{P(s)}. \quad (10.16)$$

It will be assumed that the multiplicative error is stable. From Equation 10.16, it is apparent that this assumption will be satisfied if the number and location of any unstable poles of the true plant are the same as those of the plant model.

The characteristics of increasing gain and phase uncertainty can be represented by assuming that the multiplicative error is unknown except for an increasing upper bound on its magnitude. That is, it will be assumed that $\Delta(s)$ is any stable transfer function that satisfies

$$|\Delta(j\omega)| < M_\Delta(\omega), \quad (10.17)$$

where (typically) $M_\Delta(\omega) \rightarrow \infty$ as $\omega \rightarrow \infty$.

If the only information available about the uncertainty is Equation 10.17, then $\Delta(s)$ is referred to as unstructured uncertainty. In that case, a necessary and sufficient condition for the feedback system to be stable for all plants described by Equations 10.15 through 10.17 is that the system be stable when $\Delta(s) = 0$ and that the complementary sensitivity function satisfy the bound [22]

$$|T(j\omega)| < \frac{1}{M_\Delta(\omega)}, \quad \forall \omega. \quad (10.18)$$

Equation 10.18 demonstrates that the presence of high-frequency uncertainty forces the complementary sensitivity function to become small to insure that the system is robustly stable. This in turn implies that an upper limit on bandwidth is imposed on the closed-loop system.

10.2.5 Summary of Feedback System Performance Specification

In the previous section we saw that the sensitivity and complementary sensitivity functions each characterize important properties of a feedback system. This fact motivates stating design specifications directly as frequency-dependent bounds upon the magnitudes of these functions. Hence, we typically require that

$$|S(j\omega)| \leq M_S(\omega), \quad \forall \omega, \quad (10.19)$$

and

$$|T(j\omega)| \leq M_T(\omega), \quad \forall \omega. \quad (10.20)$$

The bounds $M_S(\omega)$ and $M_T(\omega)$ will generally depend on the size of the disturbance and noise signals, the level of plant uncertainty, and the extent to which the effect of these phenomena upon the system output must be diminished (see Equations 10.6, 10.7, 10.14, and 10.18).

It is interesting to note that the two design specifications represent two different aspects of control system design. The bound (Equation 10.19) on the sensitivity function typically represents the potential benefits of feedback, such as disturbance rejection, tracking and robust performance. The bound (Equation 10.20) on the complementary sensitivity function represents desired limits on the cost of feedback: amplification of measurement noise, increased control signal requirements, and possible introduction of instability into the feedback loop.

10.3 Design Trade-Offs at a Single Frequency

10.3.1 Introduction

Often the requirements imposed by various design objectives are mutually incompatible. It is therefore important to understand when a given design specification is achievable and when it must be relaxed by making trade-offs between conflicting design goals. The objective of this section is to explore the limitations that are imposed by the structure of the feedback loop in Figure 10.1.

The structural trade-offs presented in this section express the limitation that there is only one degree of design freedom in the feedback loop. This degree-of-freedom can be exercised by specifying any one of the associated transfer functions. Because the sensitivity and complementary sensitivity functions are both uniquely determined by the loop transfer function, these transfer functions cannot be specified independently. Hence, the properties of the feedback loop are completely determined once any one of $L(s)$, $S(s)$, or $T(s)$ are specified, and these properties can be analyzed in terms of the chosen transfer function. In particular, the performance bounds (Equations 10.19 and 10.20) are not independent, and may lead to conflicts.

This section presents explicit relationships between the sensitivity function, the complementary sensitivity function, and the loop transfer function of the feedback system of Figure 10.1. These relationships can be used to explore whether design specifications in the form of (Equation 10.19 and 10.20) are consistent, and if not, how the specifications might be modified to be achievable.

10.3.2 Relationship between Closed-Loop Transfer Functions and Design Specifications

One important design trade-off may be quantified by noting that the sensitivity and complementary sensitivity functions satisfy the identity

$$S(j\omega) + T(j\omega) = 1. \quad (10.21)$$

Equation 10.21 is a structural identity in the sense that it is a consequence of the topology of the feedback loop.

It follows from Equation 10.21 that $|S(j\omega)|$ and $|T(j\omega)|$ both cannot be very small at the same frequency. Hence, at each frequency, there exists a trade-off between those feedback properties such as sensitivity reduction and disturbance response that are quantified by $|S(j\omega)|$ and those properties such as measurement noise response and robustness to high-frequency uncertainty that are quantified by $|T(j\omega)|$.

In applications it often happens that levels of uncertainty and sensor noise become significant at high frequencies, while disturbance rejection and sensitivity reduction are generally desired over a lower frequency range. Hence, the trade-off imposed by Equation 10.21 is generally performed by requiring $M_S(\omega)$ to be small at low frequencies, $M_T(\omega)$ to be small at high frequencies, and neither $M_S(\omega)$ nor $M_T(\omega)$ to be excessively large at any frequency.

This situation is illustrated in Figure 10.2. The bound $M_S(\omega)$ is small at low frequencies, representing the frequencies over which disturbance rejection and tracking are important. It increases with increasing frequency until it becomes greater than one at high frequencies. Conversely, the bound $M_T(\omega)$ begins somewhat greater than one at low frequencies, and rolls off (decreases in magnitude) at higher frequencies where the plant model error and measurement noise become significant. The sensitivity and complementary sensitivity functions shown in Figure 10.2 satisfy the design objectives (Equations 10.19 and 10.20).

Equation 10.21 can be used to derive conditions that the design objective functions $M_S(\omega)$ and $M_T(\omega)$ must satisfy. Taking the absolute value of the right-hand side of Equation 10.21, using the triangle inequality and applying the bounds on the sensitivity and complementary sensitivity functions (Equations 10.19 and 10.20), the following inequality is obtained:

$$M_S(\omega) + M_T(\omega) \geq 1. \quad (10.22)$$

FIGURE 10.2 Typical sensitivity function, complementary sensitivity function, and specification bounds.

Equation 10.22 reinforces the observations made previously; the design objectives cannot be specified to require both the sensitivity function and the complementary sensitivity function to be small at the same frequency.

The structural identity can also be used to explore limits on more detailed specifications of control system objectives. For example, suppose that at a given frequency ω the dominant objective that specifies the weighting on the complementary sensitivity function is that the control signal should remain bounded when subject to an output disturbance which is unknown but bounded:

$$|U(j\omega)| < M_u(\omega), \quad \forall |D_o(j\omega)| \leq M_{d_o}(\omega). \tag{10.23}$$

Then, combining Equations 10.7 and 10.23, the design specification on the complementary sensitivity Equation 10.20 becomes

$$|T(j\omega)| \leq |P(j\omega)| \frac{M_u(\omega)}{M_{d_o}(\omega)} = M_T(\omega). \tag{10.24}$$

Substituting this value for the design specification bound on the complementary sensitivity into the inequality (Equation 10.22) yields

$$M_S(\omega) + |P(j\omega)| \frac{M_u(\omega)}{M_{d_o}(\omega)} \geq 1. \tag{10.25}$$

Inequality (Equation 10.25) requires the design specification on the sensitivity function to increase as the plant magnitude decreases relative to the available control authority for a given disturbance. Thus, the desire to reject disturbances (reflected by smaller $M_S(\omega)$) is limited. The trade-off between disturbance rejection and control amplitude is quantified by Equation 10.25.

10.3.3 Relation between Open and Closed-Loop Specifications

Because specifying one of the transfer functions $S(s)$, $T(s)$, or $L(s)$ completely determines the others, any one of them can be used as a basis for analysis and design. Classical “loop-shaping” design methods

proceeded by directly manipulating the loop transfer function $L(s)$ (using, e.g., lead and lag filters) to alter the feedback properties of the system. As is well known, these methods are quite effective in coping with the type of design problems for which they were developed. One reason for the success of these methods is that, for a scalar system, open-loop gain and phase can be readily related to feedback properties. Indeed, the following relations are well known (e.g., [22,36]) and can readily be deduced from Equations 10.2 and 10.3:

$$|L(j\omega)| \gg 1 \Leftrightarrow |S(j\omega)| \ll 1 \text{ and } T(j\omega) \approx 1 \quad (10.26)$$

and

$$|L(j\omega)| \ll 1 \Leftrightarrow |S(j\omega)| \approx 1 \text{ and } |T(j\omega)| \ll 1. \quad (10.27)$$

At frequencies for which open-loop gain is approximately unity, feedback properties depend critically upon the value of open-loop phase:

$$|L(j\omega)| \approx 1 \text{ and } \angle L(j\omega) \approx \pm 180^\circ \Leftrightarrow |S(j\omega)| \gg 1 \text{ and } |T(j\omega)| \gg 1. \quad (10.28)$$

These approximations (Equations 10.26 through 10.28) yield the following rules of thumb useful in design. First, large loop gain yields small sensitivity and good disturbance rejection properties, although noise appears directly in the system output. Second, small loop gain is required for small noise response and for robustness against large multiplicative uncertainty. Finally, at frequencies near gain crossover ($|L(j\omega)| \approx 1$), the phase of the system must remain bounded sufficiently far away from $\pm 180^\circ$ to provide an adequate stability margin and to prevent amplifying disturbances and noise.

It is also possible to relate open-loop gain to the magnitude of the plant input. From Equations 10.26 and 10.2, it follows that

$$|L(j\omega)| \gg 1 \Leftrightarrow |S(j\omega)C(j\omega)| \approx |P^{-1}(j\omega)|. \quad (10.29)$$

Hence, requiring loop gain to be large at frequencies for which the plant gain is small may lead to unacceptably large response of the plant input to noise and disturbances (see also Equation 10.25).

Recall the discussion of the requirements imposed on the magnitudes of the sensitivity and complementary sensitivity by the performance objectives (Equations 10.19 and 10.20) (see Figure 10.2). From that discussion and the approximations (Equations 10.26 through 10.28), it follows (cf., [22]) that corresponding specifications upon open-loop gain and phase might appear as in Figure 10.3. These specifications reflect the fact that loop gains must be large at low frequencies for disturbance rejection and sensitivity reduction and must be small at high frequencies to provide stability robustness. At intermediate frequencies the phase of the system must remain bounded away from $\pm 180^\circ$ to prevent excessively large values of $|S(j\omega)|$ and $|T(j\omega)|$. To obtain the benefits of feedback over as large a frequency range as possible, it is also desirable that ω_L be close to ω_H . Of course, gain and phase must also satisfy the encirclement condition dictated by the Nyquist stability criterion.

FIGURE 10.3 Gain and phase specifications.

10.4 Constraints Imposed by Stability

10.4.1 Introduction

Implicit in our construction of design specifications such as those illustrated by Figures 10.2 and 10.3 is the assumption that the transfer functions can be prescribed independently in different frequency regions or that open-loop gain and phase can be independently manipulated. However, the requirement that the closed-loop system be stable imposes additional constraints on the transfer functions that relate the values of the functions in different frequency regions. These constraints will be referred to as analytic constraints because they result from the requirement that the transfer functions have certain analytic properties.

As has been noted in Section 10.3, any of the transfer functions $S(s)$, $T(s)$, or $L(s)$ can be used to characterize the performance and properties of the feedback system. This section will present the constraints imposed by stability for each of these transfer functions.

10.4.2 Bode Gain-Phase Relation and Interpretations

We have shown in the previous section how classical control approaches view design specifications in terms of limits on the gain and the phase of the open loop transfer function. However, the gain and phase are not mutually independent: the value of one is generally determined once the other is specified. There are many ways to state this relationship precisely; the one most useful for our purposes was derived by Bode [7]. This relation has been used by many authors (*cf.* [22,36]) to analyze the implications that the gain-phase relation has upon feedback design.

Theorem 10.1: Bode Gain-Phase Relation

*Assume that $L(s)$ is a rational function with real coefficients and with no poles or zeros in the CRHP. Then, at each frequency $s = j\omega_0$, the phase of $L(s)$ must satisfy the integral relation**

$$\angle L(j\omega_0) - \angle L(0) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{d \log |L|}{d\nu} \log \coth \frac{|\nu|}{2} d\nu, \quad (10.30)$$

where

$$\nu = \log \left(\frac{\omega}{\omega_0} \right). \quad (10.31)$$

Theorem 10.1 states conditions (i.e., $L(s)$ rational, stable, and minimum phase) under which knowledge of open-loop gain along the $j\omega$ -axis suffices to determine open-loop phase to within a factor of $\pm\pi$. Constraints analogous to Equation 10.30 hold for unstable or nonminimum phase systems. Hence, gain and phase cannot be manipulated independently in design.

Equation 10.30 shows that the phase of a transfer function is related to the slope (on a log-log scale) of the magnitude of the transfer function. The presence of the weighting function $\log \coth(|\nu|/2) = \log |(\omega + \omega_0)/(\omega - \omega_0)|$ shows that the dependence of $\angle L(j\omega_0)$ upon the rate of gain decrease at frequency ω diminishes rapidly as the distance between ω and ω_0 increases (see Figure 10.4). Hence this integral supports a rule of thumb stating that a 20N dB/decade rate of gain decrease in the vicinity of frequency ω_0 implies that $\angle L(j\omega_0) \approx -90\text{N}^\circ$. In many practical situations, the open loop transfer function is sufficiently well behaved that the value of phase at a frequency is largely determined by that of the gain over a decade-wide interval centered at the frequency of interest [7].

The Bode gain-phase relation may be used to assess whether a design specification of the type shown in Figure 10.3 is achievable. Since a 20N dB/decade rate of gain decrease in the vicinity of crossover implies

* Throughout this article, the notation $\log(\cdot)$ will be used to denote the natural logarithm.

FIGURE 10.4 Weighting function in gain-phase integral.

that phase at crossover is roughly -90° , it follows that the rate of gain decrease cannot be much greater than 20 dB/decade if the Nyquist stability criterion is to be satisfied and if an acceptable phase margin is to be maintained. One implication of this fact is that the frequency ω_L in Figure 10.3 cannot be too close to the frequency ω_H . Hence, the frequency range over which loop gain can be large to obtain sensitivity reduction is limited by the need to ensure stability robustness against uncertainty at higher frequencies, and to maintain reasonable feedback properties near crossover. As discussed in [22,36], relaxing the assumption that $L(s)$ has no right-half-plane poles or zeros does not lessen the severity of this trade-off. Indeed, the trade-off only becomes more difficult to accomplish.

10.4.3 The Bode Sensitivity Integral

The purpose of this section is to present and discuss the constraint imposed by stability on the sensitivity function. This constraint was first developed in the context of feedback systems in [7]. This integral quantifies a trade-off between sensitivity reduction and sensitivity increase that must be performed whenever the open-loop transfer function has at least two more poles than zeros.

The magnitude of the sensitivity function of a scalar feedback system can be obtained easily using a Nyquist plot of $L(j\omega)$. Indeed, since $S(j\omega) = 1/(1 + L(j\omega))$, the magnitude of the sensitivity function is equal to the reciprocal of the distance from the Nyquist plot to the critical point. In particular, sensitivity is less than one at frequencies for which $L(j\omega)$ is outside the unit circle centered at the critical point. Sensitivity is greater than one at frequencies for which $L(j\omega)$ is inside this unit circle.

To motivate existence of the integral constraint, consider the open-loop transfer function $L(s) = 2/(s + 1)^2$. As shown in Figure 10.5, there exists a frequency range over which the Nyquist plot of $L(j\omega)$ penetrates the unit circle centered at $-1 + j0$ and sensitivity is thus greater than one. In practice, the open-loop transfer function will generally have at least two more poles than zeros [36]. If $L(s)$ is stable, then,

FIGURE 10.5 Effect of a two-pole rolloff upon the Nyquist plot of $L(s) = 2/(s + 1)^2$.

using the gain-phase relation (Equation 10.30), it is straightforward to show that $L(j\omega)$ will asymptotically have a phase lag of at least -180° . Hence there will always exist a frequency range over which sensitivity is greater than one. This behavior may be quantified using a classical theorem due to Bode [7], which was extended in [31] to allow unstable poles in the open-loop transfer function. An excellent discussion of the implications that the Bode sensitivity integral has for open-loop unstable systems can be found in [62].

Theorem 10.2: Bode Sensitivity Integral

Suppose that the open-loop transfer function $L(s)$ is rational and has right-half-plane poles $\{p_i : i = 1, \dots, N_p\}$, with multiple poles included according to their multiplicity. If $L(s)$ has at least two more poles than zeros, and if the associated feedback system is stable, then the sensitivity function must satisfy

$$\int_0^\infty \log |S(j\omega)| d\omega = \pi \sum_{i=1}^{N_p} \text{Re}(p_i). \tag{10.32}$$

It is possible to extend Theorem 10.2 to systems for which $L(s)$ has relative degree one and a possible time delay. For details, see [56, Theorem 3.1.4].

Theorem 10.2 shows that a trade-off exists between sensitivity properties in different frequency ranges. Indeed, for stable open-loop systems, the area of sensitivity reduction must equal the area of sensitivity increase on a plot of the logarithm of the sensitivity versus linear frequency (see Figure 10.6). In this respect, the benefits and costs of feedback are balanced exactly.

The extension of Bode’s theorem to open-loop unstable systems shows that the area of sensitivity increase exceeds that of sensitivity reduction by an amount proportional to the distance from the unstable poles to the left half-plane. A little reflection reveals that this additional sensitivity increase is plausible for

FIGURE 10.6 Areas of sensitivity reduction ($\log |S(j\omega)| < 0$) and sensitivity increase ($\log |S(j\omega)| > 0$) for $L(s) = 1/(s(s+1))$.

the following reason. When the system is open-loop unstable, then it is obviously necessary to use feedback to achieve closed-loop stability, as well as to obtain sensitivity reduction. One might expect that this additional benefit of feedback would be accompanied by a certain cost, and the integral (Equation 10.32) substantiates that hypothesis.

By itself, the trade-off quantified by Equation 10.32 does not impose a meaningful design limitation. It is true that requiring a large area of sensitivity reduction over a low-frequency interval implies that an equally large area of sensitivity increase must be present at higher frequencies. However, it is possible to achieve an arbitrary large area of sensitivity increase by requiring $|S(j\omega)| = 1 + \delta$, $\forall \omega \in (\omega_1, \omega_2)$, where δ can be chosen arbitrarily small and the interval (ω_1, ω_2) is adjusted to be sufficiently large.

The analysis in the preceding paragraph ignores the effect of limitations upon system bandwidth that are always present in a practical design. For example, it is almost always necessary to decrease open-loop gain at high frequencies to maintain stability robustness against large modeling errors due to unmodeled dynamics. Small open-loop gain is also required to prevent sensor noise from appearing at the system output. Finally, requiring open-loop gain to be large at a frequency for which plant gain is small may lead to unacceptably large response of the plant input to noise and disturbances. Hence the natural bandwidth of the plant also imposes a limitation upon open-loop bandwidth.

One or more of the bandwidth constraints just cited is usually present in any practical design. It is reasonable, therefore, to assume that open-loop gain must satisfy a frequency-dependent bound of the form

$$|L(j\omega)| \leq \epsilon \left(\frac{\omega_c}{\omega} \right)^{1+k}, \quad \forall \omega \geq \omega_c, \quad (10.33)$$

where $\epsilon < 1/2$ and $k > 0$. This bound imposes a constraint upon the rate at which loop gain rolls off, as well as the frequency at which rolloff commences and the level of gain at that frequency.

When a bandwidth constraint such as Equation 10.33 is imposed, it is obviously not possible to require the sensitivity function to exceed one over an arbitrarily large frequency interval. When Equation 10.33 is satisfied, there is an upper bound on the area of sensitivity increase which can be present at frequencies greater than ω_c . The corresponding limitation imposed by the sensitivity integral (Equation 10.32) and the rolloff constraint (Equation 10.33) is expressed by the following result [28].

Corollary 10.1:

Suppose, in addition to the assumptions of Theorem 10.2, that $L(s)$ satisfies the bandwidth constraint given by Equation 10.33. Then the tail of the sensitivity integral must satisfy

$$\left| \int_{\omega_c}^{\infty} \log |S(j\omega)| d\omega \right| \leq \frac{3\epsilon\omega_c}{2k}. \quad (10.34)$$

The bound in Equation 10.34 implies that the sensitivity trade-off imposed by the integral constraint in Equation 10.32 must be accomplished primarily over a finite frequency interval. As a consequence, the amount by which $|S(j\omega)|$ must exceed one cannot be arbitrarily small. Suppose that the sensitivity function is required to satisfy the upper bound

$$|S(j\omega)| \leq \alpha < 1, \quad \forall \omega \leq \omega_\ell < \omega_c. \quad (10.35)$$

If the bandwidth constraint (Equation 10.33) and the sensitivity bound (Equation 10.35) are both satisfied, then the integral constraint (Equation 10.32) may be manipulated to show that [28]

$$\sup_{\omega \in (\omega_\ell, \omega_c)} \log |S(j\omega)| \geq \frac{1}{\omega_c - \omega_\ell} \left(\pi \sum_{i=1}^{N_p} \text{Re}(p_i) + \omega_\ell \log \left(\frac{1}{\alpha} \right) - \frac{3\epsilon\omega_c}{2k} \right). \quad (10.36)$$

The bound in Equation 10.36 shows that increasing the area of low-frequency sensitivity reduction by requiring α to be very small or ω_ℓ to be very close to ω_c , will necessarily cause a large peak in sensitivity at frequencies between ω_ℓ and ω_c . Hence, the integral constraint (Equation 10.32) together with the bandwidth constraint (Equation 10.33) imposes a trade-off between sensitivity reduction and sensitivity increase which must be accounted for in design.

It may be desirable to impose a bandwidth constraint such as Equation 10.33 directly on the complementary sensitivity function $T(s)$ since $T(s)$ directly expresses the feedback properties of sensor noise response and stability robustness, while $L(s)$ does so only indirectly. Analogous results to those stated in Corollary 10.1 can be obtained in this case.

10.4.4 Complementary Sensitivity Integral

The complementary sensitivity function is constrained by the stability requirement for the closed-loop system in a manner analogous to the sensitivity function. The following result is due to Middleton and Goodwin [45]. One difference between the two results is that the trade-off described by the Bode sensitivity integral (Equation 10.32) is worsened if the system is open-loop unstable. As we shall see, the analogous trade-off described by the complementary sensitivity integral becomes worse if the open-loop transfer function contains a time delay and/or zeros in the right half-plane.

Theorem 10.3: Complementary Sensitivity Integral

Suppose that the open loop transfer function $L(s)$ is given by the product of a rational transfer function and a delay element,

$$L(s) = \tilde{L}(s)e^{-s\tau}, \quad (10.37)$$

FIGURE 10.7 Areas of complementary sensitivity increase ($\log |T(j\omega)| < 0$) and complementary sensitivity decrease ($\log |T(j\omega)| > 0$) for $L(s) = (s + 1)/s^2$.

where $\tilde{L}(s)$ is assumed to be rational with right-half-plane zeros $\{z_i : i = 1, \dots, N_z\}$ (with multiple zeros included according to their multiplicity). If $L(s)$ has at least one pole at the origin (i.e., one integrator), and if the associated feedback system is stable, then the complementary sensitivity function must satisfy

$$\int_0^\infty \log |T(j\omega)| \frac{d\omega}{\omega^2} = \pi \sum_{i=1}^{N_z} \operatorname{Re} \left(\frac{1}{z_i} \right) + \frac{\pi}{2} \tau - \frac{\pi}{2} K_v^{-1}, \quad (10.38)$$

where K_v is the velocity constant of the system,

$$K_v = \lim_{s \rightarrow 0} sL(s). \quad (10.39)$$

The complementary sensitivity integral (Equation 10.38) has a similar interpretation to the Bode sensitivity integral. Recall that the complementary sensitivity function characterizes the response of the system to sensor noise and the robustness of the system to high-frequency model errors. Theorem 10.3 states that if the open-loop transfer function is minimum phase (i.e., it has no right-half-plane zeros, and no delay) and is a Type II system, then the area of amplified sensor noise response must equal the area of attenuated sensor noise response. In the case of the complementary sensitivity function, the areas are computed with respect to an inverse frequency scale (see Figure 10.7). The presence of nonminimum phase zeros or delays worsens the trade-off (i.e., increases the required area of noise amplification). For Type I systems, the trade-off is improved by the term involving the velocity constant on the right-hand side of Equation 10.39.

As for the sensitivity integral, the complementary sensitivity integral does not imply that the peak in the complementary sensitivity transfer function must be large. It is possible to accommodate the required increase in the magnitude of the complementary sensitivity function by allowing it to be only slightly greater than one for frequencies close to zero (since the area is computed with respect to inverse

frequency). However, when combined with tracking requirements imposed at low frequencies (analogous to the rolloff requirement in Equation 10.33), the integral constraint in Equation 10.38 can be used to develop a lower bound on the peak of the complementary sensitivity function.

Assume that the open-loop transfer function satisfies

$$|L(j\omega)| \geq \delta \left(\frac{\omega_p}{\omega} \right)^{1+k}, \quad \forall \omega \leq \omega_p, \quad (10.40)$$

where $\delta > 2$ and $k > 0$. This bound imposes a constraint upon the tracking performance of the system.

When a performance constraint such as Equation 10.40 is imposed, it is obviously not possible to require the complementary sensitivity function to exceed one over an arbitrarily large inverse frequency interval. When Equation 10.40 is satisfied, there is an upper bound on the area of complementary sensitivity increase which can be present at frequencies less than ω_p . The corresponding limitation imposed by the complementary sensitivity integral (Equation 10.38) and the rolloff constraint (Equation 10.40) is expressed by the following result.

Corollary 10.2:

Suppose, in addition to the assumptions of Theorem 10.3, that $L(s)$ satisfies the performance constraint given by Equation 10.40. Then the low-frequency tail of the complementary sensitivity integral must satisfy

$$\left| \int_0^{\omega_p} \log |T(j\omega)| \frac{d\omega}{\omega^2} \right| \leq \frac{3}{2k\delta\omega_p}. \quad (10.41)$$

The bound in Equation 10.41 implies that the complementary sensitivity trade-off imposed by the integral constraint in Equation 10.38 must be accomplished primarily over a finite inverse frequency interval. As a consequence, the amount by which $|T(j\omega)|$ must exceed one cannot be arbitrarily small.

Suppose that the complementary sensitivity function is required to satisfy the upper bound

$$|T(j\omega)| \leq \alpha < 1, \quad \forall \omega \geq \omega_h > \omega_p. \quad (10.42)$$

If the performance constraint given by Equation 10.40 and the complementary sensitivity bound in Equation 10.42 are both satisfied, then the integral constraint (Equation 10.38) may be manipulated to show that

$$\sup_{\omega \in (\omega_p, \omega_h)} \log |T(j\omega)| \geq \frac{1}{\frac{1}{\omega_p} - \frac{1}{\omega_h}} \left\{ \pi \sum_{i=1}^{N_z} \operatorname{Re} \left(\frac{1}{z_i} \right) + \frac{\log \frac{1}{\alpha}}{\omega_h} - \frac{3}{2k\delta\omega_p} + \frac{\pi}{2} \tau - \frac{\pi}{2} K_v^{-1} \right\}. \quad (10.43)$$

The bound in Equation 10.43 shows that increasing the area of high-frequency complementary sensitivity reduction by requiring α to be very small or ω_h to be very close to ω_p will necessarily cause a large peak in sensitivity at frequencies between ω_p and ω_h . Hence, the integral constraint (Equation 10.38) together with the performance constraint (Equation 10.40) imposes a trade-off between complementary sensitivity reduction and complementary sensitivity increase which must be accounted for in design.

10.5 Limitations Imposed by Right-Half-Plane Poles and Zeros

10.5.1 Introduction

As discussed in Section 10.2, design specifications are often stated in terms of frequency-dependent bounds on the magnitude of closed-loop transfer functions. It has long been known that control system

design is more difficult for nonminimum phase or unstable systems. The sensitivity and complementary sensitivity integrals presented in Section 10.4 indicated that nonminimum phase zeros and unstable poles could worsen the individual design trade-offs. In fact, right-half-plane poles and zeros impose additional constraints upon the control system design. This section examines these limitations in detail.

10.5.2 Limitations for Nonminimum Phase Systems

Suppose that the plant possesses zeros in the open right-half-plane. Examples of such systems abound, including the inverted pendulum and cart [56], rear steering bicycle [4], fuel cells [63], acoustic ducts [54], and continuously variable transmission [41]. Then the internal stability requirement dictates that these zeros also appear, with at least the same multiplicity, in the open-loop transfer function $L(s) = P(s)C(s)$. Let the set of all open right-half-plane zeros of $L(s)$ (including any present in the compensator) be denoted by

$$\{z_i : i = 1, \dots, N_z\}. \quad (10.44)$$

Defining the Blaschke product (all-pass filter)

$$B_z(s) = \prod_{i=1}^{N_z} \frac{z_i - s}{\bar{z}_i + s}, \quad (10.45)$$

we can factor the open-loop transfer function into the form

$$L(s) = L_m(s)B_z(s), \quad (10.46)$$

where $L_m(s)$ has no zeros in the open right-half-plane. Note that

$$|L(j\omega)| = |L_m(j\omega)|, \quad \forall \omega, \quad (10.47)$$

and, in the limit as $\omega \rightarrow \infty$,

$$\angle \left(\frac{z_i - j\omega}{\bar{z}_i + j\omega} \right) \rightarrow -180^\circ. \quad (10.48)$$

These facts show that open right-half-plane zeros contribute additional phase lag without changing the gain of the system (hence the term “nonminimum phase zero”). The effect that this additional lag has upon feedback properties can best be illustrated using a simple example.

Consider the nonminimum phase plant $P(s) = \frac{1}{(s+1)} \frac{(1-s)}{(1+s)}$ and its minimum phase counterpart $P_m(s) = 1/s + 1$. Figure 10.8 shows that the additional phase lag contributed by the zero at $s = 1$ causes the Nyquist plot to penetrate the unit circle and the sensitivity to be larger than one. Experiments with various compensation schemes reveal that using large loop gain over some frequency range to obtain small sensitivity in that range tends to cause sensitivity to be large at other frequencies.

Assume that the open-loop transfer function can be factored as

$$L(s) = L_0(s)B_z(s)B_p^{-1}(s)e^{-s\tau}, \quad (10.49)$$

where $\tau \geq 0$ represents a possible time delay, $L_0(s)$ is a proper rational function with no poles or zeros in the open right plane, and $B_z(s)$ is the Blaschke product (Equation 10.45) containing the open right-half-plane zeros of the plant plus those of the compensator. The Blaschke product

$$B_p(s) = \prod_{i=1}^{N_p} \frac{p_i - s}{p_i + s} \quad (10.50)$$

contains all the poles of both plant and compensator in the open right-half-plane, again counted according to multiplicity. We emphasize once more that internal stability requirements dictate that

FIGURE 10.8 Additional phase lag contributed by a nonminimum phase zero.

all right-half-plane poles and zeros of the plant must appear with at least the same multiplicity in $L(s)$ and hence cannot be canceled by right-half-plane zeros and poles of the compensator.

One constraint that right-half-plane zeros impose upon the sensitivity function is immediately obvious from the definition $S(j\omega) = 1/(1 + L(j\omega))$. Suppose that $L(s)$ has a zero at $s = z$. It follows that

$$S(z) = 1. \tag{10.51}$$

Poles of $L(s)$ also constrain the sensitivity function. If $L(s)$ has a pole at $s = p$, then

$$S(p) = 0. \tag{10.52}$$

From Equations 10.51 and 10.52, it is clear that if the plant (and thus $L(s)$) has zeros or poles at points of the open right-half-plane, then the value of the sensitivity function is constrained at those points. Naturally, the value of sensitivity along the $j\omega$ -axis, where the design specifications are imposed and the conjectured trade-off must take place, is of more concern.

Theorem 10.4:

Suppose that the open-loop transfer function $L(s)$ has a zero, $z = x + jy$, with $x > 0$. Assume that the associated feedback system is stable. Then the sensitivity function must satisfy

$$\int_0^\infty \log |S(j\omega)| W(z, \omega) d\omega = \pi \log |B_p^{-1}(z)|, \tag{10.53}$$

where $W(z, \omega)$ is a weighting function. For a real zero, $z = x$,

$$W(x, \omega) = \frac{2x}{x^2 + \omega^2} \quad (10.54)$$

and, for a complex zero, $z = x + jy$,

$$W(z, \omega) = \frac{x}{x^2 + (y - \omega)^2} + \frac{x}{x^2 + (y + \omega)^2}. \quad (10.55)$$

A number of remarks about this theorem are in order. First, as discussed in [28], the integral relations are valid even if $S(s)$ has zeros (or poles) on the $j\omega$ -axis. Second, a zero z with multiplicity $m > 1$ imposes additional interpolation constraints on the first $m - 1$ derivatives of $\log S(s)$ evaluated at the zero. These interpolation constraints also have equivalent statements as integral relations [28].

We now show that Equation 10.53 imposes a sensitivity trade-off. To see this, note first that the weighting function satisfies $W(z, \omega) > 0, \forall \omega$, and that the Blaschke product satisfies $\log |B_p^{-1}(z)| \geq 0$. Using these facts, it follows easily from Equation 10.53 that requiring sensitivity reduction ($\log |S(j\omega)| < 0$) over some frequency range implies that there must be sensitivity amplification ($\log |S(j\omega)| > 0$) at other frequencies. Hence, if the plant is nonminimum phase, one cannot use feedback to obtain the benefits of sensitivity reduction over one frequency range unless one is willing to pay the attendant price in terms of increased sensitivity elsewhere.

Theorem 10.4 verifies the conjecture that a sensitivity trade-off is present whenever a system is nonminimum phase. Recall it was also conjectured that the severity of the trade-off is a function of the phase lag contributed by the zero at frequencies for which sensitivity reduction is desired. This conjecture can be verified by using the form of the weighting function $W(z, \omega)$ defined in Equations 10.54 and 10.55.

Consider first the case of a real zero $z = x$. Equation 10.46 shows that, as a function of frequency, the additional phase lag contributed by this zero is

$$\theta(x, \omega) = \angle \frac{x - j\omega}{x + j\omega}. \quad (10.56)$$

Noting that

$$\frac{d\theta(x, \omega)}{d\omega} = \frac{-2x}{x^2 + \omega^2}, \quad (10.57)$$

it follows that the weighting function in Equation 10.54 satisfies

$$W(x, \omega) = -\frac{d\theta(x, \omega)}{d\omega}. \quad (10.58)$$

Hence the weighting function appearing in the sensitivity constraint is equal to (minus) the rate at which the phase lag due to the zero increases with frequency.

One can use the weighting function (Equation 10.58) to compute the weighted length of a frequency interval. Note that sensitivity reduction is typically required over a low-frequency interval $\Omega = (0, \omega_1)$ and that the weighted length of such an interval equals

$$\begin{aligned} W(x, \Omega) &= \int_0^{\omega_1} W(x, \omega) d\omega \\ &= -\theta(x, \omega_1). \end{aligned} \quad (10.59)$$

Hence, the weighted length of the interval is equal to (minus) the phase lag contributed by the zero at the upper endpoint of the interval. It follows that, as $\omega_1 \rightarrow \infty$, the weighted length of the $j\omega$ -axis equals π .

For a complex zero, the weighting function (Equation 10.55) is equal to minus the average of the additional phase lag contributed by the zero and by its complex conjugate:

$$W(z, \omega) = -\frac{1}{2} \left(\frac{d\theta(z, \omega)}{d\omega} + \frac{d\theta(\bar{z}, \omega)}{d\omega} \right). \quad (10.60)$$

Hence, the weighted length of the frequency interval $\Omega = (0, \omega_1)$ is

$$W(x, \omega) = -\frac{1}{2} (\theta(z, \omega_1) + \theta(\bar{z}, \omega_1)). \quad (10.61)$$

As we have already remarked, the integral constraint in Equation 10.53 implies that a trade-off exists between sensitivity reduction and sensitivity increase in different frequency ranges. An interesting interpretation of this trade-off is available using the weighting function. Suppose first that $L(s)$ has no poles in the open right-half-plane. Then the integral constraint is

$$\int_0^\infty \log |S(j\omega)| W(x, \omega) d\omega = 0. \quad (10.62)$$

Equation 10.62 states that the weighted area of sensitivity increase must equal the weighted area of sensitivity reduction. Since the weighted length of the $j\omega$ -axis is finite, it follows that the amount by which sensitivity must exceed one at higher frequencies cannot be made arbitrarily small.

If the open-loop system has poles in the open-right-half-plane, then the weighted area of sensitivity increase must exceed that of sensitivity reduction. In particular,

$$\log |B_p^{-1}(z)| = \sum_{i=1}^{N_p} \log \left| \frac{\bar{p}_i + z}{p_i - z} \right|. \quad (10.63)$$

The right-hand side of Equation 10.63 is always greater than zero, and becomes large whenever the zero z approaches the value of one of the unstable poles p_i . It follows (unsurprisingly) that systems with approximate pole-zero cancellations in the open right half-plane will necessarily have poor sensitivity properties.

We can use the integral constraint in Equation 10.53 to obtain some simple lower bounds on the size of the peak in sensitivity accompanying a given level of sensitivity reduction over a low-frequency interval. Bounds of this type were first discussed by Francis and Zames [26, Theorem 3]. The results presented here will show how the relative location of the zero to the interval of sensitivity reduction influences the size of the peak in sensitivity outside that interval.

Suppose that the sensitivity function is required to satisfy the upper bound

$$|S(j\omega)| \leq \alpha < 1, \quad (10.64)$$

where $\Omega = (0, \omega_1)$ is a low-frequency interval of interest. Define the infinity norm of the sensitivity function:

$$\|S\|_\infty = \sup_{\omega \geq 0} |S(j\omega)|. \quad (10.65)$$

Assuming that the upper bound in Equation 10.64 is satisfied, the integral constraint in Equation 10.53 can be used to compute a lower bound on $\|S\|_\infty$ for each nonminimum phase zero of $L(s)$.

Corollary 10.3:

Suppose that the conditions in Theorem 10.4 are satisfied and that the sensitivity function is bounded as in Equation 10.64. Then the following lower bound must be satisfied at each nonminimum phase

zero of $L(s)$:

$$\|S\|_{\infty} \geq \left(\frac{1}{\alpha}\right)^{\frac{W(z,\Omega)}{\pi-W(z,\Omega)}} \left|B_p^{-1}(z)\right|^{\frac{\pi}{\pi-W(z,\Omega)}}. \quad (10.66)$$

The bound in Equation 10.66 shows that if sensitivity is required to be very small over the interval $(0, \omega_1)$, then there necessarily exists a large peak in sensitivity outside this interval. Furthermore, the smallest possible size of this peak will become larger if the open-loop system has unstable poles near any zero.

The size of the sensitivity peak also depends upon the location of the interval $(0, \omega_1)$ relative to the zero. Assume for simplicity that the system is open-loop unstable and the zero is real. Then

$$\|S\|_{\infty} \geq \left(\frac{1}{\alpha}\right)^{\frac{W(x,\Omega)}{\pi-W(x,\Omega)}}. \quad (10.67)$$

Recall that the weighted length of the interval $\Omega = (0, \omega_1)$ is equal to (minus) the phase lag contributed by the zero at the upper endpoint of that interval. Since the zero eventually contributes 180° phase lag, it follows that as $\omega_1 \rightarrow \infty$, $W(x, \Omega) \rightarrow \pi$. Thus the exponent in Equation 10.67 becomes unbounded and, since $\alpha < 1$, so does the peak in sensitivity. To summarize, requiring sensitivity to be small throughout a frequency range extending into the region where the nonminimum phase zero contributes a significant amount of phase lag implies that there will necessarily exist a large peak in sensitivity at higher frequencies. On the other hand, if the zero is located so that it contributes only a negligible amount of phase lag at frequencies for which sensitivity reduction is desired, then it does not impose a serious limitation upon sensitivity properties of the system. Analogous results hold, with appropriate modifications, for a complex zero.

Suppose now that the open-loop system has poles in the open right-half-plane. It is interesting to note that, in this case, the bound (Equation 10.66) implies the existence of a peak in sensitivity even if no sensitivity reduction is present!

Recall next the approximation in Equation 10.26 which shows that small sensitivity can be obtained only by requiring open-loop gain to be large. It is easy to show that $|S(j\omega)| \leq \alpha < 1$ implies that $|L(j\omega)| \geq (1/\alpha) - 1$. The inequality in Equation 10.67 implies that, to prevent poor feedback properties, open-loop gain should not be large over a frequency interval extending into the region for which a nonminimum phase zero contributes significant phase lag. This observation substantiates a classical design rule of thumb: loop gain must be rolled off before the phase lag contributed by the zero becomes significant. However, if one is willing and able to adopt some nonstandard design strategies (such as having multiple gain crossover frequencies) then [37] it is possible to manipulate the design trade-off imposed by a nonminimum phase zero to obtain some benefits of large loop gain at higher frequencies. One drawback of these strategies is that loop gain must be small, and hence the benefits of feedback must be lost over an intermediate frequency range.

10.5.3 Limitations for Unstable Systems

We shall show in this section that unstable poles impose constraints upon the complementary sensitivity function which, loosely speaking, are dual to those imposed upon the sensitivity function by nonminimum phase zeros. That such constraints exist might be conjectured from the existence of the interpolation constraint in Equation 10.52 and the algebraic identity in Equation 10.21. Together, these equations show that if $L(s)$ has a pole $s = p$, then the complementary sensitivity function satisfies

$$T(p) = 1. \quad (10.68)$$

Furthermore, if $L(s)$ has a zero at $s = z$, then

$$T(z) = 0. \quad (10.69)$$

The previous results for the sensitivity function, together with the fact that $T(s)$ is constrained to equal one at open right-half-plane poles of $L(s)$, suggests that similar constraints might exist for $|T(j\omega)|$ due to the presence of such poles. It is also possible to motivate the presence of the integral constraint on $|T(j\omega)|$ using an argument based upon the inverse Nyquist plot [53] and the fact that $|T(j\omega)| > 1$ whenever $L^{-1}(j\omega)$ is inside the unit circle centered at the critical point.

As in Section 10.5.2, it is assumed that $L(s)$ has the form given in Equation 10.49. The following theorem states the integral constraint on the complementary sensitivity function due to unstable poles.

Theorem 10.5:

Suppose that the open-loop transfer function has a pole, $p = x + jy$, with $x > 0$. Assume that the associated feedback system is stable. Then the complementary sensitivity function must satisfy

$$\int_0^{\infty} \log |T(j\omega)| W(x, \omega) d\omega = \pi \log |B_z^{-1}(p)| + \pi x \tau, \quad (10.70)$$

where $W(p, \omega)$ is a weighting function. For a real pole, $p = x$,

$$W(x, \omega) = \frac{2x}{x^2 + \omega^2}, \quad (10.71)$$

and, for a complex pole, $p = x + jy$,

$$W(p, \omega) = \frac{x}{x^2 + (y - \omega)^2} + \frac{x}{x^2 + (y + \omega)^2}. \quad (10.72)$$

Remarks analogous to those following Theorem 10.4 apply to this result also. The integral relations are valid even if $T(s)$ has zeros on the $j\omega$ -axis, and there are additional constraints on the derivative of $\log T(s)$ at poles with multiplicity greater than one.

The integral constraint in Equation 10.70 shows that there exists a trade-off between sensor noise response properties in different frequency ranges whenever the system is open-loop unstable. Since $|T(j\omega)|$ is the reciprocal of the stability margin against multiplicative uncertainty, it follows that a trade-off between stability robustness properties in different frequency ranges also exists. Using analysis methods similar to those in the preceding section, one can derive a lower bound on the peak in the complementary sensitivity function present whenever $|T(j\omega)|$ is required to be small over some frequency interval. One difference is that $|T(j\omega)|$ is generally required to be small over a high, rather than a low, frequency range.

It is interesting that time delays worsen the trade-off upon sensor noise reduction imposed by unstable poles. This is plausible for the following reason. Use of feedback around an open-loop unstable system is necessary to achieve stability. Time delays, as well as nonminimum phase zeros, impede the processing of information around a feedback loop. Hence, it is reasonable to expect that design trade-offs due to unstable poles are exacerbated when time delays or nonminimum phase zeros are present. This interpretation is substantiated by the fact that the term due to the time delay in Equation 10.70 is proportional to the product of the length of the time delay and the distance from the unstable pole to the left half-plane.

10.5.4 Summary

Nonminimum phase or unstable systems impose additional trade-offs for control system design. Nonminimum phase zeros limit the frequency range over which control system performance can be achieved, while unstable poles require active control over certain frequency ranges and reduce the overall performance that can be achieved. Quantitative expressions of these trade-offs are given by the integral

constraints of Theorems 10.4 and 10.5. These constraints can be used together with bounds on the desired performance to compute approximations that provide useful insight into the design trade-offs.

10.6 Time-Domain Integral Constraints

10.6.1 Introduction

One class of limitations on feedback system performance can be described as time domain integral constraints. These date back at least as far as classical works such as [68], which analyze various error constants and their effects on performance. Such constraints, for single-degree-of-freedom unity feedback systems, can be described in a straightforward manner using classical control techniques and have been explored for example in [43,45]. They are based on the unity feedback system depicted in Figure 10.1.

10.6.2 Double Integrators

As an initial case, suppose that we have a feedback loop that incorporates two integrators. For example, this may arise from a situation where the plant includes an integrator and we also specify a controller that incorporates integral action. In this case, it follows that the open-loop transfer function can be written as $L(s) = \frac{1}{s^2} \bar{L}(s)$, where $\bar{L}(0) \neq 0$. Then consider the error response to a unit step change in the reference, $R(s) = \frac{1}{s}$,

$$E(s) = S(s)R(s) = \left(\frac{1}{1+L(s)} \right) \frac{1}{s} = \left(\frac{s^2}{s^2 + \bar{L}(s)} \right) \frac{1}{s}. \quad (10.73)$$

Assuming closed-loop stability, it follows that $s = 0$ is in the region of convergence of $E(s)$ and $E(0) = S(0)R(0) = 0$, that is,

$$E(0) = \int_0^{\infty} e(t) dt = 0. \quad (10.74)$$

Equation 10.74 can be viewed as an equal area criterion on the step response. This in turn implies that either the error signal is zero for all time, or it must alternate signs. Therefore, since the error must be negative for some times, there must be overshoot in the step response, since $y(t) = 1 - e(t)$ will exceed 1 whenever $e(t)$ is negative. Figure 10.9 illustrates an example response for a system containing a double integrator.

We conclude from this motivating example that a stable unity feedback system with a double integrator displays unavoidable overshoot in the step response. More general versions of the integral constraint (Equation 10.74) can be derived to quantify the effect of open-loop CRHP poles and zeros on the closed-loop step response, as we discuss next.

10.6.3 Right-Half-Plane Poles and Zeros

We have seen in Section 10.5 that open-loop right-half-plane poles and zeros impose interpolation constraints on the sensitivity and complementary sensitivity functions. Namely, if $L(s)$ has a CRHP zero at $s = z$, then for any internally stable closed-loop system the interpolation constraints given in Equations 10.51 and 10.69 hold. On the other hand, if $L(s)$ has a CRHP pole at $s = p$, then Equations 10.52 and 10.68 hold.

Recall that $S(s)$ and $T(s)$ govern the output and error response of the system to exogenous inputs through Equations 10.4 and 10.5. Closed-loop stability implies that CRHP poles and zeros are in the region of convergence of the Laplace transform, and it thus follows from Equation 10.52 that $E(p) = S(p)R(p) = 0$, and from Equation 10.69 that $Y(z) = T(z)R(z) = 0$. These constraints are expressed in integral form in the following theorem.

FIGURE 10.9 Example closed loop error step response for a double integrator open loop transfer function.

Theorem 10.6:

Consider any closed-loop stable linear time-invariant SISO system as illustrated in Figure 10.1 with zero initial conditions and a step reference signal. Then, for any CRHP pole p of $P(s)$, the error signal $e(t)$ satisfies

$$\int_0^{\infty} e^{-pt} e(t) dt = 0. \tag{10.75}$$

Furthermore, for any CRHP zero z of $P(s)$, the output signal $y(t)$ satisfies

$$\int_0^{\infty} e^{-zt} y(t) dt = 0. \tag{10.76}$$

The integral constraints in Equations 10.75 and 10.76 are weighted equal area criteria on the step responses $e(t)$ and $y(t)$. Some direct consequences of these results follow as trade-offs in the step response specifications (see Figure 10.10) in the case of *real* CRHP poles and zeros (see [43,45] for further details):

- The closed-loop unity feedback step response of a plant with a real RHP pole must overshoot, that is, the error signal, $e(t)$, must change sign. If we take a slightly unusual definition of rise time

$$t_r = \max\{t_r : y(t) < t/t_r \quad \forall t \leq t_r\},$$

and if we define the overshoot as the maximum amount by which the output exceeds the reference, $y_{os} = \max_{t \geq 0} \{y(t) - 1\}$, then for a real open-loop pole at $s = p > 0$, the overshoot must satisfy the

FIGURE 10.10 Step response specifications.

lower bound

$$y_{os} \geq \frac{pt_r}{2}. \quad (10.77)$$

- The closed-loop step response of a plant with a real RHP zero must undershoot, that is, there must exist times for which the output is negative. If we take the non standard definition of settling time

$$t_s = \min_{t_s \geq 0} \{t_s : y(t) \geq 0.9 \quad \forall t \geq t_s\},$$

then for any system with a real open-loop zero at $s = z > 0$, the undershoot must satisfy the lower bound

$$y_{us} = -\min_t \{-y(t)\} \geq \frac{0.9}{e^{zt_s} - 1}. \quad (10.78)$$

The above time domain integrals provide a number of insights into fundamental limits on the behavior of stable closed-loop systems with real RHP open-loop poles or zeros. The effects of slow OLHP open-loop poles on transient performance have been examined in [46]. Trade-offs in the step response due to $j\omega$ -axis zeros have been studied in [33]. Extensions to multivariable systems has been pursued in [40], in which directional properties of multivariable systems may permit step response trade-offs that include possible transients in other loops.

10.7 Further Extensions and Comments

A range of extensions to the basic trade-offs and limitations discussed previously are available. In this section, we briefly review some of the main points and key references for a selection of these results. We conclude the section with a brief discussion of cases in which tracking performance limitations may be alleviated.

10.7.1 Limitations in Discrete-Time and Sampled-Data Control

Integral constraints imposed by feedback stability on the sensitivity and complementary sensitivity functions also apply to discrete-time systems. The first discrete-time extensions of the Bode integral for the sensitivity and complementary sensitivity functions were obtained by Sung and Hara [64,65]. A unified formulation of continuous and discrete-time results appeared in [43] and [45]. These results show that the design trade-offs arising from these integral constraints in continuous-time systems carry over to discrete-time systems with analogous interpretations.

FIGURE 10.11 Linear time-invariant discrete-time feedback system.

We present here the discrete-time Bode sensitivity integral as given in [64]. Consider the discrete-time feedback system shown in Figure 10.11, where all signals are now functions of the discrete-time variable $k = 0, 1, 2, \dots$, and the plant and controller are represented by the discrete-time rational transfer functions $P_d(z)$ and $C_d(z)$.

The discrete-time open-loop, sensitivity, and complementary sensitivity functions are defined analogously to their continuous-time counterparts:

$$L_d(z) = P_d(z) C_d(z), \quad S_d(z) = \frac{1}{1 + L_d(z)}, \quad T_d(z) = \frac{L_d(z)}{1 + L_d(z)}.$$

Suppose that the open-loop transfer function $L_d(s)$ has no pole-zero cancellations in $\bar{\mathbb{D}}^c = \{z : |z| \geq 1\}$. Then the discrete-time closed-loop system is stable if $S_d(z)$ and $T_d(z)$ have no poles in the open unit disk $\mathbb{D} = \{z : |z| < 1\}$.

Theorem 10.7: Bode Discrete-Time Sensitivity Integral

If the loop transfer function $L_d(z)$ is strictly proper and the closed-loop system shown in Figure 10.11 is stable, then

$$\frac{1}{\pi} \int_0^\pi \log |S_d(e^{j\theta})| d\theta = \sum_{i=1}^{N_p} \log |\phi_i|, \quad (10.79)$$

where $\{\phi_i \in \bar{\mathbb{D}}^c, i = 1, \dots, N_p\}$ are the unstable poles of $L_d(z)$.

As in the continuous-time case, the Bode discrete-time sensitivity integral (Equation 10.79) shows that there also exists a balance of areas of sensitivity reduction and amplification for discrete-time systems. A significant difference with the continuous-time case is that in the Bode discrete-time sensitivity integral (Equation 10.79) integration is performed over a *finite* interval, and thus the balance of areas of sensitivity reduction and amplification directly implies design trade-offs, even if no bandwidth constraints are imposed on the discrete-time system.

One should note that if the discrete plant corresponds to the linear time-invariant discretization of an analog plant to be controlled digitally through periodic sampling and hold devices, the analysis of design trade-offs and limitations based on the study of discrete-time sensitivity functions may not capture the real (continuous-time) behavior. Indeed, it is known, for example, that the sampled zeros of a discretized plant can be manipulated by appropriate choice of the hold device [24, Chapter 10]. Hence, the discretization of a nonminimum phase analog plant may be rendered minimum phase, consequently relaxing design limitations in the *sampled* response. However, design limitations and design trade-offs remain in the intersample response independently of the type of hold device used, as shown in [29]. Intersample behavior must thus be taken into account to detect potential difficulties in the continuous-time response.

FIGURE 10.12 Feedback control over a communication channel.

10.7.2 Limitations in Control with Communication Constraints

The increased application of communications and networking technology in the new generation of control systems has prompted many recent studies of limitations in control schemes in which the feedback loop is closed over a communication channel (see, e.g., the papers in [2] and the references therein). While a comprehensive theory of limitations in control over communication channels is yet unavailable, several important questions have been answered for simplified channel models (see, e.g., [11,50]).

A simple scheme of a (discrete-time) control system with feedback over a communication channel is illustrated in Figure 10.12. Here, the block C_s encapsulates processes such as encoding, sensor filtering, and control computations to generate the signal v_k sent over the communication channel. The communication channel may include quantization effects, delay, noise, data loss, and data-rate constraints. The block C_r encapsulates processes such as decoding and actuator signal processing based on the received signal w_k .

This section presents a generalization of the discrete-time Bode Sensitivity Integral seen in Section 10.7.1 to systems with feedback over a noisy communication channel with limited capacity. This result links a fundamental limitation to feedback performance to a fundamental limitation in communications by using the information theoretic concepts developed by Shannon [60].

For an additive white Gaussian noise channel (AWGN) model, the received signal w_k in Figure 10.12 is given as

$$w_k = v_k + n_k, \quad (10.80)$$

where n_k is a white Gaussian signal with variance \mathcal{N} independent of the transmitted signal v_k . The transmitted signal v_k is subject to a channel input power constraint $E\{v_k^2\} < \mathcal{P}$. The (information) capacity \mathcal{C} of the channel is given by the famous Shannon formula [60]

$$\mathcal{C} = \frac{1}{2} \log_2 \left(1 + \frac{\mathcal{P}}{\mathcal{N}} \right) \text{ bits/sample.} \quad (10.81)$$

Given a source that produces information at rate \mathcal{R} , Shannon showed that it is possible to communicate this information reliably (i.e., with arbitrarily small probability of error) over a channel with capacity $\mathcal{C} \geq \mathcal{R}$. On the other hand, if $\mathcal{R} > \mathcal{C}$, then reliable communication is not possible.

Suppose that a feedback system uses information transmitted over a communication channel in the feedback loop, as depicted in Figure 10.12. Then it is natural to ask how the capacity of the channel limits properties of the feedback system. For example, it is of interest to determine the minimum channel capacity required to stabilize an unstable discrete-time plant. The authors of [50,66] show that stabilization is possible if and only if the data rate of the channel is greater than $\sum_{i=1}^{N_p} \log |\phi_i|$, where the ϕ_i are the unstable plant eigenvalues. Similarly, it is shown in [11] that an unstable discrete-time plant with relative degree equal to one and no zeros outside the open unit disk may be stabilized over a Gaussian communication channel if and only if the channel capacity (Equation 10.81) satisfies the same lower

bound identified in [50]:

$$\mathcal{C} \geq \sum_{i=1}^{N_p} \log |\phi_i|. \quad (10.82)$$

In addition to stabilization, feedback may also be used in a control design for the purpose of disturbance attenuation. We have seen that the Bode sensitivity integral limits the ability to attenuate disturbances for the discrete-time feedback system of Figure 10.11. A generalized version of the Bode sensitivity integral derived by Martins and Dahleh [42] shows that the disturbance attenuation properties of a feedback system with a communication channel in the feedback loop, as depicted in Figure 10.12, are limited by the capacity of the channel. To state this result, assume in Figure 10.12 that the blocks C_s and C_r are (possibly nonlinear and time-varying) causal operators, and let the exogenous disturbance d_k be a stationary Gaussian moving average process with a nontrivial power spectral density $\Phi_d(\omega)$. Assume also that the feedback system is mean-square stable, and that the control input sequence u_k is asymptotically stationary and has a well-defined power spectral density $\Phi_u(\omega)$. Then a sensitivity function can be defined as [42, Definition 3.2]

$$S_i(\omega) = \sqrt{\Phi_u(\omega)/\Phi_d(\omega)}. \quad (10.83)$$

The following result is found in [42, Theorem 6.3].

Theorem 10.8:

If the transfer function $P_d(z)$ is strictly proper and the closed-loop system shown in Figure 10.12 is stable, then

$$\frac{1}{\pi} \int_0^\pi \min\{0, \log S_i(\omega)\} d\omega \geq \sum_{k=1}^{N_p} \log |\phi_k| - \mathcal{C}, \quad (10.84)$$

where $\{\phi_i \in \bar{\mathbb{D}}^c, i = 1, \dots, N_p\}$ are the unstable poles of $P_d(z)$.

Theorem 10.8 shows that if the capacity of the Gaussian channel is equal to the minimum required for stabilization, then it is not possible to achieve $S_i(\omega) < 1$ at any frequency, and thus disturbance attenuation is not possible. If disturbance attenuation is required in a feedback design, it is thus necessary that the channel capacity exceed that required for stabilization.

Although we have presented Theorem 10.8 in the context of a Gaussian channel, in fact, the result holds for any channel, and the reader is referred to Martins and Dahleh [42] for further discussion.

10.7.3 Cheap Control and Achievable H_2 Performance

An alternate approach to considering some performance limitations has been to consider so-called *cheap control* problems, wherein an output performance is optimized, while (for the sake of analysis) ignoring any cost associated with the control signal. For example, it was shown in [52] that for the system as shown in Figure 10.1, and with a unit step reference, the minimum achievable quadratic error performance for any stabilizing control, even given full state measurement and a nonlinear controller, must satisfy the so-called *cheap control* performance limitation:

$$\int_0^\infty e^2(t) dt \geq 2 \sum_{z_i \in \text{ORHP}} z_i^{-1}. \quad (10.85)$$

A series of works such as [17] considered a similar problem, but in an output feedback situation where it was shown that in the case of linear time-invariant control, the inequality in Equation 10.85 is strict if and only if the plant includes both ORHP poles and zeros.

The quantification of performance limitations via cheap control (time domain) has been linked to the Bode sensitivity and complementary sensitivity integrals (frequency domain) by Seron et al. [57] and Middleton and Braslavsky [44], the former of which also extends the analysis to nonlinear systems. A key observation in that paper is that the best achievable performance, as the cost associated with the control signal tends to zero, is determined by the least amount of “energy” (in the L_2 sense) required to stabilize the unstable *zero dynamics* of the plant, which is nonzero if the plant is nonminimum phase.

Limitations to optimal cheap control performance have been studied also in linear filtering problems [9,39], and decoupling problems in multivariable systems [12].

10.7.4 MIMO Systems

Multivariable feedback systems incorporate a number of extra challenges compared to SISO loops. In particular, directional properties of transfer functions may play an important role. In addition, the range of transfer functions that are important to overall performance is larger, since the relevant open-loop transfer function matrices, $L_o(s) = P(s)C(s)$ and $L_i(s) = C(s)P(s)$, are identical only in special cases. In the multiple input multiple output (MIMO) case, the output sensitivity, $S_o(s)$, and complementary sensitivity, $T_o(s)$, (both of which take values in $\mathbb{C}^{m \times m}$ where m is the number of outputs) are defined as

$$\begin{aligned} S_o(s) &= (I + L_o(s))^{-1}, \\ T_o(s) &= (I + L_o(s))^{-1}L_o(s). \end{aligned} \quad (10.86)$$

Several classes of results have been obtained for multivariable systems, and we briefly review some of the key points below. For simplicity of exposition, we restrict attention to (1) loops referred to the output; (2) cases where the loop transfer function and its inverse are generically full rank; and (3) cases where the open-loop poles and zeros are disjoint. In particular, we assume:

$$\begin{aligned} \det(L_o(s)) &= 0 \quad \text{only for isolated values of } s \in \mathbb{C} \\ \det(L_o^{-1}(s)) &= 0 \quad \text{only for isolated values of } s \in \mathbb{C} \\ \{\det(L_o(z)) = 0\} &\Rightarrow \{\det(L_o^{-1}(z)) \neq 0\} \quad \text{for any } z \in \mathbb{C}. \end{aligned} \quad (10.87)$$

10.7.4.1 “Average” Sensitivity Integral

Consider the output sensitivity and output complementary sensitivity functions defined in Equation 10.86. There are various measures of interest for a transfer function matrix, but one that is particularly amenable to performance limitations analysis is the determinant. In particular, as shown in [28],

$$\int_0^\infty \log |\det(S_o(j\omega))| d\omega = \pi \sum_{i=1}^{N_p} \text{Re}(p_i). \quad (10.88)$$

If we let $\sigma_i(\cdot)$ denote the i th singular value of a matrix, Equation 10.88 can be rewritten as

$$\int_0^\infty \sum_{j=1}^m \log (\sigma_j(S_o(j\omega))) d\omega = \pi \sum_{i=1}^{N_p} \text{Re}(p_i).$$

Therefore, this generalization of the Bode Sensitivity Integral (Equation 10.32) gives a measure of the overall performance. However, it lacks detail about the worst-case or individual loop performances and therefore several extensions of this analysis have been considered.

10.7.4.2 Sensitivity Integral Inequalities

One form of generalizations that provides some alternate information to the “Average” performance results of Section 10.7.4.1 examines the behavior of the maximum singular value (i.e., the induced 2-norm) of the output sensitivity matrix. Indeed, it can be shown (see, e.g., [8,15]) that

$$\int_0^{\infty} \log \|S_o(j\omega)\| d\omega \geq \pi \max_{i=1\dots N_p} \operatorname{Re}(p_i). \quad (10.89)$$

Inequality in Equation 10.89 arises from the directional properties of the multivariable system (see, e.g., Definition 10.1), which we now turn to study in more detail.

10.7.4.3 Direction-Based Analysis

Directional properties of vector signals and matrix transfer functions play an important role in multivariable systems. The appropriate MIMO generalization of a zero* of the loop transfer function matrix, $L_o(s)$, is as an isolated value of s for which $L_o(s)$ drops rank. Under Equation 10.87 this is equivalent to isolated values of s for which $\det(L_o(s)) = 0$. Similarly, a pole of $L_o(s)$ is an isolated value of s for which $\det(L_o^{-1}(s)) = 0$. This leads to the following definition of MIMO zeros and poles and their input directions†.

Definition 10.1: Multivariable Poles and Zeros

1. Subject to Equation 10.87, we say $L_o(s)$ has a zero at $s = z$ with input direction d_z if

$$L_o(z)d_z = 0.$$

2. Subject to Equation 10.87, we say $L_o(s)$ has a pole at $s = p$ with input direction d_p if

$$L_o^{-1}(p)d_p = 0.$$

It then follows that we have interpolation constraints on the output sensitivity and complementary sensitivity functions as follows.

Lemma 10.1: Multivariable Interpolation Constraints

Subject to Equation 10.87, we have the following:

1. If $s = z$ is a zero of $L_o(s)$ with input direction d_z , then

$$S_o(z)d_z = d_z,$$

$$T_o(z)d_z = 0.$$

* Note that in fact there are a number of different definitions of MIMO zeros. In this case, we are considering MIMO transmission zeros.

† Similar definitions and results apply to output directions, which we omit for brevity.

2. If $s = p$ is a pole of $L_o(s)$ with input direction d_p , then

$$\begin{aligned} S_o(p)d_p &= 0, \\ T_o(p)d_p &= d_p. \end{aligned}$$

Using Lemma 10.1 we can generalize earlier SISO results such as Theorems 10.4 and 10.5 as follows:

Theorem 10.9:

Take any appropriately dimensioned vector d .

1. If $s = z$ is a zero of $L_o(s)$ with input direction d_z , then

$$\int_0^\infty \log \left| d^T S_o(j\omega) d_z \right| W(z, \omega) d\omega \geq \pi \log |d^T d_z|.$$

2. If $s = p$ is a pole of $L_o(s)$ with input direction d_p , then

$$\int_0^\infty \log \left| d^T T_o(j\omega) d_p \right| W(p, \omega) d\omega \geq \pi \log |d^T d_p|.$$

Note that the results in Theorem 10.9 are inequalities, since in general the expression for the relevant Blaschke products are much more complex in this case than in the SISO case (Equation 10.50). We also note that by taking d aligned with d_z or d_p as appropriate, and using unit length vectors, we can make the right-hand sides of the bounds in Theorem 10.9 equal to zero.

10.7.4.4 Other MIMO Results

There are a wide range of multivariable feedback results available, and this section has concentrated on a few specific forms of these results. A summary and analysis of many of the available results is contained in [56]. The results of [17] considered achievable H_2 performance of multivariable systems for example. The authors of [30] consider systems in which the performance variable is not identical to the measured variable and the disturbance and actuator affect the system through different dynamics. A range of other results are included in the special issue [16].

10.7.5 Time-Varying and Nonlinear Systems

The theory of fundamental feedback limitations for general time-varying and nonlinear systems is much less developed than that for linear time-invariant systems. One of the main challenges in extending notions such as the Bode integral is that, in contrast to the linear time-invariant case, it is in general impossible to obtain a complete characterization of the system action as an operator via a simple transformation to the frequency domain. A number of significant results, however, have been obtained in the last couple of decades showing that some fundamental feedback limitations remain in more general classes of systems.

One way of extending notions associated with transfer functions to nonlinear systems is to apply the theory of input/output (I/O) nonlinear operators on linear spaces. Using this approach, Shamma [59] shows that nonminimum phase dynamics impose an “area balance” constraint to the nonlinear sensitivity I/O operator analogous to that captured by the Bode integral for linear systems. The result shows that if the nonlinear plant is nonminimum phase (defined by conditions on the domain and range of the plant I/O operator [56, §12]), an arbitrarily small value of frequency-weighted sensitivity necessarily implies an arbitrarily large response to some admissible disturbance. A dual “area balance” constraint exists for the nonlinear complementary sensitivity I/O operator when the plant is open-loop unstable [56, §13.4].

Nonlinear equivalents of the interpolation constraints (Equations 10.51 and 10.69) can also be developed, and applied to quantify control design trade-offs [56, §13] and [58].

Another approach to characterize fundamental limitations in classes of nonlinear systems arises from the study of cheap control problems, as in Section 10.7.3. This idea has been applied to study limitations in nonminimum phase, and nonright invertible strict-feedback nonlinear systems [10,57].

An information theoretic approach has been pursued in Iglesias [38,69] to obtain a time-domain interpretation of the Bode sensitivity integral and extend fundamental sensitivity limitations results to classes of time-varying, and nonlinear systems. Following a similar approach, Martins and Dahleh [42] extended the Bode sensitivity integral to control systems with feedback over capacity-constrained communication channels (see Section 10.7.2) that may include arbitrary time-varying and nonlinear components in the loop, with the only restriction of being causal.

10.7.6 Alleviation of Tracking Performance Limitations

From the previous discussions, it can be seen that there are a number of inherent limitations on feedback system performance, including tracking performance. For plants with CRHP zeros, we have seen a number of fundamental limitations on achievable performance. For example, the time-domain integrals based on CRHP zeros in Theorem 10.6 constrain the output behavior, for any reference signal, for any stabilizing control. In particular, a simple generalization of the time-domain integral in Theorem 10.6 shows that with a nonminimum phase zero at $s = z$ and a given reference signal with Laplace transform, $R(s)$, then

$$\int_0^{\infty} e^{-zt} e(t) dt = R(z). \quad (10.90)$$

Frequency-domain integrals such as the complementary sensitivity integral (see Section 10.4.4) and the Poisson sensitivity integral (Theorem 10.4) apply for any stabilizing linear time-invariant control scheme. In addition, there are various extensions of the cheap control results of Equation 10.85 to alternate reference signals. Here we wish to consider various problem settings in which it may be possible to alleviate the limitations on tracking performance imposed by plant CRHP zeros.

10.7.6.1 Preview Control

Preview control refers to a scenario wherein the reference trajectory, $r(t)$, may be prespecified, and therefore, at time t , the control may use advance knowledge of future or impending reference changes, $r(\tau): \tau \in [t, t + T_{pre}]$. In the case of infinite preview ($T_{pre} \rightarrow +\infty$), references such as [14] showed how nonlinear system inversion (and therefore perfect tracking) may be performed. A more detailed analysis of such systems from a performance limitations perspective is discussed in [18,47]. In particular, it is shown from a time-domain integral perspective; from a Poisson sensitivity integral perspective; and, from an achievable H_{∞} performance perspective, that use of preview T_{pre} with $\text{Re}\{zT_{pre}\}$ sufficiently large almost eliminates the tracking performance limitations due to a CRHP plant zero z . Of course, such preview alters only reference tracking performance and does not alter feedback properties such as noise performance, disturbance response, and stability robustness.

10.7.6.2 Path Tracking

Path tracking (see, e.g., [1,48]) is an alternate control paradigm in which a reference trajectory, $r(t)$, is not given as a prespecified function of time. Instead, the primary tracking objective may be to ensure that at all times, the output is close to a prespecified path ($r(\theta(t))$), that is, that $\|y(t) - r(\theta(t))\|$ is small for all time where $\theta(t)$ is, at least partially, free for the control designer to choose. This allows some additional degrees-of-freedom, and may be helpful in removing some of the limitations on tracking performance imposed by nonminimum phase zeros.

For example, if we have some freedom in the selection of $r(t)$, it may be possible to select $\theta(t)$ in such a way that $R(z)$ is small or even zero. In this case, the constraint (Equation 10.90) on the time-domain performance does not necessarily demand poor tracking performance. Clearly, the feedback noise, disturbance and robustness properties will still be affected by the usual performance trade-offs.

10.7.6.3 Reset Controllers and Other Hybrid Structures

Reset controllers have been shown to overcome some of the limitations inherent to linear time-invariant control, alleviating design trade-offs in the system time response, such as that between overshoot and rise time discussed in Section 10.6 [6,25]. A reset controller is a linear time-invariant system with states that reset to zero when the controller input is zero. This idea was first introduced by Clegg [19], who studied the effect of a reset integrator in a feedback loop. A reset control system may be viewed as a *hybrid* system, which incorporates both continuous dynamics and discrete events. It is possible that hybrid systems present a different set of performance limitations, and advantages in some problems as those discussed in [6,25]. However, a general theory of performance limitations for hybrid control systems remains to be developed.

10.8 Summary and Further Reading

In this chapter, we have discussed design limitations and trade-offs present in feedback design problems. Beginning with the pioneering work of Bode on fundamental feedback relationships, and their implications for feedback amplifier design, a rather complete theory has been developed for linear time-invariant feedback systems. The core of this chapter presented the main results of this theory, as quantified by fundamental relationships in the frequency domain for the sensitivity and complementary sensitivity functions. As discussed, these relationships arise from the basic structure of the feedback loop and the requirement of feedback stability, and are parameterized by the right-half-plane poles and zeros, and time delays of the open-loop system. These relationships have direct implications on the achievable performance and robustness properties of the feedback loop, and thus help a control engineer to achieve informed design trade-offs.

There have been many extensions to the theory of fundamental limitations since the first version of this article was published. We have included a brief account of several of these topics: alternative developments in the time-domain, extensions to multivariable systems, time-varying and nonlinear systems, and control systems with feedback over a communication channel. Finally, we have also included a section discussing the alleviation of performance limitations in some tracking problems.

Diverse applications of the theory of fundamental design limitations also abound. A few examples to illustrate the scope of applications include combustion [5], platooning [55], magnetic bearings [67], haptics [35], ship roll stabilization [51], and autocatalysis [13].

The study of performance limitations in feedback systems is at the core of feedback design, and can provide helpful knowledge in practical control engineering problems. On the one hand, the knowledge of these limitations and their associated trade-offs provides benchmarks against which different control structures and designs may be compared, and guides the deliberate selection of a design solution that achieves a reasonable compromise between conflicting design goals. On the other hand, if a reasonable compromise cannot be achieved for a particular system, then knowledge of design trade-offs may be used to modify the plant, to improve sensors and actuators, and to develop better models so that a tractable design problem is obtained.

The reader who wants to know more can find material in many places. Several textbooks include chapters on the theory of fundamental design limitations, including Franklin et al. [27], Doyle et al. [23] Zhou et al. [70], Goodwin et al. [34], Skogestad and Postlethwaite [61], Aström and Murray [3], and Glad and Ljung [32]. A comprehensive treatment of the theory up through 1997 is given by Seron et al. [56].

Bode's original book [7] is still instructive, and a recent monograph describes the context in which the limitations described by the gain-phase relation arose [49]. An excellent perspective on the importance of the theory of fundamental design limitations was given by Gunter Stein in the inaugural Bode Lecture in 1989, reprinted in [62].

11.1 Introduction

At first glance, the notion of deterministic uncertainty may seem to be a contradiction in terms—after all, the word “deterministic” is often used to signify the absence of any form of uncertainty. We will explain later on that, properly interpreted, this choice of words does indeed make sense. For the moment, we concentrate on the notion of uncertainty.

Uncertainty in the control context comes in two basic versions—uncertain signals and uncertainty in the way the plant maps input signals into output signals (“plant uncertainty”).

Most processes we wish to control are subject to influences from their environment—some of them known (measured disturbances, reference inputs), others uncertain signals (unmeasured disturbances, and noise corrupting measurements). All these signals are labeled “external,” because they originate in the “outside world.”*

A plant model, by definition, is a simplified representation of a real system, and is usually geared toward a specific purpose. Models that are meant to be used for feedback controller design tend to be especially crude. This is because (1) most popular design techniques can handle only very restricted classes of models and (2) in a feedback configuration, one can potentially get away with more inaccurate models than in applications that are based on a pure feedforward structure.

Meaningful analysis and design, however, are possible only if signal and plant uncertainty is, in some sense, “limited.” In other words, we have to assume that there exists some, however incomplete, knowledge about signal and plant uncertainty—we need an *uncertainty model*. Such an uncertainty model defines an admissible *set of plant models*, \mathcal{G} , and an admissible *set of uncertain external input signals*, \mathcal{W} (Figure 11.1). The adjective in “deterministic uncertainty model” points to the fact that we do not attempt to assign probabilities (or probability densities) to the elements of the sets \mathcal{G} and \mathcal{W} —every element is considered to be as likely as any other one. Based on this, one can ask the key (robustness) questions in control

* Control inputs, on the other hand, are generated within the control loop, and are called “internal input signals.”

FIGURE 11.1 Signal and plant uncertainty models.

systems analysis: Is closed-loop stability guaranteed for every plant model in \mathcal{G} ? Do desired closed-loop performance properties hold for every external input in \mathcal{W} and every $G \in \mathcal{G}$?

One has to keep in mind, however, that no class of mathematical models is able to describe every detail of reality, that is, the physical plant is not a mathematical model and therefore cannot be an element in \mathcal{G} . Robustness of a desired closed-loop property with respect to any specific plant uncertainty model does not therefore guarantee that the *real* control system will also have this property. If the uncertainty model is chosen in a sensible way (that’s what this chapter is about), it will, however, increase the likelihood for the real system to “function properly.”

We will first discuss signal uncertainty. Then, we will summarize the most common plant uncertainty models. Finally, we will briefly mention the topic of model validation, that is, whether a given set of experimental data is compatible with given uncertainty models \mathcal{G} and \mathcal{W} . We will work in a continuous-time framework, and all signals will be real and (except for some of the examples) vector valued.

11.2 Characterization of Uncertain Signals

Formulating a signal uncertainty model almost always involves a trade-off between conflicting principles: One wants the model to be “tight,” that is, contain only signals that make physical sense; tightening uncertainty, however, typically implies imposing additional restrictions on the model—it gets unwieldy and more difficult to use for analysis and design purposes.

The following two widely used uncertainty models are on the extreme (simple) end of the spectrum. The first is

$$\mathcal{W}_2(c) := \{w_u(t) \mid \|w_u\|_2 \leq c\}, \tag{11.1}$$

where the norm is

$$\|w_u\|_2 := \left(\int_{-\infty}^{\infty} w_u(t)^T w_u(t) dt \right)^{1/2},$$

that is, the admissible input set consists of all signals with \mathcal{L}_2 -norm (energy) less than or equal to a given constant c ; the second is

$$\mathcal{W}_\infty(c) := \{w_u(t) \mid \|w_u\|_\infty \leq c\}, \tag{11.2}$$

where the norm is

$$\|w_u\|_\infty := \sup_t \max_i |w_{u_i}(t)|,$$

that is, the admissible input set consists of all signals with \mathcal{L}_∞ -norm (maximum magnitude) less than or equal to a given constant c . If necessary, these models can be refined by introducing suitable weights or filters: In this case, admissible input signals are

$$\bar{w}_u(t) := \int_{-\infty}^t W(t - \tau) w_u(\tau) d\tau, \tag{11.3}$$

where $w_u(t)$ ranges over the sets (Equation 11.1 or 11.2). Even such a modified uncertainty description remains pretty crude. Whether it is adequate depends on the control problem at hand. If the answer turns

out to be “no,” one has to cut back the “size” of the admissible signal classes by bringing in additional *a priori* information. This is illustrated in the following example.

Example 11.1:

Suppose we want to control room temperature. Clearly, outdoor temperature, T_o , is a disturbance signal for our control problem. Assume that, for one reason or another, we cannot measure T_o . In Toronto, T_o can go up to $+30^\circ\text{C}$ in summer and down to -30°C in winter. In this case, a simple uncertainty model is given by

$$T_o(t) \in \mathcal{W}_\infty(30^\circ) = \{w_u(t) \mid \|w_u\|_\infty \leq 30^\circ\text{C}\}.$$

Clearly, this set contains many signals that do not make physical sense; it admits, for example, temperatures of $+30^\circ$ during a winter night and -30° at noon in summer. A tighter uncertainty set is obtained if we write $T_o(t) = T_a(t) + T_\Delta(t)$, where $T_a(t)$ represents the average seasonal and daily variation of temperature, and $T_\Delta(t)$ is a deviation term. The signal $T_a(t)$ could, for example, be modeled as the output of an autonomous dynamic system (a so-called *exosystem*) with a pair of poles at $s = \pm j(365 \text{ days})^{-1}$ (accounting for seasonal variations) and $s = \pm j(24 \text{ h})^{-1}$ (accounting for daily variations). For the deviation term, we can now assume a much stricter \mathcal{L}_∞ -norm bound, for example, 10° . Furthermore, it makes sense to restrict the maximal rate of change of $T_\Delta(t)$ to, say, $5^\circ/\text{h}$. This is achieved if we define the admissible set of deviations via

$$T_\Delta(t) = \int_{-\infty}^t W(t - \tau)w_u(\tau) \, d\tau,$$

where the weighting function $W(t)$ is given by

$$W(t) = \begin{cases} 5e^{-t/2}, & t \geq 0 \\ 0, & t < 0 \end{cases}$$

(with t in hours) and $w_u(t)$ lives in the set $\mathcal{W}_\infty(1^\circ)$.

11.3 Characterization of Uncertain Plant Models

Sometimes the plant can be modeled by a finite set, say by linearizing at a finite number of operating points. Then a controller can be designed for each plant in the set. Implementation involves a table lookup for which controller to apply, together with a way of smoothly transitioning when a switch is required.

More commonly in robust control design, one tries to characterize the plant family \mathcal{G} by specifying a nominal plant model together with a family of perturbations, denoted \mathcal{D} , away from the nominal. As for the set of admissible input signals, we have two requirements for \mathcal{D} :

1. \mathcal{D} should be *tight* (i.e., contain only perturbations that somehow “mirror” the difference between our nominal model and the real system). If we include perturbations that make no physical sense, we will end up with a controller that tries to accommodate “too many” models and might therefore be “too conservative.”
2. \mathcal{D} should be easy to use for analysis and design purposes.

Again, both requirements rarely go together. By imposing *structure* on a perturbation model, we will in general be able to capture uncertainty more precisely; *unstructured* perturbation models, on the other hand, are in general easier to use in design procedures.

For the lack of space, we can only present the most common plant uncertainty models—the ones that are widely used for controller design and synthesis purposes. It is not surprising that, in a sense, this purpose reflects back onto the model itself: Some models we will be dealing with involve restrictive assumptions

that can only be justified through a utilitarian argument—without these assumptions it would be a lot harder (or even impossible) to give robustness tests. We will look at unstructured perturbation models first. Such models are typically specified by giving, at every frequency, an upper bound on the maximum singular value of the transfer function matrix, this being a matrix generalization of the magnitude of a complex number. Then, we will deal with a specific class of structured perturbations that can be graphically characterized by Nyquist arrays. Finally, we will discuss a fairly general class of structured perturbations that includes the others.

11.3.1 Unstructured Plant Uncertainty Models

In what follows, $G(s)$ will denote the nominal plant model, $G_r(s)$ the transfer function matrix of a perturbed plant model, and $\Delta(s)$ the transfer function matrix of a perturbation. The dimensions of $G(s)$ are $p \times q$. It is assumed that the elements of $G(s)$, $G_r(s)$, and $\Delta(s)$ are proper real-rational transfer functions. The number of *unstable* poles of G and G_r , that is, those in the closed right half-plane, are denoted m_G and m_{G_r} .

11.3.1.1 Additive Modeling Perturbations

Additive perturbations are defined by (see Figure 11.2)

$$G_r(s) := G(s) + \Delta_A(s). \tag{11.4}$$

The class of unstructured additive perturbations we will be looking at is given by

$$\mathcal{D}_A := \{ \Delta_A \mid \bar{\sigma}[\Delta_A(j\omega)] < l_A(\omega); m_{G_r} = m_G \}. \tag{11.5}$$

Thus, the set of admissible Δ_A is characterized by two assumptions: (1) for each frequency ω , we know a (finite) upper bound $l_A(\omega)$ for the size of Δ_A (in the sense of the maximal singular value); (2) Δ_A cannot change the number of unstable poles of the model. Thus l_A is an *envelope function* on the size of the perturbation. The regularity of the function l_A is not too important; it can be assumed to be, for example, piecewise continuous. The second assumption seems pretty artificial, but is needed if we want to give simple robustness tests.* It trivially holds for all stable perturbation matrices. Obviously, $l_A(\omega)$ being finite for every ω implies that Δ_A does not have any poles on the imaginary axis. A typical perturbation bound $l_A(\omega)$ is shown in Figure 11.3: The DC gain is usually known precisely ($\Delta_A(0) = 0$); at high frequencies, we often have $G_r \rightarrow 0$, $G \rightarrow 0$ (G_r and G are strictly proper), and therefore $\Delta_A \rightarrow 0$.

The following example illustrates how an additive perturbation model typically can be obtained from frequency-response data.

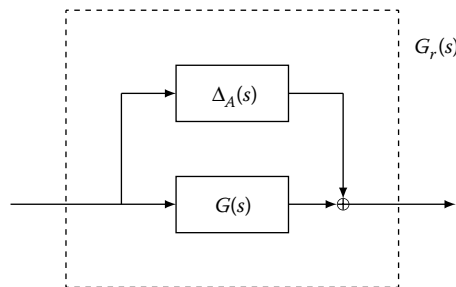

FIGURE 11.2 Additive model perturbation.

* A stability robustness test was first reported in Cruz et al. (1981).

FIGURE 11.3 Typical bound for additive modeling perturbation.

Example 11.2:

For simplicity, assume the plant is single-input/single-output (SISO). Suppose that the plant is stable and its transfer function is arrived at by means of frequency-response experiments: Magnitude and phase are measured at a number of frequencies, $\omega_i, i = 1, \dots, M$, and this experiment is repeated several, say N , times. Let the magnitude-phase measurement for frequency ω_i and experiment k be denoted (G_{ik}, ϕ_{ik}) . Based on these data, select nominal magnitude-phase pairs (G_i, ϕ_i) for each frequency ω_i , and fit a nominal transfer function $G(s)$ to these data. Then fit a weighting function $l_A(s)$ so that

$$\left| G_{ik} e^{j\phi_{ik}} - G_i e^{j\phi_i} \right| < |l_A(\omega_i)|, \quad i = 1, \dots, M; \quad k = 1, \dots, N.$$

The next example shows how to “cover” a parameter-uncertainty model by an additive perturbation model.

Example 11.3:

Consider the plant model

$$\frac{k}{s+1}, \quad 5 < k < 10.$$

Thus, the gain k is uncertain. Let us take the midpoint for the nominal plant:

$$G(s) = \frac{7.5}{s+1}.$$

Then the envelope function is determined via

$$\left| \frac{k}{j\omega+1} - G(j\omega) \right| < l_A(\omega), \quad 5 < k < 10,$$

that is, $l_A(\omega) = |2.5/(j\omega + 1)|$.

11.3.1.2 Multiplicative Perturbations

Multiplicative (or proportional) perturbations at the plant output are defined by the following relation between G and G_r (see Figure 11.4):

$$G_r(s) := (I_p + \Delta_M(s))G(s). \tag{11.6}$$

Such proportional perturbations are invariant with respect to multiplication (from the right) by a known transfer function matrix (e.g., a compensator).

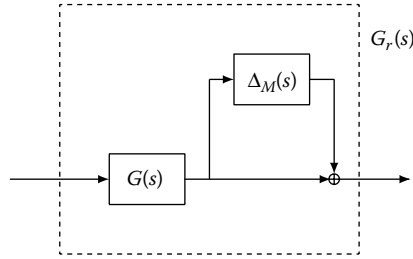

FIGURE 11.4 Multiplicative (proportional) model perturbation.

We consider the following class of (proportional perturbation) models:

$$\mathcal{D}_M := \mathcal{D}_{M1} \cup \mathcal{D}_{M2}, \tag{11.7}$$

$$\mathcal{D}_{M1} := \{ \Delta_M \mid \bar{\sigma}[\Delta_M(j\omega)] < l_M(\omega); \Delta_M \text{ stable} \}, \tag{11.8}$$

$$\mathcal{D}_{M2} := \{ \Delta_M \mid \bar{\sigma}[\Delta_M(j\omega)] < l_M(\omega); m_{G_r} = m_G \}. \tag{11.9}$$

Hence, admissible perturbations are either stable or do not change the number of unstable poles of the plant model. Again, in both cases, we assume that we know an upper bound for the perturbation frequency response $\Delta_M(j\omega)$. A typical perturbation bound l_M is shown in Figure 11.5: Exact knowledge of DC gain implies $\Delta_M(0) = 0$; neglecting high-order dynamics often causes Δ_M to be greater than 1 at high frequency.

The perturbation class \mathcal{D}_A is of a simpler form than Equations 11.7 through 11.9, because an additive stable perturbation transfer function matrix does not affect the number of unstable poles. As the following example shows, this is not always true for multiplicative perturbations: A stable proportional perturbation *can* cancel unstable model poles. For example,

$$G(s) = \frac{-4}{s-1}, \quad \Delta_M(s) = \frac{-2}{s+1},$$

$$G_r(s) = [1 + \Delta_M(s)]G(s) = \frac{-4}{s+1}.$$

Stability robustness results for this class of perturbations have been given in Doyle and Stein (1981).

11.3.1.3 Coprime Factor Perturbations

For this uncertainty description, we need the concept of a left coprime factorization over \mathcal{RH}_∞^* (Vidyasagar, 1985). Here, we will give only a very brief introduction to this subject. Details can be

FIGURE 11.5 Typical bound for multiplicative model perturbation.

* \mathcal{RH}_∞ denotes the set of proper stable real-rational transfer functions.

found elsewhere in this book. Consider a finite-dimensional linear time-invariant (FDLTI) SISO system. Clearly, its transfer function, $G(s)$, can be represented by a pair of polynomials with real coefficients— $N_P(s)$, a numerator, and $M_P(s)$, a denominator polynomial: $G(s) = N_P(s)/M_P(s)$. Furthermore, $N_P(s)$ and $M_P(s)$ can always be chosen to be coprime, meaning that all common divisors of $N_P(s)$, $M_P(s)$ are invertible in the set of polynomials (i.e., are real constants). Thus, there is no pole–zero cancellation when forming $N_P(s)/M_P(s)$.

For several reasons, it proves to be an advantage to use a straightforward generalization, and to replace polynomials by proper stable transfer functions (i.e., elements from the set \mathcal{RH}_∞): We write $G(s) = N(s)/M(s)$, where $N(s), M(s) \in \mathcal{RH}_\infty$ can always be chosen to be coprime. This is called a *coprime factorization over \mathcal{RH}_∞* . Coprimeness in the \mathcal{RH}_∞ -context means that all common divisors are invertible in \mathcal{RH}_∞ (i.e., stable, minimum-phase, biproper transfer functions). Hence, when forming $N(s)/M(s)$, no cancellation of poles and zeros in the closed right half-plane can occur. Obviously, such a factorization is nonunique. However, it can be made unique up to sign by requiring $|N(j\omega)|^2 + |M(j\omega)|^2 = 1$, that is, the 1×2 matrix $[N(s) \ M(s)]$ is allpass. This is called a *normalized coprime factorization* (Vidyasagar, 1988).

These concepts can be easily extended to the multivariable case. However, as matrix multiplication is not commutative, we have to distinguish between *left* and *right coprime factorizations*: A pair $\tilde{N}(s), \tilde{M}(s)$ of stable transfer function matrices with appropriate dimensions is called a left coprime factorization of $G(s)$ if $G(s) = \tilde{M}^{-1}(s)\tilde{N}(s)$, and all common left divisors of $\tilde{N}(s)$ and $\tilde{M}(s)$ are invertible in \mathcal{RH}_∞ . Similar for the concept of right coprime factorization.

Now we are in a position to define coprime factor perturbations. These are additive stable perturbation terms in both the numerator and the denominator of a left (or right) coprime factorization (see Figure 11.6):

$$\begin{aligned}
 G &= \tilde{M}^{-1}\tilde{N}; \quad \tilde{M}, \tilde{N} \dots \text{left coprime} \\
 G_r &= \underbrace{(\tilde{M} + \Delta_M)^{-1}}_{\tilde{M}_r^{-1}} \underbrace{(\tilde{N} + \Delta_N)}_{\tilde{N}_r}; \quad \tilde{M}_r, \tilde{N}_r \dots \text{left coprime.}
 \end{aligned}
 \tag{11.10}$$

Specifically, we will consider the following class of unstructured coprime factor perturbations:

$$\mathcal{D}_{MN} := \{[\Delta_M \ \Delta_N] \mid \bar{\sigma}[\Delta_M(j\omega) \ \Delta_N(j\omega)] < l_{MN}(\omega); \ \Delta_M, \Delta_N \text{ stable}\}.
 \tag{11.11}$$

A typical perturbation bound $l_{MN}(\omega)$ may look as shown in Figure 11.3. Restricting the class \mathcal{D}_{MN} to stable transfer function matrices does not imply any loss of generality, as both \tilde{M}, \tilde{N} (denominator, numerator of the nominal model) and $\tilde{M} + \Delta_M, \tilde{N} + \Delta_N$ (denominator, numerator of any perturbed model) are stable by definition. Note that we do not have any restrictive assumptions regarding the number of unstable poles of admissible models $G_r(s)$: Perturbations from the set \mathcal{D}_{MN} can both increase or decrease the

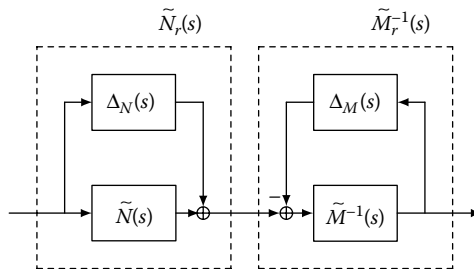

FIGURE 11.6 Coprime factor perturbation.

number of unstable model poles. For example,

$$G(s) = \frac{1}{s + \varepsilon} = \underbrace{\left[\frac{s + \varepsilon}{s + 1} \right]^{-1}}_{\tilde{M}(s)^{-1}} \underbrace{\left[\frac{1}{s + 1} \right]}_{\tilde{N}(s)},$$

$$\Delta_N = 0, \quad \Delta_M(s) = \frac{-2\varepsilon}{s + 1},$$

$$G_r(s) = \frac{1}{s - \varepsilon} = \underbrace{\left[\frac{s - \varepsilon}{s + 1} \right]^{-1}}_{\tilde{M}_r(s)^{-1}} \underbrace{\left[\frac{1}{s + 1} \right]}_{\tilde{N}_r(s)}.$$

Coprime factor perturbations are especially useful for describing uncertainty in flexible structures. They allow covering a family of transfer function matrices with slightly damped uncertain pole-pairs by a (relatively speaking) small perturbation set.

Example 11.4:

Consider a nominal transfer function

$$G(s) = \frac{10}{(s + 0.05 - 5j)(s + 0.05 + 5j)}.$$

Suppose a perturbed model has a slightly different pair of poles:

$$G_r(s) = \frac{10}{(s + 0.05 - 6j)(s + 0.05 + 6j)}.$$

We first determine the magnitude of the smallest additive perturbation that, centered around $G(s)$, covers $G_r(s)$, and scale it (at each frequency) by $1/|G(j\omega)|$ (this is of course equivalent to computing the magnitude of the multiplicative perturbation connecting $G(s)$ and $G_r(s)$). The result is shown in the left part of Figure 11.7.

We now compute normalized coprime factorizations, $\{N(s), M(s)\}$ and $\{N_r(s), M_r(s)\}$, for $G(s)$ and $G_r(s)$, and plot the size (maximal singular value) of the perturbation matrix

$$\begin{bmatrix} N_r(j\omega) - N(j\omega) & M_r(j\omega) - M(j\omega) \end{bmatrix}$$

over frequency. This gives a *relative (scaled)* measure of perturbation size, as both $\begin{bmatrix} N(s) & M(s) \end{bmatrix}$ and $\begin{bmatrix} N_r(s) & M_r(s) \end{bmatrix}$ are allpass. It is shown in the right half of Figure 11.7.

Clearly, there is an order of magnitude difference between the peak values of both perturbations.

FIGURE 11.7 Perturbation sizes (normalized coprime factorization case shown on the right).

FIGURE 11.8 Generalized unstructured perturbation.

(Normalized) coprime factor perturbations and their use in H_∞ -design methods have been extensively investigated in McFarlane and Glover (1989).

11.3.1.4 Generalized Unstructured Perturbations

Additive, multiplicative, and coprime factor uncertainty can be conveniently represented in a unified way—via *generalized unstructured perturbations* (McFarlane and Glover, 1989). For this purpose, we introduce a “new” (proper) transfer function matrix

$$\Theta(s) = \begin{bmatrix} \Theta_{11}(s) & \Theta_{12}(s) \\ \Theta_{21}(s) & \Theta_{22}(s) \end{bmatrix}. \tag{11.12}$$

Its partitioning implies a partitioning of its input and output vector. The lower parts of both vectors represent the “usual” plant input and output signals. The upper part of the output signal, z_Δ , is fed back into the upper part of the input signal, w_Δ , via a perturbation $\Delta(s)$ (Figure 11.8). Denote the number of rows and columns of Δ by m_Δ and l_Δ , respectively. Then, the transfer function matrix G_r of the perturbed model is given as an Upper *Linear Fractional Transformation* of Δ with respect to Θ :

$$G_r = \Theta_{22} + \Theta_{21} \Delta (I_{l_\Delta} - \Theta_{11} \Delta)^{-1} \Theta_{12} \tag{11.13}$$

$$= \Theta_{22} + \Theta_{21} (I_{m_\Delta} - \Delta \Theta_{11})^{-1} \Delta \Theta_{12}. \tag{11.14}$$

For $\Delta = 0$ (zero perturbation), we expect to recover the nominal plant model as the transfer function matrix between the plant input and the output vector. Hence, we must have $\Theta_{22} = G$. For Equations 11.13 and 11.14 to make sense, we also have to assume that

1. $(I_{l_\Delta} - \Theta_{11}(\infty)\Delta(\infty))$ (or, equivalently, $(I_{m_\Delta} - \Delta(\infty)\Theta_{11}(\infty))$) is nonsingular (i.e., G_r is uniquely defined and proper) for all admissible perturbations.
2. The transfer function matrix $\Theta(s)$ is stabilizable from the plant input and detectable from the plant output.

Specifically, we consider the following class of perturbations:

$$\mathcal{D} := \mathcal{D}_1 \cup \mathcal{D}_2, \tag{11.15}$$

$$\mathcal{D}_1 := \{ \Delta \mid \bar{\sigma}[\Delta(j\omega)] < l(\omega), \Delta \text{ stable} \}, \tag{11.16}$$

$$\mathcal{D}_2 := \{ \Delta \mid \bar{\sigma}[\Delta(j\omega)] < l(\omega), m_{G_r} = m_G \} \tag{11.17}$$

We admit all bounded (on $s = j\omega$) perturbation transfer function matrices that are either stable or do not change the number of unstable poles of the plant model.

We have not specified yet how to choose Θ if we want to translate additive, multiplicative, and coprime factor uncertainty into this general framework. By substituting into Equation 11.13, it is easy to check that

- for additive perturbations,

$$\Theta = \begin{bmatrix} 0 & I_q \\ I_p & G \end{bmatrix}, \quad \Delta = \Delta_A, \quad (11.18)$$

- for multiplicative perturbations,

$$\Theta = \begin{bmatrix} 0 & G \\ I_p & G \end{bmatrix}, \quad \Delta = \Delta_M, \quad (11.19)$$

- and for coprime factor perturbations,

$$\Theta = \begin{bmatrix} \begin{bmatrix} -\tilde{M}^{-1} \\ 0 \\ \tilde{M}^{-1} \end{bmatrix} & \begin{bmatrix} -G \\ I_q \\ G \end{bmatrix} \end{bmatrix}, \quad \Delta = [\Delta_M \quad \Delta_N]. \quad (11.20)$$

For additive uncertainty, $\mathcal{D}_1 \subset \mathcal{D}_2$ (stable perturbations do not change the number of unstable model poles). Hence, in this case, \mathcal{D} and \mathcal{D}_A are the same. In the case of coprime factor uncertainty, all perturbation terms are stable by definition. We can therefore write $\mathcal{D} = \mathcal{D}_{MN}$ without restricting generality.

This framework is especially useful for theoretical investigations. Instead of proving, say, robust stability for the three sets of perturbations \mathcal{D}_A , \mathcal{D}_M , and \mathcal{D}_{MN} , it suffices to establish this result for the class \mathcal{D} of generalized perturbations.

11.3.1.5 Which Unstructured Perturbation Model?

All of the above perturbation models are reasonably simple and easy to use in design procedures. Hence, the decision on which model to choose hinges primarily on their potential to cover a given set \mathcal{G} without including too many “physically impossible” plant models. In other words: we want the least conservative perturbation set that “does the job.” Whether this is a set of additive, multiplicative, or coprime factor perturbations depends on the problem at hand. A useful rule of thumb is: Whenever one deals with low-damped mechanical systems, it is a good idea to try coprime factor uncertainty first (compare the example in Section 11.3.1.3). For stable nonoscillatory processes, one might try an additive perturbation model first—it is more intuitive, and, if the nominal model is stable, excludes any unstable $G_r(s)$.

11.3.2 Structured Plant Uncertainty

11.3.2.1 Uncertain Parameters

Physical (or theoretical), as opposed to experimental, model building usually results in a state model, and model uncertainty is often in the form of parameter uncertainty: The (real-valued) parameters of the state model have physical meaning and are assumed to lie within given intervals. When converting to a transfer function matrix, however, one usually gets a fairly complicated set of admissible parameters. This is due to the fact that, in general, each parameter of the resulting transfer function matrix depends on several parameters of the underlying state model. Only in exceptionally simple cases (as in the following example) can we expect the set of admissible parameters to form a parallelepiped.

Example 11.5:

Consider the spring–damper system in Figure 11.9. Force is denoted by u , position by y . Newton’s law gives the transfer function

$$G(s) = \frac{1}{ms^2 + ds + c}.$$

FIGURE 11.9 Spring–damper system.

In most cases, one cannot expect to know the precise values of mass, damping, and spring constant. Hence, it makes sense to define a class of models by stating admissible parameter intervals:

$$\begin{aligned} \Delta_m &\in [m_u - m, m_o - m] := \mathcal{D}_m \\ \Delta_d &\in [d_u - d, d_o - d] := \mathcal{D}_d \\ \Delta_c &\in [c_u - c, c_o - c] := \mathcal{D}_c \\ \mathcal{G}_{mdc} &:= \left\{ \frac{1}{(m + \Delta_m)s^2 + (d + \Delta_d)s + (c + \Delta_c)} \mid \Delta_m \in \mathcal{D}_m, \Delta_d \in \mathcal{D}_d, \Delta_c \in \mathcal{D}_c \right\}. \end{aligned}$$

11.3.2.2 Independent Additive Perturbations in the Elements of a Transfer Function Matrix

Another straightforward (and often very useful) structured uncertainty description is the following: Consider an additive perturbation matrix $\Delta_A(s) = G_r(s) - G(s)$ and give frequency-dependent bounds $l_{ik}(\omega)$ for the magnitude of each of its elements:

$$\underbrace{\begin{bmatrix} |\Delta_{A_{11}}(j\omega)| & \dots & |\Delta_{A_{1q}}(j\omega)| \\ \vdots & \ddots & \vdots \\ |\Delta_{A_{p1}}(j\omega)| & \dots & |\Delta_{A_{pq}}(j\omega)| \end{bmatrix}}_{:=|\Delta_A|_e} \leq_e \underbrace{\begin{bmatrix} l_{11}(\omega) & \dots & l_{1q}(\omega) \\ \vdots & \ddots & \vdots \\ l_{p1}(\omega) & \dots & l_{pq}(\omega) \end{bmatrix}}_{:=L(\omega)} \tag{11.21}$$

(\leq_e denotes “elementwise less or equal”; $|\Delta_A|_e$ is a matrix with entries $|\Delta_{A_{ik}}|$). Again, we make the additional assumption that no admissible perturbation shall change the number of unstable poles. Hence, we get the following classes of perturbations and plant models:

$$\mathcal{D}_{Ae} := \{ \Delta_A \mid |\Delta_A(j\omega)|_e \leq_e L(\omega); m_{G_r} = m_G \} \tag{11.22}$$

$$\mathcal{G}_{Ae} := \{ G + \Delta_A \mid \Delta_A \in \mathcal{D}_{Ae} \}. \tag{11.23}$$

Such a set of models can be easily represented in a graphical way (Figure 11.10): Consider first the Nyquist plots of each element $g_{ik}(j\omega)$ of the nominal model (“Nyquist array”). For each frequency, draw a circle with radius $l_{ik}(\omega)$ around $g_{ik}(j\omega)$. This gives a set of bands covering the nominal Nyquist plots. Then, a transfer function matrix G_r is a member of the model set (Equation 11.23) if and only if the Nyquist plot of each element $g_{r_{ik}}(j\omega)$ is contained in the appropriate band, and G_r and G have the same number of unstable poles. The usefulness of this uncertainty model for controller design purposes stems mainly from the fact that it fits “naturally” into the framework of Nyquist-array methods. Stability robustness results can be found in Owens and Chotai (1984) and Lunze (1984).

11.3.2.3 Generalized Structured Plant Uncertainty

A more general structured perturbation model has become very popular, as the so-called μ -theory (Doyle, 1982, 1985) provides analysis and synthesis tools to deal with such uncertainty sets. As a motivation for this general perturbation model, consider the following example from Maciejowski (1989).

FIGURE 11.10 Graphical representation of the model class \mathcal{G}_{Ae} .

Example 11.6:

Let $G(s)$ be a 2×2 plant model with additive unstructured uncertainty $\Delta_A(s)$ and independent multiplicative perturbations $\tilde{\delta}_1(s), \tilde{\delta}_2(s)$ in each input channel (Figure 11.11). Assume that $\Delta_A(s), \tilde{\delta}_1(s)$, and $\tilde{\delta}_2(s)$ are stable, proper, and bounded by

$$\begin{aligned} |\tilde{\delta}_1(j\omega)| &< l_1(\omega), \\ |\tilde{\delta}_2(j\omega)| &< l_2(\omega), \\ \bar{\sigma}[\Delta_A(j\omega)] &< l_3(\omega). \end{aligned}$$

It is easy to see that we could subsume all three uncertainty terms in a single (additive) perturbation matrix $\tilde{\Delta}_A(s)$:

$$\begin{aligned} G_r &= (G + \Delta_A) \left(I_2 + \begin{bmatrix} \tilde{\delta}_1 & 0 \\ 0 & \tilde{\delta}_2 \end{bmatrix} \right) \\ &= G + \underbrace{\left(\Delta_A \begin{bmatrix} 1 + \tilde{\delta}_1 & 0 \\ 0 & 1 + \tilde{\delta}_2 \end{bmatrix} + G \begin{bmatrix} \tilde{\delta}_1 & 0 \\ 0 & \tilde{\delta}_2 \end{bmatrix} \right)}_{:= \tilde{\Delta}_A}. \end{aligned}$$

FIGURE 11.11 Example for a model with independent perturbations.

be easily done, if each perturbation bound $l_i(\omega)$ can be written as magnitude of a frequency response $w_i(j\omega)$: In this case, we just have to multiply Θ_{11} and Θ_{12} from the left (or Θ_{11} and Θ_{21} from the right) by a suitably dimensioned diagonal matrix containing the $w_i(s)$. As only magnitude is important, we can always choose the transfer functions $w_i(s)$ to be stable and minimum-phase. Hence, we get the following class of perturbations:

$$\mathcal{D}_s := \left\{ \Delta_s \mid \Delta_s = \begin{bmatrix} \delta_1 I_{l_1} & 0 & \dots & & 0 \\ & 0 & \ddots & & \vdots \\ & \vdots & & \delta_k I_{l_k} & \\ & & & & \Delta_{k+1} \\ & & & & \ddots & 0 \\ 0 & \dots & & & & 0 & \Delta_v \end{bmatrix}, \Delta_s \text{ stable, } \bar{\sigma}[\Delta_s(j\omega)] < 1 \right\}. \quad (11.25)$$

Example 11.7:

Let us look at the previous example again: Suppose $w_1(s)$, $w_2(s)$, and $w_3(s)$ are stable minimum-phase transfer functions with

$$|w_1(j\omega)| = l_1(\omega),$$

$$|w_2(j\omega)| = l_2(\omega),$$

$$|w_3(j\omega)| = l_3(\omega).$$

Then we get

$$\begin{aligned} \Theta(s) &= \begin{bmatrix} \begin{bmatrix} 0 & 0 \\ w_3/l_2 & 0 \end{bmatrix} & \begin{bmatrix} \text{diag}\{w_1, w_2\} \\ w_3/l_2 \end{bmatrix} \\ \begin{bmatrix} G & l_2 \end{bmatrix} & G \end{bmatrix} \\ \Delta_s &= \begin{bmatrix} \delta_1 & 0 & 0 & 0 \\ 0 & \delta_2 & 0 & 0 \\ 0 & 0 & & \Delta_3 \\ 0 & 0 & & \end{bmatrix} \\ &= \begin{bmatrix} \frac{\tilde{\delta}_1}{w_1} & 0 & 0 & 0 \\ 0 & \frac{\tilde{\delta}_2}{w_2} & 0 & 0 \\ 0 & 0 & & \frac{1}{w_3} \Delta_A \\ 0 & 0 & & \end{bmatrix} \end{aligned}$$

and—as expected –

$$\begin{aligned} G_r &= \mathcal{F}_U(\Theta, \Delta_s) \\ &= G + \left(\Delta_A \begin{bmatrix} 1 + \tilde{\delta}_1 & 0 \\ 0 & 1 + \tilde{\delta}_2 \end{bmatrix} + G \begin{bmatrix} \tilde{\delta}_1 & 0 \\ 0 & \tilde{\delta}_2 \end{bmatrix} \right). \end{aligned}$$

All structured perturbation models in this section can be written as in Equations 11.24 and 11.25. However, when “translating” parameter perturbations into this framework, one has to take into account that \mathcal{D}_s admits complex perturbations, whereas parameters (and therefore parameter perturbations) in a state or transfer function model are real.

11.4 Model Validation

Model validation is understood to be the procedure of establishing whether a set of experimental data is compatible with given signal and plant uncertainty models, \mathcal{W} and \mathcal{G} . It is *not* the (futile) attempt to show that an uncertainty model can *always* explain the true plant's input/output behavior—future experiments might well provide data that are inconsistent with \mathcal{W} and \mathcal{G} .

Model validation is a rapidly expanding area, and—for the lack of space—we can only hope to give a flavor of the subject by looking at a comparatively simple version of the problem: We assume that

1. \mathcal{W} is a singleton (i.e., there is no signal uncertainty).
2. Plant uncertainty is in the form of stable generalized unstructured perturbation (i.e., $G_r(s) = \mathcal{F}_U(\Theta(s), \Delta(s))$, where $\Delta(s) \in \mathcal{D}_1$ —see Section 11.3.1.4, and $\Theta_{21}(s)$ is invertible.
3. Experimental data are given in the form of M frequency-response measurements $G_r(j\omega_1), \dots, G_r(j\omega_M)$.

The plant uncertainty model of item 2 contains the cases of coprime factor perturbations and of stable additive and multiplicative perturbations.

With the invertibility condition for Θ_{21} in force, we can rewrite the perturbed plant model as follows:

$$G_r = \mathcal{F}_U(\Theta, \Delta) \quad (11.26)$$

$$= \Theta_{22} + \Theta_{21}(I_{m_\Delta} - \Delta\Theta_{11})^{-1}\Delta\Theta_{12} \quad (11.27)$$

$$= (\Delta\Gamma_{12} + \Gamma_{22})^{-1}(\Delta\Gamma_{11} + \Gamma_{21}), \quad (11.28)$$

where

$$\begin{bmatrix} \Gamma_{11} & \Gamma_{12} \\ \Gamma_{21} & \Gamma_{22} \end{bmatrix} := \begin{bmatrix} \Theta_{12} - \Theta_{11}\Theta_{21}^{-1}\Theta_{22} & -\Theta_{11}\Theta_{21}^{-1} \\ \Theta_{21}^{-1}\Theta_{22} & \Theta_{21}^{-1} \end{bmatrix}. \quad (11.29)$$

This can be easily checked by substituting Equation 11.29 into Equation 11.28. Multiplying Equation 11.28 by $(\Delta\Gamma_{12} + \Gamma_{22})$ from the left gives

$$\Delta \underbrace{(\Gamma_{12}G_r - \Gamma_{11})}_{:=W} = \underbrace{(\Gamma_{21} - \Gamma_{22}G_r)}_{:=U}. \quad (11.30)$$

Consistency of experimental data $G_r(j\omega_1), \dots, G_r(j\omega_M)$ and uncertainty model is equivalent to the existence of a transfer function matrix $\Delta(s) \in \mathcal{D}_1$ that solves Equation 11.30 for $\omega_1, \dots, \omega_M$. Clearly, a necessary condition for this is that the system of linear equations over \mathbb{C}

$$\Delta_i W(j\omega_i) = U(j\omega_i) \quad (11.31)$$

has a solution Δ_i with $\bar{\sigma}[\Delta_i] < l(\omega_i)$ for each $i \in \{1, \dots, M\}$. Using interpolation theory, it has been shown in Boulet and Francis (1994) that this condition is also sufficient*. If suitable Δ_i exist, one can always find a stable transfer function matrix $\Delta(s)$ such that $\Delta(j\omega_i) = \Delta_i$, $i = 1, \dots, M$, and $\bar{\sigma}[\Delta(j\omega)] < l(\omega)$ for all $\omega \in \mathbb{R}$.

11.5 Further Reading

Any book on robust control contains information on plant model uncertainty. We especially recommend Vidyasagar (1985), McFarlane and Glover (1989), Lunze (1989), Glad and Ljung (2000), and Skogestad and Postlethwaite (2005). Parts of this chapter are based on Raisch (1994). See also Doyle et al. (1992).

* Their proof is for coprime factor perturbations. It carries over to the slightly more general case considered here.

On the problem of fitting a model to frequency-response data, see Hindi et al. (2002) and Balas et al. (2009), and from time-domain data see Volker and Engell (2005).

Several papers related to model validation can be found in a special issue of the *IEEE Transactions on Automatic Control* dealing with “System identification for robust control design” (IEEE, 1992).

12.1 Introduction

A linear system with white noise added to the input and, often but not always, white noise added to the output is the most common model for randomness in control systems. It is the basis for Kalman filtering and the linear quadratic Gaussian (LQG) or H_2 optimal regulator. This chapter presents the basic facts about linear systems and white noise and the intuition and ideas underlying them. Results are emphasized, not mathematically rigorous proofs. It is assumed that the reader is familiar with the elementary aspects of probability at, for example, the level of Leon-Garcia [1].

There are many reasons why people so commonly use a linear system driven by white noise as a model of randomness despite the fact that no system is truly linear and no noise is truly white. One of the reasons is that such a model is both elementary and tractable. The calculations are easy. The results can be understood without a deep knowledge of the mathematics of stochastic processes.

A second reason is that a large class of stochastic processes can be represented as the output of a linear system driven by white noise. The precise result can be found later in this chapter. The generality and tractability of this model can be quite dangerous because they often lead people to use it inappropriately. Some of the limitations of the model will also be discussed.

Scalar discrete-time stochastic processes are described first, because this is the simplest case. This is followed by a discussion of the ways single-input single-output (SISO) discrete-time linear systems operate

on scalar discrete-time stochastic processes. Vector discrete-time stochastic processes and multiple-input multiple-output (MIMO) linear systems, a notationally more difficult but conceptually identical situation, are then briefly covered.

The second half of this chapter describes continuous-time stochastic processes and linear systems in the same order as was used for discrete time.

12.2 Discrete Time

The only difference between an n -dimensional vector random variable and a scalar discrete-time stochastic process over n time steps is in how they are interpreted. Mathematically, they are identical. As an aid to understanding discrete-time stochastic processes, this equivalence will be emphasized in the following.

12.2.1 Basics

The usual precise mathematical definition of a random variable [2,3,9] is unnecessary here. It is sufficient to define an n -dimensional random variable by means of its probability density function.

Definition 12.1:

An n -dimensional random variable, denoted $\underline{\mathbf{x}} = [\mathbf{x}_1 \ \mathbf{x}_2 \ \dots \ \mathbf{x}_n]'$, takes values $\underline{x} \in R^n$ according to a probability that can be determined from the probability density function (pdf) $p_{\underline{\mathbf{x}}}(\underline{x})$.

Unfortunately, the notation needed to describe stochastic processes precisely is very complicated. Thus, it is important to recognize that bold letters always denote random variables while the values that may be taken by a random variable are denoted by standard letters. For example, \mathbf{x} is a random variable that may take values x . Underlined lower case letters will always denote vectors or discrete-time stochastic processes. Underlined capital letters will denote matrices. A list of all the notation used in this chapter appears at the end of the chapter. The reader is assumed to know the basic properties of pdfs.

Definition 12.2:

A scalar discrete-time stochastic process over n time steps, $\mathbf{x}(1), \mathbf{x}(2), \dots, \mathbf{x}(n)$, denoted $\underline{\mathbf{x}}$, takes values $x(k) \in R$, where R denotes the real numbers and $k = 1, 2, \dots, n$, according to a probability that can be determined from the pdf $p_{\underline{\mathbf{x}}}(\underline{x})$.

The equivalence of the two definitions is obvious once $\mathbf{x}(1), \mathbf{x}(2), \dots, \mathbf{x}(n)$ is written as a vector $[\mathbf{x}(1) \ \mathbf{x}(2) \ \dots \ \mathbf{x}(n)]' = [\mathbf{x}_1 \ \mathbf{x}_2 \ \dots \ \mathbf{x}_n]'$, where $'$ denotes the transpose. The equivalence is emphasized by using the same notation for both. The context will make it clear which is meant whenever it matters.

It is important to be able to specify the relationships among a collection of random variables. A simple special case is that they are completely unrelated.

Definition 12.3:

The n -vector random variable (equivalently, discrete-time stochastic process) $\underline{\mathbf{x}}$, is composed of n independent

random variables $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ if and only if their joint pdf has the form

$$p_{\underline{\mathbf{x}}}(\underline{\mathbf{x}}) = \prod_{k=1}^n p_{\mathbf{x}_k}(x_k) = p_{\mathbf{x}_1}(x_1)p_{\mathbf{x}_2}(x_2) \dots p_{\mathbf{x}_n}(x_n). \quad (12.1)$$

Independence is an extreme case. More typically, and more interestingly, the individual elements of a vector random variable or a scalar discrete-time stochastic process are related. One way to characterize these relationships is by means of the conditional pdf, $p_{\underline{\mathbf{x}}_1|\underline{\mathbf{x}}_2}(\underline{\mathbf{x}}_1|\underline{\mathbf{x}}_2)$. When $p_{\underline{\mathbf{x}}_2}(\underline{\mathbf{x}}_2) \neq 0$, the conditional pdf is given by

$$p_{\underline{\mathbf{x}}_1|\underline{\mathbf{x}}_2}(\underline{\mathbf{x}}_1|\underline{\mathbf{x}}_2) = \frac{p_{\underline{\mathbf{x}}}(\underline{\mathbf{x}})}{p_{\underline{\mathbf{x}}_2}(\underline{\mathbf{x}}_2)}, \quad (12.2)$$

where $\underline{\mathbf{x}}_1$ is the m -vector $[\mathbf{x}_1 \ \mathbf{x}_2 \ \dots \ \mathbf{x}_m]'$; $\underline{\mathbf{x}}_2$ is the $(n - m)$ -vector $[\mathbf{x}_{m+1} \ \mathbf{x}_{m+2} \ \dots \ \mathbf{x}_n]'$; $\underline{\mathbf{x}}$ is the n -vector $[\mathbf{x}_1 \ \mathbf{x}_2 \ \dots \ \mathbf{x}_n]'$; and the $\underline{\mathbf{x}}_i$ s have the same dimensions as the corresponding $\underline{\mathbf{x}}_i$ s. It is often possible to avoid working directly with pdfs, especially in the study of linear systems. Instead, one uses expectations.

12.2.2 Expectation

Definition 12.4:

The expected value, expectation, or mean, of a scalar random variable, \mathbf{x} , is denoted by $E(\mathbf{x})$ or m and given by

$$m \triangleq E(\mathbf{x}) \triangleq \int_{-\infty}^{\infty} xp_{\mathbf{x}}(x) dx. \quad (12.3)$$

Applying Definition 12.4 to the scalar random variable $\mathbf{x}(k)$, the k th element of the scalar discrete-time stochastic process, $\underline{\mathbf{x}}$, gives

$$m(k) \triangleq E(\mathbf{x}(k)) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} x(k)p_{\underline{\mathbf{x}}}(\underline{\mathbf{x}})dx_1dx_2 \dots dx_n. \quad (12.4)$$

Note that the integrations over $x_\ell, \ell \neq k$, simply give the necessary marginal density $p_{\mathbf{x}(k)}(x(k))$.

The computation in Equation 12.4 can be repeated for all $k = 1, 2, \dots, n$ and the result is organized as an n -vector

$$E(\underline{\mathbf{x}}) = [E(\mathbf{x}(1)) \ E(\mathbf{x}(2)) \ \dots \ E(\mathbf{x}(n))]'. \quad (12.5)$$

One can also take the expectation with respect to functions of $\underline{\mathbf{x}}$. Two of these are particularly important.

Definition 12.5:

The covariance of the scalar random variables, \mathbf{x}_k and \mathbf{x}_ℓ , is denoted by $r_{k\ell}$, and given by

$$r_{k\ell} \triangleq E((\mathbf{x}_k - m(k))(\mathbf{x}_\ell - m(\ell))) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} (x_k - m(k))(x_\ell - m(\ell))p_{\mathbf{x}_k\mathbf{x}_\ell}(x_k, x_\ell)dx_kdx_\ell. \quad (12.6)$$

Definition 12.5 can be applied to each pair $\mathbf{x}(k)\mathbf{x}(\ell), k, \ell = 1, 2, \dots, n$ of elements of the discrete-time scalar stochastic process $\underline{\mathbf{x}}$. The result is a collection of n^2 elements $r_{k\ell}, k, \ell = 1, 2 \dots n$. It is conventional to emphasize the time dependence by defining

$$r(k, \ell) \triangleq r_{k\ell}. \quad (12.7)$$

It should be obvious from Equation 12.6 that

$$r(k, \ell) = r(\ell, k) \quad \text{for all } k, \ell \quad (12.8)$$

and that (because $p_{\underline{x}}(x) \geq 0$ for all \underline{x}),

$$r(k, k) \geq 0 \quad \text{for all } k. \quad (12.9)$$

In the context of discrete-time stochastic processes, $r(k, \ell)$ is known as the autocovariance function of the stochastic process \underline{x} . It can be helpful, in trying to understand the properties of the autocovariance function, to write it as a matrix.

$$\underline{R} = \begin{bmatrix} r(1, 1) & r(1, 2) & \dots & r(1, n) \\ r(2, 1) & r(2, 2) & & \\ \vdots & & \ddots & \vdots \\ r(n, 1) & \dots & & r(n, n) \end{bmatrix}. \quad (12.10)$$

In the context of n -vector random variables, the matrix \underline{R} is known as the covariance matrix. The autocovariance will be discussed further subsequently. Another important expectation will be defined first.

Definition 12.6:

The characteristic function of a scalar random variable, \mathbf{x} , is denoted by $f_{\mathbf{x}}(\omega)$ and given by

$$f_{\mathbf{x}}(\omega) \triangleq E(e^{j\omega\mathbf{x}}) = \int_{-\infty}^{\infty} e^{j\omega x} p_{\mathbf{x}}(x) dx, \quad (12.11)$$

where

$$j \triangleq \sqrt{-1}.$$

Note that $f_{\mathbf{x}}(\omega)$ is a deterministic function of ω , not a random variable. Note also that $f_{\mathbf{x}}(-\omega)$ is the Fourier transform of $p_{\mathbf{x}}(x)$ and is thus equivalent to $p_{\mathbf{x}}(x)$ in the same way that Fourier transform pairs are usually equivalent; there is a unique correspondence between a function and its transform.

The generalization to the case of n -vector random variables or discrete-time stochastic processes over n time steps is as follows.

Definition 12.7:

The characteristic function of an n -vector random variable (or discrete-time stochastic process), $\underline{\mathbf{x}}$, is denoted $f_{\underline{\mathbf{x}}}(\underline{\omega})$ and given by

$$f_{\underline{\mathbf{x}}}(\underline{\omega}) = E \left(e^{j \sum_{k=1}^n \omega_k \mathbf{x}_k} \right) = E(e^{j\underline{\omega}'\underline{\mathbf{x}}}). \quad (12.12)$$

The characteristic function is particularly useful for studying the effect of linear mappings on a stochastic process. As an example, consider the operation of an $m \times n$ real matrix \underline{L} on the n -vector random variable $\underline{\mathbf{x}}$.

Let $\underline{\mathbf{y}} = \underline{L}\underline{\mathbf{x}}$;

$$f_{\underline{\mathbf{y}}}(\underline{\omega}) = E(e^{j\underline{\omega}'\underline{\mathbf{y}}}) = E(e^{j\underline{\omega}'\underline{L}\underline{\mathbf{x}}}) = E(e^{j(\underline{L}'\underline{\omega})'\underline{\mathbf{x}}}) = f_{\underline{\mathbf{x}}}(\underline{L}'\underline{\omega}). \quad (12.13)$$

12.2.3 Example: Discrete-Time Gaussian Stochastic Processes

Definition 12.8:

An n -vector random variable (or discrete-time stochastic process), \underline{x} , is a Gaussian (normal) random variable (discrete-time stochastic process) if and only if it has the n -dimensional Gaussian (normal) pdf

$$p_{\underline{x}}(\underline{x}) = \frac{1}{(2\pi)^{n/2}(\det \underline{R})^{1/2}} e^{-\frac{1}{2}(\underline{x}-\underline{m})' \underline{R}^{-1}(\underline{x}-\underline{m})}, \tag{12.14}$$

where

$$\begin{aligned} \underline{m} &= E(\underline{x}), \\ \underline{R} &= E((\underline{x} - \underline{m})(\underline{x} - \underline{m})'), \quad \text{the covariance matrix of } \underline{x}. \end{aligned}$$

The definition implies that \underline{R} is symmetric ($\underline{R} = \underline{R}'$, see Equations 12.8 and 12.10 and that \underline{R} must be positive definite ($\underline{y}' \underline{R} \underline{y} > 0$ for all n -vectors $\underline{y} \neq 0$ and often indicated by $\underline{R} > 0$).

It is easy to demonstrate that the characteristic function of the n -vector Gaussian random variable, \underline{x} , with mean \underline{m} and covariance matrix \underline{R} is

$$f_{\underline{x}}(\omega) = e^{j\omega' \underline{m} - \frac{1}{2} \omega' \underline{R} \omega}. \tag{12.15}$$

Any n -vector random variable or stochastic process that has a characteristic function in the form of Equation 12.15 is Gaussian. In fact, some authors [2] define a scalar Gaussian random variable by Equation 12.15 with m and R scalars, rather than by Equation 12.14. The reason is that Equation 12.15 is well defined when $R = 0$, whereas Equation 12.14 blows up. A scalar Gaussian random variable x with variance $R = 0$ and mean m makes perfectly good sense. It is the deterministic equality $x = m$.

One other special case of the n -vector Gaussian random variable is particularly important. When $r_{k\ell} = 0$ for all $k \neq \ell$, \underline{R} is a diagonal matrix. The pdf becomes

$$\begin{aligned} p_{\underline{x}}(\underline{x}) &= \frac{1}{(2\pi)^{n/2} r_{11}^{1/2} r_{22}^{1/2} \dots r_{nn}^{1/2}} e^{-\frac{1}{2} \left(\frac{(x_1 - m_1)^2}{r_{11}} + \frac{(x_2 - m_2)^2}{r_{22}} + \dots + \frac{(x_n - m_n)^2}{r_{nn}} \right)} \\ &= \left(\frac{1}{\sqrt{2\pi} r_{11}^{1/2}} e^{-\frac{1}{2} \frac{(x_1 - m_1)^2}{r_{11}}} \right) \left(\frac{1}{\sqrt{2\pi} r_{22}^{1/2}} e^{-\frac{1}{2} \frac{(x_2 - m_2)^2}{r_{22}}} \right) \dots \left(\frac{1}{\sqrt{2\pi} r_{nn}^{1/2}} e^{-\frac{1}{2} \frac{(x_n - m_n)^2}{r_{nn}}} \right) \\ &= p_{x_1}(x_1) p_{x_2}(x_2) \dots p_{x_n}(x_n). \end{aligned} \tag{12.16}$$

In other words, the x_k are independent random variables. It is an important property of Gaussian random variables that they are independent if and only if their covariance matrix is diagonal, as has just been proven.

Finally, the characteristic function will be used to prove that if $\underline{y} = \underline{L}\underline{x}$, where \underline{L} is an $m \times n$ real matrix and \underline{x} is an n -vector Gaussian random variable with mean \underline{m} and covariance \underline{R} , then \underline{y} is an m -vector Gaussian random vector with mean $\underline{L}\underline{m}$ and covariance $\underline{L}\underline{R}\underline{L}'$. The proof is as follows:

$$\begin{aligned} \underline{y} &= \underline{L}\underline{x}, \\ f_{\underline{y}}(\omega) &= f_{\underline{x}}(\underline{L}'\omega) \end{aligned}$$

by Equation 12.15

$$= e^{j(\underline{L}'\omega)' \underline{m} - \frac{1}{2} (\underline{L}'\omega)' \underline{R} (\underline{L}\omega)} = e^{j\omega' \underline{L}\underline{m} - \frac{1}{2} \omega' \underline{L}\underline{R}\underline{L}'\omega} = e^{j\omega' (\underline{L}\underline{m}) - \frac{1}{2} \omega' (\underline{L}\underline{R}\underline{L}')\omega}. \tag{12.17}$$

Finally, the uniqueness of Fourier transforms (characteristic functions), and the fact that Equation 12.17 is the characteristic function of an m -vector Gaussian random variable with mean $\underline{L}\underline{m}$ and covariance matrix $\underline{L}\underline{R}\underline{L}'$, completes the proof.

12.2.4 Stationarity, Ergodicity, and White Noise

Several important properties of a discrete-time stochastic process are, strictly speaking, properly defined only for processes for which $k = \dots -2, -1, 0, 1, 2, \dots$ (i.e., $-\infty < k < \infty$).

Let

$$\underline{\mathbf{x}} = [\dots \mathbf{x}_{-2} \mathbf{x}_{-1} \mathbf{x}_0 \mathbf{x}_1 \mathbf{x}_2 \dots]' \triangleq \mathbf{x}_{(-\infty, \infty)} \quad (12.18)$$

denote either the scalar discrete-time stochastic process on the interval $-\infty < k < \infty$ or the equivalent infinite-dimensional vector random variable. It is difficult to visualize and write explicitly the pdf for an infinite-dimensional random variable, but that is not necessary. The pdfs for all possible finite-dimensional subsets of the elements of $\underline{\mathbf{x}}$ completely characterize the pdf of $\underline{\mathbf{x}}$. Similarly, $E(\underline{\mathbf{x}}) = \underline{\mathbf{m}}$ is computable term by term from the \mathbf{x}_i taken one at a time and $E((\underline{\mathbf{x}} - \underline{\mathbf{m}})(\underline{\mathbf{x}} - \underline{\mathbf{m}})') = \underline{\mathbf{R}}$ is computable from all pairs $\mathbf{x}_i, \mathbf{x}_j$ taken two at a time.

Example 12.1:

Let $\underline{\mathbf{x}}$ be a Gaussian scalar discrete-time stochastic process with mean $E(\mathbf{x}_k) = m_k = 0$ for all k , $-\infty < k < \infty$ and covariance

$$E(\mathbf{x}_k \mathbf{x}_\ell) = r(k, \ell) = \begin{cases} 1 & k = \ell \\ 1/2 & |k - \ell| = 1 \\ 0 & \text{otherwise.} \end{cases}$$

Note that this completely describes the pdf of $\underline{\mathbf{x}}$ even though $\underline{\mathbf{x}}$ is infinite-dimensional.

This apparatus makes it possible to define two forms of time-invariance for discrete-time stochastic processes.

Definition 12.9:

A scalar discrete-time stochastic process $\underline{\mathbf{x}}$, defined on $-\infty < k < \infty$ is stationary if and only if

$$\begin{aligned} &P_{\mathbf{x}_{k_1}, \mathbf{x}_{k_2}, \dots, \mathbf{x}_{k_n}}(x_{k_1}, x_{k_2}, \dots, x_{k_n}) \\ &= P_{\mathbf{x}_{k_1+k_p}, \mathbf{x}_{k_2+k_p}, \dots, \mathbf{x}_{k_n+k_p}}(x_{k_1+k_p}, x_{k_2+k_p}, \dots, x_{k_n+k_p}) \end{aligned} \quad (12.19)$$

for all possible choices $-\infty < k_\ell, k_p < \infty$, $\ell = 1, 2, \dots, n$ and all finite n .

The region of definition of stochastic processes defined on $(-\infty, \infty)$ will be emphasized by using the notation $\mathbf{x}_{(-\infty, \infty)}$ to denote such processes.

It can be difficult to verify Definition 12.9. There is a weaker-and-easier-to-use form of stationarity. It requires a preliminary definition.

Definition 12.10:

A scalar discrete-time stochastic process, $\underline{\mathbf{x}}$, is a second-order process if, and only if, $E(\mathbf{x}_k^2) < \infty$ for all k , $-\infty < k < \infty$.

Definition 12.11:

A second-order scalar discrete-time stochastic process, $\mathbf{x}_{(-\infty, \infty)}$ is wide-sense stationary if, and only if, its mean \underline{m} and autocovariance $r(k, \ell)$ satisfy

$$m(k) = m, \quad \text{a constant for all } k, \quad -\infty < k < \infty, \tag{12.20}$$

$$r(k, \ell) = r(k + i, \ell + i) \quad \text{for all } k, \ell, i, \quad -\infty < k, \ell, i < \infty. \tag{12.21}$$

It is customary to define

$$r(k) \triangleq r(k + \ell, \ell) \quad \text{for all } k, \ell, \quad -\infty < k, \ell < \infty. \tag{12.22}$$

It is obvious that a stationary discrete-time stochastic process is also wide-sense stationary because the invariance of the pdfs implies invariance of the expectations. Because the pdf of an n -vector Gaussian random variable is completely defined by its mean, \underline{m} , and covariance, \underline{R} , a scalar wide-sense Gaussian stationary discrete-time stochastic process is also stationary.

The apparatus needed to define discrete-time white noise is now in place.

Definition 12.12:

A scalar second-order discrete-time stochastic process, $\mathbf{x}_{(-\infty, \infty)}$, is a white noise process if and only if

$$m(k) = E(\mathbf{x}_k) = 0 \quad \text{for all } k, \quad -\infty < k < \infty, \tag{12.23}$$

$$r(k) = E(\mathbf{x}_{\ell+k}\mathbf{x}_\ell) = r\delta(k) \quad \text{for all } -\infty < k, \ell < \infty, \tag{12.24}$$

where

$$r \geq 0$$

and

$$\delta(k) = \begin{cases} 1 & k = 0 \\ 0 & \text{otherwise.} \end{cases} \tag{12.25}$$

If, in addition, \mathbf{x}_k is Gaussian for all k , the process is Gaussian white noise. An explanation of the term “white noise” requires an explanation of transforms of stochastic processes. This will be forthcoming shortly. First, the question of estimating the pdf will be introduced.

In the real world of engineering, someone has to determine the pdf of a given random variable or stochastic process. The typical situation is that one has some observations of the process and some prior knowledge about the process. For example, the physics often indicates that a discrete-time stochastic process, \mathbf{x} , $-\infty < k < \infty$, is wide-sense stationary—at least as an adequate approximation to reality. If one is content with second-order properties of the process, this reduces the problem to determining m and $r(k)$, $-\infty < k < \infty$, from observations of the process. The discussion here will be limited to this important, but greatly simplified, version of the general problem.

In order to have a precisely specified problem with a well-defined solution, assume that the data available are one observation (sample) of the stochastic process over the complete time interval $-\infty < k < \infty$. This is certainly impossible for individuals having a finite lifespan, but the idealized mathematical result based on this assumption clarifies the practical situation.

Define

$$\mathbf{m}_\ell = \frac{1}{2\ell} \sum_{k=-\ell}^{\ell} \mathbf{x}_k, \quad (12.26)$$

$$\mathbf{r}_\ell(k) = \frac{1}{2\ell} \sum_{i=-\ell}^{\ell} \mathbf{x}_{i+k} \mathbf{x}_i. \quad (12.27)$$

Note that \mathbf{m}_ℓ and $\mathbf{r}_\ell(k)$ are denoted by bold letters in Equations 12.26 and 12.27. This indicates that they are random variables, unlike the expectations m and $r(k)$, which are deterministic quantities. It can then be proved that

$$\lim_{\ell \rightarrow \infty} E[(\mathbf{m}_\ell - m)^2] = 0, \quad (12.28)$$

provided

$$\lim_{|k| \rightarrow \infty} r(k) = 0. \quad (12.29)$$

A similar result holds for $\mathbf{r}_\ell(k)$ (see [2, pp. 77–80]).

In order to apply this result to a real problem one must know, *a priori*, that Equation 12.29 holds. Again, this is often known from the physics.

The convergence result in Equation 12.28 is fairly weak. It would be preferable to prove that \mathbf{m}_ℓ converges to m almost surely (with probability 1). It is possible to prove this stronger result if the process is ergodic as well as stationary. This subject is both complicated and technical. See [2,4] for engineering-oriented discussions and [3] for a more mathematical introduction.

12.2.5 Transforms

In principle, one can apply any transform that is useful in the analysis of discrete-time signals to discrete-time stochastic processes. The two obvious candidates are the Z -transform and the discrete Fourier transform [5]. There is a slight theoretical complication. To see this, consider the discrete Fourier transform of the discrete-time stochastic process $\mathbf{x}_{(-\infty, \infty)}$

$$\mathbf{x}_f(\Omega) \triangleq \sum_{k=-\infty}^{\infty} \mathbf{x}(k) e^{-j\Omega k}. \quad (12.30)$$

Note that $\mathbf{x}_f(\Omega)$ is an infinite-dimensional random vector for each fixed value of Ω (it is a function of the random variables $\mathbf{x}(k)$; so it is a random variable) and $\mathbf{x}_f(\Omega)$ is defined for all Ω , $-\infty < \Omega < \infty$, not just integer values of Ω . In other words, $\mathbf{x}_f(\Omega)$ is a stochastic process in the continuous variable Ω . As is usual with the discrete Fourier transform, $\mathbf{x}_f(\Omega)$ is periodic in Ω with period 2π .

A very important use of transforms in the study of discrete-time stochastic processes is the spectral density function.

Definition 12.13:

Let $\mathbf{x}_{(-\infty, \infty)}$ be a wide-sense stationary scalar discrete-time stochastic process with mean m and autocovariance function $r(k)$. Assume $\sum_{k=-\infty}^{\infty} |r(k)| < \infty$. Then the discrete Fourier transform of the autocovariance function $r(k)$,

$$s(\Omega) \triangleq \sum_{k=-\infty}^{\infty} r(k) e^{-j\Omega k}, \quad (12.31)$$

is well defined and known as the spectral density function of $\mathbf{x}_{(-\infty, \infty)}$.

FIGURE 12.1 A symbolic representation of a discrete-time linear system, S , with input $\underline{u} = [\dots u_{-2} u_{-1} u_0 u_1 \dots]'$ and output $\underline{y} = [\dots y_{-1} y_0 y_1 \dots]'$.

Note, as the notation emphasizes, that no part of Equation 12.31 is random. Both the spectral density and the autocovariance are deterministic descriptors of the stochastic process, $\mathbf{x}_{(-\infty, \infty)}$.

The inverse of Equation 12.31 is the usual inverse of the discrete Fourier transform. That is,

$$r(k) = \frac{1}{2\pi} \int_{2\pi} s(\Omega) e^{j\Omega k} d\Omega, \tag{12.32}$$

where $\int_{2\pi}$ means the integral is taken over any interval of duration 2π .

When $m = 0$,

$$r(0) = E(\mathbf{x}_k^2) = \int_{2\pi} s(\Omega) \frac{d\Omega}{2\pi}. \tag{12.33}$$

If $\mathbf{x}_{(-\infty, \infty)}$ is a voltage, current, or velocity, then $r(0)$ can be interpreted as average power, at least to within a constant of proportionality. With this interpretation of $r(0)$, $s(\Omega_0)$ (where Ω_0 is any fixed frequency) must be the average power per unit frequency in $\mathbf{x}_{(-\infty, \infty)}$ at frequency Ω_0 [2]. This is why it is called the spectral density.

Example 12.2:

Suppose $\mathbf{x}_{(-\infty, \infty)}$ is a white-noise process (see Definition 12.12) with $r(k) = \delta(k)$. The spectral density function for this process is

$$s(\Omega) = \sum_{k=-\infty}^{\infty} \delta(k) e^{-j\Omega k} = 1. \tag{12.34}$$

Hence it is called “white noise.” Like white light, all frequencies are equally present in a white noise process. A reasonable conjecture is that it is called “noise” because, in the early days of radio and telephone, such a stochastic process was heard as a recognizable and unwanted sound.

12.2.6 Single-Input Single-Output Discrete-Time Linear Systems

It is convenient, both pedagogically and notationally, to begin with SISO discrete-time linear systems described by their impulse response, $h(k, \ell)$. The notation is shown in Figure 12.1.

Definition 12.14:

The impulse response of a SISO discrete-time linear system is denoted by $h(k, \ell)$, where $h(k, \ell)$ is the value of the output at instant k , when the input is a unit impulse at instant ℓ .

The response of a linear system S to an arbitrary input, $u_{(-\infty, \infty)}$, is then given by a convolution sum

$$y(k) = \sum_{\ell=-\infty}^{\infty} h(k, \ell) u(\ell); \quad -\infty < k < \infty. \tag{12.35}$$

The crucial point is that S is a linear map, as is easily proved from Equation 12.35. Linear maps take Gaussian stochastic processes (random variables) into Gaussian stochastic processes. A special case of this, when S can be written as an $n \times m$ matrix, was proved earlier (Equation 12.17).

Example 12.3:

Consider a SISO discrete-time linear system, S , with input, $\mathbf{u}_{(-\infty, \infty)}$, a discrete-time Gaussian stochastic process having mean $m_u(k)$, and autocovariance $r_u(k, \ell)$. Knowing that the system is linear and that the input is Gaussian, the output, $\mathbf{y}_{(-\infty, \infty)}$, must be a Gaussian stochastic process; what are its mean and autocovariance? They can be calculated element by element:

$$\begin{aligned} m_y(k) &= E(\mathbf{y}(k)) = E\left(\sum_{\ell=-\infty}^{\infty} h(k, \ell)\mathbf{u}(\ell)\right) = \sum_{\ell=-\infty}^{\infty} h(k, \ell)E(\mathbf{u}(\ell)) \\ &= \sum_{\ell=-\infty}^{\infty} h(k, \ell)m_u(\ell); \quad -\infty < k < \infty, \end{aligned} \quad (12.36)$$

$$\begin{aligned} r_y(k, \ell) &= E((\mathbf{y}(k) - m_u(k))(\mathbf{y}(\ell) - m_u(\ell))) \\ &= E\left(\left(\sum_{i=-\infty}^{\infty} h(k, i)(\mathbf{u}(i) - m_u(i))\right)\left(\sum_{j=-\infty}^{\infty} h(\ell, j)(\mathbf{u}(j) - m_u(j))\right)\right) \\ &= \sum_{i=-\infty}^{\infty} \sum_{j=-\infty}^{\infty} h(k, i)h(\ell, j)E((\mathbf{u}(i) - m_u(i))(\mathbf{u}(j) - m_u(j))) \\ &= \sum_{i=-\infty}^{\infty} \sum_{j=-\infty}^{\infty} h(k, i)h(\ell, j)r_u(i, j). \end{aligned} \quad (12.37)$$

Of course, not every stochastic process is Gaussian. However, careful review of the previous example shows that Equations 12.36 and 12.37 are valid formulas for the mean and autocovariance of $y_{(-\infty, \infty)}$ whenever $\mathbf{u}_{(-\infty, \infty)}$ is a second-order scalar discrete-time stochastic process with mean $m_u(k)$ and autocovariance $r_u(i, j)$ and the system S is asymptotically stable. This is a very important point. The second-order properties of a stochastic process are easily computed. The calculations are even simpler if the input process is wide-sense stationary and the linear system is time-invariant.

Example 12.4:

Consider a SISO discrete-time linear time-invariant (LTI) system, S , with input, $\mathbf{u}_{(-\infty, \infty)}$, a wide-sense stationary second-order discrete-time stochastic process having mean m_u and autocovariance $r_u(k)$. Denote the impulse response of S by $h(k)$, where $h(k) \triangleq h(k + \ell, \ell)$ and assume that S is asymptotically stable.

$$\begin{aligned} m_y(k) &= E(\mathbf{y}(k)) = E\left(\sum_{\ell=-\infty}^{\infty} h(k - \ell)\mathbf{u}(\ell)\right) = \sum_{\ell=-\infty}^{\infty} h(k - \ell)E(\mathbf{u}(\ell)) \\ &= \sum_{\hat{\ell}=-\infty}^{\infty} h(\hat{\ell})E(\mathbf{u}(k - \hat{\ell})) = \alpha m_u, \end{aligned} \quad (12.38)$$

where

$$\alpha = \sum_{\hat{\ell}=-\infty}^{\infty} h(\hat{\ell}).$$

Similarly, using Equation 12.37, and defining $\hat{\ell} = k - i$ and $\hat{k} = \ell - j$

$$r_y(k, \ell) = \sum_{i=-\infty}^{\infty} \sum_{j=-\infty}^{\infty} h(k-i)h(\ell-j)r_u(i-j) = \sum_{\hat{\ell}=-\infty}^{\infty} \sum_{\hat{k}=-\infty}^{\infty} h(\hat{\ell})h(\hat{k})r_u(k-\ell-\hat{\ell}+\hat{k}). \quad (12.39)$$

Note that the convolution sum in Equation 12.39 depends only on the difference $k - \ell$. Thus, Equations 12.38 and 12.39 prove that $m_y(k) = m_y$, a constant, and that $r_y(k, \ell) = r_y(k - \ell) = r_y(\bar{k})$, where $\bar{k} \triangleq k - \ell$. This proves that $\mathbf{y}_{(-\infty, \infty)}$ is also wide-sense stationary.

Although the computations in Equation 12.39 still appear to be difficult, they clearly involve deterministic convolution. It is well known that the Fourier transform can be used to simplify such calculations. The impulse responses of many discrete-time LTI systems, $h(k)$, $-\infty < k < \infty$, have discrete Fourier transforms, $h_f(\Omega)$, $0 \leq \Omega < 2\pi$. The exceptions include unstable systems. Assume $h_f(\Omega)$ exists in the preceding example and that $\mathbf{u}_{(-\infty, \infty)}$ is wide-sense stationary with mean m_u and spectral density function $s(\Omega)$. From the definition of the discrete Fourier transform

$$h_f(\Omega) = \sum_{k=-\infty}^{\infty} h(k)e^{-j\Omega k}, \quad (12.40)$$

it is evident that Equation 12.38 becomes

$$m_y = h_f(0)m_u. \quad (12.41)$$

Using the inversion formula (Equation 12.32) in Equation 12.39 gives

$$\begin{aligned} r_y(k) &= \sum_{\ell=-\infty}^{\infty} \sum_{i=-\infty}^{\infty} h(\ell)h(i) \left(\frac{1}{2\pi} \int_{2\pi} s_u(\Omega)e^{j\Omega(k-\ell+i)} d\Omega \right) \\ &= \int_{2\pi} \sum_{i=-\infty}^{\infty} h(i)s_u(\Omega)e^{j\Omega(k+i)} \left(\sum_{\ell=-\infty}^{\infty} h(\ell)e^{-j\Omega\ell} \right) \frac{d\Omega}{2\pi} \\ &= \int_{2\pi} \left(\sum_{i=-\infty}^{\infty} h(i)e^{j\Omega i} \right) h_f(\Omega)s_u(\Omega)e^{j\Omega k} \frac{d\Omega}{2\pi} \\ &= \int_{2\pi} h_f(-\Omega)h_f(\Omega)s_u(\Omega)e^{j\Omega k} \frac{d\Omega}{2\pi} \\ &= \int_{2\pi} |h_f(\Omega)|^2 s_u(\Omega)e^{j\Omega k} \frac{d\Omega}{2\pi}. \end{aligned} \quad (12.42)$$

By the uniqueness of Fourier transforms, Equation 12.42 implies

$$s_y(\Omega) = |h_f(\Omega)|^2 s_u(\Omega). \quad (12.43)$$

SISO linear systems in state-space form generally have an n -vector state. When either the initial state is random or the input is a stochastic process, this state is a vector stochastic process. The ideas and notation for such processes are described in the following section. This is followed by a description of linear systems in state-space form.

12.2.7 Vector Discrete-Time Stochastic Processes and LTI Systems

The vector case involves much more complicated notation but no new concepts.

Definition 12.15:

An m -vector discrete-time stochastic process over n time steps, denoted $\underline{\mathbf{X}} \triangleq \{[\mathbf{x}_1(k) \ \mathbf{x}_2(k) \ \dots \ \mathbf{x}_m(k)]'; k = 1, 2, \dots, n\}$, takes values $\underline{\mathbf{X}} = \{[\mathbf{x}_1(h) \ \mathbf{x}_2(k) \ \dots \ \mathbf{x}_m(k)]'; k = 1, 2, \dots, n\}$ according to a probability that can be determined from the pdf $p_{\underline{\mathbf{X}}}(\underline{\mathbf{X}})$.

It can be helpful to visualize such a process as an $m \times n$ matrix

$$\underline{\mathbf{X}} = \begin{bmatrix} \mathbf{x}_1(1) & \mathbf{x}_1(2) & \dots & \mathbf{x}_1(n) \\ \mathbf{x}_2(1) & \mathbf{x}_2(2) & \dots & \mathbf{x}_2(n) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{x}_m(1) & \mathbf{x}_m(2) & \dots & \mathbf{x}_m(n) \end{bmatrix}. \quad (12.44)$$

The notation is that bold capital underlined letters denote vector stochastic processes.

All of the scalar results apply, with obvious modifications, to the vector case. For example, $E(\mathbf{X})$ can be computed element by element from Definition 12.4.

$$E(x_\ell(k)) = \int_{-\infty}^{\infty} xp_{\mathbf{x}_\ell(k)}(x) dx \quad (12.45)$$

for all $\ell = 1, 2, \dots, m, k = 1, 2, \dots, n$ (see Equation 12.4).

Then, the nm results of Equation 12.45 can be organized as an m -vector over n time steps, $\underline{m}(k) = [m_1(k) \ m_2(k) \ \dots \ m_m(k)]'$, where

$$m_\ell(k) = E(\mathbf{x}_\ell(k)). \quad (12.46)$$

Similarly, the autocovariance of $\underline{\mathbf{X}}$ in Equation 12.44 can be computed element by element using Definition 12.5 and Equation 12.7. The results are conventionally organized as an autocovariance matrix at each pair of times. That is

$$\underline{R}(k, \ell) = \begin{bmatrix} r_{11}(k, \ell) & r_{12}(k, \ell) & \dots & r_{1m}(k, \ell) \\ r_{21}(k, \ell) & r_{22}(k, \ell) & \dots & r_{2m}(k, \ell) \\ \vdots & \vdots & \ddots & \vdots \\ r_{m1}(k, \ell) & r_{m2}(k, \ell) & \dots & r_{mm}(k, \ell) \end{bmatrix}, \quad (12.47)$$

where

$$r_{ij}(k, \ell) \triangleq E((x_i(k) - m_i(k))(x_j(\ell) - m_j(\ell))).$$

Example 12.5:

Discrete-time m -vector white noise: Any white noise must be wide-sense stationary and have zero mean. Thus, letting $\underline{\xi}(k)$ denote an m -vector white noise at the instant k ,

$$\begin{aligned} \underline{m}_\xi(k) &= E(\underline{\xi}(k)) = \underline{0} \quad \text{for all } k, -\infty < k < \infty, \\ \underline{R}_\xi(k, \ell) &= E(\underline{\xi}(k)\underline{\xi}'(\ell)) = \underline{0} \quad \text{for all } k \neq \ell, -\infty < k, \ell < \infty, \end{aligned} \quad (12.48)$$

because white noise must have autocovariance equal to zero except when $k = \ell$. When $k = \ell$, the autocovariance can be any positive-semidefinite matrix. Thus,

$$\underline{R}_\xi(k, \ell) = \underline{R}_\xi \delta(k - \ell), \quad (12.49)$$

where \underline{R}_ξ can be any positive-semidefinite matrix ($\underline{y}'\underline{R}_\xi\underline{y} \geq 0$ for all m -vectors \underline{y}).

Finally, as is customary with stationary processes,

$$R_{\xi}(k) \triangleq R_{\xi}(k + \ell, \ell) = R_{\xi} \delta(k). \quad (12.50)$$

Reading vector versions of all the previous results would be awfully tedious. Thus, the vector versions will not be written out here. Instead, an example of the way linear systems operate on vector discrete-time stochastic processes will be presented.

The previous discussion of linear systems dealt only with impulse responses and, under the added assumption of time invariance, Fourier transforms. Initial conditions were assumed to be zero. The following example includes nonzero initial conditions and a state-space description of the linear system. The system is assumed to be LTI. The time-varying case is not harder, but the notation is messy.

Example 12.6:

Let \underline{x}_0 be an n -dimensional second-order random variable with mean \underline{m}_{x_0} and covariance R_{x_0} . Let $\underline{\xi}$ and $\underline{\theta}$ be, respectively, m -dimensional and p -dimensional second-order discrete-time stochastic processes on $0 \leq k \leq k_f$. Let $E(\underline{\xi}) = \underline{0}$, $E(\underline{\theta}) = \underline{0}$, $E(\underline{\xi}(k)\underline{\xi}'(\ell)) = \underline{\Xi} \delta(k - \ell)$, $E(\underline{\theta}(k)\underline{\theta}'(\ell)) = \underline{\Theta} \delta(k - \ell)$, and $E(\underline{\xi}(k)\underline{\theta}'(\ell)) = \underline{0}$ for all $0 \leq k, \ell \leq k_f$. Strictly speaking, $\underline{\Xi}$ and $\underline{\Theta}$ are not white-noise processes because they are defined only on a finite interval. However, in the context of state-space analysis it is standard to call them white noise processes. Finally, assume $E((\underline{x}_0 - \underline{m}_{x_0})\underline{\xi}'(k)) = 0$ and $E((\underline{x}_0 - \underline{m}_{x_0})\underline{\theta}'(k)) = 0$ for all $0 \leq k \leq k_f$.

Suppose now that the n -vector random variable $\underline{x}(k + 1)$ and the p -vector random variable $\underline{y}(k)$ are defined recursively for $k = 0, 1, 2, \dots, k_f$ by

$$\underline{x}(k + 1) = \underline{A}\underline{x}(k) + \underline{L}\underline{\xi}(k); \quad \underline{x}(0) = \underline{x}_0, \quad (12.51)$$

$$\underline{y}(k) = \underline{C}\underline{x}(k) + \underline{\theta}(k), \quad (12.52)$$

where \underline{A} is a deterministic $n \times n$ matrix, \underline{L} is a deterministic $n \times m$ matrix, and \underline{C} is a deterministic $p \times n$ matrix. What can be said about the stochastic processes $\underline{X} = \{\underline{x}(k); k = 0, 1, 2, \dots, k_f + 1\}$ and $\underline{Y} = \{\underline{y}(k); k = 0, 1, 2, \dots, k_f\}$?

The means and autocovariances of \underline{X} and \underline{Y} are easily computed. For example,

$$E(\underline{x}(k + 1)) = E(\underline{A}\underline{x}(k) + \underline{L}\underline{\xi}(k)) = \underline{A}E(\underline{x}(k)) + \underline{L}E(\underline{\xi}(k)) = \underline{A}E(\underline{x}(k)). \quad (12.53)$$

Similarly,

$$E(\underline{y}(k)) = \underline{C}E(\underline{x}(k)). \quad (12.54)$$

Note that Equation 12.53 is a simple deterministic recursion for $E(\underline{x}(k + 1))$ starting from $E(\underline{x}(0)) = \underline{m}_{x_0}$. Thus,

$$E(\underline{x}(k)) = \underline{m}_x(k) = \underline{A}^k \underline{m}_{x_0}, \quad (12.55)$$

$$E(\underline{y}(k)) = \underline{C}\underline{A}^k \underline{m}_{x_0}. \quad (12.56)$$

Similarly, recursive equations for the autocovariances of \underline{X} and \underline{Y} can be derived. Because the expressions for \underline{Y} are just deterministic algebraic transformations of those for \underline{X} , only those for \underline{X} are given here.

$$\begin{aligned} R_x(k + 1, k + 1) &\triangleq E((\underline{x}(k + 1) - \underline{m}_x(k + 1))(\underline{x}(k + 1) - \underline{m}_x(k + 1))') \\ &= E((\underline{A}(\underline{x}(k) - \underline{m}_x(k)) + \underline{L}\underline{\xi}(k))(\underline{A}(\underline{x}(k) - \underline{m}_x(k)) + \underline{L}\underline{\xi}(k))') \\ &= \underline{A}E((\underline{x}(k) - \underline{m}_x(k))(\underline{x}(k) - \underline{m}_x(k))')\underline{A}' + \underline{L}\underline{\Xi}\underline{L}' \\ &= \underline{A}R_x(k, k)\underline{A}' + \underline{L}\underline{\Xi}\underline{L}', \end{aligned} \quad (12.57)$$

$$R_x(k + 1, k) \triangleq E((\underline{x}(k + 1) - \underline{m}_x(k + 1))(\underline{x}(k) - \underline{m}_x(k))') = \underline{A}R_x(k, k). \quad (12.58)$$

Note that Equations 12.57 and 12.58 use the assumption that $E((\underline{\mathbf{x}}(k) - \underline{m}_x(k))\underline{\xi}(\ell)) = 0$ for all $0 \leq k, \ell \leq k_f$. Furthermore, the recursion in Equation 12.57 begins with $\underline{R}_x(0, 0) = \underline{R}_{x_0}$.

12.3 Continuous Time

Continuous-time stochastic processes are technically much more complicated than discrete-time stochastic processes. Fortunately, most of the complications can be avoided by the restriction to second-order processes and linear systems. This is what will be done in this article because linear systems and second-order processes are by far the most common analytical basis for the design of control systems involving randomness.

A good understanding of the discrete-time case is helpful because the continuous-time results are often analogous to those in discrete time.

12.3.1 Basics

It is very difficult to give a definition of continuous-time stochastic process that is both elementary and mathematically correct. For discrete-time stochastic processes every question involving probability can be answered in terms of the finite-dimensional pdfs. For continuous-time stochastic processes the finite-dimensional pdfs are not sufficient to answer every question involving probability. See [2, pp. 59–62] for a readable discussion of the difficulty.

In the interest of simplicity and because the questions of interest here are all answerable in terms of the finite-dimensional pdfs, the working definition of a continuous-time stochastic process will be as follows.

Definition 12.16:

A scalar continuous-time stochastic process, denoted by $\mathbf{x}_{[t_s, t_f]}$, takes values $x(t) \in R$ for all real $t, t_s \leq t \leq t_f$, according to a probability that can be determined from the family of finite-dimensional pdfs. $p_{\mathbf{x}(t_1), \mathbf{x}(t_2), \dots, \mathbf{x}(t_n)}(x(t_1), x(t_2), \dots, x(t_n))$ for all finite collections of t_k, t_k real and all possible positive integers $n, t_s \leq t_k \leq t_f, k = 1, 2, \dots, n$.

The essential feature of this definition is the idea of a signal that is a function of the continuous time, t , and also random. The definition itself will not be used directly. Its main purpose is to allow the definitions of expectation and second-order process.

12.3.2 Expectations

As for discrete-time stochastic processes, the expectation, expected value, or mean of a scalar continuous-time stochastic process follows directly from Definitions 12.16 and 12.4.

$$m(t) \triangleq E(\mathbf{x}(t)) = \int_{-\infty}^{\infty} x p_{\mathbf{x}(t)}(x) dx. \quad (12.59)$$

Note that $m(t)$ is defined where $\mathbf{x}_{[t_s, t_f]}$ is, that is, on the interval $t_s \leq t \leq t_f$.

The covariance function is defined and computed for continuous-time stochastic processes in exactly the same way as for discrete-time stochastic processes. See Equations 12.6 and 12.7.

Definition 12.17:

The covariance function of a scalar continuous-time stochastic process $\mathbf{x}_{[t_s, t_f]}$ is denoted $r(t, \tau)$ and is given by

$$\begin{aligned} r(t, \tau) &= E((\mathbf{x}(t) - m(t))(\mathbf{x}(\tau) - m(\tau))) \\ &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} (x - m(t))(y - m(\tau)) p_{\mathbf{x}(t), \mathbf{x}(\tau)}(x, y) dx dy. \end{aligned} \tag{12.60}$$

As in the discrete-time case, it should be obvious from Equation 12.60 that

$$r(t, \tau) = r(\tau, t) \quad \text{for all } t, \tau, \quad t_s \leq t, \tau \leq t_f \tag{12.61}$$

and

$$r(t, t) \geq 0 \quad \text{for all } t, \quad t_s \leq t \leq t_s. \tag{12.62}$$

Because $r(t, \tau)$ is a function of two variables and not a matrix, it is necessary to extend the idea of nonnegative definiteness to such functions in order to define and demonstrate this aspect of the “shape” of the covariance function. The idea behind the following definition is to form every possible symmetric matrix from time samples of $r(t, \tau)$ and then to require that all those matrices be positive semidefinite in the usual sense.

Definition 12.18:

A real-valued function $g(t, \tau)$; $t, \tau \in R, t_s \leq t, \tau \leq t_f$; is positive semidefinite if, for every finite collection t_1, t_2, \dots, t_n ; $t_s \leq t_i \leq t_f$ for $i = 1, 2, \dots, n$ and every real n -vector $\underline{\alpha} = [\alpha_1, \alpha_2, \dots, \alpha_n]'$

$$\sum_{k=1}^n \sum_{\ell=1}^n \alpha_k \alpha_{\ell} g(t_k, t_{\ell}) \geq 0. \tag{12.63}$$

The function $g(t, \tau)$ is positive definite if strict inequality holds in Equation 12.63 whenever t_1, t_2, \dots, t_n are distinct and $\underline{\alpha} \neq \underline{0}$.

It is easy to prove that an autocovariance function, $r(t, \tau)$, must be positive semidefinite. First,

$$E \left(\sum_{k=1}^n \alpha_k (\mathbf{x}(t_k) - m(t_k)) \right)^2 \geq 0 \tag{12.64}$$

because the expectation of a perfect square must be ≥ 0 . Then,

$$\begin{aligned} 0 &\leq E \left(\sum_{k=1}^n \alpha_k (\mathbf{x}(t_k) - m(t_k)) \right)^2 \\ &= E \left(\sum_{k=1}^n \sum_{\ell=1}^n \alpha_k \alpha_{\ell} (\mathbf{x}(t_k) - m(t_k)) (\mathbf{x}(t_{\ell}) - m(t_{\ell})) \right) \\ &= \sum_{k=1}^n \sum_{\ell=1}^n \alpha_k \alpha_{\ell} E((\mathbf{x}(t_k) - m(t_k))(\mathbf{x}(t_{\ell}) - m(t_{\ell}))) \\ &= \sum_{k=1}^n \sum_{\ell=1}^n \alpha_k \alpha_{\ell} r(t_k, t_{\ell}). \end{aligned}$$

The definition of the characteristic function in the case of a continuous-time stochastic process is obvious from Equations 12.11, 12.59, and 12.60. Because it is generally a function of time as well as ω it is not as useful in the continuous-time case. For this reason, it is not given here.

12.3.3 Example: Continuous-Time Gaussian Stochastic Processes

Definition 12.19:

A scalar continuous-time stochastic process $\mathbf{x}_{[t_s, t_f]}$ is a Gaussian process if the collection of random variables $\{\mathbf{x}(t_1), \mathbf{x}(t_2), \dots, \mathbf{x}(t_n)\}$ is an n -vector Gaussian random variable for every finite set $\{t_1, t_2, \dots, t_n; t_s \leq t_i \leq t_f, i = 1, 2, \dots, n\}$.

It follows from Definition 12.8 in Section 12.2.3 that a Gaussian process is completely specified by its mean

$$m(t) = E(\mathbf{x}(t)) \quad (12.65)$$

and autocovariance

$$r(t, \tau) = E((\mathbf{x}(t) - m(t))(\mathbf{x}(\tau) - m(\tau))). \quad (12.66)$$

Example 12.7:

Wiener process (also known as Brownian motion): Let $\mathbf{x}_{[0, \infty)}$ be a Gaussian process with

$$\begin{aligned} m(t) &= \mathbf{0}, \\ r(t, \tau) &= \min(t, \tau). \end{aligned} \quad (12.67)$$

Note that the interval of definition is infinite and open at the right. This is a very minor expansion of Definition 12.16.

The Wiener process plays a fundamental role in the theory of stochastic differential equations (see Chapter 59); so it is worthwhile to derive one of its properties. Consider any ordered set of times $t_0 < t_1 < t_2 < \dots < t_n$.

Define

$$\mathbf{y}_k = \mathbf{x}_{t_k} - \mathbf{x}_{t_{k-1}} \quad k = 1, 2, \dots, n.$$

Then \mathbf{y}_k is an increment in the process $\mathbf{x}_{[0, \infty)}$. Consider the collection of increments

$$\underline{\mathbf{y}} = \{\mathbf{y}_k, k = 1, 2, \dots, n\}.$$

Because $\mathbf{x}_{[0, \infty)}$ is a Wiener process, each of the \mathbf{x}_{t_k} is a Gaussian random variable (see Definition 12.19). Therefore \mathbf{y}_k , the difference of Gaussian random variables, is also a Gaussian random variable for every k and $\underline{\mathbf{y}}$ is an n -vector Gaussian random variable. Therefore, $\underline{\mathbf{y}}$ is completely characterized by its mean and covariance. The mean is zero. The covariance is diagonal, as can be seen from the following calculation.

Consider, for $j \leq k - 1$ (the means are zero),

$$\begin{aligned} E(\mathbf{y}_k \mathbf{y}_j) &= E((\mathbf{x}_{t_k} - \mathbf{x}_{t_{k-1}})(\mathbf{x}_{t_j} - \mathbf{x}_{t_{j-1}})) \\ &= E(\mathbf{x}_{t_k} \mathbf{x}_{t_j}) - E(\mathbf{x}_{t_{k-1}} \mathbf{x}_{t_j}) - E(\mathbf{x}_{t_k} \mathbf{x}_{t_{j-1}}) + E(\mathbf{x}_{t_{k-1}} \mathbf{x}_{t_{j-1}}) \\ &= t_j - t_j - t_{j-1} + t_{j-1} = 0. \end{aligned}$$

A similar calculation for $j \geq k + 1$ completes the demonstration that the covariance of $\underline{\mathbf{y}}$ is diagonal. Because $\underline{\mathbf{y}}$ is Gaussian, the fact that its covariance is diagonal proves that the $\mathbf{y}_k, k = 1, 2, \dots, n$ are independent. This is a very important property of the Wiener process. It is usually described thus: the Wiener process has independent increments.

12.3.4 Stationarity, Ergodicity, and White Noise

The concepts of stationarity and wide-sense stationarity for continuous-time stochastic processes are virtually identical to those for discrete-time stochastic processes. All that is needed is to define the continuous-time stochastic process on the infinite interval

$$\mathbf{x}_{(-\infty, \infty)} \triangleq \mathbf{x}(t) \quad \text{for all } t, -\infty < t < \infty$$

and adjust the notation in Definitions 12.9 and 12.11. Only the latter is included here so as to emphasize the focus on second-order processes.

Definition 12.20:

A scalar continuous-time stochastic process, $\mathbf{x}_{(-\infty, \infty)}$, is a second-order process if and only if $E(x^2(t)) < \infty$ for all $t, -\infty < t < \infty$.

Definition 12.21:

A second-order, continuous-time stochastic process $\mathbf{x}_{(-\infty, \infty)}$ is wide-sense stationary if and only if its mean $m(t)$ and covariance function $r(t, \tau)$ satisfy

$$m(t) = m, \text{ a constant for all } t, -\infty < t < \infty, \tag{12.68}$$

$$r(t, \tau) = r(t + \sigma, \tau + \sigma) \quad \text{for all } t, \tau, \sigma, -\infty < t, \tau, \sigma < \infty. \tag{12.69}$$

It is customary to define

$$r(t) = r(t + \tau, \tau) \quad \text{for all } t, \tau, -\infty < t < \infty. \tag{12.70}$$

The apparatus necessary to define continuous-time white noise is now in place.

Definition 12.22:

A scalar second-order continuous-time stochastic process, $\mathbf{x}_{(-\infty, \infty)}$ is a white-noise process if and only if

$$m(t) = E(\mathbf{x}(t)) = 0 \quad \text{for all } t, -\infty < t < \infty, \tag{12.71}$$

$$r(t) = r\delta(t), \quad r > 0, \quad -\infty < t < \infty, \tag{12.72}$$

where $\delta(t)$ is the unit impulse (equivalently, the Dirac delta) function [5]. As in discrete time, the process is Gaussian white noise if, in addition, $\mathbf{x}(t)$ is Gaussian for all t .

As in discrete time, it is often necessary to determine the properties of a stochastic process from a combination of prior knowledge and observations of one sample function. In order for this to be possible it is necessary that the process be stationary and that, in some form, averages over time of $\mathbf{x}(t), -\infty < t < \infty$, converge to expectations. Mathematically, this can be expressed as follows. Given a

stationary continuous-time stochastic process $\mathbf{x}_{(-\infty < t < \infty)}$, one wants

$$\lim_{t \rightarrow \infty} \frac{1}{2t} \int_{-t}^t f(\mathbf{x}(t)) dt = E(f(\mathbf{x}(0))) \quad (12.73)$$

to hold for any reasonable function $f(\cdot)$. This is true, with some minor technical conditions for processes that are stationary and ergodic. See [4] for an introduction to this important but difficult subject.

12.3.5 Transforms

Again, in parallel to the discrete-time case, any transform that is useful in the analysis of continuous-time signals can be applied to continuous-time stochastic processes. The two obvious candidates are the Laplace and Fourier transforms [5]. The most important application is the completely deterministic Fourier transform of the autocovariance of a wide-sense stationary continuous-time stochastic process.

Definition 12.23:

Let $\mathbf{x}_{(-\infty, \infty)}$ be a wide-sense stationary scalar continuous-time stochastic process with mean m and autocovariance $r(t)$. Assume $\int_{-\infty}^{\infty} |r(t)| dt < \infty$. Then the Fourier transform of the autocovariance function $r(t)$,

$$s(\omega) = \int_{-\infty}^{\infty} r(t) e^{-j\omega t} dt \quad (12.74)$$

is well defined and known as the spectral density of $\mathbf{x}_{(-\infty, \infty)}$.

The inverse of Equation 12.74 is the usual inverse of the Fourier transform.

$$r(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} s(\omega) e^{j\omega t} d\omega. \quad (12.75)$$

When $m = 0$,

$$r(0) = E(\mathbf{x}^2(t)) = \int_{-\infty}^{\infty} s(\omega) \frac{d\omega}{2\pi}. \quad (12.76)$$

If $\mathbf{x}_{(-\infty, \infty)}$ is a voltage, current, or velocity, then $r(0)$ can be interpreted as average power, at least to within a constant of proportionality. Then $s(\omega_0)$, where ω_0 is any fixed frequency, must be the average power per unit frequency in $\mathbf{x}_{(-\infty, \infty)}$ at the frequency ω_0 [2]. This is why $s(\omega)$ is called the spectral density.

Example 12.8:

Suppose $\mathbf{x}_{(-\infty, \infty)}$ is a white noise process (see Definition 12.24) with $r = 1$. The spectral density for this process is

$$s(\omega) = \int_{-\infty}^{\infty} \delta(t) e^{-j\omega t} dt = 1.$$

Because all frequencies are equally present, as in white light, a process having $s(\omega) = 1$ is called a white-noise process.

12.3.6 SISO Continuous-Time Linear Systems

It is convenient to begin with linear systems described by their impulse response, $h(t, \tau)$. The notation is shown in Figure 12.2.

Definition 12.24:

The impulse response of a SISO continuous-time system is denoted by $h(t, \tau)$, where $h(t, \tau)$ is the value of the output at instant t when the input is a unit impulse, $\delta(t - \tau)$, at instant τ .

The response of linear system, S , to an arbitrary input, $\mathbf{u}_{(-\infty, \infty)}$, is given by

$$y(t) = \int_{-\infty}^{\infty} h(t, \tau)u(\tau)d\tau, \quad -\infty < t < \infty. \tag{12.77}$$

Because the second-order properties of $\mathbf{y}_{(-\infty, \infty)}$ are completely described by its mean and autocovariance, it is worthwhile to know how to compute them from $h(t, \tau)$ and the second-order properties of $\mathbf{u}_{(-\infty, \infty)}$. The trick is to compute them at each time, t . That is,

$$m_y(t) \triangleq E(\mathbf{y}(t)) = E\left(\int_{-\infty}^{\infty} h(t, \tau)\mathbf{u}(\tau)d\tau\right).$$

By the linearity of integration

$$= \int_{-\infty}^{\infty} E(h(t, \tau)\mathbf{u}(\tau))d\tau.$$

Because $h(t, \tau)$ is deterministic,

$$= \int_{-\infty}^{\infty} h(t, \tau)E(\mathbf{u}(\tau))d\tau.$$

That is,

$$m_y(t) = \int_{-\infty}^{\infty} h(t, \tau)m_u(\tau)d\tau, \tag{12.78}$$

where

$$m_u(t) \triangleq E(\mathbf{u}(t)).$$

Similarly,

$$\begin{aligned} r_y(t, \tau) &= E((y(t) - m_y(t))(y(\tau) - m_y(\tau))) \\ &= E\left(\int_{-\infty}^{\infty} h(t, \sigma_1)(\mathbf{u}(\sigma_1) - m_u(\sigma_1))d\sigma_1 \int_{-\infty}^{\infty} h(\tau, \sigma_2)(\mathbf{u}(\sigma_2) - m_u(\sigma_2))d\sigma_2\right) \\ &= E\left(\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h(t, \sigma_1)h(\tau, \sigma_2)(\mathbf{u}(\sigma_1) - m_u(\sigma_1))(\mathbf{u}(\sigma_2) - m_u(\sigma_2))d\sigma_1d\sigma_2\right) \\ &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h(t, \sigma_1)h(\tau, \sigma_2)E((\mathbf{u}(\sigma_1) - m_u(\sigma_1))(\mathbf{u}(\sigma_2) - m_u(\sigma_2)))d\sigma_1d\sigma_2 \\ &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h(t, \sigma_1, \sigma_2)r_u(\sigma_1, \sigma_2)d\sigma_1d\sigma_2, \end{aligned} \tag{12.79}$$

FIGURE 12.2 Representation of a system with input $\mathbf{u}_{(-\infty, \infty)}$ and output $\mathbf{y}_{(-\infty, \infty)}$.

where

$$r_u(t, \tau) \triangleq E((\mathbf{u}(t) - m_u(t))(\mathbf{u}(\tau) - m_u(\tau))).$$

As in the discrete-time case, the Fourier transform can be used to simplify the calculations when the linear system is also time-invariant and $\mathbf{u}_{(-\infty, \infty)}$ is wide-sense stationary. Denote the impulse response by $h(t)$, where $h(t) = h(t + \tau, \tau)$. Let $m_u = E(\mathbf{u}(t))$, and $r_u(t) = E((\mathbf{u}(t + \tau) - m_u)(\mathbf{u}(\tau) - m_u))$. It is then easy to show, by paralleling the argument leading to Equation 12.41, that

$$m_y = h_f(0)m_u, \quad (12.80)$$

where

$$h_f(\omega) = \int_{-\infty}^{\infty} h(t)e^{-j\omega t} dt, \text{ the Fourier transform of } h(t).$$

Similarly,

$$r_y(t) = \int_{-\infty}^{\infty} |h_f(\omega)|^2 s_u(\omega) e^{j\omega t} \frac{d\omega}{2\pi}, \quad (12.81)$$

where $s_u(\omega)$ denotes the spectral density of $\mathbf{u}_{(-\infty, \infty)}$ (see Equation 12.74). This follows from virtually the same argument as Equation 12.42. By the uniqueness of Fourier transforms, Equation 12.81 implies

$$s_y(\omega) = |h_f(\omega)|^2 s_u(\omega). \quad (12.82)$$

It is necessary to define the notation for n -vector continuous-time stochastic processes before describing continuous-time systems in state-space form. Both of these are done in the following section.

12.3.7 Vector Continuous-Time Stochastic Process and LTI Systems

The vector case involves no new concepts but requires a more complicated notation. Because only second-order stochastic processes are discussed here all that is needed is a notation for the process, its mean, and its autocovariance.

An n -vector continuous-time stochastic process, $\underline{\mathbf{x}}_{[t_1, t_2]}$, is an n -vector random variable, $\underline{\mathbf{x}}(t) = [\mathbf{x}_1(t) \ \mathbf{x}_2(t) \ \dots \ \mathbf{x}_n(t)]'$ at each instant of time t , $t_1 \leq t \leq t_2$. As throughout this chapter, vectors are denoted by lower-case underlined letters. Random variables and stochastic processes are bold letters.

The mean of a vector stochastic process is defined at each instant of time; the autocovariance is defined for paired times. Thus, when $\underline{\mathbf{x}}(t)$ is an n -vector random variable defined for all t , $t_1 \leq t \leq t_2$ (i.e., $\underline{\mathbf{x}}_{[t_1, t_2]}$ is an n -vector stochastic process)

$$\underline{m}_x(t) = E(\underline{\mathbf{x}}(t)) \quad t_1 \leq t \leq t_2 \quad (12.83)$$

will denote its mean and

$$\underline{R}_x(t, \tau) = E((\underline{\mathbf{x}}(t) - \underline{m}_x(t))(\underline{\mathbf{x}}(\tau) - \underline{m}_x(\tau))') \quad t_1 \leq t, \quad \tau \leq t_2 \quad (12.84)$$

will denote its autocovariance. Note the transpose in Equation 12.84 and the capital \underline{R}_x . This emphasizes that the autocovariance is an $n \times n$ matrix for each pair t and τ . As in the discrete-time case, Equations 12.83 and 12.84 are evaluated element by element. Thus,

$$m_{x_i}(t) = E(\mathbf{x}_i(t)) \quad i = 1, 2, \dots, n, \quad (12.85)$$

$$r_{x_{ij}}(t, \tau) = E((\mathbf{x}_i(t) - m_{x_i}(t))(\mathbf{x}_j(\tau) - m_{x_j}(\tau))). \quad (12.86)$$

Example 12.9:

Continuous-time n -vector white noise: Any white noise must be wide-sense stationary and have zero mean. Letting $\underline{\xi}(t)$ denote an n -vector continuous-time white noise at the instant t ,

$$m_{\underline{\xi}}(t) = E(\underline{\xi}(t)) = \underline{0} \quad \text{for all } t, \quad -\infty < t < \infty, \tag{12.87}$$

$$R_{\underline{\xi}}(t, \tau) = E(\underline{\xi}(t)\underline{\xi}'(\tau)) = \underline{0} \quad \text{for all } t \neq \tau \quad -\infty < t, \tau < \infty \tag{12.88}$$

because the autocovariance of white noise must be equal to 0 except when $t = \tau$. At $t = \tau$, the autocovariance reduces to a covariance matrix (denoted by $\underline{\Xi}$, which must be positive semidefinite because it is a covariance matrix) times a unit impulse. A rigorous derivation of this is hard but the analogy to Equation 12.49 should be convincing. Thus, for all $-\infty < t, \tau < \infty$

$$R_{\underline{\xi}}(t, \tau) = \underline{\Xi}\delta(t - \tau), \tag{12.89}$$

where $\underline{\Xi}$ is any positive semidefinite matrix.

Now that vector continuous-time stochastic processes and vector white noise have been introduced it is possible to develop the state-space description of linear continuous-time systems driven by continuous-time stochastic processes. For convenience, only the case of LTI systems is described.

Example 12.10:

LTI system and white noise: Let \underline{x}_0 be an n -dimensional second-order random variable with mean m_{x_0} and covariance R_{x_0} . Let $\underline{\xi}_{[0,\infty)}$ and $\underline{\theta}_{[0,\infty)}$ be q - and p -dimensional wide-sense stationary second-order continuous-time stochastic processes satisfying, for all $t \in [0, \infty)$

$$E(\underline{\xi}(t)) = \underline{0} \text{ and } E(\underline{\theta}(t)) = \underline{0}, \tag{12.90}$$

$$R_{\underline{\xi}}(t) = E(\underline{\xi}(t + \tau)\underline{\xi}'(\tau)) = \underline{\Xi}\delta(t), \tag{12.91}$$

$$R_{\underline{\theta}}(t) = E(\underline{\theta}(t + \tau)\underline{\theta}'(\tau)) = \underline{\Theta}\delta(t), \tag{12.92}$$

where $\underline{\Xi}$ and $\underline{\Theta}$ are symmetric positive semidefinite matrices of appropriate dimension.

Strictly speaking $\underline{\xi}_{[0,\infty)}$ and $\underline{\theta}_{[0,\infty)}$ are not white noise processes because they are defined only in $[0, \infty)$. However, in the context of state-space analysis it is standard to call them white-noise processes. Obviously, what matters is not the name, but Equations 12.90 through 12.92.

For convenience, assume that

$$E((\underline{x}_0 - m_{x_0})\underline{\xi}'(t)) = \underline{0}, \tag{12.93}$$

$$E((\underline{x}_0 - m_{x_0})\underline{\theta}'(t)) = \underline{0}, \tag{12.94}$$

and

$$E(\underline{\xi}(t)\underline{\theta}'(\tau)) = \underline{0} \quad \text{for all } t, \tau \in [0, \infty). \tag{12.95}$$

The assumptions in Equations 12.93 through 12.95 remove some terms from the subsequent expressions, thereby saving space and the effort to compute them, but are otherwise inessential.

Define the n - and p -vector random variables $\underline{x}(t)$ and $\underline{y}(t)$ by

$$\frac{d\underline{x}}{dt}(t) = \underline{A}\underline{x}(t) + \underline{B}u(t) + \underline{L}\underline{\xi}(t); \quad \underline{x}(0) = \underline{x}_0, \tag{12.96}$$

$$\underline{y}(t) = \underline{C}\underline{x}(t) + \underline{\theta}(t), \tag{12.97}$$

where $u(t)$ is a deterministic m -vector, the control, and all the matrices are real, deterministic, and have the appropriate dimensions (that is, \underline{A} is $n \times n$, \underline{B} is $n \times m$, \underline{C} is $p \times n$, and \underline{L} is $n \times q$). The structure of this system is shown in Figure 12.3.

It follows from Equations 12.96 and 12.97 that $\underline{\mathbf{x}}_{[0,\infty)}$ and $\underline{\mathbf{y}}_{[0,\infty)}$ are vector continuous-time stochastic processes. Assuming that $\underline{u}(t)$ is bounded for all t guarantees that $\underline{\mathbf{x}}_{[0,t_f)}$ and $\underline{\mathbf{y}}_{[0,t_f)}$ are second-order for all finite t_f . What are their second-order statistics?

To compute the mean of $\underline{\mathbf{x}}(t)$ take the expected value of both sides of Equation 12.96. That is,

$$E(\underline{\dot{\mathbf{x}}}(t)) = E(\underline{A}\underline{\mathbf{x}}(t) + \underline{B}\underline{u}(t) + \underline{L}\underline{\xi}(t)).$$

Interchanging the order of expectation and d/dt (both are linear; so their order can be reversed) and using linearity on the right-hand side of the equation gives

$$\frac{d}{dt}E(\underline{\mathbf{x}}(t)) = \underline{A}E(\underline{\mathbf{x}}(t)) + \underline{B}\underline{u}(t); \quad E(\underline{\mathbf{x}}(0)) = \underline{m}_{x_0} \tag{12.98}$$

or

$$\dot{\underline{m}}_x(t) = \underline{A}\underline{m}_x(t) + \underline{B}\underline{u}(t); \quad \underline{m}_x(0) = \underline{m}_{x_0}.$$

This is just a deterministic ordinary differential equation in state-space form for $E(\underline{\mathbf{x}}(t))$. Once $E(\underline{\mathbf{x}}(t))$ has been computed, taking expectation of both sides of Equation 12.97 gives

$$E(\underline{\mathbf{y}}(t)) = \underline{C}E(\underline{\mathbf{x}}(t)). \tag{12.99}$$

This is a deterministic algebraic equation.

A derivation of the autocovariance of $\underline{\mathbf{x}}_{[0,t_f)}$ is beyond the scope of this chapter. A derivation can be found in [6, pp. 111–113].

The result is that

$$\underline{R}_x(t, t) = E((\underline{\mathbf{x}}(t) - \underline{m}_x(t))(\underline{\mathbf{x}}(t) - \underline{m}_x(t))')$$

satisfies the differential equation

$$\dot{\underline{R}}_x(t, t) = \underline{A}\underline{R}_x(t, t) + \underline{R}_x(t, t)\underline{A}' + \underline{L}\underline{\Xi}\underline{L}' \tag{12.100}$$

with initial condition $\underline{R}_x(0, 0) = \underline{R}_{x_0}$ and $\underline{R}_x(t, \tau)$, with $t \geq \tau$, satisfies the differential equation

$$\frac{\partial \underline{R}_x(t, \tau)}{\partial t} = \underline{A}\underline{R}_x(t, \tau) \tag{12.101}$$

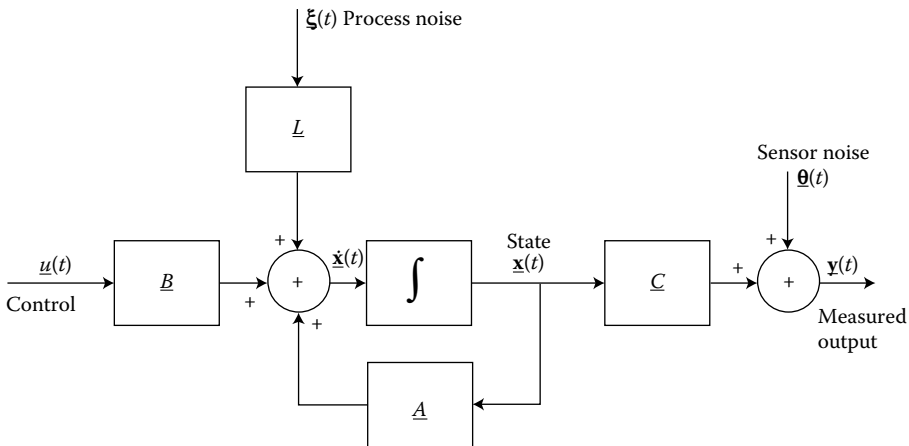

FIGURE 12.3 Block diagram of the LTI system described by Equations 12.96 and 12.97.

while $\underline{R}_x(\tau, t)$, again with $t \geq \tau$, satisfies

$$\frac{\partial R_x(\tau, t)}{\partial t} = R_x(\tau, t) \underline{A}' \tag{12.102}$$

The initial condition for both Equations 12.102 and 12.103 is $\underline{R}_x(\tau, \tau)$, computed from Equation 12.100.

12.4 Conclusions

The second-order properties of many zero-mean stochastic processes can be reproduced by an LTI system with white-noise input. The precise result for scalar continuous-time systems is the following [2]. Let $s(\omega)$ be a real nonnegative absolutely integrable function such that

$$\int_{-\infty}^{\infty} \frac{|\ln s(\omega)|}{1 + \omega^2} d\omega < \infty. \tag{12.103}$$

Then there exists a square integrable function $h_f(\omega)$, $-\infty < \omega < \infty$, such that

$$|h_f(\omega)|^2 = s(\omega), \tag{12.104}$$

$$h(t) = \int_{-\infty}^{\infty} h_f(\omega) e^{j\omega t} \frac{d\omega}{2\pi} = 0 \quad \text{for } t < 0, \tag{12.105}$$

$$h_f(\sigma + j\omega) = \int_{-\infty}^{\infty} e^{j(\sigma + j\omega)t} h(t) dt \neq 0, \quad \omega > 0, \tag{12.106}$$

Because the spectral density of white noise is one for all ω , Equation 12.104 means that the spectral density, $s(\omega)$, is identical to the spectral density of the output of an LTI system with impulse response $h(t)$ driven by a white-noise input. Equation 12.105 means that $h(t)$ is causal. Equation 12.106 means that the transfer function $h_f(\omega)$ is minimum phase. Similar results hold in discrete time and for vector signals [7,8].

The restriction to second-order processes with zero mean is unimportant because the mean is deterministic. Thus, the only significant limitation on the use of a linear system driven by white noise as a model for second-order stochastic processes is Equation 12.103. The major limitation of the model is that the second-order statistics are not always a good description of a stochastic process. The second-order statistics are most useful when the process is approximately Gaussian. Processes that are very different from Gaussian, especially in the vicinity of the mean, are not usually well modeled by their second-order statistics.

12.5 Notation

Lower case letters such as x , y , and r denote real, deterministic scalars. The same letters when underlined denote vectors.

Lower case letters i, j, k, ℓ, m , and n denote integers (j is also used to indicate $\sqrt{-1}$ and m for mean—the meaning should be evident from the context).

Upper case, underlined, capital letters such as \underline{A} , \underline{B} , \underline{C} , \underline{L} , $\underline{\Theta}$, and $\underline{\Xi}$ denote real deterministic matrices.

Lower case, bold letters such as \mathbf{x} and \mathbf{y} denote scalar random variables. The same letters when underlined denote vector random variables (or discrete-time stochastic processes).

Upper case, underlined bold letters such as $\underline{\mathbf{X}}$, $\underline{\mathbf{Y}}$, $\underline{\mathbf{\Theta}}$, and $\underline{\mathbf{\Xi}}$ denote vector discrete-time stochastic processes.

Lower case, bold letters with interval subscripts such as $\mathbf{x}_{(-\infty, \infty)}$ denote stochastic processes.

13.1 Introduction

The purpose of this chapter is to provide an overview of Kalman filtering concepts. We cover only a small portion of the material associated with Kalman filters. Our choice of material is primarily motivated by the material needed in the design and analysis of multivariable feedback control systems for linear time-invariant (LTI) systems and, more specifically, by the design philosophy commonly called the linear quadratic Gaussian (LQG) method. Thus, from a technical perspective, we cover, without proofs, the so-called steady-state, constant-gain LTI Kalman filters.

More details regarding different formulations and solutions of Kalman filtering problems (continuous-time linear time-varying, discrete-time linear time-varying, and time-invariant) can be found in several classic and standard textbooks on the subject of estimation theory. Please see Further Reading at the end of this chapter.

The steady-state constant-gain Kalman filter is an algorithm that is used to estimate the state variables of a continuous-time LTI system, subject to stochastic disturbances, on the basis of noisy measurements of certain output variables. Thus, the Kalman filtering algorithm combines the information regarding the plant dynamics, the probabilistic information regarding the stochastic disturbances that influence the plant state variables, as well as that regarding the measurement noise that corrupts the sensor measurements, and the deterministic controls.

Credit for “inventing” this algorithm is usually given to Dr. Rudolph E. Kalman, who presented the key ideas in the late 1950s and early 1960s. Although the Kalman filter is an alternative representation of the Wiener filter [1], Kalman’s contribution was to tie the state estimation problem to the state-space models, and the (then new) concepts of controllability and observability [2–5]. Thousands of papers have been

written about the Kalman filter and its numerous applications to navigation, tracking, and estimator and controller design in defense and industrial applications.

13.2 Problem Definition

In this section we present the definition of the basic stochastic estimation problem for which the Kalman filter (KF) yields an “optimal” solution. First we present the plant state dynamics. We deal with a finite-dimensional LTI system whose state vector $\underline{\mathbf{x}}(t)$, $\underline{\mathbf{x}}(t) \in R^n$ (a real n -vector), obeys the stochastic differential equation

$$\dot{\underline{\mathbf{x}}}(t) = \underline{A}\underline{\mathbf{x}}(t) + \underline{B}\underline{\mathbf{u}}(t) + \underline{L}\underline{\xi}(t) \quad (13.1)$$

where $\underline{\mathbf{u}}(t)$, $\underline{\mathbf{u}}(t) \in R^m$ is the deterministic control vector (assumed known), $\underline{\xi}(t)$, $\underline{\xi}(t) \in R^q$ is a vector-valued stochastic process, often called the *process noise*, that acts as a disturbance to the plant dynamics. Vectors are underlined, lower case letters and matrices are underlined, upper case letters. The process noise $\underline{\xi}(t)$ is assumed to have certain statistical properties, corresponding to a stationary (time-invariant) continuous-time *white* Gaussian noise with zero mean, i.e.,

$$E\{\underline{\xi}(t)\} = 0, \quad \text{for all } t \quad (13.2)$$

and its covariance matrix is defined by

$$\text{cov} [\underline{\xi}(t); \underline{\xi}(\tau)] = E\{\underline{\xi}(t)\underline{\xi}'(\tau)\} = \underline{\Xi}\delta(t - \tau) \quad (13.3)$$

with $\delta(t - \tau)$ being the Dirac delta function (impulse at $t = \tau$). The matrix $\underline{\Xi}$ is called the intensity matrix of $\underline{\xi}(t)$ and it is a symmetric positive definite matrix, i.e.,

$$\underline{\Xi} = \underline{\Xi}' > 0 \quad (13.4)$$

Remark 13.1

Continuous-time white noise does not exist in nature; it is the limit of a broadband stochastic process. In the frequency domain, continuous-time white noise corresponds to a stochastic process with constant power spectral density as a function of frequency. This implies that continuous-time white noise has constant power at all frequencies, and therefore has infinite energy! White noise is completely unpredictable, as can be seen from Equation 13.3 because it is uncorrelated for any $t \neq \tau$, while it has finite variance and standard deviation at $t = \tau$. This is obviously an approximation to reality. As with the Dirac delta function, $\delta(t)$, white noise creates some subtle mathematical issues, but is nonetheless extremely useful in engineering.

Remark 13.2

The state $\underline{\mathbf{x}}(t)$, the solution of Equation 13.1, is a well-defined physical stochastic process, a so-called colored Gaussian random process, and it has finite energy. Its power spectral density rolls off at high frequencies.

Next, we turn our attention to the measurement equation. We assume that our sensors cannot directly measure all of the physical state variables, the components of the vector $\underline{\mathbf{x}}(t)$ of the plant given in Equation 13.1. Rather, in the classical Kalman filter formulation we assume that we can measure only certain output variables (linear combinations of the state variables) in the presence of additive continuous-time white noise.

The mathematical model of the measurement process is as follows:

$$\underline{y}(t) = \underline{C}\underline{x}(t) + \underline{\theta}(t) \tag{13.5}$$

The vector $\underline{y}(t) \in R^p$ represents the sensor measurement. The measurement or sensor noise $\underline{\theta}(t) \in R^p$ is assumed to be a continuous-time white Gaussian random process, independent of $\underline{\xi}(t)$, with zero mean, i.e.,

$$E\{\underline{\theta}(t)\} = 0, \quad \text{for all } t \tag{13.6}$$

and covariance matrix

$$\text{cov} [\underline{\theta}(t); \underline{\theta}(\tau)] = E\{\underline{\theta}(t)\underline{\theta}'(\tau)\} = \underline{\Theta}\delta(t - \tau) \tag{13.7}$$

where the sensor noise intensity matrix is symmetric and positive definite, i.e.,

$$\underline{\Theta} = \underline{\Theta}' > 0 \tag{13.8}$$

Figure 13.1 shows a visualization, in block diagram form, of Equations 13.1 and 13.5.

13.2.1 The State Estimation Problem

Imagine that we have been observing the control $\underline{u}(\tau)$ and the output $\underline{y}(\tau)$ over the infinite past up to the present time t . Let

$$U(t) = \{\underline{u}(\tau); -\infty < \tau \leq t\} \tag{13.9}$$

$$Y(t) = \{\underline{y}(\tau); -\infty < \tau \leq t\} \tag{13.10}$$

denote the past histories of the control and output, respectively.

The state estimation problem is as follows: given $U(t)$ and $Y(t)$, find a vector $\hat{\underline{x}}(t)$, at time t , which is an “optimal” estimate of the present state $\underline{x}(t)$ of the system defined by Equation 13.1.

Under the stated assumptions regarding the Gaussian nature of $\underline{\xi}(t)$ and $\underline{\theta}(t)$ the “optimal” state estimate is the same for an extremely large class of optimality criteria [6]. This generally optimal estimate

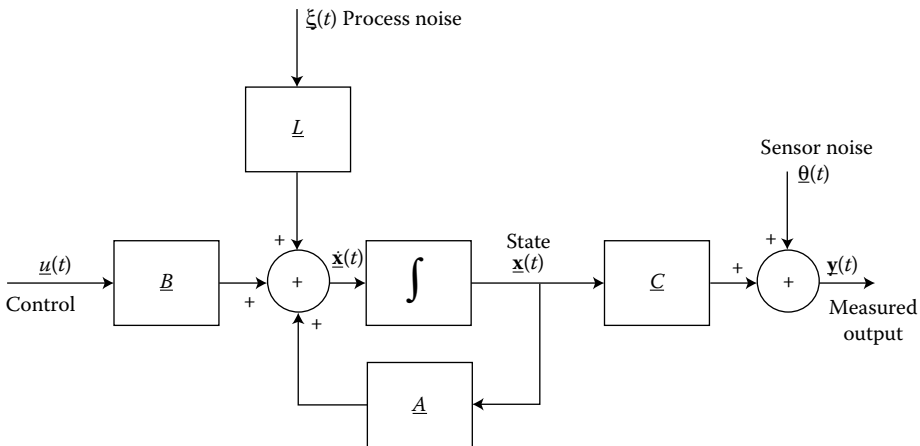

FIGURE 13.1 A stochastic linear dynamic system.

is the conditional mean of the state, i.e.,

$$\hat{\underline{\mathbf{x}}}(t) \triangleq E\{\underline{\mathbf{x}}(t)|U(t), Y(t)\} \quad (13.11)$$

One can relax the Gaussian assumption and define the optimality of the state estimate $\hat{\underline{\mathbf{x}}}(t)$ in different ways. One popular way is to demand that $\hat{\underline{\mathbf{x}}}(t)$ be generated by a *linear* transformation on the past “data” $U(t)$ and $Y(t)$, such that the state estimation error $\tilde{\underline{\mathbf{x}}}(t)$

$$\tilde{\underline{\mathbf{x}}} \triangleq \underline{\mathbf{x}}(t) - \hat{\underline{\mathbf{x}}}(t) \quad (13.12)$$

has zero mean, i.e.,

$$E\{\tilde{\underline{\mathbf{x}}}(t)\} = \underline{\mathbf{0}} \quad (13.13)$$

and the cost functional

$$J = E \left\{ \sum_{i=1}^n \tilde{\mathbf{x}}_i^2(t) \right\} = E \{ \tilde{\underline{\mathbf{x}}}'(t) \tilde{\underline{\mathbf{x}}}(t) \} = \text{tr}[E\{\tilde{\underline{\mathbf{x}}}(t) \tilde{\underline{\mathbf{x}}}'(t)\}] \quad (13.14)$$

is minimized.

The cost functional J has the physical interpretation that it is the sum of the error variances $E\{\tilde{\mathbf{x}}_i^2(t)\}$ for each state variable. If we let $\underline{\Sigma}$ denote the covariance matrix (stationary) of the state estimation error

$$\underline{\Sigma} \triangleq E\{\tilde{\underline{\mathbf{x}}}(t) \tilde{\underline{\mathbf{x}}}'(t)\} \quad (13.15)$$

then the cost, J , of Equation 13.14 can also be written as

$$J = \text{tr}[\underline{\Sigma}] \quad (13.16)$$

Bottom Line: We need an algorithm that translates the signals we can observe, $\underline{\mathbf{u}}(t)$ and $\underline{\mathbf{y}}(t)$, into a state estimate $\hat{\underline{\mathbf{x}}}(t)$, such that the state estimation error $\tilde{\underline{\mathbf{x}}}$ is “small” in some well-defined sense. The KF is the algorithm that does just that!

13.3 Summary of the Kalman Filter Equations

13.3.1 Additional Assumptions

In this section we summarize the on-line and off-line equations that define the Kalman filter. Before we do that we make two additional “mild” assumptions

$$[\underline{\mathbf{A}}, \underline{\mathbf{L}}] \text{ is stabilizable (or controllable)} \quad (13.17)$$

$$[\underline{\mathbf{A}}, \underline{\mathbf{C}}] \text{ is detectable (or observable)} \quad (13.18)$$

$[\underline{\mathbf{A}}, \underline{\mathbf{L}}]$ is controllable, means that the process noise $\underline{\xi}(t)$ excites all modes of the system defined by Equation 13.1; $[\underline{\mathbf{A}}, \underline{\mathbf{C}}]$ is observable means that the “noiseless” output $\underline{\mathbf{y}}(t) = \underline{\mathbf{C}}\underline{\mathbf{x}}(t)$ contains information about all state variables. If $[\underline{\mathbf{A}}, \underline{\mathbf{L}}]$ is stabilizable, the modes of the system that are not excited by $\underline{\xi}(t)$ are asymptotically stable; if $[\underline{\mathbf{A}}, \underline{\mathbf{C}}]$ is detectable, the unobserved modes are asymptotically stable.

13.3.2 The Kalman Filter Dynamics

The function of the KF is to generate in real time the state estimate $\hat{\underline{\mathbf{x}}}(t)$ of the state $\underline{\mathbf{x}}(t)$. The KF is actually an LTI dynamic system, of identical order (n) to the plant Equation 13.1, and is driven by (1) the

deterministic control input $\underline{u}(t)$, and (2) the measured output vector $\underline{y}(t)$. The Kalman filter dynamics are given as follows:

$$\frac{d\hat{\underline{x}}(t)}{dt} = \underline{A}\hat{\underline{x}}(t) + \underline{B}u(t) + \underline{H}[\underline{y}(t) - \underline{C}\hat{\underline{x}}(t)] \tag{13.19}$$

A block diagram visualization of Equation 13.19 is shown in Figure 13.2. Note that in Equation 13.19 all variables have been defined previously, except for the KF gain matrix \underline{H} , whose calculation is carried out off-line and is discussed shortly.

The filter gain matrix \underline{H} multiplies the so-called *residual* or *innovations* vector

$$\underline{r}(t) \triangleq \underline{y}(t) - \underline{C}\hat{\underline{x}}(t) \tag{13.20}$$

and updates the time rate of change, $d\hat{\underline{x}}(t)/dt$, of the state estimate $\hat{\underline{x}}(t)$. The residual $\underline{r}(t)$ is like an “error” between the *measured* output $\underline{y}(t)$, and the *predicted* output $\underline{C}\hat{\underline{x}}(t)$.

Remark 13.3

From an intuitive point of view the KF, defined by Equation 13.19 and illustrated in Figure 13.2, can be thought as a model-based observer or state reconstructor. The reader should carefully compare the structures depicted in Figures 13.1 and 13.2. The plant/sensor properties, reflected by the matrices \underline{A} , \underline{B} , and \underline{C} , are duplicated in the KF*. The state estimate $\hat{\underline{x}}(t)$ is continuously updated by the actual sensor measurements, through the formation of the residual $\underline{r}(t)$ and the “closing” of the loop with the filter gain matrix \underline{H} .

The KF dynamics of Equation 13.19 can also be written in the form

$$\frac{d\hat{\underline{x}}(t)}{dt} = [\underline{A} - \underline{H}\underline{C}]\hat{\underline{x}}(t) + \underline{B}u(t) + \underline{H}\underline{y}(t) \tag{13.21}$$

From the structure of Equation 13.21 we can immediately see that the stability of the KF is governed by the matrix $\underline{A} - \underline{H}\underline{C}$. At this point of our development we remark that the assumption in Equation 13.18,

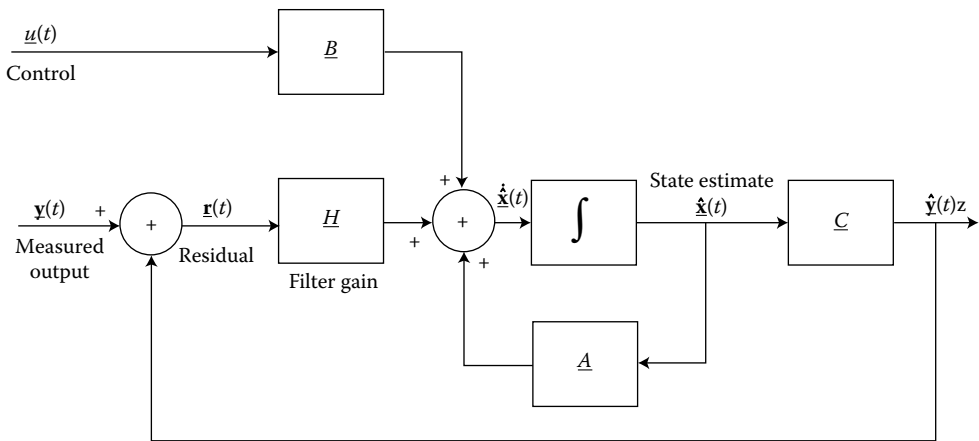

FIGURE 13.2 The structure of the Kalman Filter. The control, $\underline{u}(t)$, and measured output, $\underline{y}(t)$, are those associated with the stochastic system of Figure 13.1. The filter gains matrix \underline{H} is computed in a special way.

* No signal corresponding to $\underline{L}\xi(t)$ shows up in Figure 13.2. This is because we assumed that $\xi(t)$ had zero-mean and was completely unpredictable. Thus, the best estimate for $\xi(t)$ given data up to time t is 0.

i.e., the detectability of $[A, C]$, guarantees the existence of at least one filter gain matrix \underline{H} such that the KF is stable, i.e.,

$$\operatorname{Re}\lambda_i[\underline{A} - \underline{H}\underline{C}] < 0; \quad i = 1, 2, \dots, n \quad (13.22)$$

where λ_i is the i th eigenvalue of $[\underline{A} - \underline{H}\underline{C}]$.

13.3.3 Properties of Model-Based Observers

We have remarked that the KF gain matrix \underline{H} is calculated in a very special way. However, it is extremely useful to examine the structure of Equations 13.19 or 13.21 and Figure 13.2 with a filter gain matrix \underline{H} that is arbitrary except for the requirement that Equation 13.22 holds. Thus, for the development that follows in this subsection think of \underline{H} as being a fixed matrix.

As before let $\tilde{\underline{x}}(t)$ denote the state estimation error vector

$$\tilde{\underline{x}}(t) \triangleq \underline{\mathbf{x}}(t) - \hat{\underline{\mathbf{x}}}(t) \quad (13.23)$$

It follows that

$$\frac{d\tilde{\underline{x}}(t)}{dt} = \frac{d\underline{\mathbf{x}}(t)}{dt} - \frac{d\hat{\underline{\mathbf{x}}}(t)}{dt} \quad (13.24)$$

Next, we substitute Equations 13.1, 13.5, and 13.21 into Equation 13.24 and use Equation 13.23 as appropriate. After some easy algebraic manipulations we obtain the following stochastic vector differential equation for the state estimation error $\tilde{\underline{x}}(t)$:

$$\frac{d\tilde{\underline{x}}(t)}{dt} = [\underline{A} - \underline{H}\underline{C}]\tilde{\underline{x}}(t) + \underline{L}\xi(t) - \underline{H}\theta(t) \quad (13.25)$$

Note that, in view of Equation 13.22, the estimation error dynamic system is stable. Also note that the deterministic signal $\underline{B}u(t)$ does not appear in the error Equation 13.25.

Under our assumptions that the system is stable and was started at the indefinite past ($t_0 \rightarrow -\infty$), it is easy to verify that

$$E\{\tilde{\underline{x}}(t)\} = \underline{0} \quad (13.26)$$

This implies that any stable model-based estimator of the form shown in Figure 13.2, with any filter gain matrix \underline{H} , gives us *unbiased* (that is, $E(\hat{\underline{\mathbf{x}}}(t)) = E(\underline{\mathbf{x}}(t))$) estimates.

Using next elementary facts from stochastic linear system theory one can calculate the error covariance matrix $\underline{\Sigma}$ of the state estimation error $\tilde{\underline{x}}(t)$

$$\underline{\Sigma} \triangleq \operatorname{cov}[\tilde{\underline{\mathbf{x}}}(t); \tilde{\underline{\mathbf{x}}}(t)] = E\{\tilde{\underline{\mathbf{x}}}(t)\tilde{\underline{\mathbf{x}}}'(t)\} \quad (13.27)$$

The matrix $\underline{\Sigma}$ is the solution of the so-called *Lyapunov matrix equation* (linear in $\underline{\Sigma}$)

$$[\underline{A} - \underline{H}\underline{C}]\underline{\Sigma} + \underline{\Sigma}(\underline{A} - \underline{H}\underline{C})' + \underline{L}\underline{\Xi}\underline{L}' + \underline{H}\underline{\Theta}\underline{H}' = \underline{0} \quad (13.28)$$

with

$$\underline{\Sigma} = \underline{\Sigma}' \geq \underline{0} \quad (13.29)$$

Thus, for any given filter gain matrix \underline{H} we can calculate* the associated error covariance matrix $\underline{\Sigma}$ from Equation 13.28. Recalling Equation 13.16, we can evaluate, for a given \underline{H} , the quality of the estimator by calculating

$$J = \operatorname{tr}[\underline{\Sigma}] \quad (13.30)$$

The specific way that the KF gain is calculated is by solving a constrained static deterministic optimization problem. Minimize Equation 13.30 with respect to the elements h_{ij} of the matrix \underline{H} subject to the algebraic constraints given in Equations 13.28 and 13.29.

* The MATLAB[®] and MATRIXx[™] software packages can solve Lyapunov equations.

13.3.4 The Kalman Filter Gain and Associated Filter Algebraic Riccati Equation (FARE)

We now summarize the off-line calculations that define fully the Kalman filter (Equation 13.19 or 13.21).

The KF gain matrix \underline{H} is computed by

$$\underline{H} = \underline{\Sigma} \underline{C}' \underline{\Theta}^{-1} \quad (13.31)$$

where $\underline{\Sigma}$ is the unique, symmetric, and at least positive semidefinite solution matrix of the so-called filter algebraic Riccati equation (FARE)

$$\underline{0} = \underline{A} \underline{\Sigma} + \underline{\Sigma} \underline{A}' + \underline{L} \underline{E} \underline{L}' - \underline{\Sigma} \underline{C}' \underline{\Theta}^{-1} \underline{C} \underline{\Sigma} \quad (13.32)$$

with

$$\underline{\Sigma} = \underline{\Sigma}' \geq \underline{0} \quad (13.33)$$

Remark 13.4

The formula for the KF gain can be obtained by setting

$$\frac{\partial}{\partial h_{ij}} \text{tr}[\underline{\Sigma}] = 0 \quad (13.34)$$

where $\underline{\Sigma}$ is given by Equation 13.28. The result is Equation 13.31. Substituting Equation 13.31 into Equation 13.28 one deduces the FARE (Equation 13.32).

13.3.5 Duality between the KF and LQ Problems

The mathematical problems associated with the solution of the LQ and KF are dual. This duality was recognized by R.E. Kalman as early as 1960 [2].

The duality can be used to deduce several properties of the KF simply by “dualizing” the results of the LQ problem. A summary of the KF properties is given in Section 13.4.

13.4 Kalman Filter Properties

13.4.1 Introduction

In this section we summarize the key properties of the Kalman filter. These properties are the “dual” of those for the LQ controller.

13.4.2 Guaranteed Stability

Recall that the KF algorithm is

$$\frac{d\hat{\mathbf{x}}(t)}{dt} = [\underline{A} - \underline{H}\underline{C}]\hat{\mathbf{x}}(t) + \underline{B}u(t) + \underline{H}\underline{y}(t) \quad (13.35)$$

Then, under the assumptions of Section 35.3, the matrix $[\underline{A} - \underline{H}\underline{C}]$ is strictly stable, i.e.,

$$\text{Re}\lambda_i[\underline{A} - \underline{H}\underline{C}] < 0; \quad i = 1, 2, \dots, n \quad (13.36)$$

13.4.3 Frequency Domain Equality

One can readily derive a frequency domain equality for the KF. In the development that follows, let

$$\underline{\Xi} = \underline{I} \quad (13.37)$$

Let us make the following definitions: let $\underline{G}_{KF}(s)$ denote the KF loop-transfer matrix

$$\underline{G}_{KF}(s) \triangleq \underline{C}(s\underline{I} - \underline{A})^{-1}\underline{H} \quad (13.38)$$

$$\underline{G}_{KF}^H(s) \triangleq \underline{H}'(-s\underline{I} - \underline{A}')^{-1}\underline{C}' \quad (13.39)$$

where $[A]^H$ denotes the complex conjugate of the transpose of an arbitrary complex matrix A . Let $\underline{G}_{FOL}(s)$ denote the filter open-loop transfer matrix (from $\underline{\xi}(t)$ to $\underline{y}(t)$)

$$\underline{G}_{FOL}(s) \triangleq \underline{C}(s\underline{I} - \underline{A})^{-1}\underline{L} \quad (13.40)$$

$$\underline{G}_{FOL}^H(s) \triangleq \underline{L}'(-s\underline{I} - \underline{A}')^{-1}\underline{C}' \quad (13.41)$$

Then the following equality holds

$$[\underline{I} + \underline{G}_{KF}(s)]\underline{\Theta}[\underline{I} + \underline{G}_{KF}(s)]^H = \underline{\Theta} + \underline{G}_{FOL}(s)\underline{G}_{FOL}^H(s) \quad (13.42)$$

If

$$\underline{\Theta} = \mu\underline{I} \quad \mu > 0 \quad (13.43)$$

then Equation 13.42 reduces to

$$[\underline{I} + \underline{G}_{KF}(s)][\underline{I} + \underline{G}_{KF}(s)]^H = \underline{I} + \frac{1}{\mu}\underline{G}_{FOL}(s)\underline{G}_{FOL}^H(s) \quad (13.44)$$

13.4.4 Guaranteed Robust Properties

The KF enjoys the same type of robustness properties as the LQ regulator. The following properties are valid if

$$\underline{\Theta} = \text{diagonal matrix} \quad (13.45)$$

From the frequency domain equality (Equation 13.42) we deduce the inequality

$$[\underline{I} + \underline{G}_{KF}(s)][\underline{I} + \underline{G}_{KF}(s)]^H \geq \underline{I} \quad (13.46)$$

From the definition of singular values we then deduce that

$$\sigma_{\min}[\underline{I} + \underline{G}_{KF}(s)] \geq 1 \quad \text{or} \quad \sigma_{\max}[\underline{I} + \underline{G}_{KF}(s)]^{-1} \leq 1 \quad (13.47)$$

$$\sigma_{\min}[\underline{I} + \underline{G}_{KF}^{-1}(s)] \geq \frac{1}{2} \quad \text{or} \quad \sigma_{\max}[\underline{I} + \underline{G}_{KF}(s)]^{-1}\underline{G}_{KF} \leq 2 \quad (13.48)$$

13.5 The Accurate Measurement Kalman Filter

We summarize the properties of the Kalman Filter (KF) problem when the intensity of the sensor noise approaches zero. In a mathematical sense this is the “dual” of the so-called “cheap-control” LQR problem. The results are fundamental to the loop transfer recovery (LTR) method applied at the plant input.

13.5.1 Problem Definition

Consider as before, the stochastic LTI system

$$\dot{\underline{\mathbf{x}}}(t) = \underline{\mathbf{A}}\underline{\mathbf{x}}(t) + \underline{\mathbf{L}}\underline{\xi}(t) \quad (13.49)$$

$$\underline{\mathbf{y}}(t) = \underline{\mathbf{C}}\underline{\mathbf{x}}(t) + \underline{\theta}(t) \quad (13.50)$$

We assume that the process noise $\underline{\xi}(t)$ is white, zero-mean, and with unit intensity, i.e.,

$$E\{\underline{\xi}(t)\underline{\xi}'(\tau)\} = \underline{\mathbf{I}}\delta(t - \tau) \quad (13.51)$$

We also assume that the measurement noise $\underline{\theta}(t)$ is white, zero-mean, and with intensity indexed by μ , that is,

$$E\{\underline{\theta}(t)\underline{\theta}'(\tau)\} = \mu\underline{\mathbf{I}}\delta(t - \tau) \quad (13.52)$$

Definition 13.1:

The accurate measurement KF problem is defined by the limiting case

$$\mu \rightarrow 0 \quad (13.53)$$

corresponding to essentially noiseless measurements.

Under the assumptions that $[\underline{\mathbf{A}}, \underline{\mathbf{L}}]$ is stabilizable and that $[\underline{\mathbf{A}}, \underline{\mathbf{C}}]$ is detectable we know that the KF is a stable system and generates the state estimates $\hat{\underline{\mathbf{x}}}(t)$ by

$$\frac{d\hat{\underline{\mathbf{x}}}(t)}{dt} = [\underline{\mathbf{A}} - \underline{\mathbf{H}}_\mu \underline{\mathbf{C}}]\hat{\underline{\mathbf{x}}}(t) + \underline{\mathbf{H}}_\mu \underline{\mathbf{y}}(t) \quad (13.54)$$

where we use the subscript μ to stress the dependence of the KF gain matrix $\underline{\mathbf{H}}_\mu$ upon the parameter μ .

We recall that $\underline{\mathbf{H}}_\mu$ is computed by

$$\underline{\mathbf{H}}_\mu = \frac{1}{\mu} \underline{\Sigma}_\mu \underline{\mathbf{C}}' \quad (13.55)$$

where the error covariance matrix $\underline{\Sigma}_\mu$, also dependent upon μ , is calculated by the solution of the FARE:

$$\underline{\mathbf{0}} = \underline{\mathbf{A}}\underline{\Sigma}_\mu + \underline{\Sigma}_\mu \underline{\mathbf{A}}' + \underline{\mathbf{L}}\underline{\mathbf{L}}' - \frac{1}{\mu} \underline{\Sigma}_\mu \underline{\mathbf{C}}' \underline{\mathbf{C}} \underline{\Sigma}_\mu \quad (13.56)$$

We seek insight about the limiting behavior of both $\underline{\Sigma}_\mu$ and $\underline{\mathbf{H}}_\mu$ as $\mu \rightarrow 0$.

13.5.2 The Main Result

In this section we summarize the main result in terms of a theorem.

Theorem 13.1:

Suppose that the transfer function matrix from the white noise $\underline{\xi}(t)$ to the output $\underline{\mathbf{y}}(t)$ for the system defined by Equations 13.49 and 13.50, i.e., the transfer function matrix

$$\underline{W}(s) \triangleq \underline{C}(s\underline{I} - \underline{A})^{-1}\underline{L} \quad (13.57)$$

is minimum phase. Then,

$$\lim_{\mu \rightarrow 0} \underline{\Sigma}_\mu = \underline{0} \quad (13.58)$$

and

$$\lim_{\mu \rightarrow 0} \sqrt{\mu} \underline{H}_\mu = \underline{LW}; \quad \underline{W}'\underline{W} = \underline{I} \quad (13.59)$$

Proof. This is theorem 4.14 in Kwakernaak and Sivan [7], pp. 370–371.

Remark 13.5

It can be shown that the requirement that $\underline{W}(s)$, given by Equation 13.57, be minimum phase is both a necessary and sufficient condition for the limiting properties given by Equations 13.58 and 13.59.

Remark 13.6

The implication of Equation 13.58 is that, in the case of exact measurements upon a minimum phase plant, the KF yields exact state estimates, since the error covariance matrix is zero. This assumes that the KF has been operating upon the data for a sufficiently long time so that initial transient errors have died out.

Remark 13.7

For a non-minimum phase plant

$$\lim_{\mu \rightarrow 0} \underline{\Sigma}_\mu \neq \underline{0} \quad (13.60)$$

Hence, perfect state estimation is impossible for non-minimum phase plants.

Remark 13.8

The limiting behavior (with $\underline{L} = \underline{B}$) of the Kalman Filter gain

$$\lim_{\mu \rightarrow 0} \sqrt{\mu} \underline{H}_\mu = \underline{BW}; \quad \underline{W}'\underline{W} = \underline{I} \quad (13.61)$$

is the precise dual of the limiting behavior of the LQ control gain

$$\lim_{\rho \rightarrow 0} \sqrt{\rho} \underline{G}_\rho = \underline{WC}; \quad \underline{W}'\underline{W} = \underline{I} \quad (13.62)$$

for the minimum phase plant

$$\underline{G}(s) = \underline{C}(s\underline{I} - \underline{A})^{-1}\underline{B} \quad (13.63)$$

The relation (Equation 13.61) has been used by Doyle and Stein [8] to apply the LTR method at the plant input, while Equation 13.62 has been used by Kwakernaak [9] to apply the LTR method at the plant output (see also Kwakernaak and Sivan [7], pp. 419–427).

14.1 Introduction

An ordinary differential equation of the form

$$\dot{x}(t) + f(t)x(t) - b(t)x^2(t) + c(t) = 0 \quad (14.1)$$

is known as a *Riccati equation*, deriving its name from Jacopo Francesco, Count Riccati (1676–1754) [1,2], who studied a particular case of this equation from 1719 to 1724.

For several reasons, a differential equation of the form of Equation 14.1, and generalizations thereof comprise a highly significant class of nonlinear ordinary differential equations. First, they are intimately related to ordinary linear homogeneous differential equations of the second order. Second, the solutions of Equation 14.1 possess a very particular structure in that the general solution is a fractional linear function in the constant of integration. In applications, Riccati differential equations appear in the classical problems of the calculus of variations and in the associated disciplines of optimal control and filtering.

The *matrix* Riccati differential equation refers to the equation [3–5]

$$\dot{X}(t) + X(t)A(t) - D(t)X(t) - X(t)B(t)X(t) + C(t) = 0 \quad (14.2)$$

defined on the vector space of real $m \times n$ matrices. Here, A, B, C , and D are real matrix functions of the appropriate dimensions. Of particular interest are the matrix Riccati equations that arise in optimal control and filtering problems and that enjoy certain symmetry properties. This chapter is concerned

with these symmetric matrix Riccati differential equations and concentrates on the following four major topics:

- Basic properties of the solutions
- Existence and properties of constant solutions
- Asymptotic behavior of the solutions
- Methods for the numerical solution of the Riccati equations

14.2 Optimal Control and Filtering: Motivation

The following problems of optimal control and filtering are of great engineering importance and serve to motivate our study of the Riccati equations.

A linear-quadratic *optimal control* problem [6] consists of the following. Given a linear system

$$\dot{x}(t) = Fx(t) + Gu(t), \quad x(t_0) = c, \quad y(t) = Hx(t), \quad (14.3)$$

where x is the n -vector state, u is the q -vector control input, y is the p -vector of regulated variables, and F, G, H are constant real matrices of the appropriate dimensions. One seeks to determine a control input function u over some fixed time interval $[t_1, t_2]$ such that a given quadratic cost functional of the form

$$\eta(t_1, t_2, T) = \int_{t_1}^{t_2} [y'(t)y(t) + u'(t)u(t)] dt + x'(t_2)Tx(t_2), \quad (14.4)$$

with T being a constant real symmetric ($T = T'$) and nonnegative definite ($T \geq 0$) matrix, is afforded a minimum in the class of all solutions of Equation 14.3, for any initial state c .

A unique optimal control exists for all finite $t_2 - t_1 > 0$ and has the form

$$u(t) = -G'P(t, t_2, T)x(t),$$

where $P(t, t_2, T)$ is the solution of the matrix Riccati differential equation

$$-\dot{P}(t) = P(t)F + F'P(t) - P(t)GG'P(t) + H'H \quad (14.5)$$

subject to the terminal condition

$$P(t_2) = T.$$

The optimal control is a linear state feedback, which gives rise to the closed-loop system

$$\dot{x}(t) = [F - GG'P(t, t_2, T)]x(t)$$

and yields the minimum cost

$$\eta^*(t_1, t_2, T) = c'P(t_1, t_2, T)c. \quad (14.6)$$

A Gaussian *optimal filtering* problem [7] consists of the following. Given the p -vector random process z modeled by the equations

$$\begin{aligned} \dot{x}(t) &= Fx(t) + Gv(t), \\ z(t) &= Hx(t) + w(t), \end{aligned} \quad (14.7)$$

where x is the n -vector state and v, w are independent Gaussian white random processes (respectively, q -vector and p -vector) with zero means and identity covariance matrices. The matrices F, G , and H are constant real ones of the appropriate dimensions.

Given known values of z over some fixed time interval $[t_1, t_2]$ and assuming that $x(t_1)$ is a Gaussian random vector, independent of v and w , with zero mean and covariance matrix S , one seeks to determine an estimate $\hat{x}(t_2)$ of $x(t_2)$ such that the variance

$$\sigma(S, t_1, t_2) = E f' [x(t_2) - \hat{x}(t_2)] [x(t_2) - \hat{x}(t_2)]' f \tag{14.8}$$

of the error encountered in estimating any real-valued linear function f of $x(t_2)$ is minimized.

A unique optimal estimate exists for all finite $t_2 - t_1 > 0$ and is generated by a linear system of the form

$$\dot{\hat{x}}(t) = F\hat{x}(t) + Q(S, t_1, t)H'e(t), \quad \hat{x}(t_0) = 0, \quad e(t) = z(t) - H\hat{x}(t),$$

where $Q(S, t_1, t)$ is the solution of the matrix Riccati differential equation

$$\dot{Q}(t) = Q(t)F' + FQ(t) - Q(t)H'HQ(t) + GG' \tag{14.9}$$

subject to the initial condition

$$Q(t_1) = S.$$

The minimum error variance is given by

$$\sigma^*(S, t_1, t_2) = f' Q(S, t_1, t_2) f. \tag{14.10}$$

Equations 14.5 and 14.9 are special cases of the matrix Riccati differential equation 14.2 in that A, B, C , and D are constant real $n \times n$ matrices such that

$$B = B', \quad C = C', \quad D = -A'.$$

Therefore, symmetric solutions $X(t)$ are obtained in the optimal control and filtering problems.

We observe that the control Equation 14.5 is solved *backward* in time, while the filtering Equation 14.9 is solved *forward* in time. We also observe that the two equations are *dual* to each other in the sense that

$$P(t, t_2, T) = Q(S, t_1, t)$$

on replacing F, G, H, T , and $t_2 - t$ in Equation 14.5 respectively, by F', H', G', S , and $t - t_1$ or, vice versa, on replacing F, G, H, S , and $t - t_1$ in Equation 14.9 respectively, by F', H', G', T , and $t_2 - t$. This makes it possible to dispense with both cases by considering only one prototype equation.

14.3 Riccati Differential Equation

This section is concerned with the basic properties of the prototype matrix Riccati differential equation

$$\dot{X}(t) + X(t)A + A'X(t) - X(t)BX(t) + C = 0, \tag{14.11}$$

where A, B , and C are constant real $n \times n$ matrices with B and C being symmetric and nonnegative definite,

$$B = B', \quad B \geq 0 \quad \text{and} \quad C = C', \quad C \geq 0. \tag{14.12}$$

By definition, a *solution* of Equation 14.11 is a real $n \times n$ matrix function $X(t)$ that is absolutely continuous and satisfies Equation 14.11 for t on an interval on the real line R .

Generally, solutions of Riccati differential equations exist only locally. There is a phenomenon called finite escape time: the equation

$$\dot{x}(t) = x^2(t) + 1$$

has a solution $x(t) = \tan t$ in the interval $(-\frac{\pi}{2}, 0)$ that cannot be extended to include the point $t = -\frac{\pi}{2}$. However, Equation 14.11 with the sign-definite coefficients as shown in Equation 14.12 does have global solutions.

Let $X(t, t_2, T)$ denote the solution of Equation 14.11 that passes through a constant real $n \times n$ matrix T at time t_2 . We shall assume that

$$T = T' \quad \text{and} \quad T \geq 0. \quad (14.13)$$

Then the solution exists on every finite subinterval of R , is symmetric, nonnegative definite and enjoys certain monotone properties.

Theorem 14.1:

Under the assumptions of Equations 14.12 and 14.13, Equation 14.11 has a unique solution $X(t, t_2, T)$ satisfying

$$X(t, t_2, T) = X'(t, t_2, T), \quad X(t, t_2, T) \geq 0$$

for every T and every finite t, t_2 , such that $t \geq t_2$.

This can most easily be seen by associating Equation 14.11 with the optimal control problem described in Equations 14.3 through 14.6. Indeed, using Equation 14.12, one can write $B = GG'$ and $C = H'H$ for some real matrices G and H . The quadratic cost functional η of Equation 14.4 exists and is nonnegative for every T satisfying Equation 14.13 and for every finite $t_2 - t$. Using Equation 14.6, the quadratic form $c'X(t, t_2, T)c$ can be interpreted as a particular value of η for every real vector c .

A further consequence of Equations 14.4 and 14.6 follows.

Theorem 14.2:

For every finite t_1, t_2 and τ_1, τ_2 such that $t_1 \leq \tau_1 \leq \tau_2 \leq t_2$,

$$X(t_1, \tau_1, 0) \leq X(t_1, \tau_2, 0)$$

$$X(\tau_2, t_2, 0) \leq X(\tau_1, t_2, 0)$$

and for every $T_1 \leq T_2$,

$$X(t_1, t_2, T_1) \leq X(t_1, t_2, T_2).$$

Thus, the solution of Equation 14.11 passing through $T = 0$ does not decrease as the length of the interval increases, and the solution passing through a larger T dominates that passing through a smaller T .

The Riccati Equation 14.11 is related in a very particular manner with linear Hamiltonian systems of differential equations.

Theorem 14.3:

Let

$$\Phi(t, t_2) = \begin{bmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{21} & \Phi_{22} \end{bmatrix}$$

be the fundamental matrix solution of the linear Hamiltonian matrix differential system

$$\begin{bmatrix} \dot{U}(t) \\ \dot{V}(t) \end{bmatrix} = \begin{bmatrix} A & -B \\ -C & -A' \end{bmatrix} \begin{bmatrix} U(t) \\ V(t) \end{bmatrix}$$

that satisfies the transversality condition

$$V(t_2) = TU(t_2).$$

If the matrix $\Phi_{11} + \Phi_{12}T$ is nonsingular on an interval $[t, t_2]$, then

$$X(t, t_2, T) = (\Phi_{21} + \Phi_{22}T)(\Phi_{11} + \Phi_{12}T)^{-1} \tag{14.14}$$

is a solution of the Riccati Equation 14.11.

Thus, if $V(t_2) = TU(t_2)$, then $V(t) = X(t, t_2, T)U(t)$ and the formula of Equation 14.14 follows.

Let us illustrate this with a simple example. The Riccati equation

$$\dot{x}(t) = x^2(t) - 1, \quad x(0) = T$$

satisfies the hypotheses of Equations 14.12 and 14.13. The associated linear Hamiltonian system of equations reads

$$\begin{bmatrix} \dot{u}(t) \\ \dot{v}(t) \end{bmatrix} = \begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix} \begin{bmatrix} u(t) \\ v(t) \end{bmatrix}$$

and has the solution

$$\begin{bmatrix} u(t) \\ v(t) \end{bmatrix} = \begin{bmatrix} \cosh t & -\sinh t \\ -\sinh t & \cosh t \end{bmatrix} \begin{bmatrix} u(0) \\ v(0) \end{bmatrix},$$

where $v(0) = Tu(0)$. Then the Riccati equation has the solution

$$x(t, 0, T) = \frac{-\sinh t + T \cosh t}{\cosh t - T \sinh t}$$

for all $t \leq 0$. The monotone properties of the solution are best seen in Figure 14.1.

FIGURE 14.1 Graph of solutions.

14.4 Riccati Algebraic Equation

The constant solutions of Equation 14.11 are just the solutions of the quadratic equation

$$XA + A'X - XBX + C = 0, \quad (14.15)$$

called the *algebraic Riccati equation*. This equation can have real $n \times n$ matrix solutions X that are symmetric or nonsymmetric, sign definite or indefinite, and the set of solutions can be either finite or infinite. These solutions will be studied under the standing assumption of Equation 14.12, namely

$$B = B', \quad B \geq 0 \quad \text{and} \quad C = C', \quad C \geq 0.$$

14.4.1 General Solutions

The solution set of Equation 14.15 corresponds to a certain class of n -dimensional invariant subspaces of the associated $2n \times 2n$ matrix

$$H = \begin{bmatrix} A & -B \\ -C & -A' \end{bmatrix}. \quad (14.16)$$

This matrix has the *Hamiltonian* property

$$\begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix} H = -H' \begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix}.$$

It follows that H is similar to $-H'$ and therefore, the spectrum of H is symmetrical with respect to the imaginary axis.

Now suppose that X is a solution of Equation 14.15. Then

$$H \begin{bmatrix} I \\ X \end{bmatrix} = \begin{bmatrix} I \\ X \end{bmatrix} (A - BX).$$

Denote $J = U^{-1}(A - BX)U$, the Jordan form of $A - BX$ and put $V = XU$. Then

$$H \begin{bmatrix} U \\ V \end{bmatrix} = \begin{bmatrix} U \\ V \end{bmatrix} J,$$

which shows that the columns of

$$\begin{bmatrix} U \\ V \end{bmatrix}$$

are Jordan chains for H , that is, sets of vectors x_1, x_2, \dots, x_r such that $x_1 \neq 0$ and for some eigenvalue λ of H

$$\begin{aligned} Hx_1 &= \lambda x_1 \\ Hx_j &= \lambda x_j + x_{j+1}, \quad j = 2, 3, \dots, r. \end{aligned}$$

In particular, x_1 is an eigenvector of H . Thus, we have the following result.

Theorem 14.4:

Equation 14.15 has a solution X if and only if there is a set of vectors x_1, x_2, \dots, x_n forming a set of Jordan chains for H and if

$$x_i = \begin{bmatrix} u_i \\ v_i \end{bmatrix},$$

where u_i is an n -vector, then u_1, u_2, \dots, u_n are linearly independent.

Furthermore, if

$$U = [u_1 \dots u_n], \quad V = [v_1 \dots v_n],$$

every solution of Equation 14.15 has the form $X = VU^{-1}$ for some set of Jordan chains x_1, x_2, \dots, x_n for H .

To illustrate, consider the scalar equation

$$X^2 + pX + q = 0,$$

where p, q are real numbers and $q \leq 0$. The Hamiltonian matrix

$$H = \begin{bmatrix} -\frac{p}{2} & -1 \\ q & \frac{p}{2} \end{bmatrix}$$

has eigenvalues λ and $-\lambda$, where

$$\lambda^2 = \left(\frac{p}{2}\right)^2 - q.$$

If $\lambda \neq 0$ there are two eigenvectors of H , namely

$$x_1 = \begin{bmatrix} 1 \\ -\frac{p}{2} + \lambda \end{bmatrix}, \quad x_2 = \begin{bmatrix} 1 \\ -\frac{p}{2} - \lambda \end{bmatrix},$$

which correspond to the solutions

$$X_1 = -\frac{p}{2} + \lambda, \quad X_2 = -\frac{p}{2} - \lambda.$$

If $\lambda = 0$ there exists one Jordan chain,

$$x_1 = \begin{bmatrix} 1 \\ -\frac{p}{2} \end{bmatrix}, \quad x_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix},$$

which yields the unique solution

$$X_1 = -\frac{p}{2}.$$

Theorem 14.4 suggests that, generically, the number of solutions of Equation 14.15 to be expected will not exceed the binomial coefficient $\binom{2n}{n}$, the number of ways in which the vectors x_1, x_2, \dots, x_n can be chosen from a basis of $2n$ eigenvectors for H . The solution set is infinite if there is a continuous family of Jordan chains. To illustrate this point consider Equation 14.15 with

$$A = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}.$$

The Hamiltonian matrix

$$H = \begin{bmatrix} 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

has the eigenvalue 0, associated with two Jordan chains

$$x_1 = \begin{bmatrix} a \\ b \\ 0 \\ 0 \end{bmatrix}, \quad x_2 = \begin{bmatrix} c \\ d \\ -a \\ -b \end{bmatrix}, \quad \text{and} \quad x_3 = \begin{bmatrix} c \\ d \\ 0 \\ 0 \end{bmatrix}, \quad x_4 = \begin{bmatrix} a \\ b \\ -c \\ -d \end{bmatrix},$$

where a, b and c, d are real numbers such that $ad - bc = 1$. The solution set of Equation 14.15 consists of the matrix

$$X_{13} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

and two continuous families of matrices

$$X_{12}(a, b) = \begin{bmatrix} ab & -a^2 \\ b^2 & -ab \end{bmatrix} \quad \text{and} \quad X_{34}(c, d) = \begin{bmatrix} -cd & c^2 \\ -d^2 & cd \end{bmatrix}.$$

Having in mind the applications in optimal control and filtering, we shall be concerned with the solutions of Equation 14.15 that are symmetric and nonnegative definite.

14.4.2 Symmetric Solutions

In view of Theorem 14.4, each solution X of Equation 14.15 gives rise to a factorization of the characteristic polynomial χ_H of H as

$$\chi_H(s) = (-1)^n q(s) q_1(s),$$

where $q = \chi_{A-BX}$. If the solution is *symmetric*, $X = X'$, then $q_1(s) = q(-s)$. This follows from

$$\begin{bmatrix} I & 0 \\ X & I \end{bmatrix}^{-1} \begin{bmatrix} A & -B \\ -C & -A' \end{bmatrix} \begin{bmatrix} I & 0 \\ X & I \end{bmatrix} = \begin{bmatrix} A - BX & -B \\ 0 & -(A - BX)' \end{bmatrix}.$$

There are two symmetric solutions that are of particular importance. They correspond to a factorization

$$\chi_H(s) = (-1)^n q(s) q(-s)$$

in which q has all its roots with nonpositive real part; it follows that $q(-s)$ has all its roots with nonnegative real part. We shall designate these solutions X_+ and X_- .

One of the basic results concerns the existence of these particular solutions [8]. To state the result, we recall some terminology. A pair of real $n \times n$ matrices (A, B) is said to be *controllable (stabilizable)* if the $n \times 2n$ matrix $[\lambda I - A \quad B]$ has linearly independent rows for every complex λ (respectively, for every complex λ such that $Re \lambda \geq 0$). The numbers λ for which $[\lambda I - A \quad B]$ loses rank are the eigenvalues of A that are not controllable (stabilizable) from B . A pair of real $n \times n$ matrices (A, C) is said to be *observable (detectable)* if the $2n \times n$ matrix $\begin{bmatrix} \lambda I - A \\ C \end{bmatrix}$ has linearly independent columns for every complex λ (respectively, for every complex λ such that $Re \lambda \geq 0$). The numbers λ for which $\begin{bmatrix} \lambda I - A \\ C \end{bmatrix}$ loses rank are the eigenvalues of A that are not observable (detectable) in C . Finally, let $\dim V$ denote the dimension of a linear space V and $\text{Im } M, \text{Ker } M$ the image and the kernel of a matrix M , respectively.

Theorem 14.5:

There exists a unique symmetric solution X_+ of Equation 14.15 such that all eigenvalues of $A - BX_+$ have nonpositive real part if and only if (A, B) is stabilizable.

Theorem 14.6:

There exists a unique symmetric solution X_- of Equation 14.15 such that all eigenvalues of $A - BX_-$ have nonnegative real part if and only if $(-A, B)$ is stabilizable.

We observe that both (A, B) and $(-A, B)$ are stabilizable if and only if (A, B) is controllable. It follows that both solutions X_+ and X_- exist if and only if (A, B) is controllable.

For two real symmetric matrices X_1 and X_2 , the notation $X_1 \geq X_2$ means that $X_1 - X_2$ is nonnegative definite. Since $A - BX_+$ has no eigenvalues with positive real part, neither has $X_+ - X_-$. Hence, $X_+ - X_- \geq 0$. Similarly, one can show that $X - X_- \geq 0$, thus introducing a partial order among the set of symmetric solutions of Equation 14.15.

Theorem 14.7:

Suppose that X_+ and X_- exist. If X is any symmetric solution of Equation 14.15, then

$$X_+ \geq X \geq X_-.$$

That is why X_+ and X_- are called the *extreme* solutions of Equation 14.15; X_+ is the maximal symmetric solution, while X_- is the minimal symmetric solution. The set of all symmetric solutions of Equation 14.15 can be related to a certain subset of the set of invariant subspaces of the matrix $A - BX_+$ or the matrix $A - BX_-$. Denote \mathcal{V}_0 and \mathcal{V}_+ the invariant subspaces of $A - BX_+$ that correspond, respectively, to the pure imaginary eigenvalues and to the eigenvalues having negative real part. Denote \mathcal{W}_0 and \mathcal{W}_- the invariant subspaces of $A - BX_-$ that correspond, respectively, to the pure imaginary eigenvalues and to the eigenvalues having positive real part. Then it can be shown that $\mathcal{V}_0 = \mathcal{W}_0$ is the kernel of $X_+ - X_-$ and the symmetric solution set corresponds to the set of all invariant subspaces of $A - BX_+$ contained in \mathcal{V}_+ or, equivalently, to the set of all invariant subspaces of $A - BX_-$ contained in \mathcal{W}_- .

Theorem 14.8:

Suppose that X_+ and X_- exist. Let X_1, X_2 be symmetric solutions of Equation 14.15 corresponding to the invariant subspaces $\mathcal{V}_1, \mathcal{V}_2$ of \mathcal{V}_+ (or $\mathcal{W}_1, \mathcal{W}_2$ of \mathcal{W}_-). Then $X_1 \geq X_2$ if and only if $\mathcal{V}_1 \supset \mathcal{V}_2$ (or if and only if $\mathcal{W}_1 \subset \mathcal{W}_2$).

This means that the symmetric solution set of Equation 14.15 is a complete *lattice* with respect to the usual ordering of symmetric matrices. The maximal solution X_+ corresponds to the invariant subspace \mathcal{V}_+ of $A - BX_+$ or to the invariant subspace $\mathcal{W} = 0$ of $A - BX_-$, whereas the minimal solution X_- corresponds to the invariant subspace $\mathcal{V} = 0$ of $A - BX_+$ or to the invariant subspace \mathcal{W}_- of $A - BX_-$.

This result allows one to count the distinct symmetric solutions of Equation 14.15 in some cases. Thus, let α be the number of distinct eigenvalues of $A - BX_+$ having negative real part and let $m_1, m_2, \dots, m_\alpha$ be the multiplicities of these eigenvalues. Owing to the symmetries in H , the matrix $A - BX_-$ exhibits the same structure of eigenvalues with positive real part.

Theorem 14.9:

Suppose that X_+ and X_- exist. Then the symmetric solution set of Equation 14.15 has finite cardinality if and only if $A - BX_+$ is cyclic on \mathcal{V}_+ (or if and only if $A - BX_-$ is cyclic on \mathcal{W}_-). In this case, the set contains exactly $(m_1 + 1) \dots (m_\alpha + 1)$ solutions.

Simple examples are most illustrative. Consider Equation 14.15 with

$$A = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 1 & 0 \\ 0 & 3 \end{bmatrix}$$

and determine the lattice of symmetric solutions. We have

$$\chi_H(s) = s^4 - 5s^2 + 4$$

and the following eigenvectors of H :

$$x_1 = \begin{bmatrix} 1 \\ 0 \\ -1 \\ 0 \end{bmatrix}, \quad x_2 = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \end{bmatrix}, \quad x_3 = \begin{bmatrix} 0 \\ 1 \\ 0 \\ -1 \end{bmatrix}, \quad x_4 = \begin{bmatrix} 0 \\ 1 \\ 0 \\ 3 \end{bmatrix}$$

are associated with the eigenvalues 1, -1, 2, and -2, respectively. Hence, the pair of solutions

$$X_+ = \begin{bmatrix} 1 & 0 \\ 0 & 3 \end{bmatrix}, \quad X_- = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}$$

corresponds to the factorization

$$\chi_H(s) = (s^2 - 3s + 2)(s^2 + 3s + 2)$$

and the solutions

$$X_{2,3} = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad X_{1,4} = \begin{bmatrix} -1 & 0 \\ 0 & 3 \end{bmatrix}$$

correspond to the factorization

$$\chi_H(s) = (s^2 - s - 2)(s^2 + s - 2).$$

There are four subspaces invariant under the matrices

$$A - BX_+ = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix}, \quad A - BX_- = \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix}$$

each corresponding to one of the four solutions above. The partial ordering

$$X_+ \geq X_{2,3} \geq X_-, \quad X_+ \geq X_{1,4} \geq X_-$$

defines the lattice visualized in Figure 14.2.

As another example, we consider Equation 14.15 where

$$A = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

and classify the symmetric solution set.

FIGURE 14.2 Lattice of solutions.

We have

$$\chi_H(s) = (s - 1)^2(s + 1)^2$$

and a choice of eigenvectors corresponding to the eigenvalues 1, -1 of H is

$$x_1 = \begin{bmatrix} 1 \\ 0 \\ -1 \\ 0 \end{bmatrix}, \quad x_2 = \begin{bmatrix} 0 \\ 1 \\ 0 \\ -1 \end{bmatrix}, \quad x_3 = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \end{bmatrix}, \quad x_4 = \begin{bmatrix} 0 \\ 1 \\ 0 \\ 1 \end{bmatrix}.$$

Hence,

$$X_+ = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad X_- = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}$$

are the extreme solutions.

We calculate

$$A - BX_+ = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, \quad A - BX_- = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

and observe that the set of subspaces invariant under $A - BX_+$ or $A - BX_-$ (other than the zero and the whole space, which correspond to X_+ and X_-) is the family of one-dimensional subspaces parameterized by their azimuth angle θ . These correspond to the solutions

$$X_\theta = \begin{bmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{bmatrix}.$$

Therefore, the solution set consists of X_+ , X_- and the continuous family of solutions X_θ . It is a complete lattice and $X_+ \geq X_\theta \geq X_-$ for every θ .

14.4.3 Definite Solutions

Under the standing assumption (Equation 14.12), namely

$$B = B', \quad B \geq 0 \quad \text{and} \quad C = C', \quad C \geq 0,$$

one can prove that $X_+ \geq 0$ and $X_- \leq 0$. The existence of X_+ , however, excludes the existence of X_- and vice versa, unless (A, B) is controllable.

If X_+ does exist, any other solution $X \geq 0$ of Equation 14.15 corresponds to a subspace \mathcal{W} of \mathcal{W}_- that is invariant under $A - BX$. From Equation 14.15,

$$X(A - BX) + (A - BX)'X = -XBX - C.$$

The restriction of $A - BX$ to \mathcal{W} has eigenvalues with positive real part. Since $-XBX - C \leq 0$, it follows from the Lyapunov theory that X restricted to \mathcal{W} is nonpositive definite and hence zero. We conclude

that the solutions $X \geq 0$ of Equation 14.15 correspond to those subspaces \mathcal{W} of \mathcal{W}_- that are invariant under A and contained in $\text{Ker } C$.

The set of symmetric nonnegative definite solutions of Equation 14.15 is a sublattice of the lattice of all symmetric solutions [9,10]. Clearly X_+ is the largest solution and it corresponds to the invariant subspace $\mathcal{W} = 0$ of A . The smallest nonnegative definite solution will be denoted by X_* and it corresponds to \mathcal{W}_* , the largest invariant subspace of A contained in $\text{Ker } C$ and associated with eigenvalues having positive real part.

The nonnegative definite solution set of Equation 14.15 has finite cardinality if and only if A is cyclic on \mathcal{W}_* . In this case, the set contains exactly $(p_1 + 1) \dots (\rho + 1)$ solutions, where ρ is the number of distinct eigenvalues of A associated with \mathcal{W}_* and p_1, p_2, \dots, p_ρ are the multiplicities of these eigenvalues.

Analogous results hold for the set of symmetric solutions of Equation 14.15 that are nonpositive definite. In particular, if X_- exists, then any other solution $X \leq 0$ of Equation 14.15 corresponds to a subspace \mathcal{V} of \mathcal{V}_+ that is invariant under A and contained in $\text{Ker } C$. Clearly X_- is the smallest solution and it corresponds to the invariant subspace $\mathcal{V} = 0$ of A . The largest nonpositive definite solution is denoted by X_x and it corresponds to \mathcal{W}_x , the largest invariant subspace of A contained in $\text{Ker } C$ and associated with eigenvalues having negative real part.

Let us illustrate this with a simple example. Consider Equation 14.15 where

$$A = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

and classify the two sign-definite solution sets. We have

$$X_+ = \begin{bmatrix} 8 & 4 \\ 4 & 4 \end{bmatrix}, \quad X_- = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}.$$

The matrix A has one eigenvalue with positive real part, namely 1, and a basis for \mathcal{W}_* is

$$x_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad x_2 = \begin{bmatrix} 0 \\ -1 \end{bmatrix}.$$

Thus, there are three invariant subspaces of \mathcal{W}_* corresponding to the three nonnegative definite solutions of Equation 14.15

$$X_+ = \begin{bmatrix} 8 & 4 \\ 4 & 4 \end{bmatrix}, \quad X_1 = \begin{bmatrix} 0 & 0 \\ 0 & 2 \end{bmatrix}, \quad X_* = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}.$$

These solutions make a lattice and

$$X_+ \geq X_1 \geq X_*.$$

The matrix A has no eigenvalues with negative real part. Therefore, $\mathcal{V}_* = 0$ and X_- is the only nonpositive definite solution of Equation 14.15.

Another example for Equation 14.15 is provided by

$$A = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \quad C = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}.$$

It is seen that neither (A, B) nor $(-A, B)$ is stabilizable; hence, neither X_+ nor X_- exists. The symmetric solution set consists of one continuous family of solutions

$$X_\alpha = \begin{bmatrix} 0 & 0 \\ 0 & \alpha \end{bmatrix}$$

for any real α . Therefore, both sign-definite solution sets are infinite; the nonnegative solution set is unbounded from above while the nonpositive solution set is unbounded from below.

14.5 Limiting Behavior of Solutions

The length of the time interval $t_2 - t_1$ in the optimal control and filtering problems is rather artificial. For this reason, an infinite time interval is often considered. This brings in the question of the limiting behavior of the solution $X(t, t_2, T)$ for the Riccati differential equation 14.11.

In applications to optimal control, it is customary to fix t and let t_2 approach $+\infty$. Since the coefficient matrices of Equation 14.11 are constant, the same result is obtained if t_2 is held fixed and t approaches $-\infty$. The limiting behavior of $X(t, t_2, T)$ strongly depends on the terminal matrix $T \geq 0$. For a suitable choice of T , the solution of Equation 14.11 may converge to a constant matrix $X \geq 0$, a solution of Equation 14.15. For some matrices T , however, the solution of Equation 14.11 may fail to converge to a constant matrix, but it may converge to a periodic matrix function.

Theorem 14.10:

Let (A, B) be stabilizable. If t and T are held fixed and $t_2 \rightarrow \infty$, then the solution $X(t, t_2, T)$ of Equation 14.11 is bounded on the interval $[t, \infty)$.

This result can be proved by associating an optimal control problem with Equation 14.11. Then stabilizability of (A, B) implies the existence of a stabilizing (not necessarily optimal) control. The consequent cost functional of Equation 14.4 is finite and dominates the optimal one.

If (A, B) is stabilizable, then X_+ exists and each real symmetric nonnegative definite solution X of Equation 14.15 corresponds to a subset \mathcal{W} of \mathcal{W}_* , the set of A -invariant subspaces contained in $\text{Ker } C$ and associated with eigenvalues having positive real part. The convergence of the solution $X(t, t_2, T)$ of Equation 14.11 to X depends on the properties of the image of \mathcal{W}_* under T , see [11].

For simplicity, it is assumed that the eigenvalues $\lambda_1, \lambda_2, \dots, \lambda_\rho$ of A associated with \mathcal{W}_* are simple and, except for pairs of complex conjugate eigenvalues, have different real parts. Let the corresponding eigenvectors be ordered according to decreasing real parts of the eigenvalue

$$v_1, v_2, \dots, v_\rho,$$

and denote \mathcal{W}_i the A -invariant subspace of \mathcal{W}_* spanned by v_1, v_2, \dots, v_i .

Theorem 14.11:

Let (A, B) be stabilizable and the subspaces \mathcal{W}_i of \mathcal{W}_ satisfy the above assumptions. Then, for all fixed t and a given terminal condition $T \geq 0$, the solution $X(t, t_2, T)$ of Equation 14.11 converges to a constant solution of Equation 14.15 as $t_2 \rightarrow \infty$ if and only if the subspace \mathcal{W}_{k+1} corresponding to any pair λ_k, λ_{k+1} of complex conjugate eigenvalues is such that $\dim T\mathcal{W}_{k+1}$ equals either $\dim T\mathcal{W}_{k-1}$ or $\dim T\mathcal{W}_{k-1} + 2$.*

Here is a simple example. Let

$$A = \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}.$$

The pair (A, B) is stabilizable and A has two eigenvalues $1 + j$ and $1 - j$. The corresponding eigenvectors

$$v_1 = \begin{bmatrix} j \\ 1 \end{bmatrix}, \quad v_2 = \begin{bmatrix} -j \\ 1 \end{bmatrix}$$

span \mathcal{W}_* . Now consider the terminal condition

$$T = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}.$$

Then,

$$T\mathcal{W}_0 = 0, \quad T\mathcal{W}_2 = \text{Im} \begin{bmatrix} 1 \\ 0 \end{bmatrix}.$$

Theorem 14.11 shows that $X(t, t_2, T)$ does not converge to a constant matrix; in fact,

$$X(t, t_2, T) = \frac{1}{1 + e^{2(t-t_2)}} \begin{bmatrix} 2 \cos^2(t-t_2) & -\sin 2(t-t_2) \\ -\sin 2(t-t_2) & 2 \sin^2(t-t_2) \end{bmatrix}$$

tends to a periodic solution if $t_2 \rightarrow \infty$. On the other hand, if we select

$$T_0 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

we have

$$T_0\mathcal{W}_0 = 0, \quad T_0\mathcal{W}_2 = 0$$

and $X(t, t_2, T_0)$ does converge. Also, if we take

$$T_1 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

we have

$$T_1\mathcal{W}_0 = 0, \quad T_1\mathcal{W}_2 = \mathcal{R}^2$$

and $X(t, t_2, T_1)$ converges as well.

If the solution $X(t, t_2, T)$ of Equation 14.11 converges to a constant matrix X_T as $t_2 \rightarrow \infty$, then X_T is a real symmetric nonnegative definite solution of Equation 14.15. Which solution is attained for a particular terminal condition?

Theorem 14.12:

Let (A, B) be stabilizable. Let

$$X_T = \lim_{t_2 \rightarrow \infty} X(t, t_2, T)$$

for a fixed $T \geq 0$. Then $X_T \geq 0$ is the solution of Equation 14.15 corresponding to the subspace \mathcal{W}_T of \mathcal{W}_* , defined as the span of the real vectors v_i such that $T\mathcal{W}_i = T\mathcal{W}_{i-1}$ and of the complex conjugate pairs v_k, v_{k+1} such that $T\mathcal{W}_{k+1} = T\mathcal{W}_{k-1}$.

The cases of special interest are the extreme solutions X_+ and X_* . The solution $X(t, t_2, T)$ of Equation 14.12 tends to X_+ if and only if the intersection of \mathcal{W}_* with $\text{Ker } T$ is zero, and to X_* if and only if \mathcal{W}_* is contained in $\text{Ker } T$.

This is best illustrated in the previous example, where

$$A = \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

and $\mathcal{W}_* = R^2$. Then $X(t, t_2, T)$ converges to X_+ if and only if T is positive definite; for instance, the identity matrix T yields the solution

$$X(t, t_2, I) = \frac{2}{1 + e^{2(t-t_2)}} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix},$$

which tends to

$$X_+ = \begin{bmatrix} 2 & 0 \\ 0 & 2 \end{bmatrix}.$$

On the other hand, $X(t, t_2, T)$ converges to X_* if and only if $T=0$; then

$$X(t, t_2, 0) = 0$$

and $X_*=0$ is a fixed point of Equation 14.11.

14.6 Optimal Control and Filtering: Application

The problems of optimal control and filtering introduced in Section 14.2 are related to the matrix Riccati differential equations 14.5 and 14.9, respectively. These problems are defined over a finite horizon $t_2 - t_1$. We now apply the convergence properties of the solutions to study the two optimal problems in case the horizon becomes large.

To fix ideas, we concentrate on the optimal control problem. The results can easily be interpreted in the filtering context owing to the duality between Equations 14.5 and 14.9.

We recall that the finite horizon optimal control problem is that of minimizing the cost functional of Equation 14.4,

$$\eta(t_2) = \int_{t_1}^{t_2} [y'(t)y(t) + u'(t)u(t)] dt + x'(t_2)Tx(t_2)$$

along the solutions of Equation 14.3,

$$\begin{aligned} \dot{x}(t) &= Fx(t) + Gu(t) \\ y(t) &= Hx(t). \end{aligned}$$

The optimal control has the form

$$u_0(t) = -G'X(t, t_2, T)x(t),$$

where $X(t, t_2, T)$ is the solution of Equation 14.11,

$$\dot{X}(t) + X(t)A + A'X(t) - X(t)BX(t) + C = 0$$

subject to the terminal condition $X(t_2) = T$, and where

$$A = F, \quad B = GG', \quad C = H'H.$$

The optimal control can be implemented as a state feedback and the resulting closed-loop system is

$$\begin{aligned} \dot{x}(t) &= [F - GG'X(t, t_2, T)]x(t) \\ &= [A - BX(t, t_2, T)]x(t). \end{aligned}$$

Hence, the relevance of the matrix $A - BX$, which plays a key role in the theory of the Riccati equation.

The *infinite horizon* optimal control problem then amounts to finding

$$\eta_* = \inf_{u(t)} \lim_{t_2 \rightarrow \infty} \eta(t_2) \quad (14.17)$$

and the corresponding optimal control $u_*(t)$, $t \geq t_1$ achieving this minimum cost.

The *receding horizon* optimal control problem is that of finding

$$\eta_{**} = \lim_{t_2 \rightarrow \infty} \inf_{u(t)} \eta(t_2) \quad (14.18)$$

and the limiting behavior $u_{**}(t)$, $t \geq t_1$ of the optimal control $u_o(t)$.

The question is whether η_* is equal to η_{**} and whether u_* coincides with u_{**} . If so, the optimal control for the infinite horizon can be approximated by the optimal control of the finite horizon problem for a sufficiently large time interval.

It turns out [12] that these two control problems have different solutions corresponding to different solutions of the matrix Riccati algebraic Equation 14.15,

$$XA + A'X - XBX + C = 0.$$

Theorem 14.13:

Let (A, B) be stabilizable. Then the infinite horizon optimal control problem of Equation 14.17 has a solution

$$\eta_* = x'(t_1)X_o x(t_1), \quad u_*(t) = -G'X_o x(t)$$

where $X_o \geq 0$ is the solution of Equation 14.15 corresponding to \mathcal{W}_o , the largest A -invariant subspace contained in $\mathcal{W}_* \cap \text{Ker } T$.

Theorem 14.14:

Let (A, B) be stabilizable. Then the receding horizon optimal control problem of Equation 14.18 has a solution if and only if the criterion of Theorem 14.5 is satisfied and, in this case,

$$\eta_{**} = x'(t_1)X_T x(t_1), \quad u_{**}(t) = -G'X_T x(t)$$

where $X_T \geq 0$ is the solution of Equation 14.16 corresponding to \mathcal{W}_T and defined in Theorem 14.5.

The equivalence result follows.

Theorem 14.15:

The solution of the infinite horizon optimal control problem is exactly the limiting case of the receding horizon optimal control problem if and only if the subspace $\mathcal{W}_* \cap \text{Ker } T$ is invariant under A .

A simple example illustrates these points. Consider the finite horizon problem defined by

$$\begin{aligned} \dot{x}_1(t) &= 2x_1(t) + u_1(t), \\ \dot{x}_2(t) &= x_2(t) + u_2(t) \end{aligned}$$

and

$$\eta(t_2) = [x_1(t_2) + x_2(t_2)]^2 + \int_{t_2}^f [u_1^2(\tau) + u_2^2(\tau)] d\tau,$$

which corresponds to the data

$$A = \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

and

$$T = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}.$$

Clearly $\mathcal{W}_* = R^2$ and the subspace

$$\mathcal{W}_* \cap \text{Ker } T = \text{Im} \begin{bmatrix} 1 \\ -1 \end{bmatrix}$$

is not invariant under A . Hence, the infinite and receding horizon problems are not equivalent.

The lattice of symmetric nonnegative definite solutions of Equation 14.11 has the four elements

$$X_+ = \begin{bmatrix} 4 & 0 \\ 0 & 2 \end{bmatrix}, \quad X_1 = \begin{bmatrix} 0 & 0 \\ 0 & 2 \end{bmatrix}, \quad X_2 = \begin{bmatrix} 4 & 0 \\ 0 & 0 \end{bmatrix}, \quad X_* = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

depicted in Figure 14.3.

Since the largest A -invariant subspace of $\mathcal{W}_* \cap \text{Ker } T$ is zero, the optimal solution X_o of Equation 14.11 is the maximal element X_+ . The infinite horizon optimal control reads

$$\begin{aligned} u_{1*}(t) &= -4x_1(t), \\ u_{2*}(t) &= -2x_2(t), \end{aligned}$$

and affords the minimum cost

$$\eta_* = 4x_1^2(t_1) + 2x_2^2(t_1).$$

Now the eigenvectors of A spanning \mathcal{W}_* are

$$v_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad v_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

FIGURE 14.3 The four elements of the lattice of solutions.

and their T -images

$$Tv_1 = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \quad Tv_2 = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

are linearly dependent. Hence, \mathcal{W}_T is spanned by v_2 only,

$$\mathcal{W}_T = \text{Im} \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

and the optimal limiting solution X_T of Equation 14.11 equals X_2 . The receding horizon optimal control reads

$$\begin{aligned} u_{1**}(t) &= -4x_1(t) \\ u_{2**}(t) &= 0 \end{aligned}$$

and affords the minimum cost

$$\eta_{**}(t) = 4x_1^2(t_1).$$

The optimal control problems with large horizon are practically relevant if the optimal closed-loop system

$$\dot{x}(t) = (A - BX)x(t)$$

is stable. A real symmetric nonnegative definite solution X of Equation 14.15 is said to be *stabilizing* if the eigenvalues of $A - BX$ all have negative real part. It is clear that the stabilizing solution, if it exists, is the maximal solution X_+ . Thus, the existence of a stabilizing solution depends on $A - BX_+$ having eigenvalues with only negative real part.

Theorem 14.16:

Equation 14.15 has a stabilizing solution if and only if (A, B) is stabilizable and the Hamiltonian matrix H of Equation 14.16 has no pure imaginary eigenvalue.

The optimal controls over large horizons have a certain stabilizing effect. Indeed, if $X \geq 0$ is a solution of Equation 14.15 that corresponds to an A -invariant subspace \mathcal{W} of \mathcal{W}_* , then the control $u(t) = -G'Xx(t)$ leaves unstable in $A - BX$ just the eigenvalues of A associated with \mathcal{W} ; all the remaining eigenvalues of A with positive real part are stabilized. Of course, the pure imaginary eigenvalues of A , if any, cannot be stabilized; they remain intact in $A - BX$ for any solution X of Equation 14.15.

In particular, the infinite horizon optimal control problem leaves unstable the eigenvalues of A associated with \mathcal{W}_o , which are those not detectable either in C or in T , plus the pure imaginary eigenvalues. It follows that the infinite horizon optimal control results in a stable system if and only if X_o is the stabilizing solution of Equation 14.15. This is the case if and only if the hypotheses of Theorem 14.6 hold and \mathcal{W}_o , the largest A -invariant subspace contained in $\mathcal{W}_* \cap \text{Ker} T$, is zero. Equivalently, this corresponds to the pair

$$\left(\begin{bmatrix} C \\ T \end{bmatrix}, A \right)$$

being detectable.

The allocation of the closed-loop eigenvalues for the receding horizon optimal control problem is different, however. This control leaves unstable all eigenvalues of A associated with \mathcal{W}_T , where \mathcal{W}_T is a subspace of \mathcal{W}_* defined in Theorem 14.5. Therefore, the number of stabilized eigenvalues may be lower, equal to the dimension of $T\mathcal{W}_*$, whenever $\text{Ker} T$ is not invariant under A . It follows that the receding horizon optimal control results in a stable system if and only if X_T is the stabilizing solution

of Equation 14.15. This is the case if and only if the hypotheses of Theorem 14.6 hold and \mathcal{W}_T is zero. Equivalently, this corresponds to $\mathcal{W}_* \cap \text{Ker}T = 0$. Note that this case occurs in particular if $T \geq X_+$.

It further follows that under the standard assumption, namely that

$$\begin{aligned} &(A, B) \text{ stabilizable} \\ &(A, C) \text{ detectable,} \end{aligned}$$

both infinite and receding horizon control problems have solutions; these solutions are equivalent for any terminal condition T ; and the resulting optimal system is stable.

14.7 Numerical Solution

The matrix Riccati *differential* equation 14.11 admits an analytic solution only in rare cases. A numerical integration is needed and the Runge–Kutta methods can be applied.

A number of techniques are available for the solution of the matrix Riccati *algebraic* Equation 14.15. These include invariant subspace methods [13] and the matrix sign function iteration [14]. We briefly outline these methods here with an eye on the calculation of the stabilizing solution to Equation 14.15.

14.7.1 Invariant Subspace Method

In view of Theorem 14.4, any solution X of Equation 14.15 can be computed from a Jordan form reduction of the associated $2n \times 2n$ Hamiltonian matrix

$$H = \begin{bmatrix} A & -B \\ -C & -A' \end{bmatrix}.$$

Specifically, compute a matrix of eigenvectors V to perform the following reduction:

$$V^{-1}HV = \begin{bmatrix} -J & 0 \\ 0 & J \end{bmatrix},$$

where $-J$ is composed of Jordan blocks corresponding to eigenvalues with negative real part only. If the stabilizing solution X exists, then H has no eigenvalues on the imaginary axis and J is indeed $n \times n$. Writing

$$V = \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{bmatrix},$$

where each V_{ij} is $n \times n$, the solution sought is found by solving a system of linear equations,

$$X = V_{21}V_{11}^{-1}.$$

However, there are numerical difficulties with this approach when H has multiple or near-multiple eigenvalues. To ameliorate these difficulties, a method has been proposed in which a nonsingular matrix V of eigenvectors is replaced by an orthogonal matrix U of Schur vectors so that

$$U'HU = \begin{bmatrix} S_{11} & S_{12} \\ 0 & S_{22} \end{bmatrix},$$

where now S_{11} is a quasi-upper triangular matrix with eigenvalues having negative real part and S_{22} is a quasi-upper triangular matrix with eigenvalues having positive real part. When

$$U = \begin{bmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{bmatrix},$$

we observe that

$$\begin{bmatrix} V_{11} \\ V_{21} \end{bmatrix}, \begin{bmatrix} U_{11} \\ U_{21} \end{bmatrix}$$

span the same invariant subspace and X can again be computed from

$$X = U_{21}U_{11}^{-1}.$$

14.7.2 Matrix Sign Function Iteration

Let M be a real $n \times n$ matrix with no pure imaginary eigenvalues. Let M have a Jordan decomposition $M = VJ V^{-1}$ and let $\lambda_1, \lambda_2, \dots, \lambda_n$ be the diagonal entries of J (the eigenvalues of M repeated according to their multiplicities). Then the *matrix sign function* of M is given by

$$\operatorname{sgn} M = V \begin{bmatrix} \operatorname{sgn} \operatorname{Re} \lambda_1 & & \\ & \ddots & \\ & & \operatorname{sgn} \operatorname{Re} \lambda_n \end{bmatrix} V^{-1}$$

It follows that the matrix $Z = \operatorname{sgn} M$ is diagonalizable with eigenvalues ± 1 and $Z^2 = I$. The key observation is that the image of $Z + I$ is the M -invariant subspace of R^n corresponding to the eigenvalues of M with negative real part.

This property clearly provides the link to Riccati equations, and what we need is a reliable computation of the matrix sign. Let $Z_0 = M$ be an $n \times n$ matrix whose sign is desired. For $k = 0, 1$, perform the iteration

$$Z_{k+1} = \frac{1}{2c}(Z_k + c^2 Z_k^{-1}),$$

where $c = |\det Z_k|^{1/n}$. Then

$$\lim_{k \rightarrow \infty} Z_k = Z = \operatorname{sgn} M.$$

The constant c is chosen to enhance convergence of this iterative process. If $c = 1$, the iteration amounts to Newton's method for solving the equation

$$Z^2 - I = 0.$$

Naturally, it can be shown that the iteration is ultimately quadratically convergent.

Thus, to obtain the stabilizing solution X of Equation 14.15, provided it exists, we compute $Z = \operatorname{sgn} H$, where H is the Hamiltonian matrix of Equation 14.16. The existence of X guarantees that H has no eigenvalues on the imaginary axis.

Writing

$$Z = \begin{bmatrix} Z_{11} & Z_{12} \\ Z_{21} & Z_{22} \end{bmatrix},$$

where each Z_{ij} is $n \times n$, the solution sought is found by solving a system of linear equations

$$\begin{bmatrix} Z_{12} \\ Z_{22} + I \end{bmatrix} X = - \begin{bmatrix} Z_{11} + I \\ Z_{21} \end{bmatrix}.$$

14.7.3 Concluding Remarks

We have discussed two numerical methods for obtaining the stabilizing solution of the matrix Riccati algebraic equation 14.15. They are both based on the intimate connection between the Riccati equation solutions and invariant subspaces of the associated Hamiltonian matrix. The method based on Schur vectors is a direct one, while the method based on the matrix sign function is iterative.

The Schur method is now considered one of the more reliable for Riccati equations and has the virtues of being simultaneously efficient and numerically robust. It is particularly suitable for Riccati equations with relatively small dense coefficient matrices, say, of the order of a few hundreds or less. The matrix sign function method is based on the Newton iteration and features global convergence, with ultimately quadratic order. Iteration formulas can be chosen to be of arbitrary order convergence in exchange for, naturally, an increased computational burden. The effect of this increased computation can, however, be ameliorated by parallelization.

The two methods are not limited to computing the stabilizing solution only. The matrix sign iteration can also be used to calculate X_- , the antistabilizing solution of Equation 14.15, by considering the matrix $\text{sgn } H - I$ instead of $\text{sgn } H + I$. The Schur approach can be used to calculate any, not necessarily symmetric, solution of Equation 14.15, by ordering the eigenvalues on the diagonal of S accordingly.

15.1 Introduction

An observer for a dynamic system $S(x, y, u)$ with state x , output y , and input u is another dynamic system $\hat{S}(\hat{x}, y, u)$ having the property that the state \hat{x} of the observer \hat{S} converges to the state x of the process S , independent of the input u or the state x .

Among the various applications for observers, perhaps the most important is for the implementation of closed-loop control algorithms designed by state-space methods. The control algorithm is designed in two parts: a “full-state feedback” part based on the assumption that all the state variables can be measured; and an observer to estimate the state of the process based on the observed output. The concept of separating the feedback control design into these two parts is known as the *separation principle*, which has rigorous validity in linear systems and in a limited class of nonlinear systems. Even when its validity cannot be rigorously established, the separation principle is often a practical solution to many design problems.

The concept of an observer for a dynamic process was introduced in 1966 by Luenberger [1]. The generic “Luenberger observer,” however, appeared several years after the Kalman filter, which is in fact an important special case of a Luenberger observer—an observer optimized for the noise present in the observations and in the input to the process.

15.2 Linear Full-Order Observers

15.2.1 Continuous-Time Systems

Consider a linear, continuous-time dynamic system

$$\dot{x} = Ax + Bu \tag{15.1}$$

$$y = Cx \tag{15.2}$$

The more generic output

$$y = Cx + Du$$

can be treated by defining a modified output

$$\bar{y} = y - Du$$

and working with \bar{y} instead of y . The direct coupling Du from the input to the output is absent in most physical plants.

A full-order observer for the linear process defined by Equations 15.1 and 15.2 has the generic form

$$\dot{\hat{x}} = \hat{A}\hat{x} + Ky + Hu \quad (15.3)$$

where the dimension of state \hat{x} of the observer is equal to the dimension of process state x .

The matrices \hat{A} , K , and H appearing in Equation 15.3 must be chosen to conform with the required property of an observer: that the observer state must converge to the process state independent of the state x and the input u . To determine these matrices, let

$$e := x - \hat{x} \quad (15.4)$$

be the estimation error. From Equations 15.1 through 15.3

$$\begin{aligned} \dot{e} &= Ax + Bu - \hat{A}(x - e) - GCx - Hu, \\ &= \hat{A}e + (-\hat{A} + A - KC)x + (B - H)u, \end{aligned} \quad (15.5)$$

From Equation 15.5 it is seen that for the error to converge to zero, independent of x and u , the following conditions must be satisfied:

$$\hat{A} = A - KC \quad (15.6)$$

$$H = B \quad (15.7)$$

When these conditions are satisfied, the estimation error is governed by

$$\dot{e} = \hat{A}e \quad (15.8)$$

which converges to zero if \hat{A} is a “stability matrix.” When \hat{A} is constant, this means that its eigenvalues must lie in the (open) left half-plane.

Since the matrices A , B , and C are defined by the plant, the only freedom in the design of the observer is in the selection of the gain matrix K .

To emphasize the role of the observer gain matrix, and accounting for requirements of Equations 15.6 and 15.7, the observer can be written as

$$\dot{\hat{x}} = A\hat{x} + Bu + K(y - C\hat{x}) \quad (15.9)$$

A block diagram representation of Equation 15.9, as given in Figure 15.1, aids in the interpretation of the observer. Note that the observer comprises a model of the process with an added input:

$$K(y - C\hat{x}) = Kr$$

The quantity

$$r := y - C\hat{x} = y - \hat{y} \quad (15.10)$$

often called the *residual*, is the difference between the actual observation y and the “synthesized” observation

$$\hat{y} = C\hat{x}$$

produced by the observer. The observer can be viewed as a feedback system designed to drive the residual to zero: as the residual is driven to zero, the input to Equation 15.9 due to the residual vanishes and the state of Equation 15.9 looks like the state of the original process.

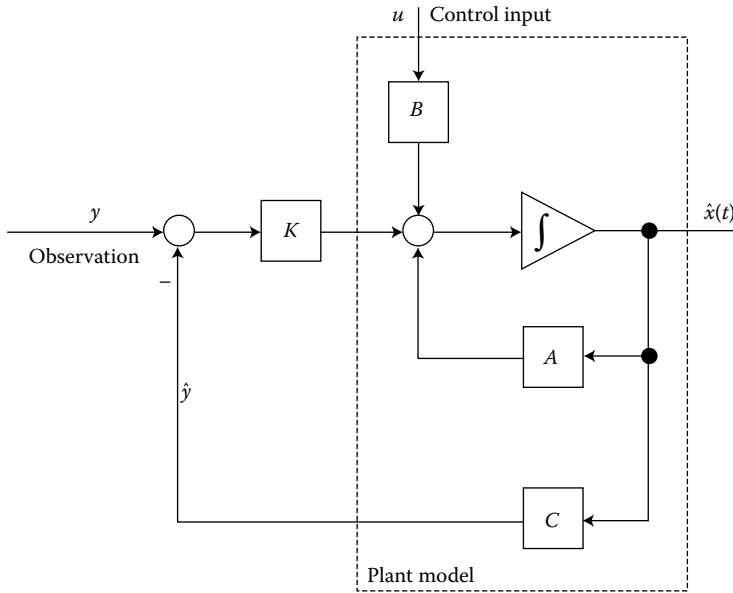

FIGURE 15.1 Full-order observer for linear process.

The fundamental problem in the design of an observer is the determination of the observer gain matrix K such that the closed-loop observer matrix

$$\hat{A} = A - KC \tag{15.11}$$

is a stability matrix.

There is considerable flexibility in the selection of the observer gain matrix. Two methods are standard: optimization and pole placement.

15.2.1.1 Optimization

Since the observer given by Equation 15.9 has the structure of a Kalman filter (see Chapter 13), its gain matrix can be chosen as a Kalman filter gain matrix, that is,

$$K = PC'R^{-1} \tag{15.12}$$

where P is the covariance matrix of the estimation error and satisfies the matrix Riccati equation

$$\dot{P} = AP + PA' - PC'R^{-1}CP + Q, \tag{15.13}$$

where R is a positive-definite matrix and Q is a positive-semidefinite matrix.

In most applications the steady-state covariance matrix is used in Equation 15.12. This matrix is given by setting \dot{P} in Equation 15.13 to zero. The resulting equation is known as the *algebraic Riccati equation*. Algorithms to solve the algebraic Riccati equation are included in popular control system software packages such as MATLAB® or SciLab.

In order for the gain matrix given by Equations 15.12 and 15.13 to be genuinely optimum, the process noise and the observation noise must be white with the matrices Q and R being their spectral densities. It is rarely possible to determine these spectral density matrices in practical applications. Hence, the matrices Q and R are best treated as design parameters that can be varied to achieve overall system design objectives.

If the observer is to be used as a state estimator in a closed-loop control system, an appropriate form for the matrix Q is

$$Q = q^2 BB' \quad (15.14)$$

As has been shown by Doyle and Stein [2], as $q \rightarrow \infty$, this observer tends to “recover” the stability margins assured by a full-state feedback control law obtained by quadratic optimization.

15.2.1.2 Pole Placement

An alternative to solving the algebraic Riccati equation to obtain the observer gain matrix is to select K to place the poles of the observer, that is, the eigenvalues of \hat{A} in Equation 15.11.

When there is a single observation, K is a column vector with exactly as many elements as eigenvalues of \hat{A} . Hence, specification of the eigenvalues of \hat{A} uniquely determines the gain matrix K . A number of algorithms can be used to determine the gain matrix, some of which are incorporated into the popular control system design software packages. Some of the algorithms have been found to be numerically ill-conditioned; so caution should be exercised in using the results.

The present author has found the Bass–Gura [3] formula to be effective in most applications. This formula gives the gain matrix as

$$K = (OW)'^{-1}(\hat{a} - a) \quad (15.15)$$

where

$$a = [a_1 \quad a_2 \quad \cdots \quad a_n]' \quad (15.16)$$

is the vector formed from the coefficients of the characteristic polynomial of the process matrix A

$$|sI - A| = s^n + a_1s^{n-1} + \cdots + a_{n-1}s + a_n \quad (15.17)$$

and \hat{a} is the vector formed from the coefficients of the desired characteristic polynomial

$$|sI - \hat{A}| = s^n + \hat{a}_1s^{n-1} + \cdots + \hat{a}_{n-1}s + \hat{a}_n \quad (15.18)$$

The other matrices in Equation 15.15 are given by

$$O = [C' \quad A'C' \quad \cdots \quad A^{n-1}C'] \quad (15.19)$$

which is the *observability matrix* of the process, and

$$W = \begin{bmatrix} 1 & a_1 & \cdots & a_n \\ 0 & 1 & \cdots & a_{n-1} \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 \end{bmatrix} \quad (15.20)$$

The determinant of W is 1; hence it is not singular. If the observability matrix O is not singular, the inverse matrix required in Equation 15.15 exists. Hence, the gain matrix K can be found that places the observer poles at arbitrary locations if (and only if) the process for which an observer is sought is observable. Numerical problems occur, however, when the observability matrix is nearly singular. Other numerical problems can arise in determination of the characteristic polynomial $|sI - A|$ for high-order systems and in the determination of $sI - \hat{A}$ when the individual poles, and not the characteristic polynomial, are specified. In such instances, it may be necessary to use an algorithm designed to handle difficult numerical calculations.

When two or more quantities are observed, there are more elements in the gain matrix than eigenvalues of \hat{A} ; hence specification of the eigenvalues of \hat{A} does not uniquely specify the gain matrix K . In addition

to placing the eigenvalues, more of the “eigenstructure” of \hat{A} can be specified. This method of selecting the gain matrix is fraught with difficulty, however, and the use of the algebraic Riccati equation is usually preferable.

The Matlab algorithm `place` can be used to place the poles of a system with multiple observations, and uses the additional freedom to improve the robustness of the resulting observer.

15.2.2 Delayed Data

In some applications, the observation data may be delayed:

$$y_d(t) = y(t - T), \quad \text{with } y(t) = Cx(t) \quad (15.21)$$

in which T is the known time delay.

If the observation vector $y(t)$ has more than one component, then it is assumed that all the components are delayed by the same amount of time T .

On recognizing that the process is time-invariant, that is,

$$\dot{x}(t - T) = Ax(t - T) + Bu(t - T) \quad (15.22)$$

an observer for the delayed state is given by

$$\dot{\hat{x}}(t - T) = A\hat{x}(t - T) + Bu(t - T) + K(y_d(t) - C\hat{x}(t - T)) \quad (15.23)$$

where K is the observer gain matrix, which can be obtained by the methods discussed above.

Having thus obtained an estimate $\hat{x}(t - T)$ of the delayed state, we extrapolate the estimate to the present time. Since there are no data in the interval $[t - T, t]$, the extrapolation simply makes use of the state transition matrix $e^{A_c T}$, with

$$A_c = A - BG$$

of the closed-loop system over the interval $[t - T, t]$. Thus the estimate of the state at time t is given by

$$\hat{x}(t) = e^{A_c T} \hat{x}(t - T) \quad (15.24)$$

where $\hat{x}(t)$ is given by Equation 15.23.

The observer requires the delayed control signal $u(t - T)$, which can be implemented by any of the “standard” methods for implementing a delay line.

15.3 Linear Reduced-Order Observers

The observer described in the previous section has the same order as the plant, irrespective of the number of independent observations. A reduced-order observer of the order $n - m$, where n is the dimension of the state vector and m is the number of observations, can also be specified. When the number of observations is comparable to the dimension of the state vector, the reduced-order observer may represent a considerable simplification.

The description of the reduced-order observer is simplified if the state vector can be partitioned into two substates:

$$x = \begin{bmatrix} x_1 \\ \dots \\ x_2 \end{bmatrix} \quad (15.25)$$

such that

$$x_1 = y = Cx \quad (15.26)$$

is the observation vector (of dimension m) and x_2 (of dimension $n - m$) comprises the components of the state vector that cannot be measured directly.

In terms of x_1 , and x_2 , the plant dynamics are written as

$$\dot{x}_1 = A_{11}x_1 + A_{12}x_2 + B_1u \tag{15.27}$$

$$\dot{x}_2 = A_{21}x_1 + A_{22}x_2 + B_2u \tag{15.28}$$

Since x_1 is directly measured, no observer is required for that substate, that is,

$$\hat{x}_1 = x_1 = y \tag{15.29}$$

For the remaining substate, we define the reduced-order observer by

$$\dot{\hat{x}}_2 = Ky + z \tag{15.30}$$

where z is the state of a system of order $n - m$:

$$\dot{z} = \hat{A}z + Ly + Hu \tag{15.31}$$

A block-diagram representation of the reduced-order observer is given in Figure 15.2a.

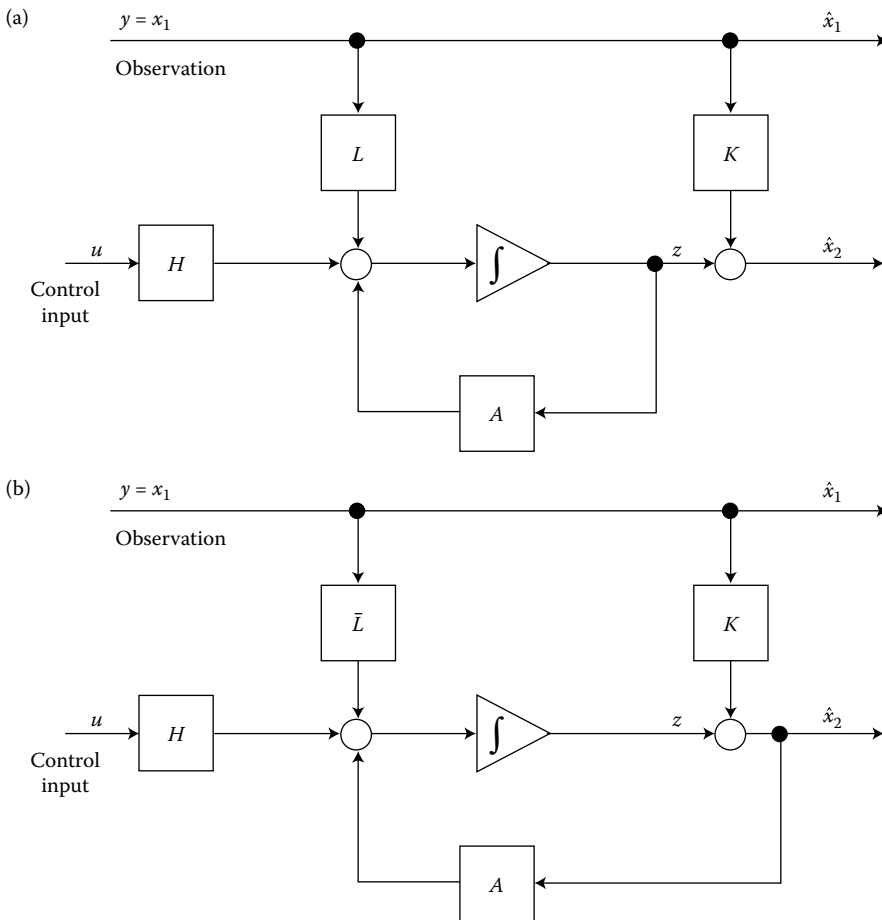

FIGURE 15.2 Reduced-order observer for linear process. (a) Feedback from z and (b) feedback from \hat{x}_2 .

The matrices \hat{A} , L , H , and K are chosen, as in the case of the full-order observer, to ensure that the error in the estimation of the state converges to zero, independent of x , y , and u .

Since there is no error in the estimation of x_1 , that is,

$$e_1 = x_1 - \hat{x}_1 = 0 \quad (15.32)$$

by virtue of Equation 15.29, it is necessary to ensure only the convergence of

$$e_2 = x_2 - \hat{x}_2 \quad (15.33)$$

to zero.

From Equations 15.28 through 15.31

$$\dot{e}_2 = (A_{21} - KA_{11} + \hat{A}K - L)x_1 + (A_{22} - KA_{12} - \hat{A})x_2 + \hat{A}e_2 + (B_2 - KB_1 - H)u \quad (15.34)$$

As in the case of the full-order observer, to make the coefficients of x_1 , x_2 , and u vanish it is necessary that the matrices in Equations 15.29 and 15.31 satisfy

$$\hat{A} = A_{22} - KA_{12}, \quad (15.35)$$

$$L = A_{21} - KA_{11} + \hat{A}K, \quad (15.36)$$

$$H = B_2 - KB_1 \quad (15.37)$$

Two of these conditions (Equations 15.35 and 15.37) are analogous to Equations 15.6 and 15.7 for the full-order observer; Equation 15.36 is a new requirement for the additional matrix L that is required by the reduced-order observer.

When these conditions are satisfied, the error in estimation of x_2 is given by

$$e_2 = \hat{A}e_2.$$

Hence, the gain matrix K must be chosen such that the eigenvalues of $\hat{A} = A_{22} - KA_{12}$ lie in the (open) left half-plane; A_{22} and A_{12} in the reduced-order observer take the roles of A and C in the full-order observer; once the gain matrix K is chosen, then there is no further freedom in the choice of L and H .

The specific form of the new matrix L in Equation 15.36 suggests another option for implementation of the dynamics of the reduced-order observer, namely

$$\dot{z} = \hat{A}\hat{x}_2 + \bar{L}y + Hu, \quad (15.38)$$

where

$$\bar{L} = A_{21} - KA_{11} \quad (15.39)$$

A block-diagram representation of this option is given in Figure 15.2b.

The selection of the gain matrix K of the reduced-order observer may be accomplished by any of the methods that can be used to select the gains of the full-order observer. In particular, pole placement, using any convenient algorithm, is feasible. Or the gain matrix can be obtained as the solution of a reduced-order Kalman filtering problem. For this purpose, one can use Equations 15.12 and 15.13, with A and C therein replaced by A_{22} and A_{12} of the reduced-order problem.

A more rigorous solution, taking into account the cross-correlation between the observation noise and the process noise [4], is available. Suppose the dynamic process is governed by

$$\dot{x}_1 = A_{11}x_1 + A_{12}x_2 + B_1u + F_1v, \quad (15.40)$$

$$\dot{x}_2 = A_{21}x_1 + A_{22}x_2 + B_2u + F_2v, \quad (15.41)$$

with the observation being noise free:

$$y = x_1 \quad (15.42)$$

In this case, the gain matrix is given by

$$K = (PA'_{12} + F_2QF'_1)R^{-1}, \quad (15.43)$$

where

$$R = F_1QF'_1,$$

and P is the covariance matrix of the estimation error e_2 , as given by

$$\dot{P} = \tilde{A}P + P\tilde{A}' - PA_{12}R^{-1}A'_{12}P + \tilde{Q}, \quad (15.44)$$

where

$$\tilde{A} = A_{22} - F_2QF'_1R^{-1}A_{12}, \quad (15.45)$$

$$\tilde{Q} = F_2QF'_2 - F_2QF'_1R^{-1}F_1QF'_2 \quad (15.46)$$

Note that Equation 15.44 becomes homogeneous when

$$\tilde{Q} = 0 \quad (15.47)$$

One of the solutions of Equation 15.44 could be

$$P = 0. \quad (15.48)$$

which would imply that the error in estimating x_2 converges to zero! We cannot expect to achieve anything better than this. Unfortunately, $P = 0$ is not the only possible solution to Equation 15.47. To test whether it is, it is necessary to check whether the resulting observer dynamics matrix

$$\hat{A} = A_{22} - F_2F^{-1}_1A_{12} \quad (15.49)$$

is a stability matrix. If not, Equation 15.47 is not the correct solution to Equation 15.44.

The eigenvalues of the “zero steady-state variance” observer dynamics matrix Equation 15.49 have an interesting interpretation: as shown in [4], these eigenvalues are the transmission zeros of the plant with respect to the noise input to the process. Hence, the variance of the estimation error converges to zero if the plant is “minimum phase” with respect to the noise input.

For purposes of robustness, as discussed in Section 4, suggest that the noise distribution matrix F includes a term proportional to the control distribution matrix B , that is,

$$F = \bar{F} + q^2BB'$$

In this case, the zero-variance observer gain would satisfy

$$H = B_2 - KB_1 = 0, \quad (15.50)$$

as $q \rightarrow \infty$.

If Equation 15.50 is satisfied, the observer poles are located at the transmission zeros of the plant. Thus, in order to use the gain given by Equation 15.50, it is necessary for the plant to be minimum phase with respect to the input. Rynaski [5] has defined observers meeting this requirement as *robust observers*.

15.4 Discrete-Time Systems

Observers for discrete-time systems can be defined in a manner analogous to continuous-time systems. Consider a discrete-time linear system

$$x_{n+1} = \Phi x_n + \Gamma u_n \quad (15.51)$$

with observations defined by

$$y_n = Cx_n \quad (15.52)$$

A full-order observer for Equation 15.51 is a dynamic system of the same order as the process whose state is to be estimated, excited by the inputs and outputs of that process and having the property that the estimation error (i.e., the difference between the state x_n of the process and the state \hat{x}_n of the observer) converges to zero as $n \rightarrow \infty$, independent of the state of the process or its inputs and outputs.

Let the observer be defined by the general linear difference equation

$$\hat{x}_{n+1} = \hat{\Phi} \hat{x}_n + Ky_n + Hu_n \quad (15.53)$$

The goal is to find conditions on the matrices Φ , K , and H such that the requirements stated above are met. To find these conditions subtract Equation 15.53 from Equation 15.51

$$x_{n+1} - \hat{x}_{n+1} = \Phi x_n + \Gamma u_n - \hat{\Phi} \hat{x}_n - Ky_n - Hu_n \quad (15.54)$$

Letting

$$e_n = x_n - \hat{x}_n$$

and using Equation 15.52 we obtain from Equation 15.54

$$e_{n+1} = \Phi e_n + (\Phi - KC - \hat{\Phi})x_n + (\Gamma - H)u_n \quad (15.55)$$

Thus, in order to meet the requirements stated above, the transition matrix $\hat{\Phi}$ of the observer must be stable (i.e., the eigenvalues of $\hat{\Phi}$ must lie within the unit circle) and, moreover,

$$\hat{\Phi} = \Phi - KC, \quad (15.56)$$

$$H = \Gamma \quad (15.57)$$

By virtue of these relations the observer can be expressed as

$$\hat{x}_{n+1} = \Phi x_n + \Gamma u_n + K(y_n - C\hat{x}_n) \quad (15.58)$$

It is seen from Equation 15.58 that the observer has the same dynamics as the underlying process, except that it has an additional input

$$K(y_n - C\hat{x}_n),$$

that is, a gain matrix K multiplying the *residual*

$$r_n = y_n - C\hat{x}_n$$

As in the continuous-time case, the observer can be interpreted as a feedback system, the role of which is that of driving residual r_n to zero.

The observer design thus reduces to the selection of the gain matrix K that makes the eigenvalues of $\hat{\Phi} = \Phi - KC$ lie at suitable locations within the unit circle.

If the discrete-time system is observable, the eigenvalues of $\Phi_c = \Phi - KC$ can be put anywhere. For a single-output plant, the Bass-Gura formula or other well-known algorithm can be used. For both single

and multiple output processes, the observer gain matrix can be selected to make the observer a Kalman filter (i.e., a minimum variance estimator).

The gain matrix of the discrete-time Kalman filter is given by

$$K = \Phi PC'(PCP' + R)^{-1}, \tag{15.59}$$

where P is the covariance matrix of the estimation error, given (in the steady state) by the *discrete-time algebraic Riccati equation*

$$P = \Phi[P - PC'(CPC' + R)^{-1}CP]\Phi' + Q \tag{15.60}$$

The matrices Q and R are the covariance matrices of the excitation noise and the observation noise, respectively. As in the case of continuous-time processes, it is rarely possible to determine these matrices with any degree of accuracy. Hence, these matrices can be regarded as design parameters that can be adjusted by the user to provide desirable observer characteristics.

15.4.1 Delayed Data

Consider the discrete-time system defined by Equation 15.51 and with delayed observations defined by

$$\begin{aligned} z_n &= Cx_n, \\ y_n &= z_{n-N}, \end{aligned}$$

where N is the time delay, assumed to be an integer. The method described in Section 15.2.2 can readily be extended to this case. As an alternative the following method can be used. Define the metastate as the $v + kN$ dimensional vector (where v is the dimension of the state vector and k is the dimension of the original observation vector)

$$\mathbf{x}_n = \begin{bmatrix} x_n \\ z_n \end{bmatrix} \quad \text{with } z_n = [z_{1n} \quad z_{2n} \quad \cdots \quad z_{Tn}]'$$

Then the metastate evolves according to

$$\mathbf{x}_{n+1} = \Phi \mathbf{x}_n + \Gamma u_n,$$

where

$$\Phi = \begin{bmatrix} \Phi & 0 & 0 & \cdots & 0 & 0 \\ C & 0 & 0 & \cdots & 0 & 0 \\ 0 & I & 0 & \cdots & 0 & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots & I & 0 \end{bmatrix}$$

and

$$\Gamma = [\Gamma' \quad 0 \quad \cdots \quad 0 \quad 0]'$$

For all components of the observation vector concurrent, the observation equation is

$$y_n = C\mathbf{x}_n = [0 \quad 0 \quad \cdots \quad 0 \quad I] x_n$$

For m time delays (each an integer multiple of the sampling time), the observation matrix is given by

$$C = [0 \quad \cdots \quad U_1 \quad \cdots \quad U_2 \quad \cdots \quad U_m],$$

where U_i is a column vector with ones in the positions of the observation components present at the i th observation and zeros otherwise. Applying the theory developed earlier to the metasytem gives the observer the presence of delayed data.

It is noted that implementation of this method requires the storage of past observations, but permits the treatment of multiple observations with different time delays.

15.5 The Separation Principle

The predominant use of an observer is to estimate the state for purposes of feedback control. In particular, in a linear system with a control designed on the assumption of full-state feedback

$$u = -Gx, \quad (15.61)$$

when the state x is not directly measured, the state \hat{x} of the observer is used in place of the actual state x in Equation 15.61. Thus, the control is implemented using

$$u = -G\hat{x}, \quad (15.62)$$

where

$$\hat{x} = x - e \quad (15.63)$$

Hence, when an observer is used, the closed-loop dynamics are given in part by

$$\dot{x} = Ax - BG(x - e) = (A - BG)x + BGe \quad (15.64)$$

This equation, together with the equation for the propagation of the error, defines the complete dynamics of the closed-loop system.

When a full-order observer is used

$$\dot{e} = \hat{A}e = (A - KC)e \quad (15.65)$$

Thus, the complete closed-loop dynamics are

$$\begin{bmatrix} \dot{x} \\ \dot{e} \end{bmatrix} = \begin{bmatrix} A - BG & BG \\ 0 & A - KC \end{bmatrix} \begin{bmatrix} x \\ e \end{bmatrix} \quad (15.66)$$

The closed-loop dynamics are governed by the upper triangular matrix

$$\mathbf{A} = \begin{bmatrix} A - BG & BG \\ 0 & A - KC \end{bmatrix}, \quad (15.67)$$

the eigenvalues of which are given by

$$|sI - \mathbf{A}| = |sI - A + BG||sI - A + KC| = 0, \quad (15.68)$$

that is, the closed-loop eigenvalues are the eigenvalues of $A - BG$, the full-state feedback system; and the eigenvalues of $A - KC$, the dynamics matrix of the observer. This is a statement of the well-known *separation principle*, which permits one to design the observer and the full-state feedback control independently, with the assurance that the poles of the closed-loop dynamic system will be the poles selected for the full-state feedback system and those selected for the observer.

When a reduced-order observer is used, it is readily established that the closed-loop dynamics are given by

$$\begin{bmatrix} \dot{x} \\ \dot{e}_2 \end{bmatrix} = \begin{bmatrix} A - BG & BG_2 \\ 0 & A_{22} - KA_{12} \end{bmatrix} \begin{bmatrix} x \\ e_2 \end{bmatrix} \quad (15.69)$$

and hence that the eigenvalues of the closed-loop system are given by

$$|sI - A + BG||sI - A_{22} + KA_{12}| = 0 \quad (15.70)$$

Thus, the separation principle also holds when a reduced-order observer is used.

It is important to recognize, however, that the separation principle applies only when the model of the process used in the observer agrees exactly with the actual dynamics of the physical process. It is not possible to meet this requirement in practice and, hence, the separation principle is an approximation at best. To assess the effect of a model discrepancy on the closed-loop dynamics, consider the following possibilities:

Case 1: Error in dynamics matrix

$$A = \bar{A} + \delta A$$

Case 2: Error in control distribution matrix

$$B = \bar{B} + \delta B$$

Case 3: Error in observation matrix

$$C = \bar{C} + \delta C$$

Using the “metastate”

$$\mathbf{x} = \begin{bmatrix} x \\ e \end{bmatrix}$$

it is readily determined [6] that the characteristic polynomial of the complete, closed-loop system for cases 1 and 3 is given by

$$|sI - \mathbf{A}| = \begin{vmatrix} sI - A_c & -BG \\ \delta A + K\delta C & sI - \hat{A} \end{vmatrix}, \quad (15.71)$$

where

$$A_c = \bar{A} - BG, \quad \hat{A} = \bar{A} - K\bar{C}$$

Similarly, using the metastate

$$\mathbf{x} = \begin{bmatrix} \hat{x} \\ e \end{bmatrix},$$

it is found that the characteristic polynomial for case 2 is given by

$$|sI - \mathbf{A}| = \begin{vmatrix} sI - \hat{A} & -\delta BG \\ KC & sI - A_c \end{vmatrix}, \quad (15.72)$$

where

$$A_c = A - \bar{B}G, \quad \hat{A} = A - KC$$

To assess the effect of perturbations of the dynamics matrices on the characteristic polynomial, the following determinantal identity can be used:

$$\begin{vmatrix} \mathcal{A} & \mathcal{B} \\ \mathcal{C} & \mathcal{D} \end{vmatrix} = |\mathcal{D}| |\mathcal{A} - \mathcal{C}\mathcal{D}^{-1}\mathcal{B}| \quad (15.73)$$

Apply Equation 15.73 to Equation 15.72 to obtain

$$\begin{aligned} |sI - \mathbf{A}| &= |sI - A_c| |sI - \hat{A} + \delta BG(sI - A_c)^{-1} KC| \\ &= |sI - A_c| |sI - \hat{A}| |I + \delta BG(sI - A_c)^{-1} KC(sI - \hat{A})^{-1}| \end{aligned} \quad (15.74)$$

upon use of

$$|\mathcal{A}\mathcal{B}| = |\mathcal{A}| |\mathcal{B}|$$

The separation principle would continue to hold if the coefficient of δB in Equation 15.74 were to vanish. It does vanish if observer matrix K satisfies the *Doyle–Stein condition* [2]

$$K(I + C\Phi K)^{-1} = B(C\Phi B)^{-1}, \quad (15.75)$$

where

$$\Phi = (sI - A)^{-1}$$

is the plant resolvent.

To verify this, note that

$$\begin{aligned} (sI - \hat{A})^{-1} &= (sI - A + KC)^{-1} = (\Phi^{-1} + KC)^{-1} \\ &= \Phi - \Phi K(I + C\Phi K)^{-1} C\Phi \end{aligned} \quad (15.76)$$

When the Doyle–Stein condition (Equation 15.75) holds, Equation 15.76 becomes

$$(sI - \hat{A})^{-1} = \Phi - \Phi B(C\Phi B)^{-1} C\Phi,$$

and so

$$C(sI - \hat{A})^{-1} = C\Phi - C\Phi B(C\Phi B)^{-1} C\Phi = 0,$$

which ensures that the coefficient of δB in Equation 15.74 vanishes and, hence, that the separation principle applies.

Regarding the Doyle–Stein condition the following remarks are in order:

- The Doyle–Stein condition can rarely be satisfied exactly. But, as shown [2], it can be satisfied approximately by making the observer a Kalman filter with a noise matrix of the form given by Equation 15.14.
- The Doyle–Stein condition is not the only way the coefficient of δB can vanish. However, the Doyle–Stein condition ensures other robustness properties.
- An analogous condition for δA and δC can be specified.

In carrying out a similar analysis for a reduced-order observer it is found that the characteristic polynomial for the closed-loop control system, when a reduced-order observer is used and the actual control distribution matrix $B = \bar{B} + \delta B$ differs from the nominal (design) value \bar{B} , is given by

$$|sI - \mathbf{A}| = \begin{vmatrix} sI - F + \Delta G_2 & \Delta G \\ -BG_2 & sI - A_c \end{vmatrix}, \quad (15.77)$$

where

$$\Delta = K\delta B_1 - B_2 \quad (15.78)$$

It is seen that the characteristic polynomial of the closed-loop system reduces to that of Equation 15.70 when

$$\Delta = 0 \quad (15.79)$$

It is noted that Equation 15.79 can hold in a single-input system in which the loop gain is the only variable parameter. In this case

$$\delta B_1 = \rho B_1, \quad \delta B_2 = \rho B_2 \quad (15.80)$$

and thus

$$\Delta = \rho(KB_1 - B_2) = -\rho H$$

Hence, if the observer is designed with

$$H = B_2 - KB_1 = 0,$$

the separation principle holds for arbitrary changes in the loop gain.

If Equation 15.79 cannot be satisfied, then, as shown in [7], condition analogous to the Doyle–Stein condition can be derived from Equation 15.77 in the case of a scalar control input (Equation 15.80):

$$[I - K(I + A_{12}\Phi_{22}K)^{-1}A_{12}\Phi_{22}](B_2 - KB_1) = 0, \quad (15.81)$$

where

$$\Phi_{22} = (sI - A_{22})^{-1}$$

15.6 Nonlinear Observers

The concept of an observer carries over to nonlinear systems. However, for a nonlinear system, the structure of the observer is not nearly as obvious as it is for a linear system. The design of observers for nonlinear systems has been addressed by several authors, such as Thau [8] and Kou et. al. [9].

An observer for a plant, consisting of a dynamic system

$$\dot{x} = f(x, u) \tag{15.82}$$

with observations given by

$$y = g(x, u) \tag{15.83}$$

is another dynamic system, the state of which is denoted by \hat{x} , excited by the output y of the plant, having the property that the error

$$e = x - \hat{x} \tag{15.84}$$

converges to zero in the steady state.

One way of obtaining an observer is to imitate the procedure used in a linear system, namely to construct a model of the original system (Equation 15.1) and force it with the “residual”:

$$r = y - \hat{y} = y - g(\hat{y}, u) \tag{15.85}$$

The equation of the observer thus becomes

$$\dot{\hat{x}} = f(\hat{x}, u) + \kappa(y - g(\hat{x}, u)), \tag{15.86}$$

where $\kappa(\)$ is a suitably chosen nonlinear function. (How to choose this function will be discussed later.) A block diagram representation of a general nonlinear observer is shown in Figure 15.3.

The differential equation for the error e can be used to study its behavior. This equation is given by

$$\begin{aligned} \dot{e} &= \dot{x} - \dot{\hat{x}} \\ &= f(x, u) - f(\hat{x}, u) - \kappa(g(x, u) - g(\hat{x}, u)) \\ &= f(x, u) - f(x - e, u) + \kappa(g(x - e, u) - g(x, u)) \end{aligned} \tag{15.87}$$

Suppose that by the proper choice of $\kappa(\)$ the error Equation 15.87 can be made asymptotically stable, so that an equilibrium state is reached for which

$$\dot{e} = 0$$

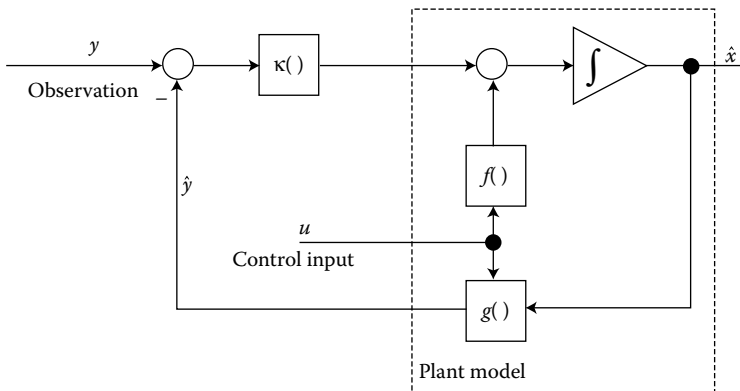

FIGURE 15.3 Structure of the nonlinear observer.

Then, in equilibrium, Equation 15.87 becomes

$$0 = f(x, u) - f(x - e, u) + \kappa(g(x - e, u) - g(x, u)) \quad (15.88)$$

Since the right-hand side of Equation 15.88 becomes zero when $e = 0$, independent of x and u , it is apparent that $e = 0$ is an equilibrium state of Equation 15.87. This implies that if $\kappa(\cdot)$ can be chosen to achieve asymptotic stability, the estimation error e converges to zero.

It is very important to appreciate that the right-hand side of Equation 15.88 becomes zero independent of x and u only when the nonlinear functions $f(\cdot, \cdot)$ and $g(\cdot, \cdot)$ used in the observer are exactly the same as in Equations 15.82 and 15.83, which define the plant dynamics and observations, respectively. Any discrepancy between the corresponding functions generally prevents the right-hand side of Equation 15.88 from vanishing and hence leads to a steady-state estimation error. Since the mathematical model of a physical process is always an approximation, in practice the steady-state estimation error generally does not tend to zero. But, by careful modeling, it is usually possible to minimize the discrepancies between the f and g functions of the true plant and the model used in the observer. This usually keeps the steady-state estimation error acceptably small.

For the same reason that the model of the plant and the observation that is used in the observer must be accurate, it is important that the control u that goes into the plant is the very same control used in the observer. If the control to the plant is subject to saturation, for example, then the nonlinear function that models the saturation must be included in the observer. Failure to observe this precaution can cause difficulties.

Including control saturation in the observer is particularly important as a means for avoiding the phenomenon known as *integrator windup*: the compensator, which has a pole at the origin, provides integral action. Imagine the transfer function of the compensator represented by an integrator in parallel with a second-order subsystem. The control signal to the integrator is oblivious to the fact that the input to the plant has saturated and hence keeps the integrator “winding up”; the error signal changes sign when the desired output reaches the set point, but the control signal does not drop from its maximum value. When the saturation is included in the observer, on the other hand, the control signal drops from its maximum value even before the error changes sign, thus correctly taking the dynamics (i.e., the lag) of the process into account.

The function $\kappa(\cdot)$ in the observer must be selected to ensure asymptotic stability of the origin ($e = 0$ in Equation 15.88). By the theorem of Lyapunov’s first method (see Chapter 43), the origin is asymptotically stable if the Jacobian matrix of the dynamics, evaluated at the equilibrium state, corresponds to an asymptotically stable linear system. For the dynamics of the error Equation 15.87 the Jacobian matrix with respect to the error e evaluated at $e = 0$ is given by

$$A_c(x) = \left(\frac{\partial f}{\partial x} \right) - K \left(\frac{\partial g}{\partial x} \right). \quad (15.89)$$

This is the nonlinear equivalent of the closed-loop observer equation of a linear system

$$A_c = A - KC,$$

where A and C are the plant dynamics and observation matrices, respectively. The problem of selecting the gain matrix for a nonlinear observer is analogous to that of a linear observer, but somewhat more complicated by the presence of the nonlinearities that make the Jacobian matrices in Equation 15.89 dependent on the state x of the plant. Nevertheless, the techniques used for selecting the gain for a linear observer can typically be adapted for a nonlinear observer. Pole placement is one method and the other is to make the observer an extended Kalman filter which, as explained later, entails online computation of the gains via the linearized variance equation.

It should be noted that the observer closed-loop dynamics matrix depends on the actual state of the system and hence is time varying. The stability of the observer thus cannot be rigorously determined by the locations of the eigenvalues of A_c .

The choice of $\kappa(\cdot)$ may be aided through the use of Lyapunov's second method. Using this method, Thau [8] considered a "mildly nonlinear" process

$$\dot{x} = f(x) = Ax + \mu\phi(x), \quad (15.90)$$

where μ is a small parameter, with linear observations

$$y = Cx$$

For this case, κ can be simply a gain matrix chosen to stabilize the linear portion of the system

$$\kappa(r) = Kr,$$

where K is chosen to stabilize

$$\hat{A} = A - KC$$

This choice of K ensures asymptotic stability of the observer if $\phi(\cdot)$ satisfies a Lipschitz condition

$$\|\phi(u) - \phi(v)\| \leq k\|u - v\|$$

and when

$$P\hat{A} + \hat{A}'P = -Q \leq -c_0I$$

In this case, asymptotic stability of the observer

$$\hat{x} = A\hat{x} + \mu\phi(\hat{x}) + K(y - C\hat{x})$$

is assured for

$$\mu < \frac{c_0}{2k\|P\|}$$

This analysis was substantially extended by Kou et al. [9].

Suggestions for the choice of the nonlinear function $\kappa(\cdot)$ have appeared in the technical literature. One suggestion [10], for example, is to use

$$\kappa(r) = \Psi(\hat{x})^{-1}Kr,$$

where K is a constant, possibly diagonal matrix, and $\Psi(x)$ is the Jacobian matrix defined by

$$\Psi(x) = \frac{\partial\Phi(x)}{\partial x}$$

with

$$\Phi(x) = \begin{bmatrix} L_f g(x) \\ L_f^2 g(x) \\ \vdots \\ L_f^n g(x) \end{bmatrix},$$

in which $L_f^n g(x)$ is the n th Lie derivative of $g(x)$ with respect to $f(x)$. (See Chapter 38.) This approach can possibly be viewed as a nonlinear generalization of the Bass-Gura formula given previously, since the matrix Ψ is akin to the observability matrix O defined earlier.

15.6.1 Using Zero-Crossing or Quantized Observations

The ability of an observer to utilize nonlinear observations is not limited to observations that exhibit only moderate nonlinearity; even highly nonlinear observations can be accommodated. Perhaps the most nonlinear observation is that of a zero-crossing detector, in which

$$y = \text{sgn}(x) = \begin{cases} 1, & x > 0 \\ -1, & x < 0 \end{cases}$$

This is the extreme special case of a quantizer, in which the output is quantized to only two levels.

Suppose, for example, that the only observation is of the zero-crossing of x_1 . The observer for this process is then given by

$$\dot{\hat{x}} = f(\hat{x}, u) - k[y - \text{sgn}(\hat{x}_1)], \tag{15.91}$$

as illustrated in Figure 15.4.

Provided that a gain k , in this case a scalar parameter, can be found that stabilizes the observer at $e = 0$, the estimation error will be reduced to zero. The partial derivative of the nonlinear function with respect to the observation does not exist in this case because the observation is discontinuous with respect to the state. The stability of the observer cannot be established by linearizing about the origin. You have to use some other methods, such as Lyapunov's second method, or determine the appropriate range of k by simulation.

Some insight into how the observer operates can be gained by considering that both y and $\text{sgn}(x_1)$ are signals that take on the values of ± 1 ; their difference, which is the residual that appears in Equation 15.91, is either 0 or ± 2 . Suppose the observer is working well; most of the time y and $\text{sgn}(x_1)$ will have the same sign and the residual will be zero. The residual will be nonzero for the short time interval in which y and $\text{sgn}(x_1)$ have different signs. The residual will thus consist of a train of narrow pulses, each of height ± 2 and of width proportional to the phase difference between y and $\text{sgn}(x_1)$, as shown in Figure 15.5. The effect of each pulse is to nudge the state of the observer to agree with the state of the plant.

The same idea extends to quantized observations, since a quantizer can be regarded as a multiple-level crossing detector.

Of course, if there are other observations in addition to the zero-crossing observation, they can be combined with the latter and, with an appropriate choice of gains, can provide enhanced performance.

15.6.2 Reduced-Order Observers

Nonlinear reduced-order observers can be developed by the same methods that one uses for linear, reduced-order observers.

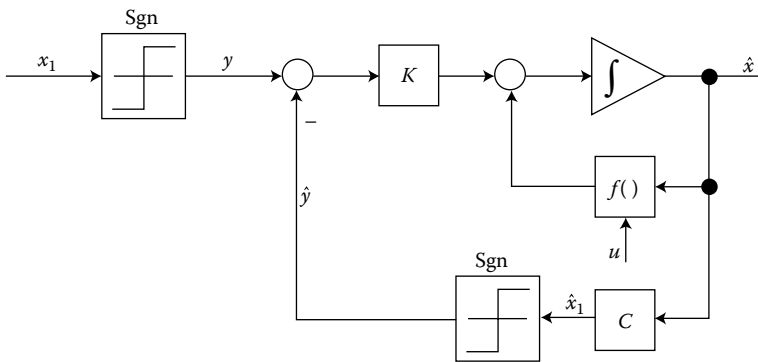

FIGURE 15.4 Observer using zero-crossing data.

FIGURE 15.5 Residual for zero-crossing observations consists of pulses.

Suppose that the state is partitioned into two substates as given by Equation 15.25 with the observation given by

$$y = g(x_1, u)$$

Provided that this expression can be solved for x_1 as a function of y and u ,

$$x_1 = \psi(y, u) = \bar{y},$$

we can use \bar{y} as the observation. The completely general case in which y contains more state variables than its dimension can probably be handled in a manner similar to that used for linear systems, as discussed by Friedland [6]. The derivation is very tortuous in linear systems and is likely to be even more so in nonlinear systems and is, hence, omitted.

Corresponding to the partitioning of the state vector x as in Equation 15.25, the dynamic equations are written as

$$\dot{x}_1 = f_1(x_1, x_2, u), \tag{15.92}$$

$$\dot{x}_2 = f_2(x_1, x_2, u), \tag{15.93}$$

The nonlinear reduced-order observer is assumed to have the same structure as the corresponding linear observer. For the estimate of the substate x_1 , we use the observation itself:

$$\hat{x}_1 = y; \tag{15.94}$$

while the substate x_2 is estimated using an observer of the form

$$\hat{x}_2 = Ky + z, \tag{15.95}$$

where z is the state of a dynamic system of the same order as the dimension of the subvector x_2 and is given by

$$\dot{z} = \phi(y, \hat{x}_2, u) \tag{15.96}$$

A block-diagram representation of the observer having the structure of Equations 15.94 through 15.96 is given in Figure 15.6.

FIGURE 15.6 Reduced-order nonlinear observer.

The object of the observer design is the determination of the gain matrix K and the nonlinear function ϕ . As for the full-order observer, these are to be selected such that

- The steady-state error in estimating x_2 converges to zero, independent of x and u . (The error in estimating x_1 is already zero when $\hat{x}_1 = y$.)
- The observer is asymptotically stable.

As in the case of the full-order observer, we proceed by deriving the differential equation for the estimation error

$$e = x_2 - \hat{x}_2 \tag{15.97}$$

Using Equations 15.93, 15.95, and 15.92, we obtain

$$\dot{e} = \dot{x}_2 - \dot{\hat{x}}_2 = f_2(y, x_2, u) - Kf_1(y, x_2, u) - \phi(y, x_2 - e, u) \tag{15.98}$$

In order for the right-hand side of Equation 15.98 to vanish when $e = 0$, it is necessary that the function $\phi(\cdot, \cdot, \cdot)$ satisfy

$$\phi(y, x_2, u) = f_2(y, x_2, u) - Kf_1(y, x_2, u) \tag{15.99}$$

for all values of y, x_2 , and u .

To achieve asymptotic stability, the linearized system

$$\dot{e} = A(x_2)e \tag{15.100}$$

with

$$A(x_2) = \left(\frac{\partial \phi}{\partial x_2} \right) = \left(\frac{\partial f_2}{\partial x_2} \right) - K \left(\frac{\partial f_1}{\partial x_2} \right) \tag{15.101}$$

must be asymptotically stable.

As in the case of the full-order observer, there are several techniques for selecting an appropriate gain matrix.

The reduced-order nonlinear observer can be further generalized by replacing the linear function Ky in Equation 15.95 by a nonlinear function $\kappa(y)$.

15.6.3 Extended Separation Principle

When an observer having the structure described above is used to estimate the state of a linear system, and the estimate is used in place of the actual state, the poles of the closed-loop system comprise the poles of the observer and the poles that would be present if full-state feedback were implemented. This is the

separation principle of linear systems. (But remember that this result holds only when the model of the plant used in implementing the observer is a faithful model of the physical plant.)

The separation principle of linear systems can be extended to nonlinear systems. Consider, in particular, the nonlinear system

$$\dot{x} = f(x, u), \quad (15.102)$$

for which a control law

$$u = \gamma(x) \quad (15.103)$$

has been designed. Use of Equation 15.103 in Equation 15.102 gives the closed-loop dynamics

$$\dot{x} = f(x, \gamma(x)) = F(x) \quad (15.104)$$

Assume that the closed-loop dynamics of the system with full-state feedback, as represented by $F(x)$, has been designed—by whatever method might be appropriate—to achieve satisfactory behavior. How will the process behave when the state \hat{x} of an observer is used in place of the true process state x [i.e., when $u = \gamma(\hat{x})$]? As earlier, let

$$\hat{x} = x - e,$$

where e is the error in estimating the state. Then Equation 15.103 becomes

$$u = \gamma(\hat{x}) = \gamma(x - e)$$

Then Equation 15.104 becomes

$$\dot{x} = f(x, \gamma(x - e)), \quad (15.105)$$

which together with Equation 15.87, becomes

$$\dot{e} = f(x, \gamma(\hat{x})) - f(x - e, \gamma(\hat{x})) + K[g(x - e, \gamma(\hat{x})) - g(x, \gamma(\hat{x}))], \quad (15.106)$$

which define the closed-loop dynamics.

There is not much that can be done with Equations 15.105 and 15.106 when f , g , and γ are general functions. However suppose these functions are sufficiently smooth to permit the use of Taylor's theorem, that is,

$$f(x, \gamma(x - e)) = f(x, \gamma(\hat{x})) - (\partial f / \partial \gamma)(\partial \gamma / \partial e)e + O(e^2), \quad (15.107)$$

$$f(x - e, \gamma(\hat{x})) = f(x, \gamma(\hat{x})) - (\partial f / \partial x)e + O(e^2), \quad (15.108)$$

$$g(x - e, \gamma(\hat{x})) = g(x, \gamma(\hat{x})) - (\partial g / \partial x)e + O(e^2), \quad (15.109)$$

where $O(e^2)$ represents terms that go to zero as $\|e\|^2$. Then Equations 15.105 and 15.106 become

$$\dot{x} = F(x) - (\partial f / \partial \gamma)(\partial \gamma / \partial e)e + O(e^2), \quad (15.110)$$

$$\dot{e} = [\partial f / \partial x + K(\partial g / \partial x)]e + O(e^2) \quad (15.111)$$

With the terms of $O(e^2)$ omitted, a block-diagram representation of Equations 15.110 and 15.111 is shown in Figure 15.7. Note that the equation for the error has no input from the state estimation. The error thus converges asymptotically to zero as in the linear case. Since the error is the input to the full-state feedback control system, if the latter is asymptotically stable, the effect of the estimation error vanishes.

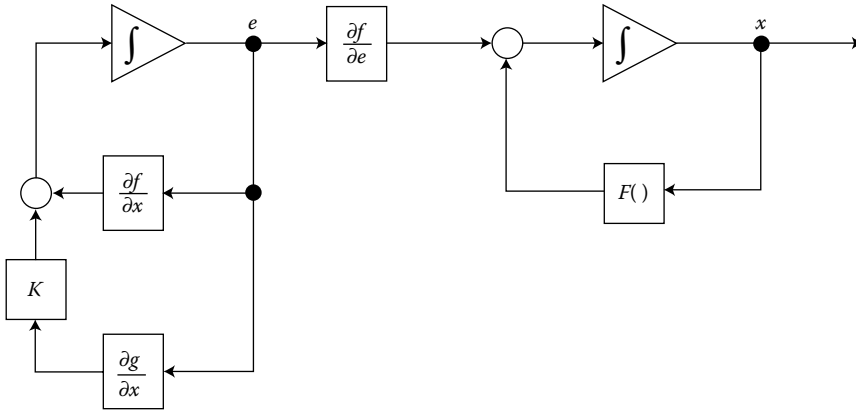

FIGURE 15.7 Illustration of the extended separation principle.

15.6.4 Extended Kalman Filter

Sometimes the nonlinear function $\kappa(\cdot)$ can simply be a constant gain. Often, however, there is no obvious method of choosing this gain and a more systematic method is required. It is often appropriate to make the observer an “extended Kalman filter,” that is, to calculate the gain matrix online from the solution of the variance equation of the Kalman filter.

Few of the many applications for which Kalman filters have been used have met the linearity requirements of the theory. Nevertheless, the theory has been successfully, if not rigorously, applied. This is done by using a nonlinear observer of the form of Equation 15.88, but with the gain matrix K therein being computed, along with the state estimate, using Equations 15.12 and 15.13. The matrices A and C in these equations are the Jacobian matrices of the dynamics and observations

$$A = [\partial f / \partial x]_{x=\hat{x}}, \tag{15.112}$$

$$C = [\partial g / \partial x]_{x=\hat{x}}, \tag{15.113}$$

for the nonlinear process defined by

$$\dot{x} = f(x, u), \tag{15.114}$$

$$y = g(x, u) \tag{15.115}$$

In the linear case, the error covariance matrix, and through it the gain matrix K , does not depend on the estimated state. In principle, these matrices can be computed before the filter is implemented and stored in the filter’s memory. In the nonlinear case, however, the matrices A and C that are used in computing P and K depend on the state estimate. Hence, in the extended Kalman filter, the observer and the Kalman filter gain matrix computation are coupled. This means that the equations for both the variance equation and the observer must be implemented online as shown schematically in Figure 15.8.

The requirement for online computation of the extended Kalman filter gain matrix can be a computational burden. Even considering that the covariance equation P is symmetric, there still are $k(k - 1)/2$ scalar differential equations in Equation 15.13 that must be integrated numerically in addition to the k scalar observer equations for a k th-order dynamic process. In a 10-order process, for example, a total of 55 equations must be integrated. It does not take a process of much higher order to overwhelm even a supercomputer. Moreover, the matrix Riccati equation (Equation 15.13) for P is notorious for being poorly behaved. Unless special measures are taken, the numerical solution to Equation 15.13 is likely to lose its positive-definite character as the theory requires. If this happens, the resulting state estimate \hat{x} will probably be useless.

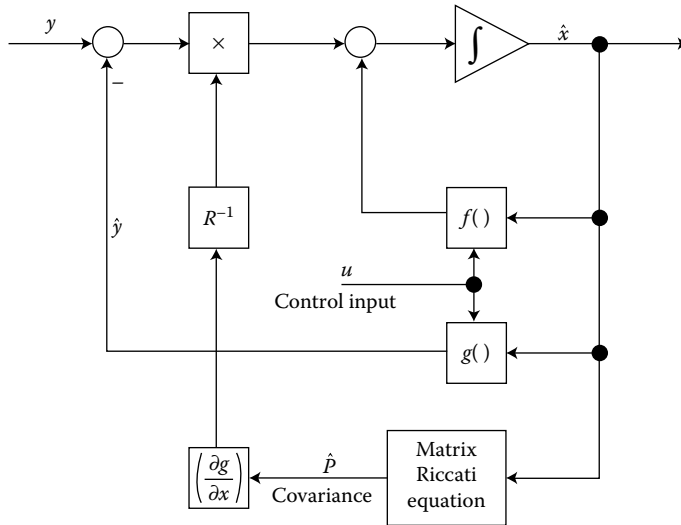

FIGURE 15.8 Schematic of the extended Kalman filter, showing coupling between state estimation and covariance computation.

Fortunately, it is rarely necessary to be a stickler for accuracy in the implementation of Equation 15.13. In the first place, the entire theory of the extended Kalman filter is only approximate. Moreover, the spectral density matrices Q and R that appear in Equation 15.13 are hardly ever known to be better than an order of magnitude. Hence, any computational method that gives a reasonable approximation to P and K is usually acceptable. Some of the approximations that have been considered include the following:

- Regard P as being piecewise constant and compute it relatively infrequently, using the discrete-time version of the Kalman filter.
- Simulate the observer and Equation 15.13 offline; examine the results and use appropriate approximations. It may be possible, for example, to approximate some of the gains by constants. The effect of the approximations must be evaluated by further simulation.
- Use a simpler model to represent the process in Equation 15.13 than is used as the process model in the observer; but be careful not to use an overly simple model in the implementation of the process dynamics.

Acknowledgment

The author is grateful to Dr. Sergey Levkov formerly of the Institute of Cybernetics in Kiev, Ukraine, for reviewing the manuscript and bringing to his attention some new references on nonlinear observers.

16.1 Introduction

Eigenstructure assignment is a useful tool that allows the designer to satisfy damping, settling time, and *mode decoupling* specifications directly by choosing eigenvalues and eigenvectors. Andry et al. [1] have applied eigenstructure assignment to design a *stability augmentation system* for the lateral dynamics of the L-1011 aircraft. Both constant gain output feedback and *gain suppression* designs are proposed. Sobel and Shapiro [30] used eigenstructure assignment to design dynamic compensators for the L-1011 aircraft. First- and second-order compensators were proposed for the case in which sideslip angle could not be measured. Later, Sobel et al. [33] proposed a systematic method for choosing the elements of the feedback gain matrix which can be suppressed to zero with minimal effect on the eigenvalue and eigenvector

* Reprinted from Sobel, K.M., Shapiro, E.Y., and Andry, A.N., Jr., *Int. J. Control*, 59(1), 13–37, 1994. With permission [27].

assignment. A design of an eigenstructure assignment gain-suppression flight controller is shown for F-18 High Angle of Attack Research Vehicle (HARV) aircraft.

Specialized task tailored modes for highly maneuverable fighter aircraft have been designed by using eigenstructure assignment. Sobel and Shapiro [29] designed an eigenstructure assignment pitch pointing and vertical translation controller for the AFTI F-16 aircraft. Pilot command tracking was achieved by using a special case of O'Brien and Broussard's [21] command generator tracker. Sobel and Shapiro [28] designed a yaw pointing and lateral translation controller for the linearized lateral dynamics of the Flight Propulsion Control Coupling (FPCC) aircraft. This conceptual control-configured vehicle has a vertical canard in addition to the more conventional control surfaces.

This chapter is organized as follows. Section 16.2 describes eigenstructure assignment using constant gain output feedback. Section 16.3 extends eigenstructure assignment to allow the designer to suppress chosen elements of the feedback gain matrix to zero. A systematic method for choosing the entries to be suppressed is discussed. Section 16.4 describes eigenstructure assignment using dynamic compensation. Each section includes an application of eigenstructure assignment to the design of a stability augmentation system for the linearized lateral dynamics of the F-18 HARV. Finally, in Section 16.5 we present a robust, sampled data, eigenstructure assignment control law design for the yaw pointing/lateral translation maneuver of the FPCC aircraft.

16.2 Eigenstructure Assignment Using Output Feedback

Consider a system modeled by the linear time-invariant matrix differential equation described by

$$\dot{x} = Ax + Bu \quad (16.1)$$

$$y = Cx \quad (16.2)$$

where x is the state vector ($n \times 1$), u is the control vector ($m \times 1$), and y is the output vector ($r \times 1$). It is assumed that the m inputs and the r outputs are independent. Also, as is usually the case in aircraft problems, it is assumed that $m < r < n$. If there are no exogenous inputs such as pilot commands, the feedback control vector u equals a matrix times the output vector y :

$$u = -Fy \quad (16.3)$$

The feedback problem can be stated as follows: Given a set of desired eigenvalues, (λ_i^d) , $i = 1, 2, \dots, r$ and a corresponding set of desired eigenvectors, (v_i^d) , $i = 1, 2, \dots, r$, find the real $m \times r$ matrix F such that the eigenvalues of $A - BFC$ contain (λ_i^d) as a subset, and the corresponding eigenvectors of $A - BFC$ are close to the respective members of the set (v_i^d) .

Srinathkumar [34] has shown that if (A, B) is a controllable pair, then the feedback gain matrix F will exactly assign r eigenvalues. It will also assign the corresponding eigenvectors, provided that v_i^d is chosen to be in the subspace spanned by the columns of $(\lambda_i I - A)^{-1}B$ for $i = 1, 2, \dots, r$. This subspace is of dimension m , which is the number of independent control variables. In general, a chosen or desired eigenvector v_i^d will not reside in the prescribed subspace and, hence, cannot be achieved. Instead, a "best possible" choice for an achievable eigenvector is made. Andry et al. [1] showed that the best possible eigenvector is the projection of v_i^d onto the subspace spanned by the columns of $(\lambda_i I - A)^{-1}B$. An alternative representation, described by Kautsky et al. [11], showed that the subspace in which the eigenvector v_i must reside is also given by the null space of $U_1^T(\lambda_i I - A)$. The matrix U_1 is obtained from the singular-value decomposition of B , given by

$$B = [U_0, U_1] \begin{bmatrix} \sum V^T \\ 0 \end{bmatrix}. \quad (16.4)$$

The method of Kautsky et al. [11] for computing the subspaces is the preferred method for numerical computation.

Finally, the complete controllability assumption may be removed by using results derived by Liebst and Garrard [14] and by Liebst et al. [15]. These results allow the designer to alter eigenvectors that correspond to uncontrollable eigenvalues.

In many practical situations, complete specification of v_i^d is neither required or known, but rather the designer is interested only in certain elements of the eigenvector. Thus, assume that v_i^d has the following structure:

$$v_i^d = [v_{i1}, x, x, x, v_{ij}, x, x, v_{im}]^T,$$

where v_{ij} are designer-specified components and x is an unspecified component. Define, as shown by Andry et al. [1], a reordering operation $\{\}^{R_i}$ so that

$$\{v_i^d\}^{R_i} = \begin{bmatrix} \ell_i \\ d_i \end{bmatrix}, \quad (16.5)$$

where ℓ_i is a vector of specified components of v_i^d and d_i is a vector of unspecified components of v_i^d . The rows of the matrix $(\lambda_i I - A)^{-1}B$ are also reordered to conform with the reordered components of v_i^d . Thus,

$$\{(\lambda_i I - A)^{-1}B\}^{R_i} = \begin{bmatrix} \tilde{L}_i \\ D_i \end{bmatrix}. \quad (16.6)$$

Then, as shown by Andry et al. [1], the achievable eigenvector v_i^a is given by

$$v_i^a = (\lambda_i I - A)^{-1}B\tilde{L}_i^\dagger \ell_i, \quad (16.7)$$

where $(\cdot)^\dagger$ denotes the appropriate pseudoinverse of (\cdot) .

The output feedback gain matrix using eigenstructure assignment [1] is described by

$$F = -(Z - A_1 V)(CV)^{-1}, \quad (16.8)$$

where A_1 is the first m rows of the matrix A in Equation 16.1, V is the matrix whose columns are the r achievable eigenvectors, Z is a matrix whose columns are $\lambda_i z_i$, where the i th eigenvector v_i is partitioned as $v_i = \begin{bmatrix} z_i \\ w_i \end{bmatrix}$ with z_i an $m \times 1$ vector, and C is the output matrix in Equation 16.2. The result of Equation 16.8 assumes that the system described by Equations 16.1 and 16.2 has been transformed into a system in which the control distribution matrix B is a lead block identity matrix.

An alternative representation for the feedback gain matrix F developed by Sobel et al. [32] is

$$F = -V_b \Sigma_b^{-1} U_{b0}^T (V \Lambda - AV) V_r \Sigma_r^{-1} U_{r0}^T, \quad (16.9)$$

where the singular-value decompositions of the matrices B and CV are given by

$$B = [U_{b0} U_{b1}] \begin{bmatrix} \Sigma_b V_b^T \\ 0 \end{bmatrix}, \quad (16.10)$$

$$CV = [U_{r0} U_{r1}] \begin{bmatrix} \Sigma_r V_r^T \\ 0 \end{bmatrix} \quad (16.11)$$

and where Λ is an $r \times r$ diagonal matrix with entries $\lambda_i, i = 1, 2, \dots, r$. The method described by Equation 16.9 is the preferred method for numerical computation.

We conclude the discussion with a comment about the closed-loop system stability. Unfortunately, it is not yet possible to ensure that stable open-loop eigenvalues do not move into the right half of the complex plane when an eigenstructure assignment output feedback controller is utilized. This is still an open area for further research. However, for aircraft flight control systems, the closed-loop stability requirement is neither necessary nor sufficient. For example, some modes, such as the dutch roll mode, are required to meet minimum frequency and damping specifications, as described in MIL-F-8785C [18]. For these modes, stability alone is not sufficient. Other modes, such as the spiral mode, may be unstable provided that the time to double amplitude is sufficiently large. For these modes, stability may not be necessary.

16.2.1 F-18 HARV Linearized Lateral Dynamics Design Example

Consider the lateral directional dynamics of the F-18 HARV aircraft linearized at a Mach number of 0.38, an altitude of 5000 ft, and an angle of attack of 5° . The aerodynamic model is augmented with first-order actuators and a yaw rate washout filter. The eight state variables are aileron deflection δ_a , stabilator deflection δ_s , rudder deflection δ_r , sideslip angle β , roll rate p , yaw rate r , bank angle ϕ , and washout filter state x_8 . The three control variables are aileron command δ_{ac} , stabilator command δ_{sc} , and rudder command δ_{rc} . The four measurements are r_{wo}, p, β , and ϕ , where r_{wo} is the washed out yaw rate. All quantities are in the body axis frame of reference with units of degrees or degrees/second. The state-space matrices A, B , and C that completely describe the model are shown in the Appendix.

An output feedback gain matrix is now computed by using eigenstructure assignment. The desired dutch roll eigenvalues are chosen with a damping ratio of 0.707 and a natural frequency in the vicinity of 3 rad/s. The roll subsidence and spiral modes are chosen to be merged into a complex mode, as suggested by [1]. The desired eigenvalues are

Dutch roll mode:

$$\lambda_{dr}^d = -2 \pm j2$$

Roll mode:

$$\lambda_{roll}^d = -3 \pm j2$$

The desired eigenvectors are chosen to keep the quantity $|\phi/\beta|$ small. Therefore, the desired dutch roll eigenvectors will have zero entries in the rows corresponding to bank angle and roll rate. The desired roll mode eigenvectors will have zero entries in the rows corresponding to yaw rate, sideslip, and x_8 (which is filtered yaw rate). The desired eigenvectors are

$$v_{dr}^d = \begin{bmatrix} x \\ x \\ x \\ 1 \\ 0 \\ x \\ 0 \\ x \end{bmatrix} \pm j \begin{bmatrix} x \\ x \\ x \\ x \\ 0 \\ 1 \\ 0 \\ x \end{bmatrix} \quad v_{roll}^d = \begin{bmatrix} x \\ x \\ x \\ 0 \\ 1 \\ 0 \\ x \\ 0 \end{bmatrix} \pm j \begin{bmatrix} x \\ x \\ x \\ 0 \\ x \\ 0 \\ 1 \\ 0 \end{bmatrix} \begin{matrix} \delta_a \\ \delta_s \\ \delta_r \\ \beta \\ p \\ r \\ \phi \\ x_8 \end{matrix}$$

The achievable eigenvectors are computed by taking the orthogonal projection onto the null space of $U_1^T(\lambda_i I - A)$. However, care must be taken when computing the pseudoinverse of \tilde{L}_i because this matrix is ill-conditioned. Press et al. [24] suggest computing the pseudoinverse by using a singular-value decomposition in which the singular values, which are significantly smaller than the largest singular value, are treated as zero. The achievable eigenvectors given in this chapter were computed by using MATLAB[®] function PINV with TOL = 0.01. The achievable eigenvectors are shown in Table 16.1, where the underlined numbers indicate the small couplings between p, ϕ , and the dutch roll mode and between β, r, x_8 , and the roll mode. Hence, the ratio $|\phi/\beta|$ can be expected to be small.

The feedback gain matrix is computed by using Equation 16.9 and is shown in Table 16.2. From the open-loop state responses to a 1° initial sideslip, shown in Figure 16.1, we conclude that the aircraft is poorly damped with strong coupling between the dutch roll mode and the roll mode. The closed-loop state response is shown in Figure 16.2. Observe that the maximum absolute values of the bank angle and roll rate are 0.0532 and 0.2819°/s., respectively.

Finally, we consider the multivariable gain and phase margins for our design. Suppose that the modeling errors may be described by the matrix L given by

$$L = \text{Diag} (\ell_1 e^{j\phi_1}, \ell_2 e^{j\phi_2}, \dots, \ell_m e^{j\phi_m})$$

Then, as shown by Lehtomaki [13], multivariable gain and phase margins at the inputs may be defined.

TABLE 16.1 Achievable Eigenvectors for Constant Gain Output Feedback

Let $\sigma_{min}[I + FG(s)] > \alpha$, where the plant transfer matrix is given by $G(s) = C(sI - A)^{-1}B$. Then, the upward gain margin is at least as large as $1/(1 - \gamma)$ and the gain reduction margin is at least as small as $1/(1 + \gamma)$. The phase margins are at least $\pm SIN^{-1}(\gamma/2)$. The multivariable gain and phase margins for the constant gain output feedback design are shown in Table 16.2. We conclude that the margins are acceptable, especially because these margins are considered conservative.

FIGURE 16.2 F-18 closed-loop state responses for output feedback.

16.3 Eigenstructure Assignment Using Constrained Output Feedback

The feedback gain matrix given by Equation 16.8 feeds back every output to every input. We now consider the problem of constraining certain elements of F to be zero. By suppressing certain gains to zero, the designer reduces controller complexity and increases reliability.

Using the development of [1], define

$$\Omega = CV \tag{16.12}$$

$$\Psi = Z - A_1 V \tag{16.13}$$

Then the expression for the feedback gain matrix F is given by (see Equation 16.8)

$$F = -\Psi\Omega^{-1}. \tag{16.14}$$

By using the Kronecker product and the lead block identity structure of the matrix B , each row of the feedback gain matrix can be computed independently of all the other rows [1]. Let ψ_i be the i th row of the matrix Ψ . Then the solution for f_i , which is the i th row of the feedback gain matrix F , is given by

$$f_i = -\psi_i\Omega^{-1}. \tag{16.15}$$

If f_{ij} is chosen to be constrained to zero, then Andry et al. [1] show that f_{ij} should be deleted from f_i and that the j th row of Ω should be deleted. Let $\tilde{\Omega}$ be the matrix Ω with its j th row deleted and \tilde{f}_i be the row vector f_i with its j th entry deleted. Then, by using a pseudoinverse, the solution for \tilde{f}_i , whose entries are the remaining active gains in the i th row of the matrix F , is given by

$$f_i = -\psi_i\tilde{\Omega}^\dagger, \tag{16.16}$$

where $(\cdot)^\dagger$ denotes the appropriate pseudoinverse of (\cdot) . If more than one gain in a row of F is to be set to zero, the \tilde{f}_i and $\tilde{\Omega}$ must be appropriately modified.

16.3.1 Eigenvalue/Eigenvector Derivative Method for Choosing Gain-Suppression Structure

Calvo-Ramon [5] has proposed a method for choosing *a priori* which gains should be set to zero based on the sensitivities of the eigenvalues to changes in the feedback gains. The first-order sensitivity of the h th eigenvalue to changes in the ij th entry of the matrix F is denoted by $\partial\lambda_h/\partial f_{ij}$. The expected shift in the eigenvalue λ_h when constraining feedback gain f_{ij} to zero is given by

$$S_{ij}^h = (f_{ij}) \frac{\partial\lambda_h}{\partial f_{ij}}. \quad (16.17)$$

Next, combine all the eigenvalue shifts that are related to the same feedback gain f_{ij} to form a decision matrix $D^\lambda = \{d_{ij}\}$, $D^\lambda \in R^{m \times r}$, where

$$d_{ij}^\lambda = \frac{1}{n} \left[\sum_{h=1}^n \left(\bar{S}_{ij}^h \right) \left(S_{ij}^h \right) \right]^{1/2} \quad (16.18)$$

and $(\bar{\cdot})$ denotes the complex conjugate of (\cdot) .

The decision matrix D^λ is used to determine which feedback gains f_{ij} should be set to zero. If d_{ij}^λ is “small,” then setting f_{ij} to zero will have a small effect on the closed-loop eigenvalues. Conversely, if d_{ij}^λ is “large,” then setting f_{ij} to zero will have a significant effect on the closed-loop eigenvalues. The control system designer must determine which d_{ij}^λ are “small” and which are “large” for a particular problem. In this regard, it is assumed that the states, inputs, and outputs are scaled so that these variables are expressed in the same or equivalent units.

The decision matrix D^λ was used by Calvo-Ramon [5] to design a constrained output feedback controller using eigenstructure assignment. However, the sensitivities of the eigenvectors with respect to the gains were not considered when deciding which feedback gains should be set to zero. Recall that the eigenvalues determine transient response characteristics such as overshoot and settling time, whereas the eigenvectors determine mode decoupling. This mode decoupling is related, for example, to the $|\phi/\beta|$ ratio in an aircraft lateral dynamics problem. This ratio must be small, as specified in [18], which implies that the closed-loop aircraft should exhibit a significant degree of decoupling between the dutch roll mode and the roll mode. The approach of Calvo-Ramon [5] may yield a constrained controller with acceptable overshoot and settling time, but the mode decoupling may be unacceptable. Thus, consideration of both eigenvalue and eigenvector sensitivities is important when choosing which feedback gains should be constrained to zero.

Sobel et al. [33] extended the results of Calvo-Ramon [5] to include both eigenvalue and eigenvector sensitivities to the feedback gains. The eigenvector derivatives are used to compute the expected shift in eigenvector v_h when constraining feedback gain f_{ij} to be zero. This expected shift in eigenvector v_h is given by

$$\tilde{s}_{ij}^h = (f_{ij})(\partial v_h / \partial f_{ij}). \quad (16.19)$$

Then, all the eigenvector shifts related to the same feedback gain f_{ij} are combined to form an eigenvector decision matrix D^v ,

$$D^v = \frac{1}{n} \left[\sum_{h=1}^n \left(\tilde{s}_{ij}^h \right)^* \left(\tilde{s}_{ij}^h \right) \right]^{1/2}, \quad (16.20)$$

where $(\cdot)^*$ denotes the complex-conjugate transpose of (\cdot) . The gains that should be set to zero are determined by first eliminating those f_{ij} corresponding to entries of D^λ that are considered to be small. Then, those entries of D^v corresponding to those f_{ij} that were chosen to be set to zero based on D^λ are reviewed. In this way, the designer can determine whether some of the f_{ij} that may be set to zero based on eigenvalue considerations should not be constrained based on eigenvector considerations.

16.3.2 F-18 HARV Linearized Lateral Dynamics Design Example

We return to the example which was first considered in Section 16.2.1 and now we seek a constrained-output feedback controller. The eigenvalue decision matrix D^λ and the eigenvector decision matrix D^v are shown in Table 16.3. The entries of D^λ considered large are underlined in Table 16.3. Observe that only seven of the 12 feedback gains are needed when only eigenvalue sensitivities are considered. The constrained-output feedback gain matrix based on using only the information available from the eigenvalue decision matrix D^λ is shown in Table 16.4. The state responses to a 6° initial sideslip are shown in Figure 16.3. Observe the significantly increased coupling between sideslip and bank angle as compared to the unconstrained design of Section 16.2.1. The maximum absolute values of the bank angle and roll rate are now 0.5102° and $1.7881^\circ/s$ compared with 0.0532° and $0.2819^\circ/s$ obtained with the unconstrained feedback gain matrix. The increased coupling is due to ignoring the eigenvector sensitivities and illustrates the importance of the eigenvectors in achieving adequate mode decoupling.

Next, consider the entries of D^v that correspond to those f_{ij} that were chosen to be set to zero based on the eigenvalue decision matrix. The two largest d_{ij}^v that belong to this class are d_{11}^v and d_{23}^v . A new constrained-output feedback gain matrix is computed in which f_{11} and f_{23} are not set to zero. Nine gains are now needed to be unconstrained when using both eigenvalue and eigenvector information. The new feedback gain matrix is given in Table 16.4 and the state responses for a 1° initial sideslip are shown in Figure 16.4. Observe that these time responses are almost identical to the responses in Figure 16.2, which were obtained by using all 12 feedback gains. Thus, a simpler controller is obtained with a negligible change in the aircraft time responses. Finally, the multivariable gain and phase margins are shown in Table 16.4. The values of these margins are considered acceptable because singular-value-based multivariable stability margin computation is conservative.

16.4 Eigenstructure Assignment Using Dynamic Compensation

We now generalize the eigenstructure assignment flight control design methodology to include the design of low-order dynamic compensators of any given order ℓ , $0 \leq \ell \leq n - r$. Recall that n and r are the dimensions of the aircraft state and output vectors, respectively. Consider the linear time-invariant aircraft described by Equations 16.1 and 16.2 with a linear time-invariant dynamic controller specified by

$$\dot{z}(t) = Dz(t) + Ey(t), \quad (16.21)$$

$$u(t) = Fz(t) + Gy(t), \quad (16.22)$$

where the controller state vector $z(t)$ is of dimension ℓ , $0 \leq \ell \leq n - r$.

It is convenient to model the aircraft and compensator by the composite system originally proposed by Johnson and Athans [10]. Thus, define

$$\dot{\bar{x}} = \bar{A}\bar{x} + \bar{B}\bar{u}, \quad (16.23)$$

$$\bar{y} = \bar{C}\bar{x}, \quad (16.24)$$

$$\bar{u} = \bar{F}\bar{y}, \quad (16.25)$$

where

$$\bar{x} = \begin{bmatrix} x \\ z \end{bmatrix}, \quad \bar{A} = \begin{bmatrix} A|0 \\ 0|I \end{bmatrix}, \quad \bar{B} = \begin{bmatrix} B|0 \\ 0|I \end{bmatrix}, \quad \bar{C} = \begin{bmatrix} C|0 \\ 0|I \end{bmatrix}, \quad \bar{F} = \begin{bmatrix} G|F \\ E|D \end{bmatrix}.$$

Furthermore, the eigenvectors of the composite system may be described by

$$v_i = \begin{bmatrix} v_i(x) \\ v_i(z) \end{bmatrix}, \quad (16.26)$$

where $v_i(x)$ is the i th subeigenvector corresponding to the aircraft and $v_i(z)$ the i th subeigenvector corresponding to the compensator. Once the compensator dimension is chosen, the problem is solved as previously shown for the constant gain case.

The dynamic compensator design problem may be stated as follows. Given a set of desired aircraft eigenvalues $\{\lambda_i^d\}$, $i = 1, 2, \dots, r + \ell$ and a corresponding set of desired aircraft subeigenvectors $v_i^d(x)$, $i = 1, 2, \dots, r + \ell$, find real matrices $D(\ell \times \ell)$, $E(\ell \times r)$, $F(m \times \ell)$, and $G(m \times r)$ so that the eigenvalues of $A + BFC$ contain $\{\lambda_i^d\}$ as a subset and corresponding subeigenvectors $\{v_i(x)\}$ are close to the respective members of the set $\{v_i^d(x)\}$.

16.4.1 F-18 HARV Linearized Lateral Dynamics Design Example

We again return to the example first considered in Section 16.2.1. If $y = [r_{wo}, p, \beta, \phi]^T$, as was the case in Sections 16.2.1 and 16.3.1, then the designer can specify both the dutch roll mode and roll mode eigenvalues. The designer might also specify three entries in the real and imaginary parts of the dutch roll eigenvectors and four entries in the real and imaginary parts of the roll mode eigenvectors as was done in Section 16.2.1. Then achievable eigenvectors are computed.

Now suppose that the measurement is given by $y = [r_{wo}, p, \phi]^T$, but the designer is still required to assign both the dutch roll and roll mode eigenvalues. Using the results of Section 16.4, we might utilize a first-order dynamic compensator with state z_1 . The composite system has state vector $\bar{x} = [\delta_a, \delta_s, \delta_r, \beta, p, r, \phi, x_8, z_1]^T$, and the measurement vector is given by $\bar{y} = [r_{wo}, p, \phi, z_1]^T$. Thus, as before, the designer might choose to specify three or four entries of the real and imaginary parts of $v_i(x)$, $i = 1, 2, 3, 4$, which are the entries of the dutch roll and roll mode eigenvectors corresponding to the original aircraft state variables. Again, achievable eigenvectors will be computed.

We might ask whether the eigenvalue/eigenvector specifications are identical for both proposed problems. Certainly, the eigenvalue specifications and the corresponding $v_i^d(x)$ subeigenvectors may be identical. However, the $v_i^d(z)$ subeigenvector specifications must now be properly chosen. Otherwise, the modal matrix for the composite system may become numerically singular.

Finally, we remark that if the first-order compensator does not perform acceptably, then the designer might try a higher-order compensator. In the case of a second-order compensator, the composite system has state vector $\bar{x} = [\delta_a, \delta_s, \delta_r, \beta, p, r, \phi, x_8, z_1, z_2]^T$, and the measurement vector is given by $\bar{y} = [r_{wo}, p, \phi, z_1, z_2]^T$. In this case, the designer can also specify one of the compensator eigenvalues and some entries of its corresponding eigenvector.

Now consider the case when only the washed-out yaw rate, roll rate, and bank angle are measured. We form the composite system described by Equations 16.23 through 16.25 by appending a first-order compensator to the aircraft dynamics. We specify that the roll mode and dutch roll mode eigenvalues are the same as in the constant gain feedback problem in Section 16.2.1. The compensator pole is not specified, but it is chosen by the eigenstructure assignment algorithm to obtain eigenvalue and eigenvector assignment for the aircraft modes. Furthermore, because we have three sensors plus one compensator state, the eigenstructure assignment algorithm will allow us to specify four closed-loop eigenvalues. We specify that the desired aircraft subeigenvectors $v_i^d(x)$ are the same as the desired eigenvectors in the constant gain output feedback problem. The desired compensator subeigenvectors are chosen so that the dutch roll and roll modes participate in the compensator state solution. The control law is described by

$$\begin{bmatrix} \delta_a \\ \delta_s \\ \delta_r \end{bmatrix} = \begin{bmatrix} 0.1708 & -0.1383 & -0.4079 \\ -0.2723 & -0.3328 & -0.2408 \\ 1.0897 & 0.5836 & -1.5548 \end{bmatrix} \begin{bmatrix} r_{wo} \\ p \\ \phi \end{bmatrix} + \begin{bmatrix} -0.0040 \\ -1.4112 \\ 3.7731 \end{bmatrix} z_1, \tag{16.27}$$

$$\dot{z}_1 = -2.4784z_1 + 0.5906r_{wo} + 0.9817p + 3.0796\phi. \tag{16.28}$$

The desired eigenvalues, achievable eigenvalues, and desired eigenvectors are shown in Table 16.5. The separation principle does not apply to the dynamic compensator described by Equations 16.21 and 16.22. Thus, the composite system has eigenvalues at -1.7646 and -0.7549 which are due to the compensator and the yaw rate washout filter, respectively. The time responses of the aircraft states are shown in Figure 16.5 from which we observe that the responses with the dynamic compensator are slower than the responses with constant gain output feedback. However, the dynamic compensator controller is implemented without the need for a sideslip sensor. In addition, the ratio $|\phi/\beta| \approx 0.8$ as compared to $|\phi/\beta| \approx 4$ for the open-loop aircraft.

FIGURE 16.5 F-18 closed-loop state responses for first-order dynamic compensator.

The multivariable stability margins are computed using $\sigma_{\min}[I + KG(s)]$ where $G(s) = C(sI - A)^{-1}B$ and $K = -[F(sI - D)^{-1}E + G]$. The multivariable gain margins are $GM\epsilon[-2.47 \text{ dB}, 3.46 \text{ dB}]$ and the multivariable phase margin is $\pm 18.89^\circ$. If the designer considers these margins inadequate, then an optimization may be used to compute an eigenstructure assignment controller with a constraint on the minimum of the smallest singular value of the return difference matrix. In the next section, we present a robust, sampled data eigenstructure controller for the yaw pointing/lateral translation maneuver of the FPCC aircraft.

16.5 Robust, Sampled Data Eigenstructure Assignment

Sobel and Shapiro [28] used eigenstructure assignment to design a continuous-time controller for the yaw pointing/lateral translation maneuver of the FPCC aircraft. This conceptual control-configured aircraft has a vertical canard and is difficult to control because the control distribution matrix has a minimum singular value of 0.0546. The design of Sobel and Shapiro [28] is characterized by perfect decoupling, but the minimum of the smallest singular value of the return difference matrix at the aircraft inputs was only 0.18.

Sobel and Lallman [32] proposed a pseudocontrol strategy for reducing the dimension of the control space by using the singular-value decomposition. The FPCC yaw pointing/lateral translation design of Sobel and Lallman [32] yields a minimum of the smallest singular value of the return difference matrix at the aircraft inputs of 0.9835, but the lateral translation transient response has significant coupling to the heading angle.

Sobel and Shapiro [31] have proposed an extended pseudocontrol strategy. Piou and Sobel [22] extended eigenstructure assignment to linear time-invariant plants which are represented by Middleton and Goodwin's [17] unified delta model which is valid both for continuous-time and sampled data operation of the plant. Piou et al. [23] have extended Yedavalli's [35] Lyapunov approach for stability robustness

of a linear time-invariant system to the unified delta system. In this section, we design a robust, sampled data, extended pseudocontrol, eigenstructure assignment flight control law for the yaw pointing/lateral translation maneuver of the FPCC aircraft. The main goal of this section is to describe a design methodology which incorporates robustness into the eigenstructure assignment method. However, a sampled data design is used for illustration.

16.5.1 Problem Formulation

Consider a nominal linear time-invariant system described by (A, B, C) . The corresponding sampled data system is described by (A_δ, B_δ, C) and the unified delta model is described by (A_ρ, B_ρ, C) . Suppose that the nominal delta system is subject to linear time-invariant uncertainties in the entries of A_ρ, B_ρ described by dA_ρ and dB_ρ , respectively. Then, the delta system with uncertainty is given by $(A_\rho + dA_\rho, B_\rho + dB_\rho, C)$. Here $dA_\rho = dA$, $dB_\rho = dB$ in continuous time and $dA_\rho = dA_\delta, dB_\rho = dB_\delta$ in discrete time. Furthermore, suppose that bounds are available on the maximum absolute values of the elements of dA and dB so that $\{dA : dA^+ \leq A_{\max}\}$ and $\{dB : dB^+ \leq B_{\max}\}$ and where “ \leq ” is applied element by element to matrices.

Consider the constant gain output feedback control law described by $u(t) = F_\rho y(t)$, where $F_\rho = F$ in continuous time and $F_\rho = F_\delta$ in discrete time. Then, the nominal closed-loop unified delta system is given by $\rho x(t) = A_{\rho c} x(t)$, where $A_{\rho c} = A + BFC$ in continuous time and $A_\delta + B_\delta F_\delta C$ in discrete time. The uncertain closed-loop unified delta system is given by $\rho x(t) = A_{\rho c} x(t) + dA_{\rho c} x(t)$, where $dA_{\rho c} = dA + dB(FC)$ in continuous time and $dA_\delta + dB_\delta(F_\delta C)$ in discrete time. The reader is referred to Middleton and Goodwin [17] for a more detailed description.

16.5.2 Pseudocontrol and Robustness Results

The purpose of a pseudocontrol is to reduce the dimension of the control space. This reduction is needed for systems whose control distribution matrix B has a minimum singular value that is very small. After the eigenstructure assignment design is complete, the controller is mapped back into the original control space. Consider the singular-value decomposition of the matrix B_ρ given by

$$B_\rho = [U_1 U_2 U_0] \begin{bmatrix} \Sigma_1 & & \\ & \Sigma_2 & \\ & & 0 \end{bmatrix} \begin{bmatrix} V_1^T \\ V_2^T \\ V_0^T \end{bmatrix}, \quad (16.29)$$

where $\Sigma_1 = \text{diag}[\sigma_1, \dots, \sigma_a]$ and $\Sigma_2 = \text{diag}[\sigma_{a+1}, \dots, \sigma_b]$ and where $\sigma_b \leq \sigma_{b-1} \leq \dots \leq \sigma_{a+1} \leq \varepsilon$ with ε small.

Lemma 16.1:

Let the system with the pseudocontrol $\tilde{u}(t)$ be described by

$$\rho x(t) = A \rho x(t) + \tilde{B}_\rho \tilde{u}(t), \quad (16.30)$$

$$y(t) = Cx(t), \quad (16.31)$$

where

$$\tilde{B}_\rho = U_1 + U_2[\alpha_1, \alpha_2]. \quad (16.32)$$

We design a feedback pseudocontrol for the system described by Equations 16.30 through 16.32. Then, the true control $u(t)$ for the system described by (A_ρ, B_ρ, C) is given by

$$u(t) = \left[V_1 \Sigma_1^{-1} + V_2 \Sigma_2^{-1} \alpha \right] \tilde{u}(t). \quad (16.33)$$

Furthermore, when $\alpha = [0, 0]^T$, the control law $u(t)$ given by Equation 16.33 reduces to the control law given by Equation 20 in Sobel and Lallman [32].

Theorem 16.1:

The system matrix $A_{\rho c} + dA_{\rho c}$ is stable if

$$\sigma_{\max} \left(E_{2 \max}^T P_\rho^+ E_{1 \max} \right)_s < 1, \quad (16.34)$$

where

$$E_{1 \max} = A_{\rho \max} + B_{\rho \max} (F_\rho C)^+$$

and

$$E_{2 \max} = \{ I_n + \Delta [A_\rho + B_\rho (F_\rho C)] \}^+ + (\Delta/2) E_{1 \max}$$

and where P_ρ satisfies the Lyapunov equation given by

$$A_{\rho c}^T P_\rho + P_\rho A_{\rho c} + \Delta A_{\rho c} P_\rho A_{\rho c}^T = -2I_n$$

and where P_ρ^+ is the matrix formed by the modulus of the entries of the matrix P_ρ , and $(\cdot)_s$ denotes the symmetric part of a matrix.

16.5.3 FPCC Yaw Pointing/Lateral Translation Controller Design Using Robust, Sampled Data, Eigenstructure Assignment

We consider the FPCC aircraft linearized lateral dynamics which is described by Sobel and Lallman [32]. The state-space matrices A and B are shown in the Appendix. The state variables are sideslip angle β , bank angle ϕ , roll rate p , and lateral directional flight path angle ($\gamma = \Psi + \beta$), where Ψ is the heading angle. The control variables are rudder δ_r , ailerons δ_a , and vertical canard δ_c . The angles and surface deflections are in degrees, and the angular rates are in degrees/second. The five measurements are β, ϕ, p, r , and γ .

First, we design an eigenstructure assignment control law by using an orthogonal projection. The delta state-space matrices A_δ and B_δ are computed by using the MATLAB Delta Toolbox. The sampling period Δ is chosen to be 0.02 s for illustrative purposes. The desired dutch roll, roll mode, and flight path mode eigenvalues are achieved exactly because five measurements are available for feedback. The achievable eigenvectors are computed by using the orthogonal projection of the i th desired eigenvector onto the subspace which is spanned by the columns of $(\gamma_i I - A_\delta)^{-1} B_\delta$. The closed-loop delta eigenvalues $\gamma_i, i = 1, \dots, n$, and the feedback gain matrix F_δ are shown in Table 16.6. The desired closed-loop eigenvectors are shown in Table 16.7.

The orthogonal projection solution is characterized by excellent decoupling with the minimum of the smallest singular value of $(I + FG)$ equal to 0.18. Here the transfer function matrix of the delta plant is given by $G([e^{j\omega\Delta} - 1]/\Delta)$, where $0 < \omega < \pi/T$. Furthermore, the Lyapunov robust stability condition of Equation 16.34 is not satisfied.

To improve the minimum singular value of $(I + FG)$, we design a controller by using an orthogonal projection with the pseudocontrol of Sobel and Lallman [32]. This pseudocontrol mapping is given

TABLE 16.6 Comparison of FPCC Designs ($\Delta = 0.02$ s)

	Closed-Loop Eigenvalues	Feedback Gain Matrix					
		β	ϕ	p	r	γ

	$\gamma_{3,4} = -2.60 \pm j1.22$	0.8390	-1.5479	-0.7663	-0.8565	-1.2679	δ_a
	$\gamma_{fp} = -0.3248$	1.1525	-0.8794	-0.4764	-1.9712	-3.2578	δ_c

Note: Eigenvalues are computed by using feedback gains with significant digits to machine precision.

by Equation 16.33 with $\alpha = [0, 0]$. This design is characterized by a lateral translation response with significant coupling between γ and Ψ with the minimum of the smallest singular value of $(I + FG)$ equal to 0.9835. The Lyapunov sufficient robust stability condition of Equation 16.34 is not satisfied. We note that the yaw pointing responses exhibit excellent decoupling for both orthogonal projection designs.

Next, to obtain a robust design with excellent decoupling, we design a robust pseudocontrol law by using the design method proposed by Piou et al. [23]. This new design method minimizes an objective function which weights the heading angle due to a lateral flight path angle command and the lateral flight path angle due to a heading command. Constraints are placed on the time constants of the dutch roll, roll, and flight path modes, the damping ratios of the dutch roll and roll modes, and the new sufficient condition for robust stability. Mathematically, the objective function to be minimized is given by

$$J = \sum_{k=1}^{100} \left[(1 - \alpha) (\Psi_k^2)_{\gamma_c} + \alpha (\gamma_k^2)_{\Psi_c} \right]. \tag{16.35}$$

The upper limit on the index k is chosen to include the time interval $k\Delta\epsilon[0, 2]$ during which most of the transient response occurs. Of course, computation of Equation 16.35 requires that two linear simulations be performed during each function evaluation of the optimization. The constraints for continuous time and the corresponding constraints for discrete time are shown in Table 16.8 where ζ is the damping ratio.

TABLE 16.7 FPCC Desired Closed-Loop Eigenvectors

TABLE 16.8 Constraints for the FPCC Designs

Continuous Time	Discrete Time
For Complex Eigenvalues:	
$\text{Re}\lambda \in [-4, -1.5]$	$ 1 + \Delta\gamma \in [e^{-4\Delta}, e^{-1.5\Delta}]$
$\zeta \in [0.4, 0.9]$	$ 1 + \Delta\gamma \in \left[\exp\left(\frac{-0.9\phi}{[1-(0.9)^2]^{1/2}}\right), \exp\left(\frac{-0.4\phi}{[1-(0.4)^2]^{1/2}}\right) \right]$, where $\phi = \arg(1 + \Delta\gamma)$
For the Real Eigenvalue:	
$\lambda \in [-1, -0.05]$	$ 1 + \Delta\gamma \in [e^{-\Delta}, e^{-0.05\Delta}]$
For Lyapunov Robustness:	
	$\sigma_{\max}\left(E_{2\max}^T P_{\rho}^+ E_{1\max}\right) < 0.999$
For Multivariable Stability Margins (Final Design only):	
	$\min \sigma_{\min}(I + FG) \geq 0.55; 0 < \omega < \pi/T$

For illustrative purposes we have chosen $A_{\max} = 0.085A^+$ and $B_{\max} = 0$. After many trials, we found that a good value for the weight α in Equation 16.35 is $\alpha = 0.0075$.

The parameter vector contains the quantities which may be varied by the optimization. This 17-dimensional vector includes $\text{Re } \gamma_{dr}$, $\text{Im } \gamma_{dr}$, $\text{Re } \gamma_{roll}$, $\text{Im } \gamma_{roll}$, γ_{fp} , $\text{Re } z_1(1)$, $\text{Re } z_1(2)$, $\text{Im } z_1(1)$, $\text{Im } z_1(2)$, $\text{Re } z_3(1)$, $\text{Re } z_3(2)$, $\text{Im } z_3(1)$, $\text{Im } z_3(2)$, $z_5(1)$, $z_5(2)$, and the two-dimensional pseudocontrol vector α of Equation 16.32. Here, the two-dimensional complex vectors z_i contain the free eigenvector parameters, that is, the i th eigenvector v_i may be written as

$$v_i = L_i z_i, \tag{16.36}$$

where the columns of $L_i = (\gamma_i I - A_{\delta})^{-1} \tilde{B}_{\delta}$ are a basis for the subspace in which the i th eigenvector must reside. Thus, the free parameters are the vectors z_i rather than the eigenvectors v_i . The vectors z_i are two dimensional because the optimization is performed in the two-dimensional pseudocontrol space.

The optimization uses subroutine *constr* from the MATLAB Optimization Toolbox and subroutine *delsim* from the MATLAB Delta Toolbox. The optimization is initialized with the orthogonal projection pseudocontrol design which yields an initial value of 20.6 for the objective function of Equation 16.35 and a value of 1.66 for the right-hand-side (RHS) of the robustness condition of Equation 16.34. Unfortunately, the minimum of the smallest singular value of $(I + FG)$ is only 0.2607 which is less than desired.

FIGURE 16.6 FPCC yaw pointing; robust pseudocontrol with singular-value constraint.

FIGURE 16.7 FPCC lateral translation; robust pseudocontrol with singular value constraint.

To achieve a design with excellent time responses, Lyapunov robustness, and an acceptable minimum of the smallest singular value of $(I + FG)$, we repeat the optimization with the additional constraint that $\sigma_{\min}(I + FG) \geq 0.55$. Once again we initialize the optimization at the orthogonal projection pseudocontrol design. The optimization yields an optimal objective function of 0.0556 and a value of 0.999 for the RHS of the robustness condition. The time responses for yaw pointing and lateral translation are shown in Figures 16.6 and 16.7, respectively. The lateral translation response is deemed excellent even though it has some small increase in coupling compared to the design without the additional singular-value constraint. Thus, we have obtained a controller which simultaneously achieves excellent time responses, Lyapunov robustness, and an acceptable minimum of the smallest singular-value of the return difference matrix at the aircraft inputs.

16.6 Defining Terms

Stability augmentation system: A feedback control designed to modify the inherent aerodynamic stability of the airframe.

Gain suppression: A feedback control in which one or more entries of the gain matrix are constrained to be zero.

Specialized task tailored modes: A feedback control system designed for a specific maneuver such as bombing, strafing, air-to-air combat, and so on.

Mode decoupling: The elimination of interactions between modes, for example, in an aircraft mode decoupling is important so that a sideslip angle disturbance will not cause rolling motion.

Eigenstructure assignment: A feedback control designed to modify both the system's eigenvalues and eigenvectors.

Further Reading

Kautsky et al. [11] suggested that eigenstructure assignment can be used to obtain a design with eigenvalues, which are least sensitive to parameter variation, by reducing one of several sensitivity measures. Among these measures are the quadratic norm condition number of the closed-loop modal matrix and the sum of the squares of the quadratic norms of the left eigenvectors. Burrows et al. [4] have proposed a stability augmentation system for a well-behaved light aircraft by using eigenstructure assignment with an optimization which minimizes the condition number of the closed-loop modal matrix. Such an approach may sometimes produce an acceptable controller. In contrast to eigensensitivity, Doyle and Stein [7] have characterized the stability robustness of a multi-input, multi-output system by the minimum of the smallest singular value of the return difference matrix at the plant input or output. Gavito and Collins [8] have proposed an eigenstructure assignment design in which a constraint is placed on the minimum of the smallest singular value of the return difference matrix at the inputs of both an L-1011 aircraft and a CH-47 helicopter. Several authors have proposed different approaches to eigenstructure assignment. Clarke et al. [6] present a method to trade exact closed-loop eigenvalue location against an improvement in the associated eigenvector match. Bruyere et al. [3] use eigenstructure assignment in a polynomial framework. Satoh and Sugimoto [25] present a regional eigenstructure assignment using a linear matrix inequalities (LMI) approach. Nieto-Wire and Sobel [19] applied eigenstructure assignment to the design of a flight control system for a tailless aircraft. Other applications of eigenstructure assignment include air-to-air missiles [36], mechanical systems [26], and power systems [16]. Jiang [9], Konstantopoulos [12], and Ashari et al. [2] have proposed methods for reconfiguration using eigenstructure assignment. Nieto-Wire and Sobel [20] used eigenstructure assignment for the accommodation of symmetric lock in place actuator failures for a tailless aircraft.

17.1 Introduction

The linear quadratic regulator problem, commonly abbreviated as LQR, plays a key role in many control design methods. Not only is LQR a powerful design method, but in many respects it is also the mother of many current, systematic control design procedures for linear multiple-input, multiple output (MIMO) systems. Both the linear quadratic Gaussian, LQG or \mathcal{H}_2 , and \mathcal{H}_∞ controller design procedures have a usage and philosophy that are similar to the LQR methodology. As such, studying the proper usage and philosophy of LQR controllers is an excellent way to begin building an understanding of even more powerful design procedures.

From the time of its conception in the 1960s, the LQR problem has been the subject of volumes of research. Yet, as will be detailed, the LQR is nothing more than the solution to a convex, least squares optimization problem that has some very attractive properties. Namely the optimal controller automatically ensures a stable closed-loop system, achieves guaranteed levels of stability robustness, and is simple to compute. To provide a control systems engineer with the knowledge needed to take advantage of these attractive properties, this chapter is written in a tutorial fashion and from a user's point of view, without the complicated theoretical derivations of the results. A more in-depth reference that contains the theory for much of the material presented here is the text by Anderson and Moore [1], while the text by Kwakernaak and Sivan [2] is considered to be the classic text on the subject.

In addition to the standard LQR results, robustness properties and useful variations of the LQR are also discussed. In particular, we describe how sensitivity weighted LQR (SWLQR) can be used to make

high-gain LQR controllers robust to parametric modeling errors, as well as how to include frequency domain specifications in the LQR framework through the use of frequency weighted cost functionals. Since this chapter can be viewed as an introduction to optimal control for MIMO, linear, time-invariant systems, we briefly discuss the full state feedback \mathcal{H}_∞ controller and its relation to a mini-max quadratic optimal control problem for completeness.

17.2 The Time-Invariant LQR Problem

To begin, we simply state the LQR problem, its solution, and the assumptions used in obtaining the solution. The rest of this chapter is devoted to discussing the properties of the controller, how the mathematical optimization problem relates to the physics of control systems, and useful variations of the standard LQR.

Theorem 17.1: Steady State LQR

Given the system dynamics

$$\dot{x}(t) = Ax(t) + Bu(t); \quad x(t=0) = x_0 \quad (17.1)$$

with $x(t) \in \mathbb{R}^n$ and $u(t) \in \mathbb{R}^m$ along with a linear combination of states to keep small

$$z(t) = Cx(t) \quad (17.2)$$

with $z(t) \in \mathbb{R}^p$. We define a quadratic cost functional

$$J = \int_0^\infty [z^T(t)z(t) + u^T(t)Ru(t)] dt \quad (17.3)$$

in which the size of the states of interest, $z(t)$, is weighted relative to the amount of control action in $u(t)$ through the weighting matrix R .

If the following assumptions hold:

1. The entire state vector $x(t)$ is available for feedback
2. $[A \ B]$ is stabilizable and $[A \ C]$ is detectable
3. $R = R^T > 0$

Then

1. The linear quadratic controller is the unique, optimal, full state feedback control law

$$u(t) = -Kx(t) \quad \text{with } K = R^{-1}B^T S \quad (17.4)$$

that minimizes the cost, J , subject to the dynamic constraints imposed by the open-loop dynamics in Equation 17.1.

2. S is the unique, symmetric, positive semidefinite solution to the algebraic Riccati equation

$$SA + A^T S + C^T C - SBR^{-1}B^T S = 0 \quad (17.5)$$

3. The closed-loop dynamics arrived at by substituting Equation 17.4 into Equation 17.1

$$\dot{x}(t) = [A - BK]x(t) \quad (17.6)$$

are guaranteed to be asymptotically stable.

4. The minimum value of the cost J in Equation 17.3 is $J = x_0^T S x_0$.

While the theorem states the LQR result, it is still necessary to discuss how to take advantage of it. Before doing so, note that the control gains, K from Equation 17.4, can be readily computed for large-order systems using standard software packages such as MATLAB[®] and MATRIXx[™]. Hence, the remainder of this chapter is really about how the values of the design variables used in the optimization problem influence the behavior of the controllers. Here the design variables are z , the states to keep small, and R , the control weighting matrix. We begin the discussion by describing the physical motivation behind the optimization problem.

17.2.1 Physical Motivation for the LQR

The LQR problem statement and cost can be motivated in the following manner. Suppose that the system Equation 17.1 is initially excited, and that the net result of this excitation is reflected in the initial state vector x_0 . This initial condition can be regarded as an undesirable deviation from the equilibrium position of the system, $x(t) = 0$. Given these deviations, the objective of the control can essentially be viewed as selecting a control vector $u(t)$ that regulates the state vector $x(t)$ back to its equilibrium position of $x(t) = 0$ as quickly as possible.

If the system Equation 17.1 is controllable, then it is possible to drive $x(t)$ to zero in an arbitrarily short period of time. This would require very large control signals which, from an engineering point of view, are unacceptable. Large control signals will saturate actuators and if implemented in a feedback form will require high-bandwidth designs that may excite unmodeled dynamics. Hence, it is clear that there must be a balance between the desire to regulate perturbations in the state to equilibrium and the size of the control signals needed to do so.

Minimizing the quadratic cost functional from Equation 17.3 is one way to quantify our desire to achieve this balance. Realize that the quadratic nature of both terms in the cost

$$u^T(t)Ru(t) > 0 \quad \text{for } u(t) \neq 0 \tag{17.7}$$

$$z^T(t)z(t) = x^T(t)C^TCx(t) \geq 0 \quad \text{for } x(t) \neq 0 \tag{17.8}$$

ensures that they will be non-negative for all t . Further since the goal of the control law is to make the value of the cost as small as possible, larger values of the terms (Equations 17.7 and 17.8) are penalized more heavily than smaller ones. More specifically, the term (Equation 17.7) represents a penalty that helps the designer keep the magnitude of $u(t)$ “small.” Hence the matrix R , which is often called the control weighting matrix, is the designer’s tool which influences how “small” $u(t)$ will be. Selecting large values of R leads to small values of $u(t)$, which is also evident from the control gain K given in Equation 17.4.

The other term, Equation 17.8, generates a penalty in the cost when the states that are to be kept small, $z(t)$, are different from their desired equilibrium value of zero. The selection of which states to keep small, that is the choice of C in Equation 17.2, is the means by which the control system designer communicates to the mathematics the relative importance of individual state variable deviations. That is, which errors are bothersome and to what degree they are so.

Example 17.1:

Consider the single degree of freedom, undamped, harmonic oscillator shown in Figure 17.1. Using Newton’s laws, the equations of motion are

$$m\ddot{q}(t) + kq(t) = u(t) \tag{17.9}$$

Letting $x_1(t) = q(t)$ denote the position of the mass and $x_2(t) = \dot{q}(t)$ its velocity, the dynamics (Equation 17.9) can be expressed in the state space as

$$\begin{aligned} \dot{x}_1(t) &= x_2(t) \\ \dot{x}_2(t) &= -\omega^2x_1(t) + \omega^2u(t) \end{aligned} \tag{17.10}$$

FIGURE 17.1 Single degree of freedom oscillator with mass m , spring stiffness $k = 1$, and control force input $u(t)$.

or

$$\dot{x}(t) = Ax(t) + Bu(t)$$

with

$$x(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} \quad A = \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix} \quad B = \begin{bmatrix} 0 \\ \omega^2 \end{bmatrix}$$

where $\omega^2 = 1/m$ is the square of the natural frequency of the system with $k = 1$.

In the absence of control, initial conditions will produce a persistent sinusoidal motion of the mass at a frequency of ω rad/sec. As such, we seek a control law that regulates the position of the mass to its equilibrium value of $q(t) = 0$. Thus, we define the states of interest, z , as $x_1(t)$.

$$z(t) = Cx(t) \quad \text{with } C = \begin{bmatrix} 1 & 0 \end{bmatrix} \tag{17.11}$$

Since the control is scalar, the cost (Equation 17.3) takes the form

$$J = \int_0^\infty [z^2(t) + \rho u^2(t)] dt \quad \text{with } \rho > 0$$

where ρ is the control weighting parameter.

The optimal LQR control law takes the form $u(t) = -Kx(t)$ where the LQ gain K is a row vector $K = [k_1 \quad k_2]$. To determine the value of the gain, we must solve the algebraic Riccati equation 17.5. Recalling that we want a symmetric solution to the Riccati equation, letting

$$S = \begin{bmatrix} S_{11} & S_{12} \\ S_{12} & S_{22} \end{bmatrix} \tag{17.12}$$

and using the values of A , B , and C given above, the Riccati equation 17.5 becomes

$$0 = \begin{bmatrix} S_{11} & S_{12} \\ S_{12} & S_{22} \end{bmatrix} \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix} + \begin{bmatrix} 0 & -\omega^2 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} S_{11} & S_{12} \\ S_{12} & S_{22} \end{bmatrix} + \begin{bmatrix} 1 \\ 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \end{bmatrix} - \frac{1}{\rho} \begin{bmatrix} S_{11} & S_{12} \\ S_{12} & S_{22} \end{bmatrix} \begin{bmatrix} 0 \\ \omega^2 \end{bmatrix} \begin{bmatrix} 0 & \omega^2 \\ S_{12} & S_{22} \end{bmatrix}$$

Carrying out the matrix multiplications leads to the following three equations in the three unknown S_{ij} from Equation 17.12.

$$0 = 2\omega^2 S_{12} - 1 + \frac{1}{\rho} \omega^4 S_{12}^2 \tag{17.13}$$

$$0 = -S_{11} + \omega^2 S_{22} + \frac{1}{\rho} \omega^4 S_{12} S_{22} \tag{17.14}$$

$$0 = -2S_{12} + \frac{1}{\rho} \omega^4 S_{22}^2 \tag{17.15}$$

Solving Equation 17.13 for S_{12} and simplifying yields

$$S_{12} = \frac{-\rho \pm \rho \sqrt{1 + 1/\rho}}{\omega^2}$$

Both the positive and negative choices for S_{12} are valid solutions of the Riccati equation. While we are only interested in the positive semidefinite solution, we still need more information to resolve

which choice of S_{12} leads to the unique choice of $S \geq 0$. Rewriting Equation 17.15 as

$$2S_{12} = \frac{1}{\rho} \omega^4 S_{22}^2 \tag{17.16}$$

indicates that S_{12} must be positive to satisfy the equality of Equation 17.16, since the right-hand side of the equation must always be positive. Equation 17.16 indicates that there will also be a \pm sign ambiguity in selecting the appropriate S_{22} . To resolve the ambiguity we use Sylvester’s Test, which says that for $S \geq 0$ both

$$S_{11} \geq 0 \quad \text{and} \quad S_{11}S_{22} - S_{12}^2 \geq 0 \tag{17.17}$$

Solving Equation 17.15 and 17.13 using the relations in Equation 17.17, which clearly show that $S_{22} > 0$, gives the remaining elements of S

$$S_{11} = \frac{\rho}{\omega} \sqrt{2(1 + 1/\rho) (\sqrt{1 + 1/\rho} - 1)}$$

$$S_{12} = \frac{-\rho + \rho \sqrt{1 + 1/\rho}}{\omega^2}$$

$$S_{22} = \frac{\rho}{\omega^3} \sqrt{2(\sqrt{1 + 1/\rho} - 1)}$$

The final step in computing the controller is to evaluate the control gains K from Equation 17.4. Doing so gives

$$k_1 = \sqrt{1 + 1/\rho} - 1 \quad k_2 = \frac{1}{\omega} \sqrt{2(\sqrt{1 + 1/\rho} - 1)}$$

Given the control gains as a function of the control weighting ρ it is useful to examine the locus of the closed-loop poles for the system as ρ varies over $0 < \rho < \infty$. Evaluating the eigenvalues of the closed-loop dynamics from Equation 17.6 leads to a pair of complex conjugate closed-loop poles

$$\lambda_{1,2} = -\frac{\omega}{2} \sqrt{2(\sqrt{1 + 1/\rho} - 1)} \pm j \frac{\omega}{2} \sqrt{2(\sqrt{1 + 1/\rho} + 1)}.$$

A plot of the poles as ρ varies over $0 < \rho < \infty$ is shown in Figure 17.2. Notice that for large values of ρ , the poles are near their open-loop values at $\pm j\omega$, and as ρ decreases the poles move farther out into the left half-plane. This is consistent with how ρ influences the cost. Large values of ρ place a heavy penalty on the control and lead to low gains with slow transients, while small values of ρ tell the mathematics that large control gains with fast transients are acceptable.

17.2.2 Designing LQR Controllers

While the above section presents all the formulas needed to start designing MIMO LQR controllers, the point of this section is to inform the potential user of the limitations of the methodology. The most restrictive aspects of LQR controllers is that they are full-state feedback controllers. This means that every state that appears in the model of the physical system Equation 17.1 must be measured by a sensor. In fact, the notation of $z(t) = Cx(t)$ for the linear combination of states that are to be regulated to zero is deliberate. We do not call $z(t)$ the outputs of the system because all the states $x(t)$ must be measured in real time to implement the control law Equation 17.4.

Full-state feedback is appropriate and can be applied to systems whose dynamics are described by a finite set of differential equations and whose states can readily be measured. An aircraft in steady, level flight is an example of a system whose entire state can be measured with sensors. In fact, LQR control has been used to design flight control systems for modern aircraft.

FIGURE 17.2 Locus of closed-loop pole locations for the single degree of freedom oscillator with $\omega = 1$ as ρ varies over $0 < \rho < \infty$.

On the other hand, full-state feedback is typically not appropriate for flexible systems. The dynamics of flexible systems are described by partial differential equations that often require very high-order, if not infinite-dimensional, state-space models. As such, it is not feasible to measure all the states of systems that possess flexible dynamics. Returning to the aircraft example, one could not use a LQR controller to regulate the aerodynamically induced vibrations of the aircraft's wing. The number of sensors that would be needed to measure the state of the vibrating wing prohibit this.

Having discussed the implications of full-state feedback, the next restrictive aspect of LQR to discuss is the gap between what the LQR controller achieves and the desired control system performance. Recall that the LQR is the control that minimizes the quadratic cost of Equation 17.3 subject to the constraints imposed by the system dynamics. This optimization problem and the resulting optimal controller have very little to do with more meaningful control system specifications like levels of disturbance rejection, overshoot in tracking, and stability margins. This gap must always be kept in mind when using LQR to design feedback controllers. The fact that LQR controllers are in some sense optimal is of no consequence if they do not meet the performance goals. Further since control system specifications are not given in terms of minimizing quadratic costs, it becomes the job of the designer to use the LQR tool wisely. To do so it helps to adopt a means-to-an-end design philosophy where the LQR is viewed as a tool, or the means, used to achieve the desired control system performance, or the end.

One last issue to point out is that LQR controller design is an iterative process even though the methodology systematically produces optimal, stabilizing controllers. Since the LQR formulation does not directly allow one to achieve standard control system specifications, trial and error iteration over the values of the weights in the cost is necessary to arrive at satisfactory controllers. Typically LQR designs are carried out by choosing values for the design weights, synthesizing the control law, evaluating how well the control law achieves the desired robustness and performance, and iterating through this process until a satisfactory controller is found. In the sequel, various properties and weight selection tools will

be presented that provide good physical and mathematical guidance for selecting values for the LQR design variables. Yet these are only guides, and as such they will not eliminate the iterative nature of LQR controller design.

17.3 Properties of LQR

The LQR has several very important properties, which we summarize below. It is important to stress that the properties of LQR designs hinge upon the fact that full-state feedback is used and the specific way that the control gain matrix K is computed from the solution of the Riccati equation.

17.3.1 Robustness Properties

To visualize the robustness properties of LQR controllers, it is necessary to consider the loop transfer function matrix that results when implementing the control law of Equation 17.4. The LQR loop transfer function matrix, denoted by $G_{LQ}(s)$, induced by the control scheme of Equation 17.4 is given by

$$G_{LQ}(s) = K(sI - A)^{-1}B$$

and the closed-loop dynamics of Equation 17.6 using this representation are shown in Figure 17.3. An interesting fact is that $G_{LQ}(s)$ is always square and minimum phase. Note that as a consequence of this feedback architecture any unstructured modeling errors must be reflected to the inputs of the LQR loop, location 1 in Figure 17.3.

Under the *assumption that the control weight matrix $R = R^T > 0$ is diagonal*, the LQR loop transfer matrix is guaranteed to satisfy both of the inequalities

$$\begin{aligned} \sigma_{\min} [I + G_{LQ}(j\omega)] &\geq 1 \quad \forall \omega \\ \sigma_{\min} [I + G_{LQ}(j\omega)^{-1}] &\geq \frac{1}{2} \quad \forall \omega \end{aligned} \tag{17.18}$$

where σ_{\min} denotes the minimum singular value. Since the multivariable robustness properties of any design depend on the size of $\sigma_{\min} [I + G(j\omega)]$ and $\sigma_{\min} [I + G(j\omega)^{-1}]$ the following guaranteed multivariable gain and phase margins are inherent to LQR controllers as a result of Equation 17.18.

17.3.1.1 LQR Stability Robustness Properties

1. Upward gain margin is infinite
2. Downward gain margin is at least 1/2
3. Phase margin is at least $\pm 60^\circ$

These gain and phase margins can occur independently and simultaneously in all m control channels. To visualize this, consider Figure 17.4, where the $f_i(\cdot)$ can be viewed as perturbations to the individual inputs, $u_i = f_i(\cdot)\mu_i$. As a result of the gain margin properties (1) and (2), the LQR system shown in Figure 17.4

FIGURE 17.3 The LQR loop transfer matrix, $G_{LQ}(s) = K(sI - A)^{-1}B$.

FIGURE 17.4 LQR loop used to visualize the guaranteed robustness properties.

is guaranteed to be stable for any set of scalar gains β_i with $f_i = \beta_i$ where the β_i lie anywhere in the range $1/2 < \beta_i < \infty$. The phase margin property (3) ensures the LQR system shown in Figure 17.4 is guaranteed to be stable for any set of scalar phases ϕ_i with $f_i = e^{j\phi_i}$ where the ϕ_i can lie anywhere in the range $-60^\circ < \phi_i < +60^\circ$.

These inherent robustness properties of LQR designs are useful in many applications. To further appreciate what they mean, consider a single input system with a single variable we wish to keep small

$$\dot{x}(t) = Ax(t) + bu(t) \quad \text{with } z(t) = c^T x(t)$$

and let the control weight be a positive scalar, $R = \rho > 0$. Then the resulting LQR loop transfer function is scalar, and its robustness properties can be visualized by plotting the Nyquist diagram of $G_{LQ}(j\omega)$ for all ω . Figure 17.5 contains a Nyquist plot for a scalar $G_{LQ}(j\omega)$ that illustrates why the LQR obtains good gain and phase margins. Essentially, inequality Equation 17.18 guarantees that the Nyquist plot will not penetrate the unit circle centered at the critical point at $(-1, 0)$.

17.3.2 Asymptotic Properties of LQR Controllers

It is clear that the closed-loop poles of the LQR design will depend upon the values of the design parameters $z(t)$ and R . The exact numerical values of the closed-loop poles can only be determined using a digital computer, since we have to solve the Riccati equation 17.5. However, it is possible to qualitatively predict the asymptotic behavior of the closed-loop poles for the LQR as the size of the control gain is varied without solving the Riccati equation, evaluating the control gains, and computing the closed-loop poles.

FIGURE 17.5 A typical Nyquist plot for a single-input, single-output LQR controller.

17.3.2.1 Assumptions for Asymptotic LQR Properties

1. The number of variables to keep small is equal to the number of controls. That is $\dim[z(t)] = \dim[u(t)] = m$.
2. The control weight is chosen such that $R = \rho \tilde{R}$ where ρ is a positive scalar and $\tilde{R} = \tilde{R}^T > 0$.
3. $G_z(s)$ is defined to be the square transfer function matrix between the variables we wish to keep small and the controls with the loop open, $z(s) = G_z(s)u(s)$ where $G_z(s) = C(sI - A)^{-1}B$, and q is the number of transmission zeros of $G_z(s)$.

Adjusting ρ directly influences the feedback control gain. When $\rho \rightarrow \infty$, we speak of the LQR controller as having low gain since under Assumption (2)

$$u(t) = -\frac{1}{\rho} \tilde{R}^{-1} B^T Sx(t) \rightarrow 0$$

as $\rho \rightarrow \infty$. Likewise, when $\rho \rightarrow 0$ we speak of the high gain controller since $u(t)$ will clearly become large. The asymptotic properties of the LQR closed-loop poles under the stated assumptions are as follows.

17.3.2.2 LQR Asymptotic Properties

1. *Low Gain:* As $\rho \rightarrow \infty$, the closed-loop poles start at
 - a. The stable open-loop poles of $G_z(s)$
 - b. The mirror image, about the $j\omega$ -axis, of any unstable open-loop poles of $G_z(s)$
 - c. If any open-loop poles of $G_z(s)$ lie exactly on the $j\omega$ -axis, the closed-loop poles start just to the left of them
2. *High Gain:* As $\rho \rightarrow 0$, the closed-loop poles will
 - a. Go to cancel any minimum phase zeros of $G_z(s)$
 - b. Go to the mirror image, about the $j\omega$ -axis, of any non-minimum phase zeros of $G_z(s)$
 - c. The rest will go off to infinity along stable Butterworth patterns

Realize that these rules are not sufficient for constructing the entire closed-loop pole root locus. However, they do provide good insight into the asymptotic behavior of LQR controllers. In particular, the second rule highlights how the choice of $z(t)$, which defines the zeros of $G_z(s)$, influences the closed-loop behavior of LQR controllers.

Extensions of these results exist for the case where Assumption (1) is not satisfied, that is when $\dim[z(t)] \neq \dim[u(t)]$. When $\dim[z(t)] \neq \dim[u(t)]$, the low gain asymptotic result will still hold, which is to be expected. The difficulty for non-square $G_z(s)$ arises in the high-gain case as $\rho \rightarrow 0$ because it is not a simple manner to evaluate the zeros that the closed-loop poles will go toward. For details of how to evaluate the zero locations that the closed-loop poles will go toward in the cheap control limit, one can refer to [3] and [2, *problem 3.14*].

17.4 LQR Gain Selection Tools

In this section we present some variations on the standard LQR problem given in Theorem 17.1. It is best to view the following variations on LQR as tools a designer can use to arrive at controllers that meet a set of desired control system specifications. While the tools are quite useful, the choice of which tool to use is very problem specific. Hence, we also present some physical motivation to highlight when the various tools might be useful. Realize that these tools do not remove the iterative nature of LQR control design. In fact, these tools are only helpful when used iteratively and when used with an understanding of the underlying physics of the design problem and the limitations of the design model. The variations on LQR presented here are by no means a complete list.

17.4.1 Cross-Weighted Costs

Consider the linear time-invariant system with dynamics described by the state equation in Equation 17.1 and the following set of variables we wish to keep small

$$z(t) = Cx(t) + Du(t) \quad (17.19)$$

Substituting Equation 17.19 into the quadratic cost from Equation 17.3 produces the cost function

$$J = \int_0^{\infty} \left\{ x^T(t)C^T Cx(t) + 2x^T(t)C^T Du(t) + u^T(t) \left[R + D^T D \right] u(t) \right\} dt \quad (17.20)$$

which contains a cross penalty on the state and control, $2x^T(t)C^T Du(t)$. The solution to the LQR controller that minimizes the cost of Equation 17.20 will be presented here, but first we give some motivation for such a cost and choice of performance variables.

Cross-weighted cost functions and performance variables with control feed-through terms are common. The control feed-through term, $Du(t)$ in Equation 17.19, arises physically when the variables we wish to keep small are derivatives of the variables that appear in the state vector of the open-loop dynamics Equation 17.1. To see this, consider the single degree of freedom oscillator from Example 17.1 where the acceleration of the mass is the variable we wish to keep small, $z(t) = \ddot{q}(t)$. Using the definitions from the example and Equations 17.11, this can be expressed as

$$\begin{aligned} z(t) &= \ddot{q}(t) = \dot{x}_2(t) \\ &= -\omega^2 x_1(t) + \omega^2 u(t) = [-\omega^2 \ 0]x(t) + \omega^2 u(t) \end{aligned}$$

Clearly, penalizing acceleration requires the control feed-through term in the definition of the variables we wish to keep small. Control feed-through terms also arise when penalizing states of systems whose models contain neglected or unknown, higher-order modes. Such models often contain control feed-through terms to account for the low-frequency components of the dynamics of the modes that are not present in the design model. Further, as will be seen below, cross-coupled costs such as Equation 17.20 arise when frequency-dependent weighting terms are used to synthesize LQR controllers.

Theorem 17.2: Cross-Weighted LQR

Consider the system dynamics

$$\dot{x}(t) = Ax(t) + Bu(t) \quad x(t=0) = x_0 \quad (17.21)$$

with $x(t) \in \mathbb{R}^n$ and $u(t) \in \mathbb{R}^m$ and the quadratic cost with a cross penalty on state and control

$$J = \int_0^{\infty} \left[x^T(t)R_{xx}x(t) + 2x^T(t)R_{xu}u(t) + u^T(t)R_{uu}u(t) \right] dt \quad (17.22)$$

in which the size of the states is weighted relative to the amount of control action in $u(t)$ through the state weighting matrix R_{xx} , the control weighting matrix R_{uu} , and the cross weighting matrix R_{xu} .

If the following assumptions hold:

1. The entire state vector $x(t)$ is available for feedback
2. $R_{xx} = R_{xx}^T \geq 0$, $R_{uu} = R_{uu}^T > 0$, and $\begin{bmatrix} R_{xx} & R_{xu} \\ R_{xu}^T & R_{uu} \end{bmatrix} \geq 0$

3. $[A \ B]$ is stabilizable and $[A \ R_{xx}^{1/2}]$ is detectable*

Then

1. The linear quadratic controller is the unique, optimal, full-state feedback control law

$$u(t) = -Kx(t) \quad \text{with } K = R_{uu}^{-1} \left(R_{xu}^T + B^T S \right) \quad (17.23)$$

that minimizes the cost, J of Equation 17.22, subject to the dynamic constraints imposed by the open-loop dynamics in Equation 17.21.

2. Defining $A_r = (A - BR_{uu}^{-1}R_{xu}^T)$, S is the unique, symmetric, positive semi-definite solution to the algebraic Riccati equation

$$SA_r + A_r^T S + \left(R_{xx} - R_{xu}R_{uu}^{-1}R_{xu}^T \right) - SBR_{uu}^{-1}B^T S = 0 \quad (17.24)$$

3. The closed-loop dynamics arrived at by substituting Equation 17.23 into Equation 17.21 are guaranteed to be asymptotically stable.

Note that when the cost is defined by Equation 17.3 and the variables to be kept small are defined by Equation 17.19, $R_{xx} = C^T C$, $R_{xu} = C^T D$, and $R_{uu} = [R + D^T D]$ as can be seen from Equation 17.20. Also, if $R_{xu} = 0$ this theorem reduces to the standard LQR result presented in Theorem 17.1.

The assumptions used in Theorem 17.2 are essentially those used in the standard LQR result. One difference is that here we require $R_{xx} = R_{xx}^T \geq 0$, while in Theorem 17.1 this was automatically taken care of by our definition of the state cost as $x^T(t)C^T Cx(t)$ because $C^T C \geq 0$. Unfortunately, the guaranteed robustness properties presented in the previous section are not necessarily true for the LQR controllers that minimize the cost (Equation 17.22).

17.4.2 The Stochastic LQR Problem

In the stochastic LQR problem, we allow the inclusion of a white noise process in the state dynamics. Namely, the state vector $x(t)$ now satisfies the stochastic differential equation

$$\dot{x}(t) = Ax(t) + Bu(t) + L\xi(t) \quad (17.25)$$

where $\xi(t)$ is a vector valued, zero-mean, white noise process. We still assume that all the state variables can be measured exactly and used for feedback as necessary. Physically, the term $L\xi(t)$ in Equation 17.25 should be viewed as the impact of a persistent set of disturbances on a system that corrupt the desired equilibrium value of the state, $x(t) = 0$. The L matrix describes how the disturbances impact the system, and the stochastic process $\xi(t)$ captures the dynamics of how the disturbances evolve with time. In particular, since the disturbances are a white noise process, they are completely unpredictable from moment to moment.

As with the standard LQR problem, we would like to find the control law that minimizes some quadratic cost functional which captures a trade off between state cost and control cost. However, the cost functional for the standard LQR problem, Equation 17.3, cannot be used here as a result of the stochastic nature of the states. The value of the cost functional would be infinity because of the continuing excitation from $\xi(t)$. To accommodate the stochastic nature of the state, we seek the optimal control that minimizes the

* $R_{xx}^{1/2}$ is the matrix square root of R_{xx} which always exists for positive semidefinite matrices. For the cross-coupled cost in Equation 17.20, $R_{xx} = C^T C$ and $R_{xx}^{1/2} = C$.

expected value, or mean, of the standard LQR cost functional

$$J = E \left\{ \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^{\tau} \left[z^T(t)z(t) + u^T(t)Ru(t) \right] dt \right\} \quad (17.26)$$

where E is the expected value operator. The normalization by the integration time τ is necessary to ensure that the cost functional is finite. Surprisingly, the optimal control for this stochastic version of the LQR problem is identical to that of the corresponding deterministic LQR problem. In particular, Theorem 17.1 also describes the unique optimal full-state feedback control law that minimizes the cost Equation 17.26 subject to the constraints Equation 17.25. This is a result of the fact that $\xi(t)$ is a white noise process. Since the disturbances are completely unpredictable, the optimal thing to do is ignore them. As a consequence of all this, the properties of the deterministic LQR problem from Theorem 17.1 discussed in Section 17.3 are also true for this stochastic LQR problem.

Unfortunately, these results do not make it any easier to design LQR controllers to specifically reject disturbances that directly impact the state dynamics. This is because physical disturbances are typically not white in nature, and the stochastic LQR result only applies for white noise disturbances. However, these results do play a key role in synthesizing multivariable controllers when some of the states cannot be measured and fed back for control.

17.4.3 Sensitivity Weighted LQR

Synthesizing LQR controllers requires an accurate model of the system dynamics. Not only are the control gains, K , a function of the system matrices A and B , but in the high-gain limit we know that the closed-loop poles will go to cancel the zeros of $G_z(s)$. If the models upon which the control design is based are inaccurate, the closed-loop system at a minimum will not achieve the predicted performance and will, in the worst case, be unstable. This is particularly relevant for systems with lightly damped poles and zeros near the $j\omega$ axis. Hence, it is important to address the issue of stability robustness, since designers often must work with models that do not capture the dynamical behavior of their systems exactly.

Modeling errors can be classified into two main groups: unmodeled dynamics and parametric errors. Unmodeled dynamics are typically the result of unmodeled non-linear behavior and neglected high-frequency dynamics which lie beyond the control bandwidth of interest. How one can design LQR controllers that are robust to unmodeled dynamics will be discussed in the following section on frequency weighted LQR. Parametric uncertainty arises when there are errors in the values of the system parameters used to form the model. Sensitivity weighted LQR (SWLQR), is a variation on the standard LQR problem that can be used to increase the stability robustness of LQR controllers to parametric modeling errors. Before presenting the SWLQR results, we will discuss parametric modeling errors.

17.4.3.1 Parametric Modeling Errors

When parametric errors exist, the model will be able to capture the system's nominal dynamics, but the model cannot capture the exact behavior. Parametric errors occur often because it is difficult to know the exact properties of the physical devices that make up a system and because the physical properties may vary with time or the environment in which they are placed. For example, consider the single degree of freedom oscillator from Example 17.1 as the model of a car tire. While we might have some knowledge of the tire's stiffness, it is unrealistic to expect to know its exact value, as the tire is a complex physical device whose properties change with wear and temperature. Hence, the value of the spring stiffness k , which models the tire's elasticity, will be parametrically uncertain.

To deal with any sort of modeling error, one must formulate a model of the uncertainty in the nominal design model. Parametrically uncertain variables may appear directly as the elements of, or be highly nonlinear functions of, the elements of the A and B matrices. When the latter is the case, one often reduces the uncertainty model to parametric uncertainty in more fundamental system quantities such as the frequency and/or damping of the system's poles and zeros. In either case one must decide which

elements of the model, be they pole frequencies or elements of the A matrix, are uncertain and by how much they are uncertain.

This digression on parametric modeling errors and the presentation of the SWLQR results that follows is vital. To achieve high levels of performance, which means using high-gain control, LQR requires an accurate plant model. If a model contains parametric modeling errors and high-gain LQR control ($\rho \rightarrow 0$) is used, then the closed-loop poles will go to cancel zeros of $G_z(s)$ which will be in different locations than the true zeros. Such errors often lead to instability, and this is why we worry about parametric modeling errors.

17.4.3.2 SWLQR

Designing feedback controllers that are robust to parametric uncertainty is a very difficult problem. Research on this problem is ongoing, and a great deal of research has gone into this problem in the past, see [4] for a survey on this topic. Here we present only one of the many methods, SWLQR, that can be used to design LQR controllers that are robust to parametric modeling errors. While the treatment is by no means complete, it should give one a sense of how to deal with parametric modeling errors when designing LQR controllers.

The philosophy behind SWLQR is that it aims, as the title implies, to desensitize the LQR controller to parametric uncertainty. The advantage of this philosophy is that it produces a technique that is nothing more than a special way to choose the weighting matrices of the cross-weighted LQR problem presented in Section 17.4.1. A shortcoming of the method is that it does not result in a controller that is guaranteed to be robust to the parametric uncertainty in the model.

In presenting the SWLQR results, the vector of uncertain parameters to which you wish to desensitize a standard LQR controller will be denoted by α , and α_i will denote the i th element of α . To desensitize LQR controllers to the uncertain variables in α , a quadratic penalty on the sensitivity of the state to each of the uncertain variables α_i ,

$$\frac{\partial x^T(t)}{\partial \alpha_i} R_{\alpha \alpha_i} \frac{\partial x(t)}{\partial \alpha_i} \tag{17.27}$$

is added to the cross-weighted LQR cost functional (Equation 17.22). In this expression $\frac{\partial x(t)}{\partial \alpha_i}$ is known as the sensitivity state of the system and $R_{\alpha \alpha_i}$ is the sensitivity state weighting matrix, which must be positive semidefinite. Quadratic penalties for each α_i (Equation 17.27) are included in the LQR cost functional to tell the mathematics that we care not only about deviations in the state from its equilibrium position but that we also care about how sensitive the value of the state is to the known uncertain parameters of the system. The larger the value of $R_{\alpha \alpha_i}$, the more we tell the cost that we are uncertain about the influence of parameter α_i in our model on the trajectory of the state. In turn, the larger the uncertainty in the influence of parameter α_i on the state trajectory, the more robust the resulting SWLQR controller will be to the uncertain parameter α_i .

Making certain assumptions about the dynamics of the sensitivity states leads to the SWLQR result [6,7]. It is not necessary to understand or discuss these assumptions to design SWLQR controllers, and we thus simply present the SWLQR result.

The SWLQR Result

Given a stable open-loop system (Equation 17.21), let α denote the vector of uncertain variables to which you want to desensitize a LQR controller and define the sensitivity state weighting matrices $R_{\alpha \alpha_i}$ such that

$$R_{\alpha \alpha_i} = R_{\alpha \alpha_i}^T \geq 0 \quad \text{where } R_{\alpha \alpha_i} \in \mathbb{R}^{n \times n}$$

Then the SWLQR controller results from synthesizing the cross-coupled cost LQR controller from Theorem 17.2 with the following set of design weights

$$R_{xx} = \tilde{R}_{xx} + \sum_{i=1}^{n_\alpha} \frac{\partial A^T}{\partial \alpha_i} A^{-T} R_{\alpha\alpha_i} A^{-1} \frac{\partial A}{\partial \alpha_i} \quad (17.28)$$

$$R_{xu} = \tilde{R}_{xu} + \sum_{i=1}^{n_\alpha} \frac{\partial A^T}{\partial \alpha_i} A^{-T} R_{\alpha\alpha_i} A^{-1} \frac{\partial B}{\partial \alpha_i} \quad (17.29)$$

$$R_{uu} = \tilde{R}_{uu} + \sum_{i=1}^{n_\alpha} \frac{\partial B^T}{\partial \alpha_i} A^{-T} R_{\alpha\alpha_i} A^{-1} \frac{\partial B}{\partial \alpha_i} \quad (17.30)$$

In these expressions n_α denotes the number of uncertain parameters in α , and \tilde{R}_{xx} , \tilde{R}_{xu} , and \tilde{R}_{uu} are the nominal values of the weights from a standard, unrobust LQR design. The matrix derivatives $\partial A/\partial \alpha_i$ and $\partial B/\partial \alpha_i$ are taken term by term. For example, $\partial A/\partial \alpha_i$ is a matrix of the same size as A whose elements are the partial derivatives with respect to α_i of the corresponding elements in the A matrix. For

$$A = \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1n} \\ A_{21} & & & \\ \vdots & \ddots & & \\ A_{n1} & & & A_{nn} \end{bmatrix}$$

$$\frac{\partial A}{\partial \alpha_i} = \begin{bmatrix} \frac{\partial A_{11}}{\partial \alpha_i} & \frac{\partial A_{12}}{\partial \alpha_i} & \cdots & \frac{\partial A_{1n}}{\partial \alpha_i} \\ \frac{\partial A_{21}}{\partial \alpha_i} & & & \\ \vdots & \ddots & & \\ \frac{\partial A_{n1}}{\partial \alpha_i} & & & \frac{\partial A_{nn}}{\partial \alpha_i} \end{bmatrix}$$

While it might not be obvious that the modified cost expressions (Equations 17.28 through 17.30) lead to controllers that are more robust to the uncertain parameters in α , extensive empirical and experimental results verify that they do [7]. To see this mathematically, consider the state cost, $x^T(t)R_{xx}x(t)$ from Equation 17.28, when the variables we wish to keep small are defined by $z(t) = Cx(t)$,

$$\begin{aligned} x^T(t)R_{xx}x(t) &= x^T(t)C^T Cx(t) + x^T(t) \frac{\partial A^T}{\partial \alpha_1} A^{-T} R_{\alpha\alpha_1} A^{-1} \frac{\partial A}{\partial \alpha_1} x(t) \\ &+ \cdots + x^T(t) \frac{\partial A^T}{\partial \alpha_{n_\alpha}} A^{-T} R_{\alpha\alpha_{n_\alpha}} A^{-1} \frac{\partial A}{\partial \alpha_{n_\alpha}} x(t) \end{aligned}$$

This expression can also be expressed as $z^T(t)z(t)$ with $z(t) = \bar{C}x(t)$ where $\bar{C}^T = [C^T \quad C_{\alpha_1}^T \quad \cdots \quad C_{\alpha_{n_\alpha}}^T]$ and C_{α_i} is the minimal order matrix square root of

$$\frac{\partial A^T}{\partial \alpha_i} A^{-T} R_{\alpha\alpha_i} A^{-1} \frac{\partial A}{\partial \alpha_i}.$$

From this we see that the SWLQR cost modifications essentially add new variables to the vector of variables we wish to keep small, $z(t)$. In addition to the standard variables we wish to keep small for performance defined by $Cx(t)$, we tell the cost to keep the variables $C_{\alpha_i}x(t)$ small, and these are related to the sensitivity of the state to parametrically uncertain variables. Furthermore with this new $z(t)$ vector, the zeros of $G_z(s)$

will change. As a result, in the high-gain limit as $\rho \rightarrow 0$ the closed-loop poles will not go to cancel the uncertain zeros defined by the original vector of variables we wish to keep small, $z(t) = Cx(t)$.

Selecting the values of the state sensitivity weights $R_{\alpha\alpha_i}$ is, as to be expected, an iterative process. Typically $R_{\alpha\alpha_i}$ is chosen to be either $\beta_i I$ or $\beta_i \tilde{R}_{xx}$ where β_i is a positive scalar constant. Both these choices simplify the selection of $R_{\alpha\alpha_i}$ by reducing the choice to a scalar variable. When using $R_{\alpha\alpha_i} = \beta_i \tilde{R}_{xx}$, one tends to directly trade off performance, reflected by the nominal state cost $x^T(t) \tilde{R}_{xx} x(t)$ with robustness to the parametric error now captured by the state cost

$$\beta_i x^T(t) \frac{\partial A^T}{\partial \alpha_i} A^{-T} \tilde{R}_{xx} A^{-1} \frac{\partial A}{\partial \alpha_i} x(t)$$

On the other hand, selecting $R_{\alpha\alpha_i} = \beta_i I$ is a way of telling the cost that you care about both performance and robustness since the various terms in the state cost are not directly related as when $R_{\alpha\alpha_i} = \beta_i \tilde{R}_{xx}$.

Example 17.2:

Consider the mass, spring, dashpot system shown in Figure 17.6. The four masses are coupled together by dampers with identical coefficients, $c_i = 0.05 \forall i$, and springs with identical stiffnesses, $k_i = 1 \forall i$. In this system, the mass m_3 is uncertain, but known to lie within the interval $0.25 \leq m_3 \leq 1.75$ while the values of $m_1, m_2,$ and m_4 are all known to be 1. A unit intensity, zero-mean, white noise disturbance force $\xi(t)$ acts on m_4 , and the control $u(t)$ is a force exerted on m_2 . The performance variable of interest is the position of the tip mass m_4 , so $z(t) = q_4(t)$. The design goals are to synthesize a controller which is robust to the uncertainty in m_3 and that rejects the effect of the disturbance source on the position of m_4 . A combination of SWLQR and the stochastic LQR results from Section 17.4.2 will be used to meet these design goals.

Using Newton’s laws, the dynamics of this system can be expressed as

$$\mathcal{M}\ddot{q}(t) + \mathcal{C}\dot{q}(t) + \mathcal{K}q(t) = T_1 u(t) + T_2 \xi(t) \tag{17.31}$$

where $q^T(t) = [q_1(t) \ q_2(t) \ q_3(t) \ q_4(t)]^T$,

$$\mathcal{M} = \begin{bmatrix} m_1 & 0 & 0 & 0 \\ 0 & m_2 & 0 & 0 \\ 0 & 0 & m_3 & 0 \\ 0 & 0 & 0 & m_4 \end{bmatrix} \quad T_1 = \begin{bmatrix} 0 \\ 1 \\ 0 \\ 0 \end{bmatrix} \quad T_2 = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}$$

$$\mathcal{K} = \begin{bmatrix} k_1 + k_2 & -k_2 & 0 & 0 \\ -k_2 & k_2 + k_3 & -k_3 & 0 \\ 0 & -k_3 & k_3 + k_4 & -k_4 \\ 0 & 0 & -k_4 & k_4 \end{bmatrix} \quad \mathcal{C} = \begin{bmatrix} c_1 + c_2 & -c_2 & 0 & 0 \\ -c_2 & c_2 + c_3 & -c_3 & 0 \\ 0 & -c_3 & c_3 + c_4 & -c_4 \\ 0 & 0 & -c_4 & c_4 \end{bmatrix}$$

Then by defining the state vector as

$$x(t) = \begin{bmatrix} q(t) \\ \dot{q}(t) \end{bmatrix} \tag{17.32}$$

FIGURE 17.6 Mass, spring, dashpot system from Example 17.2.

the dynamics from Equation 17.31 can be represented in the state space as

$$\dot{x}(t) = Ax(t) + Bu(t) + L\xi(t)$$

with

$$A = \begin{bmatrix} 0 & I \\ -\mathcal{M}^{-1}\mathcal{K} & -\mathcal{M}^{-1}\mathcal{C} \end{bmatrix} \quad B = \begin{bmatrix} 0 \\ \mathcal{M}^{-1}\mathcal{T}_1 \end{bmatrix} \quad L = \begin{bmatrix} 0 \\ \mathcal{M}^{-1}\mathcal{T}_2 \end{bmatrix}$$

With the states defined by Equation 17.32, the performance variables we wish to keep small are

$$z(t) = Cx(t) \quad \text{where } C = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (17.33)$$

The first step in designing a SWLQR controller is to determine satisfactory values for the nominal design weights \tilde{R}_{xx} , \tilde{R}_{xu} , and \tilde{R}_{uu} . This can be done by ignoring the uncertainty and designing a LQR controller that achieves the desired system performance. Given the single-input, single-output (SISO) system with the desire to control the position of m_4 , we find a nominal LQR controller by minimizing the stochastic LQR cost functional

$$J = E \left\{ \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^\tau \left[z^T(t)z(t) + \rho u(t)^2 \right] dt \right\} \quad \rho > 0 \quad (17.34)$$

Substituting $z(t)$ from Equation 17.33 into the cost brings the integrand into the form of that in the cross-weighted cost from Equation 17.22 with $\tilde{R}_{xx} = C^T C$, $\tilde{R}_{xu} = 0$, and $\tilde{R}_{uu} = \rho$. Since m_3 is uncertain, we let it take on its median value of $m_3 = 1$ to synthesize actual controllers. After some iteration over the value of ρ , we decide that $\rho = .01$ leads to a nominal LQR controller that achieves good performance.

Figure 17.7 shows a set of transient responses for the mass spring system to an impulse applied to the disturbance source of the system. Responses for various values of the uncertain mass m_3 are shown, to illustrate how well the controllers behave in the presence of the parametric uncertainty. Notice that the LQR controller designed assuming $m_3 = 1$ is not stable over the entire range of possible values for m_3 and that even when the LQR controller is stable for values of $m_3 \neq 1$ the performance degrades. A better way to view the performance robustness of this controller to the uncertain mass in the presence of a white noise disturbance source is shown in Figure 17.8. This figure compares the root mean square (RMS) value of the tip mass position, $q_4(t)$, normalized by its open-loop RMS value as a function of the value of the uncertain mass m_3 . Such plots are often called cost “buckets,” for obvious reasons. When the closed-loop system is unstable, the cost blows up so that the wider the cost “bucket” the more robust the system will be to the parametric uncertainty. The cost bucket of Figure 17.8 clearly shows that the LQR controller is not robust to the parametric modeling error in m_3 , since the cost “bucket” completely lies within the bounds on m_3 .

Now to robustify this nominal LQR controller, we use the SWLQR modified costs from Equations 17.28 through 17.30. Here $\alpha = m_3$, $\frac{\partial B}{\partial m_3} = 0$ and

$$\frac{\partial A}{\partial m_3} = \begin{bmatrix} 0 & 0 \\ -\frac{\partial(\mathcal{M}^{-1})}{\partial m_3}\mathcal{K} & -\frac{\partial(\mathcal{M}^{-1})}{\partial m_3}\mathcal{C} \end{bmatrix}$$

where

$$\frac{\partial \mathcal{M}^{-1}}{\partial m_3} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & -m_3^{-2} & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

Using $R_{\alpha\alpha} = \beta I$ and $m_3 = 1$, we found that $\beta = 0.01$ led to a design that was significantly more robust than the LQR design. This can be seen in Figures 17.7 and 17.8 that compare the transient response and cost “buckets” of the SWLQR controller to the LQR controller. Both figures demonstrate that the SWLQR controller is stable over the entire range of possible values for m_3 . As to be expected though, we do sacrifice some nominal performance to achieve the stability robustness.

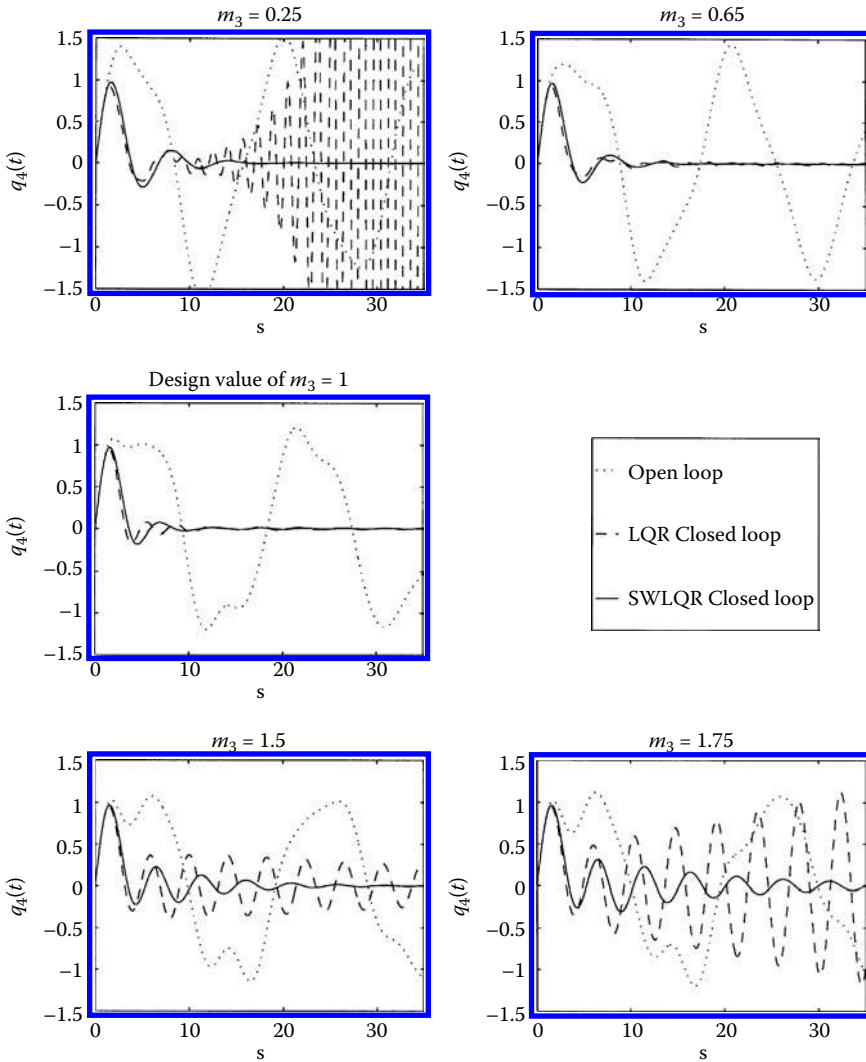

FIGURE 17.7 Transient response of the 4 mass, spring, dashpot system to an impulse applied at the disturbance source $\xi(t)$ for various values of m_3 . The open-loop transients are shown with dots, the LQR transients are shown with a dashed line, and the SWLQR transients are shown with a solid line.

17.4.4 LQR with Frequency Weighted Cost Functionals

As discussed in Section 17.2, there is often a gap between what a LQR controller achieves and the desired control system performance. This gap can essentially be viewed as the discrepancy between the time domain optimization method, LQR, and the control system specifications. Often, both control system performance and robustness specifications can be expressed and analyzed in the frequency domain, but the time domain nature of the LQR problem makes it difficult to take advantage of these attributes. Using frequency weighted cost functionals to synthesize LQR controllers leads to a useful and practical variation on the standard LQR problem that narrows the gap between the time and frequency domains.

Recall that the quadratic cost functional is our means of communicating to the mathematics the desired control system performance. We've discussed the physical interpretation of the cost in the time domain, and now to understand it in the frequency domain we apply Parseval's Theorem to it.

FIGURE 17.8 Comparison of cost “buckets” between the LQR and SWLQR controllers.

Theorem 17.3: Parseval’s

For a vector valued signal $h(t)$ defined on $-\infty < t < +\infty$ with

$$\int_{-\infty}^{\infty} h^T(t)h(t) dt < \infty$$

if we denote the Fourier transform of $h(t)$ by $h(j\omega)$ then

$$\int_{-\infty}^{\infty} h^T(t)h(t) dt = \frac{1}{2\pi} \int_{-\infty}^{\infty} h^*(j\omega)h(j\omega) d\omega$$

where $h^*(j\omega) = h^T(-j\omega)$ is the complex conjugate transpose of $h(j\omega)$.

Applying this theorem to the quadratic cost functional from Equation 17.3 with $R = \rho I$ and performance variables $z(t) = Cx(t)$ produces the cost

$$J = \frac{1}{2\pi} \int_{-\infty}^{\infty} [z^*(j\omega)z(j\omega) + \rho u^*(j\omega)u(j\omega)] d\omega$$

Notice that the time domain weight, ρ , remains constant in the frequency domain. This illustrates that the standard LQR cost functional tells the mathematics to weight the control equally at all frequencies.

To influence the desired control system performance on a frequency by frequency basis, we employ the frequency weighted cost functional

$$J = \frac{1}{2\pi} \int_{-\infty}^{\infty} [z^*(j\omega)W_1^*(j\omega)W_1(j\omega)z(j\omega) + u^*(j\omega)W_2^*(j\omega)W_2(j\omega)u(j\omega)] d\omega \quad (17.35)$$

in which both $W_1(j\omega)$ and $W_2(j\omega)$ are user-specified frequency weights [8]. Looking at the cost (Equation 17.35) for a SISO system in which the design weights will be scalar functions produces

$$J = \frac{1}{2\pi} \int_{-\infty}^{\infty} [|W_1(j\omega)|^2 |z(j\omega)|^2 + |W_2(j\omega)|^2 |u(j\omega)|^2] d\omega$$

and helps to illustrate the benefit of using frequency weighted cost functionals. The frequency weights allow us to place distinct penalties on the state and control cost at various frequencies, which is not possible to do when constant weights are used. Their main advantage is that they facilitate the incorporation of known and desired control system behavior into the synthesis process. This is why frequency weighting plays a key role in modern control design [9]. If one knows over what frequency range it is important to achieve performance and where the control energy must be small, this knowledge can be reflected into the frequency weights. Since we seek to minimize the quadratic cost (Equation 17.35), large terms in the integrand incur greater penalties than small terms and more effort is exerted to make them small. For example, if there is a rigorous bandwidth constraint set by a region of high-frequency unmodeled dynamics and if the control weight $W_2(j\omega)$ is chosen to have a large magnitude over this region then the resulting controller would not exert substantial energy in the region of unmodeled dynamics. This in turn would limit the controller's bandwidth. Similar arguments can be used to select $W_1(j\omega)$ to tell the controller synthesis at what frequencies the size of the performance variables need to be small.

To synthesize LQR controllers that minimize the frequency weighted cost functional (Equation 17.35), it is necessary to transform the cost functional back into the time domain. Doing so requires state space realization of the frequency weights $W_1(j\omega)$ and $W_2(j\omega)$. Hence we let

$$z_1(s) = W_1(s)z(s) \quad \text{with } W_1(s) = C_1(sI - A_1)^{-1}B_1 + D_1 \quad (17.36)$$

$$z_2(s) = W_2(s)u(s) \quad \text{with } W_2(s) = C_2(sI - A_2)^{-1}B_2 + D_2 \quad (17.37)$$

Using these definitions and Parseval's Theorem, the cost (Equation 17.35) becomes

$$J = \frac{1}{2\pi} \int_{-\infty}^{\infty} [z_1^*(j\omega)z_1(j\omega) + z_2^*(j\omega)z_2(j\omega)] d\omega = \int_{-\infty}^{\infty} [z_1^T(t)z_1(t) + z_2^T(t)z_2(t)] dt \quad (17.38)$$

This cost can be brought into the form of an LQR problem that we know how to solve by augmenting the dynamics of the weights (Equations 17.36 and 17.37) to the open-loop dynamics (Equations 17.1 and 17.2). Using $x_1(t)$ and $x_2(t)$ to denote, respectively, the states of $W_1(s)$ and $W_2(s)$ to carry out the augmentation produces the system

$$\begin{aligned} \dot{\mathcal{X}}(t) &= \mathcal{A}\mathcal{X}(t) + \mathcal{B}u(t) \\ \mathcal{Z}(t) &= \mathcal{C}\mathcal{X}(t) + \mathcal{D}u(t) \end{aligned} \quad (17.39)$$

with

$$\mathcal{A} = \begin{bmatrix} A & 0 & 0 \\ B_1C & A_1 & 0 \\ 0 & 0 & A_2 \end{bmatrix} \quad \mathcal{B} = \begin{bmatrix} B \\ 0 \\ B_2 \end{bmatrix} \quad \mathcal{C} = \begin{bmatrix} D_1C & C_1 & 0 \\ 0 & 0 & C_2 \end{bmatrix} \quad \mathcal{D} = \begin{bmatrix} 0 \\ D_2 \end{bmatrix}$$

where $\mathcal{X}^T(t) = [x^T(t) \ x_1^T(t) \ x_2^T(t)]$ and $\mathcal{Z}^T(t) = [z_1^T(t) \ z_2^T(t)]$ contains the outputs of $W_1(s)$ and $W_2(s)$. Notice that

$$\begin{aligned} \mathcal{Z}^T(t)\mathcal{Z}(t) &= z_1^T(t)z_1(t) + z_2^T(t)z_2(t) \\ &= \mathcal{X}^T(t)\mathcal{C}^T\mathcal{C}\mathcal{X}(t) + 2\mathcal{X}^T(t)\mathcal{C}^T\mathcal{D}u(t) + u^T(t)\mathcal{D}^T\mathcal{D}u(t) \end{aligned}$$

and thus the frequency weighted cost (Equation 17.38) becomes

$$J = \int_{-\infty}^{\infty} \left[\mathcal{X}^T(t) \mathcal{C}^T \mathcal{C} \mathcal{X}(t) + 2\mathcal{X}^T(t) \mathcal{C}^T \mathcal{D} u(t) + u^T(t) \mathcal{D}^T \mathcal{D} u(t) \right] dt$$

Realize that minimizing this cost subject to the dynamic constraints (Equation 17.39) is not only equivalent to minimizing the frequency weighted cost functional (Equation 17.35), but it is also a simple manner to carry out the optimization by using the cross-weighted LQR results from Theorem 17.2 with

$$R_{xx} = \mathcal{C}^T \mathcal{C} \quad R_{xu} = \mathcal{C}^T \mathcal{D} \quad R_{uu} = \mathcal{D}^T \mathcal{D} \tag{17.40}$$

Applying Theorem 17.2 produces the control law

$$u(t) = -K \mathcal{X}(t) = -[K_x \quad K_1 \quad K_2] \begin{bmatrix} x(t) \\ x_1(t) \\ x_2(t) \end{bmatrix} \tag{17.41}$$

where $K = R_{uu}^{-1} (R_{xu}^T + \mathcal{B}^T S)$, S is the solution to the Riccati equation

$$S \left(\mathcal{A} - \mathcal{B} R_{uu}^{-1} R_{xu}^T \right) + \left(\mathcal{A}^T - R_{xu} R_{uu}^{-1} \mathcal{B}^T \right) S + \left(R_{xx} - R_{xu} R_{uu}^{-1} R_{xu}^T \right) - S \mathcal{B} R_{uu}^{-1} \mathcal{B}^T S = 0,$$

and the control weights are defined by Equation 17.40.

Clearly the augmented state vector $\mathcal{X}(t)$ must be fed back to implement the control law (Equation 17.41). Since $x_1(t)$ and $x_2(t)$ are the fictitious states of the weights $W_1(s)$ and $W_2(s)$, it is necessary to deliberately create them in real time to apply the feedback control law (Equation 17.41). That is, using frequency weighted cost functionals to synthesize LQR controllers leads to dynamic compensators. The control law is no longer a set of static gains multiplying the measurement of the state vector $x(t)$. It is a combination of the dynamics of the weighting matrices and the static gains K . A block diagram showing the feedback architecture for the dynamic LQR controller arrived at by minimizing the frequency weighted cost functional of Equation 17.35 is shown in Figure 17.9. Realize that having to implement a dynamic compensator is the price we pay for using frequency weights to incorporate known frequency domain information into the LQR controller synthesis. Though since the order of the compensator is only equal to the combined order of the design weights, this fact should not be troublesome.

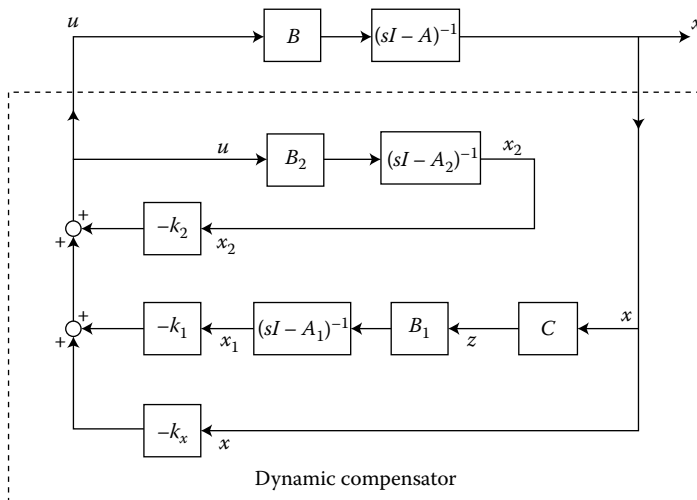

FIGURE 17.9 Block diagram for the LQR controller synthesized using the frequency weighted cost from Equation 17.35.

17.4.4.1 Selecting the Frequency Weights

Although we do not present the results here, it is possible to use any combination of frequency weights and constant weights when synthesizing LQR controllers with frequency weighted costs. For example, one could use a constant state penalty, $W_1(s) = I$, with a frequency weighted control. In any case, to satisfy the underlying LQR assumptions one must use stable design weights and ensure that $D_2^T D_2 > 0$ (so that R_{uu}^{-1} exists).

When synthesizing LQR controllers with frequency weighted cost functionals, the iteration over the values of the design weights involves selecting the dynamics of multivariable systems. Although it is not necessary, choosing the weighting matrices to be scalar functions multiplying the identity matrix,

$$W_1(s) = w_1(s)I \quad \text{and} \quad W_2(s) = w_2(s)I$$

simplifies the process of selecting useful weights. Then the process of selecting the weights reduces to selecting the transfer functions $w_1(s)$ and $w_2(s)$ so that their magnitudes have the desired effect on the cost.

To arrive at a useful set of weights, one must use one's knowledge of the physics of the system and the desired control system performance. Keeping this in mind, simply select the magnitude of $w_2(s)$ to be large relative to $|w_2(0)|$ over the frequency range where you want the control energy to be small and choose $w_1(s)$ to have a large magnitude relative to $|w_1(0)|$ over the frequency regions where you want the performance variables to be small. It is important to note that here large is relative to the values of the DC gains of the weights, $|w_1(0)|$ and $|w_2(0)|$. The DC gains specify the nominal penalties on the state and control cost in a manner similar to the constant weights of a standard LQR problem. As such, when choosing the frequency weights, it is beneficial to break the process up into two steps. The first step is to choose an appropriate DC gain to influence the overall characteristics of the controller, and the second step is to choose the dynamics so that the magnitudes of the weights reflect the relative importance of the variables over the various frequency ranges.

When choosing the frequency weights it is vital to keep in mind that the controls will have to be large over the frequency ranges where the performance variables are to be small. Likewise, if the control energy is specified to be small over a frequency range, it will not be possible to make the performance variables small there. Even though we could tell the cost to make both the performance variables and the control signals small in the same frequency range through the choice of the frequency weights, doing so will most likely result in a meaningless controller since we are asking the mathematical optimization problem to defy the underlying physics.

17.5 Mini-Max and \mathcal{H}_∞ Full-State Feedback Control

Consider the problem of rejecting the effect of the disturbances, $d(t)$, on the performance variables of interest, $z(t)$, for the system

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) + Ld(t) \\ z(t) &= Cx(t) \end{aligned} \tag{17.42}$$

LQR control is not well suited to handle this problem because the optimal control that minimizes the quadratic cost (Equation 17.3) subject to the dynamic constraints (Equation 17.42) wants to know the future values of the disturbances, which is not realistic. The stochastic version of the LQR problem is also inappropriate unless $d(t)$ is white noise, which is rarely the case. To deal optimally with the disturbances using a full-state feedback controller, it is necessary to adopt a different philosophy than that of the LQR. Rather than treating the disturbances as known or white noise signals, they are assumed to behave in a "worst case" fashion. Treating the disturbances in this way leads to the so called \mathcal{H}_∞ full-state feedback controller. \mathcal{H}_∞ controllers have become as popular as LQR controllers in recent years as a result of their

own attractive properties [10]. We introduce \mathcal{H}_∞ controllers here using the quadratic cost functional optimization point of view.

The “worst case” philosophy for dealing with the disturbances arises by including them in the quadratic cost functional with their own weight, γ , much in the same way that the controls are included in the LQR cost functional. That is we seek to optimize the quadratic cost

$$J(u, d) = \frac{1}{2} \int_0^\infty \left[z^T(t)z(t) + \rho u^T(t)u(t) - \gamma^2 d^T(t)d(t) \right] dt \quad \gamma, \rho > 0 \quad (17.43)$$

subject to the dynamic constraints of Equation 17.42. In this optimization problem both the controls and disturbances are the unknown quantities that the cost is optimized over. Note that since the disturbances enter the cost functional as a negative quadratic, they will seek to maximize $J(u, d)$. At the same time the controls seek to minimize $J(u, d)$ since they enter the cost functional as a positive quadratic. Hence, by using the cost (Equation 17.43), we are playing a mini-max differential game in which nature tries to maximize the cost through the choice of the disturbances, and we as control system designers seek to minimize the cost through the choice of the control $u(t)$. This mini-max optimization problem can be compactly stated as

$$\min_u \max_d J(u, d). \quad (17.44)$$

Since nature is allowed to pick the disturbances $d(t)$ which maximize the cost, this optimization problem deals with the disturbances by producing a control law that is capable of rejecting specific worst case disturbances.

The solution to the mini-max optimization problem (Equation 17.44) is not guaranteed to exist for all values of γ . When the solution does exist, it produces a full-state feedback control law similar in structure to the LQR controller. The solution to the mini-max differential game is summarized in the following theorem.

Theorem 17.4: Mini-Max Differential Game

Given the system dynamics

$$\dot{x}(t) = Ax(t) + Bu(t) + Ld(t) \quad (17.45)$$

with $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, and $d(t) \in \mathbb{R}^q$ along with the performance variables we wish to keep small $z(t) = Cx(t)$ with $z(t) \in \mathbb{R}^p$, we define the mini-max quadratic cost functional

$$J(u, d) = \frac{1}{2} \int_0^\infty \left[z^T(t)z(t) + \rho u^T(t)u(t) - \gamma^2 d^T(t)d(t) \right] dt \quad \gamma, \rho > 0$$

in which ρ and γ are user-specified design variables that weight the relative influence of the controls and disturbances. Under the following assumptions

1. The entire state vector $x(t)$ is available for feedback
2. $d(t)$ is a deterministic, bounded energy signal with $\int_0^\infty d^T(t)d(t) dt < \infty$
3. Both $[A \ B]$ and $[A \ L]$ are stabilizable, and $[A \ C]$ is detectable

If the optimum value of the cost $J(u, d)$ constrained by the system dynamics (Equation 17.45) exists, it is a unique saddle point of $J(u, d)$ where

1. The optimal mini-max control law is

$$u(t) = -Kx(t) \quad \text{with } K = \frac{1}{\rho} B^T S \quad (17.46)$$

2. The optimal, worst case, disturbance is

$$d(t) = \frac{1}{\gamma^2} L^T S x(t)$$

3. S is the unique, symmetric, positive semidefinite solution of the matrix Riccati equation

$$SA + A^T S + C^T C - S \left(\frac{1}{\rho} BB^T - \frac{1}{\gamma^2} LL^T \right) S = 0 \tag{17.47}$$

4. The closed-loop dynamics for Equation 17.45 using Equation 17.46

$$\dot{x}(t) = (A - BK)x(t) + Ld(t) \tag{17.48}$$

are guaranteed to be asymptotically stable.

If the solution to this optimization problem exists, it produces a stabilizing full-state feedback controller with the same structure as the LQR controller but with a different scheme for evaluating the feedback gains. Since the L matrix of Equation 17.45 appears in the Riccati equation 17.47, the mini-max control law directly incorporates the information of how the disturbances impact the system dynamics. The facts that the min-max controller guarantees a stable closed-loop and takes into consideration the nature of the disturbances make it an attractive alternative to LQR for synthesizing controllers.

17.5.1 Synthesizing Mini-Max Controllers

Mini-max controllers are not guaranteed to exist for arbitrary values of the design weight γ in the quadratic cost functional $J(u, d)$. Since γ influences the size of the $-\frac{1}{\gamma^2} LL^T$ term in the Riccati equation 17.47, there will exist values of $\gamma > 0$ for which there is either no solution to the Riccati equation or for which S will not be positive semidefinite. It turns out that there is a minimum value of γ , γ_{\min} , for which the mini-max optimization problem has a solution. Hence, useful values of γ will lie in the interval $\gamma_{\min} \leq \gamma < \infty$. Note that as $\gamma \rightarrow \infty$, the Riccati equation 17.47 becomes identical to the LQR one from Equation 17.5, and we recover the LQR controller. Likewise when $\gamma = \gamma_{\min}$, we have another special case which is known as the full-state feedback \mathcal{H}_∞ controller*. For any other value of γ in $\gamma_{\min} \leq \gamma < \infty$ we still have an admissible stabilizing mini-max controller.

As with LQR, synthesizing mini-max controllers requires solving an algebraic Riccati equation. However, the presence of the $-\frac{1}{\gamma^2} LL^T$ term in the mini-max Riccati equation 17.47 makes the process of computing an $S = S^T \geq 0$ that satisfies Equation 17.47 more complicated than finding an $S = S^T \geq 0$ that satisfies the LQR Riccati equation 17.5. The reasons for this are directly related to the issue of whether or not a solution to the mini-max optimization problem exists.

To understand how one computes mini-max controllers, it is necessary to understand how current algebraic Riccati equation solvers work. While there is a rich theory for the topic, we summarize the key results in the following theorem.

Theorem 17.5: The Algebraic Riccati Equation

The Riccati equation

$$A^T S + SA + SVS - Q = 0 \tag{17.49}$$

* See Chapter 18 for details.

is solved by carrying out a spectral factorization* of its associate Hamiltonian matrix

$$H = \begin{bmatrix} A & V \\ Q & -A^T \end{bmatrix}$$

If $V = -BB^T$, $Q = -C^T C$, $[A \ B]$ is stabilizable, and $[A \ C]$ is detectable then the Riccati equation solvers produce the unique, symmetric, positive semidefinite solution, $S = S^T \geq 0$, to the Riccati equation 17.49. Otherwise, as long as H has no $j\omega$ -axis eigenvalues, the spectral factorization can be performed and a solution, S , which satisfies Equation 17.49 is produced.

The Hamiltonian matrix for the mini-max Riccati equation, H_γ , is

$$H_\gamma = \begin{bmatrix} A & \frac{1}{\gamma^2} LL^T - \frac{1}{\rho} BB^T \\ -C^T C & -A^T \end{bmatrix} \quad (17.50)$$

The sign indefinite nature of the $1/\gamma^2 LL^T - 1/\rho BB^T$ term in H_γ makes it quite difficult to numerically test whether or not a solution to the mini-max optimization problem exists. Thus, a constructive algorithm based on the existing algebraic Riccati equation solvers is used to synthesize mini-max controllers.

Theorem 17.6: Algorithm for Computing Mini-Max Controllers

Pick a value of γ and check to see if H_γ from Equation 17.50 has any $j\omega$ -axis eigenvalues. If it does, increase γ and start over. If it does not, use an algebraic Riccati equation solver to produce a solution S to Equation 17.47. Test if $S \geq 0$. If it is not, increase gamma and start over. If $S \geq 0$, check to see if the closed-loop dynamics from Equation 17.48 are stable. If they are not, increase gamma and start over. If they are, you have constructed a mini-max controller, since you've found a $S = S^T \geq 0$ that satisfies the Riccati equation 17.47.

Theoretically, the final step of the algorithm, which requires checking the closed-loop stability is not necessary. However, we highly recommend it since the numerical stability of the solution to the Riccati equations for values of γ near γ_{\min} can be questionable.

From the algorithm for computing mini-max controllers, it can be seen that evaluating \mathcal{H}_∞ controllers for a fixed value of ρ will require a trial-and-error search over γ . To compute γ_{\min} it is best to use a bisection search over γ in the algorithm to find the smallest value of γ for which $S = S^T \geq 0$ and the closed-loop system (Equation 17.48) is stable. Current control system design packages such as MATLAB and MATRIXx employ such algorithms for computing the \mathcal{H}_∞ controller that in turn determines γ_{\min} .

While the mini-max and \mathcal{H}_∞ controllers are quite distinct from LQR controllers all the advice given for designing LQR controllers applies to mini-max controllers as well. Namely, it is necessary to iterate over the values of the design weights and independently check the robustness and performance characteristics for each design when synthesizing mini-max and \mathcal{H}_∞ controllers. It can be shown through manipulating the Riccati equation 17.47 that the robustness properties of LQR controllers from Section 17.3 apply to \mathcal{H}_∞ and mini-max controllers as well. Furthermore, modifications of the powerful sensitivity and frequency weighted LQR design tools from Section 17.4 do exist and can be used to incorporate stability robustness and known design specifications into the controller synthesis of mini-max and \mathcal{H}_∞ controllers.

* Spectral factorizations are essentially eigenvalue decompositions.

18.1 Introduction

The fundamentals of output feedback \mathcal{H}_2 (linear quadratic Gaussian or LQG) and \mathcal{H}_∞ controllers, which are the primary synthesis tools available for linear time-invariant systems, are presented in an analogous and tutorial fashion without rigorous mathematics. Since \mathcal{H}_2 and \mathcal{H}_∞ syntheses are carried out in the modern control design paradigm, a review of the paradigm is presented, along with the definitions of the \mathcal{H}_2 and \mathcal{H}_∞ norms and the methods used to compute them. The state-space formulae for the optimal controllers, under less restrictive assumptions than are usually found in the literature, are provided in an analogous fashion to emphasize the similarities between them. Rather than emphasizing the derivation of the controllers, we elaborate on the physical interpretation of the results and how one uses frequency weights to design \mathcal{H}_∞ and \mathcal{H}_2 controllers. Finally, a simple disturbance rejection design for the longitudinal motion of an aircraft is provided to illustrate the similarities and differences between \mathcal{H}_∞ and \mathcal{H}_2 controller synthesis.

18.2 The Modern Paradigm

\mathcal{H}_2 and \mathcal{H}_∞ syntheses are carried out in the modern control paradigm. In this paradigm both performance and robustness specifications can be incorporated in a common framework along with the controller synthesis. In the modern paradigm, all of the information about a system is cast into the generalized block diagram shown in Figure 18.1 [1–3]. The generalized plant, P , which is assumed to be linear and time-invariant throughout this article contains all the information a designer would like to incorporate into the synthesis of the controller, K . System dynamics, models of the uncertainty in the system's dynamics, frequency weights to influence the controller synthesis, actuator dynamics, sensor dynamics, and implementation hardware dynamics from amplifiers, and analog-to-digital and digital-to-analog converters are all included in P . The inputs and outputs of P are, in general, vector valued signals. The sensor measurements that are used by the feedback controller are denoted y , and the inputs generated

FIGURE 18.1 Generalized block diagram of the modern paradigm.

by the controller are denoted u . The components of w are all the exogenous inputs to the system. Typically these consist of disturbances, sensor noise, reference commands, and fictitious signals that drive frequency weights and models of the uncertainty in the dynamics of the system. The components of z are all the variables we wish to control. These include the performance variables of interest, tracking errors between reference signals and plant outputs, and the actuator signals which cannot be arbitrarily large and fast.

The general control problem in this framework is to synthesize a controller that will keep the size of the performance variables, z , small in the presence of the exogenous signals, w . For a classical disturbance rejection problem, z would contain the performance variables we wish to keep small in the presence of the disturbances contained in w that would tend to drive z away from zero. Hence, the disturbance rejection performance would depend on the “size” of the closed-loop transfer function from w to z , which we shall denote as $T_{zw}(s)$. This is also true for a command following control problem in which z would contain the tracking error that we would like to keep small in the presence of the commands in w that drive the tracking error away from zero.

Clearly then, the “size” of $T_{zw}(s)$ influences the effect that the exogenous signals in w have on z . Thus, in this framework, we seek controllers that minimize the “size” of the closed-loop transfer function $T_{zw}(s)$. Given that $T_{zw}(s)$ is a transfer function matrix, it is necessary to use appropriate norms to quantify its size. The two most common and physically meaningful norms that are used to classify the “size” of $T_{zw}(s)$ are the \mathcal{H}_2 and \mathcal{H}_∞ norms. As such, we seek controllers that minimize either the \mathcal{H}_2 or \mathcal{H}_∞ norm of $T_{zw}(s)$ in the modern control paradigm.

18.2.1 System Norms

Here we define and discuss the \mathcal{H}_2 and \mathcal{H}_∞ norms of the linear, time-invariant, stable system with transfer function matrix

$$G(s) = C(sI - A)^{-1}B$$

This notation is meant to be general, and the reader should not think of $G(s)$ as only the actuator to sensor transfer function of a system. Realize that $G(s)$ is a system and thus requires an appropriate norm to classify its size. By a norm, we mean a positive, scalar number that is a measure of the size of $G(s)$ over all points in the complex s -plane. This is quite different from, for example, the maximum singular value of a matrix, $\sigma_{\max}[A]$, which is a norm that classifies the size of the matrix A .

The \mathcal{H}_2 Norm

Definition 18.1: \mathcal{H}_2 Norm

The \mathcal{H}_2 norm of $G(s)$, denoted $\|G\|_2$, is defined as

$$\|G\|_2 = \left(\frac{1}{2\pi} \int_{-\infty}^{\infty} \text{trace} [G(j\omega)G^*(j\omega)] d\omega \right)^{\frac{1}{2}} = \left(\frac{1}{2\pi} \int_{-\infty}^{\infty} \sum_{i=1}^r \sigma_i^2 [G(j\omega)] d\omega \right)^{\frac{1}{2}}$$

where σ_i denotes the i th singular value, $G^*(j\omega)$ is the complex conjugate transpose of $G(j\omega)$, and r is the rank of $G(j\omega)$.

The \mathcal{H}_2 norm has an attractive, physically meaningful interpretation. If we consider $G(s)$ to be the transfer function matrix of a system driven by independent, zero mean, unit intensity white noise, u , then the sum of the variances of the outputs y is exactly the square of the \mathcal{H}_2 norm of $G(s)$. That is

$$\mathbb{E} [y^T(t)y(t)] = \|G(s)\|_2^2 \quad (18.1)$$

The \mathcal{H}_2 norm of $G(s)$ thus gives a precise measure of the “power” or signal strength of the output of a system driven with unit intensity white noise. Note that in the scalar case $\sqrt{\mathbb{E}[y^T(t)y(t)]}$ is the RMS or root mean squared value for $y(t)$ so the \mathcal{H}_2 norm specifies the RMS value of $y(t)$. A well-known fact for stochastic systems is that the mean squared value of the outputs can be computed by solving the appropriate Lyapunov equation [4]. As such, a state space procedure for computing the \mathcal{H}_2 norm of $G(s)$ is as follows [2].

Computing the \mathcal{H}_2 Norm

If L_c denotes the controllability Gramian of (A, B) and L_o the observability Gramian of (A, C) , then

$$AL_c + L_cA^T + BB^T = 0 \quad A^T L_o + L_oA + C^T C = 0$$

and

$$\|G\|_2 = \left[\text{trace}(CL_cC^T) \right]^{\frac{1}{2}} = \left[\text{trace}(B^T L_o B) \right]^{\frac{1}{2}}$$

Note that this procedure for computing the \mathcal{H}_2 norm involves the solution of linear Lyapunov equations and can be done without iteration.

The \mathcal{H}_∞ Norm

Definition 18.2: \mathcal{H}_∞ Norm

The \mathcal{H}_∞ norm of $G(s)$, denoted $\|G\|_\infty$, is defined as

$$\|G\|_\infty = \sup_{\omega} \sigma_{\max}[G(j\omega)]$$

In this definition “sup” denotes the supremum or least upper bound of the function $\sigma_{\max}[G(j\omega)]$, and thus the \mathcal{H}_∞ norm of $G(s)$ is nothing more than the maximum value of $\sigma_{\max}[G(j\omega)]$ over all frequencies ω . The supremum must be used in the definition since, strictly speaking, the maximum of $\sigma_{\max}[G(j\omega)]$ may not exist even though $\sigma_{\max}[G(j\omega)]$ is bounded from above.

\mathcal{H}_∞ norms also have a physically meaningful interpretation when considering the system $y(s) = G(s)u(s)$. Recall that when the system is driven with a unit magnitude sinusoidal input at a specific frequency, $\sigma_{\max}[G(j\omega)]$ is the largest possible output size for the corresponding sinusoidal output. Thus, the \mathcal{H}_∞ norm is the largest possible amplification over all frequencies of a unit sinusoidal input. That is, it classifies the greatest increase in energy that can occur between the input and output of a given system. A state space procedure for calculating the \mathcal{H}_∞ norm is as follows.

Computing the \mathcal{H}_∞ Norm

Let $\|G\|_\infty = \gamma_{\min}$. For the transfer function $G(s) = C(sI - A)^{-1}B$ with A stable and $\gamma > 0$, $\|G\|_\infty < \gamma$ if and only if the Hamiltonian matrix

$$H = \begin{bmatrix} A & \frac{1}{\gamma^2}BB^T \\ -C^TC & -A^T \end{bmatrix}$$

has no eigenvalues on the $j\omega$ -axis. This fact lets us compute a bound, γ , on $\|G\|_\infty$ such that $\|G\|_\infty < \gamma$. So to find γ_{\min} , select a $\gamma > 0$ and test if H has eigenvalues on the $j\omega$ -axis. If it does, increase γ . If it does not, decrease γ and recompute the eigenvalues of H . Continue until γ_{\min} is calculated to within the desired tolerance.

The iterative computation of the \mathcal{H}_∞ norm, which can be carried out efficiently using a bisection search over γ , is to be expected given that by definition we must search for the largest value of $\sigma_{\max}[G(j\omega)]$ over all frequencies.

Note, the \mathcal{H}_2 norm is not an induced norm, whereas the \mathcal{H}_∞ norm is. Thus, the \mathcal{H}_2 norm does not obey the submultiplicative property of induced norms. That is, the \mathcal{H}_∞ norm satisfies

$$\|G_1G_2\|_\infty \leq \|G_1\|_\infty\|G_2\|_\infty$$

but the \mathcal{H}_2 norm does not have the analogous property. This fact makes synthesizing controllers that minimize $\|T_{zw}(s)\|_\infty$ attractive when one is interested in directly shaping loops to satisfy norm bounded robustness tests*. On the other hand, given the aforementioned properties of the \mathcal{H}_2 norm, synthesizing controllers that minimize $\|T_{zw}(s)\|_2$ is attractive when the disturbances, w , are stochastic in nature. In fact, \mathcal{H}_2 controllers are nothing more than linear quadratic Gaussian (LQG) controllers so the vast amount of insight into the well-understood LQG problem can be readily applied to \mathcal{H}_2 synthesis.

Example 18.1:

In this example the \mathcal{H}_2 and \mathcal{H}_∞ norms are calculated for the simple four-spring, four-mass system shown in Figure 18.2. The equations of motion for this system can be found in Example 17.2 in Chapter 17. The system has force inputs on the second and fourth masses along with two sensors that provide a measure of the displacement of these masses. The singular values of the transfer function from the inputs to outputs, which we denote by $G(s)$, are shown in Figure 18.3. The \mathcal{H}_∞ norm of the system is equal to the peak of $\sigma_1 = 260.4$, and the \mathcal{H}_2 norm of the system is equal to the square root of the sum of the areas under the square of each of the singular values, 14.5. Note that when considering the \mathcal{H}_2 norm, observing the log log plot of the transfer function can be very deceiving, since the integral is of σ_j , not $\log(\sigma_j)$, over ω , not $\log \omega$.

As pointed out in the example, the differences between the \mathcal{H}_∞ and \mathcal{H}_2 norms for a system $G(s)$ are best viewed in the frequency domain from a plot of the singular values of $G(j\omega)$. Specifically, the \mathcal{H}_∞ norm is the peak value of $\sigma_{\max}[G(j\omega)]$ while the \mathcal{H}_2 norm is related to the area underneath the singular values of $G(j\omega)$. For a more in-depth treatment of these norms the reader is referred to [1,2,5,6].

* See Chapter 20 for a detailed exposition of this concept.

FIGURE 18.2 Mass, spring, dashpot system from Example 18.1. For the example $k_i = m_i = 1 \forall i$, and $c_i = 0.05 \forall i$.

18.3 Output Feedback \mathcal{H}_∞ and \mathcal{H}_2 Controllers

Given that all the information a designer would like to include in the controller synthesis is incorporated into the system P , the synthesis of \mathcal{H}_2 and \mathcal{H}_∞ controllers is quite straightforward. In this respect all of the design effort is focused on defining P . Below, we discuss how to define P using frequency weights to meet typical control system specifications. Here we simply present the formulas for the controllers.

All the formulas will be based on the following state-space realization of P ,

$$P := \left[\begin{array}{c|cc} A & B_1 & B_2 \\ \hline C_1 & D_{11} & D_{12} \\ C_2 & D_{21} & D_{22} \end{array} \right]$$

FIGURE 18.3 Singular values of the transfer function between the inputs and outputs of the mass, spring system shown in Figure 18.2.

This notation is a shorthand representation for the system of equations

$$\dot{x}(t) = Ax(t) + B_1w(t) + B_2u(t) \quad (18.2)$$

$$z(t) = C_1x(t) + D_{11}w(t) + D_{12}u(t) \quad (18.3)$$

$$y(t) = C_2x(t) + D_{21}w(t) + D_{22}u(t) \quad (18.4)$$

Additionally, the following assumptions concerning the allowable values for the elements of P are made.

Assumptions on P

$$1. \quad D_{11} = 0 \quad (A.1)$$

$$2. \quad [A \quad B_2] \text{ is stabilizable} \quad (A.2)$$

$$3. \quad [A \quad C_2] \text{ is detectable} \quad (A.3)$$

$$4. \quad V = \begin{bmatrix} B_1 \\ D_{21} \end{bmatrix} \begin{bmatrix} B_1^T & D_{21}^T \end{bmatrix} := \begin{bmatrix} V_{xx} & V_{xy} \\ V_{xy}^T & V_{yy} \end{bmatrix} \geq 0 \quad \text{with } V_{yy} > 0 \quad (A.4)$$

$$5. \quad R = \begin{bmatrix} C_1^T \\ D_{12}^T \end{bmatrix} \begin{bmatrix} C_1 & D_{12} \end{bmatrix} := \begin{bmatrix} R_{xx} & R_{xu} \\ R_{xu}^T & R_{uu} \end{bmatrix} \geq 0 \quad \text{with } R_{uu} > 0 \quad (A.5)$$

Assumption A.1 ensures that none of the disturbances feed through to the performance variables which is necessary for \mathcal{H}_2 synthesis but may be removed for \mathcal{H}_∞ synthesis (see [7] for details.) Assumptions A.2 and A.3 are needed to guarantee the existence of a stabilizing controller while the remaining assumptions are needed to guarantee the existence of positive semidefinite solutions to the Riccati equations associated with the optimal controllers.

Theorem 18.1: \mathcal{H}_2 Output Feedback

Assuming that $w(t)$ is a unit intensity white noise signal, $E[w(t)w^T(\tau)] = I\delta(t - \tau)$, the unique, stabilizing, optimal controller which minimizes the \mathcal{H}_2 norm of $T_{zw}(s)$ is

$$K_2 := \left[\frac{A + B_2F_2 + L_2C_2 + L_2D_{22}F_2}{F_2} \mid \frac{-L_2}{0} \right] \quad (18.5)$$

where

$$\begin{aligned} F_2 &= -R_{uu}^{-1} \left(R_{xu}^T + B_2^T X_2 \right) \\ L_2 &= - \left(Y_2 C_2^T + V_{xy} \right) V_{yy}^{-1} \end{aligned} \quad (18.6)$$

and X_2 and Y_2 are the unique, positive semidefinite solutions to the following Riccati equations

$$0 = X_2 A_r + A_r^T X_2 + R_{xx} - R_{xu} R_{uu}^{-1} R_{xu}^T - X_2 B_2 R_{uu}^{-1} B_2^T X_2 \quad (18.7)$$

$$0 = A_e Y_2 + Y_2 A_e^T + V_{xx} - V_{xy} V_{yy}^{-1} V_{xy}^T - Y_2 C_2^T V_{yy}^{-1} C_2 Y_2 \quad (18.8)$$

where

$$A_r = \left(A - B_2 R_{uu}^{-1} R_{xu}^T \right) \quad \text{and} \quad A_e = \left(A - V_{xy} V_{yy}^{-1} C_2 \right)$$

Theorem 18.2: \mathcal{H}_∞ Output Feedback [8]

Assuming that $w(t)$ is a bounded \mathcal{L}_2 signal, $\int_{-\infty}^{\infty} w^T(t)w(t) dt < \infty$, a stabilizing controller which satisfies $\|T_{zw}(j\omega)\|_\infty < \gamma$ is

$$K_\infty := \left[\begin{array}{c|c} A & -Z_\infty L_\infty \\ \hline F_\infty & 0 \end{array} \right] \quad (18.9)$$

where

$$A_\infty = A + (B_1 + L_\infty D_{21}) W_\infty + B_2 F_\infty + Z_\infty L_\infty C_2 + Z_\infty L_\infty D_{22} F_\infty$$

where

$$F_\infty = -R_{uu}^{-1} (R_{xu}^T + B_2^T X_\infty) \quad W_\infty = \frac{1}{\gamma^2} B_1^T X_\infty$$

$$L_\infty = - (Y_\infty C_2^T + V_{xy}) V_{yy}^{-1} \quad Z_\infty = \left(I - \frac{1}{\gamma^2} Y_\infty X_\infty \right)^{-1}$$

and X_∞ and Y_∞ are the solutions to the following Riccati equations

$$0 = X_\infty A_r + A_r^T X_\infty + R_{xx} - R_{xu} R_{uu}^{-1} R_{xu}^T - X_\infty \left(B_2 R_{uu}^{-1} B_2^T - \frac{1}{\gamma^2} B_1 B_1^T \right) X_\infty \quad (18.10)$$

$$0 = A_e Y_\infty + Y_\infty A_e^T + V_{xx} - V_{xy} V_{yy}^{-1} V_{xy}^T - Y_\infty \left(C_2^T V_{yy}^{-1} C_2 - \frac{1}{\gamma^2} C_1^T C_1 \right) Y_\infty \quad (18.11)$$

that satisfy the following conditions

1. $X_\infty \geq 0$
2. The Hamiltonian matrix for Equation 18.10,

$$\left[\begin{array}{cc} A - B_2 R_{uu}^{-1} R_{xu}^T & -B_2 R_{uu}^{-1} B_2^T + \frac{1}{\gamma^2} B_1 B_1^T \\ -R_{xx} + R_{xu} R_{uu}^{-1} R_{xu}^T & -(A - B_2 R_{uu}^{-1} R_{xu}^T)^T \end{array} \right]$$

has no $j\omega$ -axis eigenvalues, or equivalently $A + B_1 W_\infty + B_2 F_\infty$ is stable

3. $Y_\infty \geq 0$
4. The Hamiltonian matrix for Equation 18.11,

$$\left[\begin{array}{cc} \left(A - V_{xy} V_{yy}^{-1} C_2 \right)^T & -C_2^T V_{yy}^{-1} C_2 + \frac{1}{\gamma^2} C_1^T C_1 \\ -V_{xx} + V_{xy} V_{yy}^{-1} V_{xy}^T & -A + V_{xy} V_{yy}^{-1} C_2 \end{array} \right]$$

has no $j\omega$ -axis eigenvalues, or equivalently $A + L_\infty C_2 + \frac{1}{\gamma^2} Y_\infty C_1^T C_1$ is stable

5. $\rho(Y_\infty X_\infty) < \gamma^2$, where $\rho(\cdot) = \max_i |\lambda_i(\cdot)|$ is the spectral radius

The (sub)optimal central \mathcal{H}_∞ controller which minimizes $\|T_{zw}\|_\infty$ to within the desired tolerance is K_∞ with γ equal to the smallest value of $\gamma > 0$ that satisfies conditions 1 to 5.

Unlike the \mathcal{H}_2 controller, the \mathcal{H}_∞ controller presented here is not truly optimal. Since there is no closed-form, state-space solution to the problem of minimizing the infinity norm of a multiple-input,

multiple-output (MIMO) transfer function matrix $T_{zw}(s)$, the connections between the mini-max optimization problem

$$\inf_u \sup_w \int_0^\infty \left[z^T(t)z(t) - \gamma^2 w^T(t)w(t) \right] dt \tag{18.12}$$

and \mathcal{H}_∞ optimization are used to arrive at the constructive approach for synthesizing suboptimal \mathcal{H}_∞ controllers given in Theorem 18.2. In fact, satisfying the conditions 1 to 5 of Theorem 18.2 is analogous to finding a saddle point of the optimization problem (Equation 18.12), and the search for γ_{\min} is analogous to finding the global minimum over all the possible saddle points. As such, any value of $\gamma > \gamma_{\min}$ will also satisfy conditions 1 to 5 of Theorem 18.2, and thus produce a stabilizing controller. Such controllers are neither \mathcal{H}_2 nor \mathcal{H}_∞ optimal. Since in the limit as $\gamma \rightarrow \infty$ the equations from Theorem 18.2 reduce to the equations for the \mathcal{H}_2 optimal controller, controllers with values of γ between γ_{\min} and infinity provide a trade off between \mathcal{H}_∞ and \mathcal{H}_2 performance. Along these lines, it is also worth noting that there is a rich theory for mixed $\mathcal{H}_2/\mathcal{H}_\infty$ controllers that minimize the \mathcal{H}_2 norm of $T_{zw}(s)$ subject to additional \mathcal{H}_∞ constraints. See [9–11] for details.

The value of $w(t)$ that maximizes the cost in Equation 18.12 is known as the worst case disturbance, as it seeks to maximize the detrimental effect the disturbances have on the system. In this regard, \mathcal{H}_∞ controllers provide optimal disturbance rejection to worst case disturbance, whereas the \mathcal{H}_2 controllers provide optimal disturbance rejection to stochastic disturbances.

Both \mathcal{H}_2 and \mathcal{H}_∞ controllers are observer-based compensators [2], which can be seen from their block diagrams, shown in Figures 18.4 and 18.5. The regulator gains F_2 and F_∞ arise from synthesizing the full-state feedback controller, which minimizes the appropriate size of $z^T(t)z(t)$ constrained by the system dynamics Equation 18.2. Then the control law is formed by applying these regulator gains to an estimate of the states $x(t)$. The states, $x(t)$, are estimated using the noisy measurements of $y(t)$ from Equation 18.4, and L_2 and $Z_\infty L_\infty$ are the corresponding filter gains of the estimators.

In particular, F_2 is the full-state feedback LQR gain that minimizes the quadratic cost

$$J_{LQ} = E \left\{ \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^\tau \left[z^T(t)z(t) \right] dt \right\}$$

constrained by the dynamics of Equation 18.2, and L_2 is the Kalman filter gain from estimating the states x based on the measurements $y(t)$. Under the assumption that $z(t)$ is an ergodic process*

$$J_{LQ} = \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^\tau z^T(t)z(t)dt = E \left[z^T(t)z(t) \right] = \|T_{zw}\|_2^2 \tag{18.13}$$

and this is exactly why \mathcal{H}_2 synthesis is nothing more than LQG control.

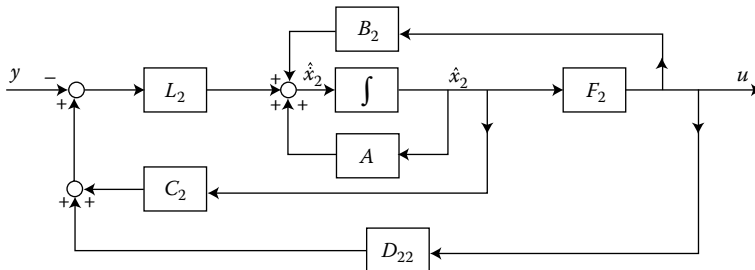

FIGURE 18.4 Block diagram of K_2 from Equation 18.9. Note, the Kalman Filter estimate of the states $x(t)$ from Equation 18.2, $\hat{x}_2(t)$, are the states of K_2 .

* Assuming $z(t)$ is ergodic implies that its mean can be computed from the time average of a measurement of $z(t)$ as $t \rightarrow \infty$ [4].

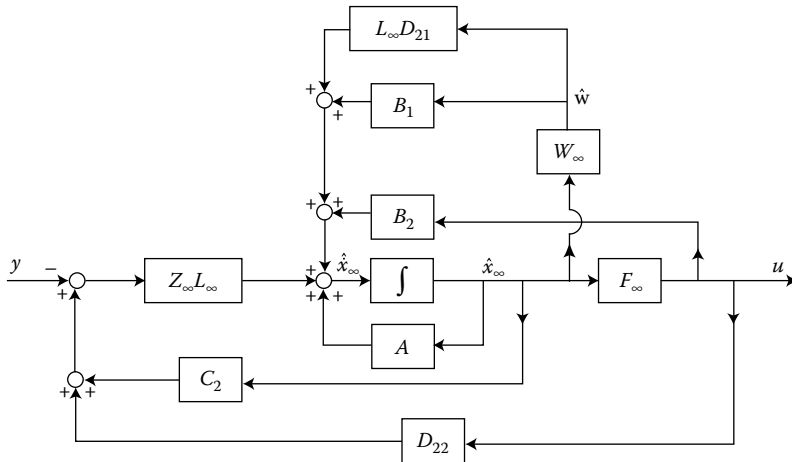

FIGURE 18.5 Block diagram of K_∞ from Equation 18.9. Note, the \mathcal{H}_∞ optimal estimate of the states $x(t)$ from Equation 18.2, $\hat{x}_\infty(t)$, are the states of K_∞ , and $\hat{w}(t)$ is an estimate of the worst case disturbance.

Analogously, F_∞ is the full-state feedback \mathcal{H}_∞ control gain that results from optimizing the mini-max cost of Equation 18.12, and W_∞ is the full-state feedback gain that produces the worst case disturbance which maximizes the cost of Equation 18.12*. Unlike the Kalman filter in the \mathcal{H}_2 controller, the \mathcal{H}_∞ optimal estimator must estimate the states of P in the presence of the worst case disturbance which is evident from the block diagram of K_∞ shown in Figure 18.5 [12]. This is why the filter gain of the \mathcal{H}_∞ optimal estimator, $Z_\infty L_\infty$, is coupled to the regulator portion of the problem through X_∞ from Equation 18.10.

Since the \mathcal{H}_2 controller is an LQG controller, the closed-loop poles of $T_{zw}(s)$ separate into the closed-loop poles of the regulator, $\text{eig}(A - B_2 F_2)$, and estimator, $\text{eig}(A - L_2 C_2)$. A consequence of this separation property is that the \mathcal{H}_2 Riccati equations (Equations 18.7 and 18.8) can be solved directly without iteration. Since the worst case disturbance must be taken into consideration when synthesizing the \mathcal{H}_∞ optimal estimator, the regulator and estimator problems in the \mathcal{H}_∞ synthesis are coupled. Thus, the \mathcal{H}_∞ controller does not have a separation structure that is analogous to that of the \mathcal{H}_2 controller. In addition, the \mathcal{H}_∞ Riccati equations (Equations 18.10 and 18.11) are further coupled through the γ parameter, and we must iterate over the value of γ to find solutions of the \mathcal{H}_∞ Riccati equations that satisfy conditions 1 to 5 of Theorem 18.2.

Note that in the literature the following set of additional, simplifying assumptions on the values of the elements of P are often made to arrive at less complicated sets of equations for the optimal \mathcal{H}_∞ and \mathcal{H}_2 controllers [6,13,14].

Additional Assumptions on P

1. $D_{22} = 0$ (No control feed-through term)
2. $C_1^T D_{12} = 0$ (No cross penalty on control and state)
3. $B_1 D_{21}^T = 0$ (Uncorrelated process and sensor noise)
4. $D_{12}^T D_{12} = I$ (Unity penalty on every control)
5. $D_{21}^T D_{21} = I$ (Unit intensity sensor noise on every measurement)

* See the section on \mathcal{H}_∞ Full State Feedback in Chapter 17 for details.

18.4 Designing \mathcal{H}_2 and \mathcal{H}_∞ Controllers

The results presented in the previous section are powerful because they provide the control system designer with a systematic means of designing controllers for systems whose entire state cannot be fed back. In order to take full advantage of these powerful tools, it is up to the designer to communicate to the optimization problems the desired control system performance and robustness. In the modern paradigm, this is done through the choice of the system matrix P . Since systems and their associated desired performance are diverse, there is no systematic procedure for defining P . However, by exploiting the rich mathematics of the \mathcal{H}_2 and \mathcal{H}_∞ optimization problems along with their physical interpretations, it is possible to formulate guidelines for selecting appropriate systems P for a wide variety of problems.

Regardless of the synthesis employed, P will contain both the system model and the design weights used to communicate to the optimization the desired control system performance. Any linear interconnection of design weights and model can be selected so long as Assumptions A.1 through A.5 are satisfied. To satisfy the assumption that $R_{uu} > 0$, all of the control signals must appear explicitly in z . This is to be expected, since we cannot allow the synthesis to produce arbitrarily large control signals. Similarly, to ensure $V_{yy} > 0$, every measurement y must be corrupted by some sensor noise so as to avoid singular estimation problems.

Frequency-dependent weighting matrices are often included in P , since they provide greater freedom in telling the synthesis the desired control system performance. The synthesis of \mathcal{H}_2 and \mathcal{H}_∞ controllers with frequency weights is just as straightforward as classical LQG synthesis with constant weights. Once the interconnection of the model with the defined performance variables, disturbances, and weights is specified, it is just a simple matter of state augmentation and block diagram manipulation to realize the state space form of P in Equations 18.2 through 18.4. Then given a state space representation of P , the formulas for the optimal controllers found in Theorems 18.1 and 18.2 can be used. The ability to use any admissible system interconnection with any combination of frequency weights is a direct consequence of the fact that we build an estimator for the entire state of P into the controllers. As such, the dynamics of any frequency weights will be reflected in the compensator whose order will be the same as that of P .

In either the \mathcal{H}_2 or \mathcal{H}_∞ framework, arriving at a satisfactory design will involve iteration over the values of the frequency weights. Thus, it is vital to have an in-depth understanding of the dynamics of the system when choosing the system interconnection and the values for the design variables.

18.4.1 \mathcal{H}_2 Design

Given that the \mathcal{H}_2 optimal controller is an LQG controller, it is useful to adopt a stochastic framework and use the insights afforded by the well-known LQG problem when selecting P for \mathcal{H}_2 synthesis, see [13,15]. In this respect, $w(t)$ must contain both the process and sensor noises, while $z(t)$ must contain linear combinations of both the states and controls. Furthermore, the system P must be comprised of the system model and all the design weights such as the noise intensities and the state and control weighting matrices. For example, Figure 18.6 illustrates a possible system interconnection for the classical LQG problem of minimizing a weighted sum of state and control penalties given a system whose dynamics

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t) + Ld(t) \\ y(t) &= Cx(t) + v(t)\end{aligned}\tag{18.14}$$

are driven by the uncorrelated stochastic disturbances, $d(t)$, and sensor noise, $v(t)$.

In the interconnection of Figure 18.6, W_i are weighting matrices, or design variables, that the designer selects. For the classical LQG problem, all the W_i are constant matrices. Since $w^T(t) = [w_1^T(t) \quad w_2^T(t)]$ must be a unit intensity, white noise process, W_1 and W_2 are the matrix square roots of the intensity

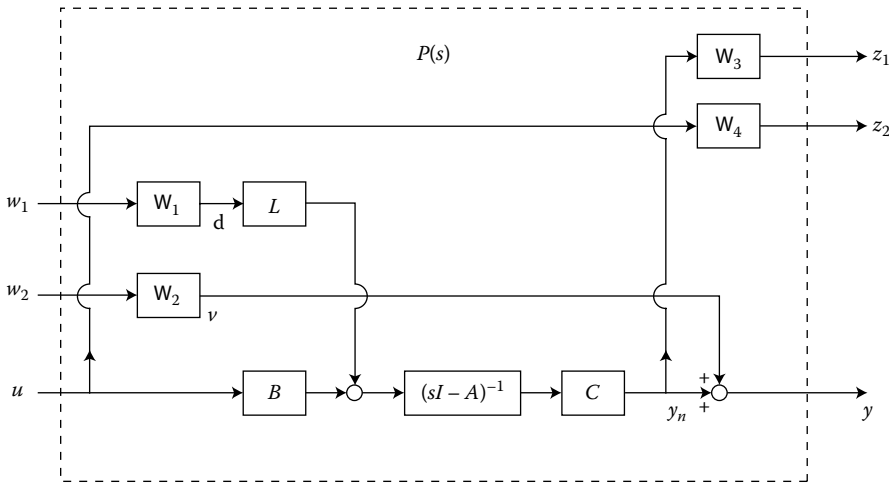

FIGURE 18.6 Block diagram interconnection for a typical $P(s)$.

matrices for the process and sensor noises d and v such that

$$E \left\{ \begin{bmatrix} d(t) \\ v(t) \end{bmatrix} \begin{bmatrix} d^T(\tau) & v^T(\tau) \end{bmatrix} \right\} = \begin{bmatrix} W_1 W_1^T & 0 \\ 0 & W_2 W_2^T \end{bmatrix} \delta(t - \tau)$$

As for the performance variable weights, W_3 is a weight on the outputs that produces a particular state weighting, and W_4 is the matrix square root of the control weighting matrix. These define the cost J_{LQ} from Equation 18.13 to be

$$J_{LQ} = E \left\{ \lim_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^\tau \left[x^T(t) C^T W_3^T W_3 C x(t) + u^T(t) W_4^T W_4 u(t) \right] dt \right\}$$

A drawback of classical LQG synthesis is that the weighting matrices are constant and thus limit our ability to place distinct penalties on the disturbances and performance variables at various frequencies. When synthesizing \mathcal{H}_2 controllers the weights W_i can, in general, be functions of frequency. Since performance and robustness specifications are readily visualized in the frequency domain, using frequency weights provides much more freedom in telling the optimization problem the desired control system behavior.

When choosing the values of the frequency weights, one should use the fact that \mathcal{H}_2 synthesis is equivalent to LQG synthesis. Any frequency weights that appear on the performance variables can be chosen using the insights afforded by the LQR problem with frequency weighted cost functionals as a result of Equation 18.13*. In brief, one uses Parseval's Theorem to arrive at a frequency domain representation of J_{LQ} from Equation 18.13. For the system interconnection shown in Figure 18.6 with scalar frequency weights $W_3(s) = w_3(s)I$ and $W_4(s) = w_4(s)I$

$$J_{LQ} \approx \frac{1}{2\pi} \int_{-\infty}^{\infty} \left[|w_3(j\omega)|^2 y_n^*(j\omega) y_n(j\omega) + |w_4(j\omega)|^2 u^*(j\omega) u(j\omega) \right] d\omega$$

From this expression of the \mathcal{H}_2 cost, it is clear that the weights should be chosen to have a large magnitude over the frequencies where we want the outputs, y_n , and controls, u , to be small.

Frequency weights that appear on the disturbance signals should be viewed as shaping filters that specify the spectral content of the process and sensor noises. The values of the weights can then be chosen

* Section 4.4 in Chapter 17 has a detailed exposition of this.

to capture the true spectral content of the disturbances, as $w(t)$ must be unit intensity white noise to apply Theorem 18.2, or they can be chosen to influence the controller to produce some desired behavior. For example, in the system shown in Figure 18.6 if $W_1(s) = w_1(s)I$, then the control will work hard to reject the disturbances, d , over the frequencies where $|w_1(j\omega)|$ is large. Likewise, if $W_2(s) = w_2(s)I$ and $|w_2(j\omega)|$ is large over a particular frequency range, then the controller will not exert much effort there because we are telling the synthesis that the sensor measurements are very noisy there.

18.4.2 \mathcal{H}_∞ Design

In the \mathcal{H}_∞ framework it is possible to use loop shaping, see [1], to achieve performance and robustness specifications that can be expressed in the frequency domain. This is due to the fact that

$$\|T_{zw}\|_\infty < \gamma \Rightarrow \|(T_{zw})_{ij}\|_\infty < \gamma \quad \forall i, j \quad (18.15)$$

where $(T_{zw})_{ij}$ denotes the closed-loop transfer function matrix between exogenous disturbance w_j and performance variable z_i . To take advantage of Equation 18.15, it is necessary to define P so that the closed-loop transfer function matrices we wish to shape appear directly in $T_{zw}(s)$ and are multiplied by frequency-dependent design weights.

These concepts are best illustrated through an example. Consider the system Equation 18.14, which can be represented in the frequency domain as

$$\begin{aligned} y(s) &= G_1(s)d(s) + G_2(s)u(s) + v(s) \\ G_1(s) &= C(sI - A)^{-1}L \\ G_2(s) &= C(sI - A)^{-1}B \end{aligned}$$

where the disturbances are now considered to be unknown but bounded \mathcal{L}_2 signals. Suppose that we are interested in designing a controller that rejects the effect of the disturbances $d(t)$ on the outputs $y(t)$ and that is robust to an unstructured additive error in the input to output system model. Then it is necessary to independently shape the closed-loop transfer function between d and y , $S(s)G_1(s)$, and the closed-loop transfer function $K(s)S(s)$. In particular, we require $S(s)G_1(s)$ to have a desirable shape, and we need to satisfy the standard additive error stability robustness test

$$\sigma_{\max}[K(j\omega)S(j\omega)] < \frac{1}{|e_a(j\omega)|}$$

where $S(s) = [I - G_2(s)K(s)]^{-1}$ and $e_a(s)$ is a transfer function whose magnitude bounds the additive error *. If $W_1 = I$ and $W_2 = I$, then the system interconnection shown in Figure 18.6 is suitable for designing \mathcal{H}_∞ controllers that achieve the loop-shaping objectives, because

$$T_{zw}(s) = \begin{bmatrix} W_3S(s)G_1(s) & W_3C(s) \\ W_4K(s)S(s)G_1(s) & W_4K(s)S(s) \end{bmatrix} \quad (18.16)$$

where $C(s) = S(s)G_2(s)K(s)$.

Notice that both of the loops of interest, $S(s)G_1(s)$ and $K(s)S(s)$, appear directly in Equation 18.16 multiplied by the design weights. By selecting scalar frequency-dependent weights, $W_3 = w_3(s)I$ and $W_4 = w_4(s)I$, an \mathcal{H}_∞ controller that achieves a specific value of γ ensures that

$$\sigma_{\max}[S(j\omega)G_1(j\omega)] < \frac{\gamma}{|w_3(j\omega)|} \quad \forall \omega \quad (18.17)$$

$$\sigma_{\max}[K(j\omega)S(j\omega)] < \frac{\gamma}{|w_4(j\omega)|} \quad \forall \omega \quad (18.18)$$

as a result of Equation 18.15. Similar bounds will also hold for the other $(T_{zw})_{ij}$ in Equation 18.16. To take advantage of Equations 18.17 and 18.18, set $\gamma = 1$ and select the values of $w_3(s)$ and $w_4(s)$ to provide

* See Chapter 9.

desirable bounds on $S(s)G_1(s)$ and $K(s)S(s)$. For example, let $w_4(s) = e_a(s)$. Then if the \mathcal{H}_∞ controller based on these values of the weights achieves $\|T_{zw}\|_\infty \approx 1$, the desired loops will in fact be shaped to satisfy Equations 18.17 and 18.18. This is how one should choose the values of the design variables to shape the loops of interest in an \mathcal{H}_∞ design.

In using this method of weight selection there are a few issues the designer must keep in mind. First of all, realize that the bounds implied by Equation 18.15 and exemplified by Equation 18.17 are not necessarily tight over all frequencies. As a result it helps to graphically inspect all the constraints implicit in the choice of $T_{zw}(s)$ as one iterates through the values of the design variables. More importantly, simply assuming $\gamma = 1$ when the values of the weights are chosen does not ensure an \mathcal{H}_∞ controller that achieves $\|T_{zw}\|_\infty \approx 1$. In fact, when $\|T_{zw}\|_\infty \gg 1$ it is a strong indication that the values of the design variables impose unrealistic constraints on the system's dynamics. One cannot choose $w_3(s)$ and $w_4(s)$ arbitrarily. They must complement each other. Another reason why the design variables cannot be chosen arbitrarily involves the fact that $\|(T_{zw})_{ij}\|_\infty < \gamma \forall i, j$. Not only will $w_3(s)$ shape the weighted sensitivity transfer function $S(s)G_1(s)$, it will also shape $C(s)$. Since $S(s) + C(s) = I$, there will clearly be restrictions on the choice of $w_3(s)$. While loops such as $C(s)$ may not be of primary interest, they will influence the overall performance of the controller and should be kept in mind when selecting the values of the weights.

The choice of P in Figure 18.6 with $W_1 = W_2 = I$ could also have been made using structured singular value concepts*. In this context, the performance variables z_2 and disturbances w_2 can be viewed as the inputs and outputs to an unknown but norm bounded unstructured uncertainty that captures the additive error in the input to output model. Likewise, the performance variables z_1 and disturbances w_1 can be viewed as the inputs and outputs to a fictitious, unknown, norm bounded unstructured uncertainty that captures the desire to reject the disturbances d at the outputs y_n . Then selecting the values of the design weights is akin to scaling the system in the same way that the D -scales, used in the D - K iteration, scale the system.

18.4.3 Additional Notes for Selecting Design Weights

To ensure that Assumptions A.1 through A.5 are satisfied once the dynamics of the frequency weights are augmented to the system model, it is necessary to use proper, stable, minimum phase weights. For example, in the system shown in Figure 18.6, $W_4(s)$ must contain an output feedthrough term to ensure $R_{uu} > 0$.

An important issue to be aware of when using frequency weights is that it is possible to define a set of weights with repetitive information. For example, in the system of Figure 18.6 with $W_2(s) = w_2(s)I$ and $W_4(s) = w_4(s)I$, specifying the magnitudes of $w_2(s)$ and $w_4(s)$ to be large over the same frequency region tells both optimization problems the same information, make the controls small there. Not only is such information redundant, it is also undesirable, since the order for the compensator is equal to the order of P .

18.5 Aircraft Design Example

To illustrate more clearly how one uses frequency weights to design \mathcal{H}_2 and \mathcal{H}_∞ controllers, we shall discuss the design of a wind gust disturbance rejection controller for a linearized model of an F-8 aircraft. As you shall see, the modern paradigm allows us to incorporate frequency domain performance and robustness specifications naturally and directly into the controller synthesis.

The F-8 is an "old-fashioned" aircraft that has been used by NASA as part of their digital fly-by-wire research program. Assuming that the aircraft is flying at a constant altitude in equilibrium flight allows us to linearize the nonlinear equations of motion. In doing so, the longitudinal dynamics decouple from

* See Chapter 20 for more details.

the lateral dynamics. The variables needed to characterize the longitudinal motion, which are defined in the schematic drawing of the F-8 shown in Figure 18.7, are the horizontal velocity, $v(t)$, pitch angle, $\theta(t)$, pitch rate, $q(t) = \dot{\theta}(t)$, angle of attack, $\alpha(t)$, and flight path angle, $\beta(t) = \theta(t) - \alpha(t)$. To control the longitudinal motion, elevators, $\delta_e(t)$, and flaperons, $\delta_f(t)$, which are just like the elevators except that they move in the same direction, were used. While the thrust also influences the longitudinal motion of the aircraft, it is considered to be constant in our designs. The measurements are the pitch and flight path angles, $y^T(t) = [\theta(t) \ \beta(t)]$.

The effect of wind gust disturbances, which primarily corrupt the angle of attack, is modeled as the output of a shaping filter driven with unit intensity white noise, $d(t)$. Using the state vector

$$x^T(t) = [\theta(t) \ \beta(t) \ q(t) \ v(t) \ x_d(t)]$$

in which $x_d(t)$ is the state of the first-order shaping filter of the wind gust disturbance model, the linearized, longitudinal equations of the F-8 aircraft are

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) + Ld(t) \\ y(t) &= Cx(t) + v(t) \end{aligned} \tag{18.19}$$

with $u^T(t) = [\delta_e(t) \ \delta_f(t)]$ and

$$A = \begin{bmatrix} 0.0 & 0.0 & 1.0 & 0.0 & 0.0 \\ 1.50 & -1.50 & 0.0 & 0.0057 & 1.50 \\ -12.0 & 12.0 & -0.60 & -0.0344 & -12.0 \\ -0.8520 & 0.290 & 0.0 & -0.0140 & -0.290 \\ 0.0 & 0.0 & 0.0 & 0.0 & -0.730 \end{bmatrix} \quad B = \begin{bmatrix} 0.0 & 0.0 \\ 0.160 & 0.80 \\ -19.0 & -3.0 \\ -0.0115 & -0.0087 \\ 0.0 & 0.0 \end{bmatrix}$$

$$L^T = [0.0 \ 0.0 \ 0.0 \ 0.0 \ 1.1459] \quad C = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \end{bmatrix}$$

The units for the angles and control signals are in degrees while the velocity has units of ft/s. The outputs are modeled as a nominal signal with additive white noise $v(t)$ that has an intensity of $\mu = 0.01 \text{ deg}^2/\text{s}$, $E\{v^T(t)v(\tau)\} = \mu I\delta(t - \tau)$, to capture the limited accuracy of the sensors.

The objective is to design controllers that reduce the effect of the wind disturbance on the system. Specifically we would like the magnitude of each output to be less than 0.25 degrees up to 1.0 rad/s as the aircraft passes through wind gusts. In addition, we require the control system to be robust to an unstructured multiplicative error reflected to the output of the plant whose magnitude is bounded by the function

$$e_m(s) = 0.1s^2$$

FIGURE 18.7 Definition of variables for the longitudinal dynamics of the F-8.

This multiplicative error captures the unmodeled dynamics associated with the flexibility of the aircraft's airframe. It will essentially constrain the bandwidth of the design to prevent these unmodeled modes from being excited.

Both of the design specifications can be represented in the frequency domain. To meet the performance specification, we require the closed-loop transfer function from d to y , $S(s)G_1(s)$, to satisfy

$$\sigma_{\max}[S(j\omega)G_1(j\omega)] < 0.25 \quad \text{for } 0 < \omega \leq 1.0 \text{ rad/s} \quad (18.20)$$

where

$$\begin{aligned} S(s) &= [I - G_2(s)K(s)]^{-1} \\ G_2(s) &= C(sI - A)^{-1}B \\ G_1(s) &= C(sI - A)^{-1}L \end{aligned}$$

To ensure stability robustness to the multiplicative error we require that

$$\sigma_{\max}[C(j\omega)] < \frac{1}{|e_m(j\omega)|} \quad \forall \omega \quad (18.21)$$

where $C(s) = S(s)G_2(s)K(s)$.

Given this representation of the design goals, we shall synthesize \mathcal{H}_2 and \mathcal{H}_∞ controllers that shape the closed-loop transfer functions $S(s)G_1(s)$ and $C(s)$ to meet these constraints. Using the system interconnection for P shown in Figure 18.8 makes good mathematical and physical sense for this problem. Mathematically, $P(s)$ shown in Figure 18.8 leads to the following closed-loop transfer function matrix,

$$T_{zw}(s) = \begin{bmatrix} w_1(s)S(s)G_1(s) & \sqrt{\mu}w_2(s)C(s) \\ \rho w_1(s)K(s)S(s)G_1(s) & \rho\sqrt{\mu}w_2(s)K(s)S(s) \end{bmatrix} \quad (18.22)$$

Notice that the loops of interest, $S(s)G_1(s)$ and $C(s)$, appear directly in Equation 18.22 and are directly influenced by the scalar frequency weights $w_1(s)$ and $w_2(s)$. Realize that the coloring filter dynamics for the wind gust disturbance are already included in the system dynamics Equation (18.19), so that $w_1(s)$ should not be viewed as a shaping filter for d . Rather $w_1(s)$ is a design variable that overemphasizes the frequency range in which the impact of d is most vital, and it is chosen to reflect in the optimization problem our desire to appropriately shape $S(s)G_1(s)$. The scalar constant weight ρ , which is a penalty on the control that must be included in the synthesis to satisfy Assumption A.5, was allowed to vary, whereas μ was held fixed to capture the limited sensor accuracy. $P(s)$ also makes good sense in terms of the physics of the design objectives. It includes the effects of both the process and sensor noises, and its performance variables, z , contain the outputs we wish to keep small in the presence of the disturbances.

To illustrate that there is a strong connection between the physical, stochastic motivation used to select the values of the weights in the \mathcal{H}_2 framework and the more mathematical norm bound motivation used in the \mathcal{H}_∞ framework, we compare the results of an \mathcal{H}_∞ and an \mathcal{H}_2 design that both use the same values of the weights. The weights were chosen as described in the previous section. After some iteration we found that with

$$\rho = 0.01, \quad w_1(s) = \frac{0.1(s + 100)}{(s + 1.25)}, \quad \text{and} \quad w_2(s) = \frac{5000(s + 3.5)}{3.5(s + 1000)}$$

both the \mathcal{H}_∞ and \mathcal{H}_2 designs met the desired performance and robustness specifications. Note that as a result of using these frequency weights, the controllers had eight states.

Figures 18.9 and 18.10 show that the loops of interest have in fact been shaped in accordance with the design goals. As seen in Figure 18.9, which compares the open and closed-loop disturbance to output transfer functions, both designs meet the performance goal from Equation 18.20. In this figure, $1/|w_1(j\omega)|$

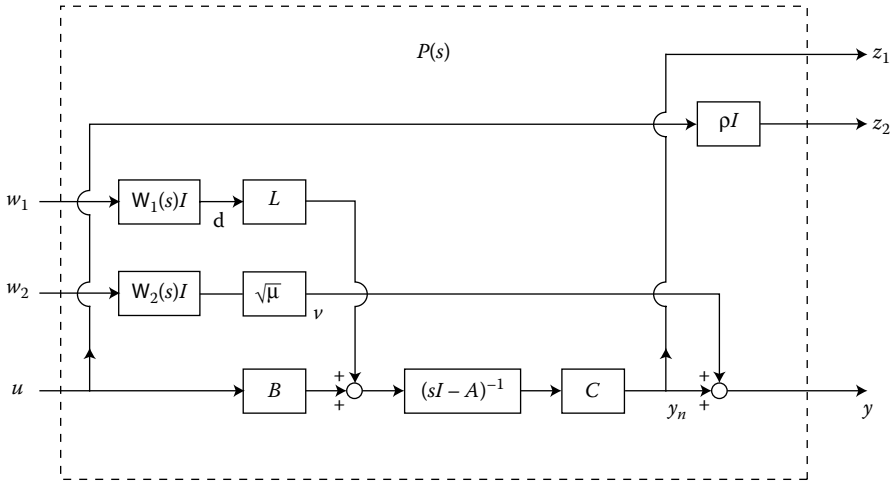

FIGURE 18.8 Generalized system $P(s)$ used in the F-8 designs.

FIGURE 18.9 Comparison of the open- and closed-loop disturbance to output transfer functions for the \mathcal{H}_∞ and \mathcal{H}_2 designs. The frequency weight $W_1(s)$ used to shape $S(s)G_1(s)$ is also shown.

is also shown to illustrate how the value of $w_1(s)$ was chosen. From an \mathcal{H}_2 perspective, the $|w_1(j\omega)|$ is large over $0 < \omega \leq 1.0$ rad/s and small elsewhere to tell the synthesis that the intensity of the disturbance is large where we desire good disturbance rejection. In the context of the \mathcal{H}_∞ design, we assumed that $\gamma = 1$ and selected $1/|w_1(j\omega)|$ to appropriately bound $\sigma_{\max}[S(j\omega)G_1(j\omega)]$ in accordance with the fact that

$$\sigma_{\max}[S(j\omega)G_1(j\omega)] < \frac{\gamma}{|w_1(j\omega)|} \quad \forall \omega \tag{18.23}$$

FIGURE 18.10 Comparison of $\sigma_{\max}[C(j\omega)]$ for the \mathcal{H}_∞ and \mathcal{H}_2 designs. The bound on the multiplicative error, $1/|e_m(j\omega)|$, and the frequency weight $W_2(s)$ used to shape $C(s)$ are also shown.

for any \mathcal{H}_∞ design which achieves $\|T_{zw}\|_\infty < \gamma$. For the values of the weights given above, $\|T_{zw}\|_\infty = 0.95$ for the \mathcal{H}_∞ design, which ensures that Equation 18.23 was satisfied. A difference in the performance achieved by both designs is expected since the same values of the weights are used to minimize different measures of the size of $T_{zw}(s)$.

Figure 18.10, which compares $\sigma_{\max}[C(j\omega)]$ for the designs, illustrates that the stability robustness criterion from Equation 18.21 is also satisfied. Again, $1/\sqrt{\mu}|w_2(j\omega)|$ is shown to illustrate the manner in which the value of $w_2(s)$ was chosen. As seen in the figure, $w_2(s)$ forces the \mathcal{H}_∞ design to roll off below the stability robustness bound, $1/|e_m(j\omega)|$, in accordance with the fact that

$$\sigma_{\max}[C(j\omega)] < \frac{\gamma}{\sqrt{\mu}|w_2(j\omega)|} \quad \forall \omega. \tag{18.24}$$

Since $|w_2(j\omega)|$ is large beyond 5.0 rad/s, it tells the \mathcal{H}_2 synthesis that the sensor noise is large there, which in turn limits the control energy beyond 5.0 rad/s.

The value of ρ also played an important role in the designs. In the \mathcal{H}_2 design, adjusting ρ directly influenced the amount of control effort used, just as a control weight would in LQG synthesis. For the \mathcal{H}_∞ design, ρ minimized the constraints that the values of $w_1(s)$ and $w_2(s)$ placed on the closed-loop transfer functions $K(s)S(s)G_1(s)$ and $K(s)S(s)$ in Equation 18.22. Since these loops are not of primary interest, choosing a small value of ρ ensured that $w_1(s)$ and $w_2(s)$ would not overly constrain these since, for example,

$$\sigma_{\max}[K(j\omega)S(j\omega)G_1(j\omega)] < \frac{\gamma}{\rho|w_1(j\omega)|} \quad \forall \omega$$

for any \mathcal{H}_∞ design.

The similarities in the achieved loop shapes are not coincidental. In fact, the dynamics of the \mathcal{H}_∞ and \mathcal{H}_2 controllers presented here are quite similar. There is a clear reason why the similarity exists even though the optimization problems used are distinct. Once all of the desired control system performance is incorporated into $P(s)$ via the design variables, the task of minimizing the \mathcal{H}_2 norm of $T_{zw}(s)$ becomes nearly identical to the task of minimizing the \mathcal{H}_∞ norm of $T_{zw}(s)$. This can be seen in Figure 18.11, which compares the values of $\sigma_{\max}[P_{zw}(j\omega)]$ and $\sigma_{\max}[T_{zw}(j\omega)]$ for the two designs. Here $P_{zw}(s)$ denotes the open-loop transfer function matrix between w and z of $P(s)$. As such, $\sigma_{\max}[P_{zw}(j\omega)]$ is an indication of the nominal cost that the controllers seek to minimize. Specifically, to minimize the \mathcal{H}_∞ norm of $T_{zw}(s)$ the peak in $\sigma_{\max}[P_{zw}(j\omega)]$ must be flattened out so that it looks like a low pass filter. Then the DC gain of the filter must be reduced to further minimize the \mathcal{H}_∞ norm of $T_{zw}(s)$. This is also the case for minimizing the \mathcal{H}_2 norm of $T_{zw}(s)$ which is dominated by the area under the spike in $\sigma_{\max}[P_{zw}(j\omega)]$ (recall that the area is evaluated linearly and that we are using a log log plot). While the optimization problems are distinct, the manner in which the cost is minimized is similar.

Figure 18.11 also provides a clear indication of how the optimization problems differ. Notice that the \mathcal{H}_2 design rolls off faster than the \mathcal{H}_∞ design. This is because the \mathcal{H}_2 design minimizes energy, or the area under $\sigma_{\max}[T_{zw}(j\omega)]$, at the expense of its peak value, whereas the \mathcal{H}_∞ design seeks to minimize the peak of $\sigma_{\max}[P_{zw}(j\omega)]$ at the expense of allowing there to be more energy at higher frequencies.

It would be improper to draw conclusions about which synthesis approach is better based on these designs, especially since the same values for the weights in $P(s)$ were used. Rather, our intent has been to illustrate the connections between the \mathcal{H}_∞ and \mathcal{H}_2 frameworks and how one can go about synthesizing \mathcal{H}_∞ and \mathcal{H}_2 controllers to meet frequency domain design specifications. We should also note that the methodology used in this example has been applied to and experimentally verified on a much more complex system [16].

FIGURE 18.11 Comparison of the open-loop “cost,” $\sigma_{\max}[P_{zw}(j\omega)]$, and the closed-loop “cost,” $\sigma_{\max}[T_{zw}(j\omega)]$, for the \mathcal{H}_∞ and \mathcal{H}_2 controllers.

19.1 Introduction*

Feedback controllers are designed to achieve certain performance specifications in the presence of both plant and signal uncertainty. Typical controller design formulations consider quadratic cost functions on the errors primarily for mathematical convenience. However, practical situations may dictate other kinds of measures. In particular, the peak values of error signals are often more appropriate for describing desired performance. This can be a consequence of uniform tracking problems, saturation constraints, rate limits, or simply a disturbance rejection problem. In addition, disturbance and noise are in general bounded and persistent because they continue to act on the system as long as the system is in operation. Such signals are better described by giving information about both the signals' frequency content and time-domain bounds on peak values.

The above class of problems motivated a formulation that involves the Peak-to-Peak gain of a system, which is mathematically given by the ℓ_1 norm of the pulse response. This formulation was first reported in [13], and the problem was completely solved in several subsequent articles [5–8,11]. The extension of the theory to incorporate plant uncertainty was reported in [3,4,9,10]. An extensive coverage of this theory with detailed references can be found in [2].

The need for developing this problem was further intensified by the failure of the frequency-domain techniques to address time-domain specifications. For instance, attempting to achieve an overshoot

* Research Supported by AFOSR under grant AFOSR-91-0368, by NSF under grant 9157306-ECS, and by Draper Laboratory under grant DL-H-467128.

constraint using \mathcal{H}_∞ or \mathcal{H}_2 by appropriately adjusting the weighting matrices can be a very frustrating experience. On the other hand, solutions to such problems will no longer be in closed form due to the complexity of the performance objectives. Exact or approximate solutions will be obtained from solving equivalent yet simpler optimization problems. The derivation of such simpler problems and the computational properties are essential components of this research direction.

19.1.1 A Design Tool

The motivation behind research in ℓ_1 theory is developing a design tool for MIMO uncertain systems. A powerful design tool in general should have three ingredients:

1. *Practicality*: The ability to translate a large set of performance specifications into conditions or constraints readily acceptable by the design tool. It is evident that not all design specifications can be immediately translated into mathematical conditions. However, the mathematical formulation should well approximate these objectives.
2. *Computability*: It is in general straightforward to formulate controller design problems as constrained optimization problems. What is not so straightforward is formulating problems that can be solved efficiently and with acceptable complexity.
3. *Flexibility*: The ability to alter a design to achieve additional performance specifications with small marginal cost.

It is evident that practicality and computability are conflicting ingredients. Computational complexity grows as a function of several parameters, which include the dimension of the system, the uncertainty description, and the performance specifications. Flexibility makes it possible to design a controller in stages, i.e., by altering a nominally good design to achieve additional specifications.

19.1.2 Motivation

We give some reasons behind the development of such a design tool, by quoting from the book: *Control of Uncertain Systems: A Linear Programming Approach*.

1. *Complex systems*: Many of today's systems, ranging from space structures to high purity distillation columns, are quite complex. The complexity comes from the very high order of the system as well as the large number of inputs and outputs. Modeling such systems accurately is a difficult task and may not be possible. A powerful methodology that deals systematically with multiple inputs and outputs and with various classes of structured uncertainty is essential.
2. *High performance requirement*: Systems are built to perform specific jobs with high accuracy. Robots are already used to perform accurate jobs such as placing components on integrated circuit boards. Aircraft are built with high maneuverability and are designed specifically for such tasks. Classical SISO design techniques cannot accommodate these problems resulting in designs that are conservative and perform poorly.
3. *Limits of performance*: In complex systems, it is time-consuming to establish, by trial and error, whether a system can meet certain performance objectives (even without uncertainty). Thus, it is necessary to develop systematic methods to quantify the fundamental limitations of systems and to highlight the trade-offs of a given design.
4. *A systematic design process*: It is inevitable that designing a controller for a system will involve iterations. Unless this procedure is made systematic, the design process can become very cumbersome and slow. The design procedure should not only exhibit a controller. It should also provide the designer with indicators for the next iteration, by showing which of the constraints are the limiting ones and which part of the uncertainty is causing the most difficulty. Note also that a general procedure should be able to accommodate a variety of constraints, both in the time and in the frequency domain.

5. *Computable methods*: It is quite straightforward to formulate important control problems, but it is not so easy to formulate solvable problems that can provide computable methods for analysis and synthesis. Much of the current research invokes high level mathematics to provide simple computable results. The computability of a methodology is the test of its success. By computability we do not mean necessarily closed form solutions. Problems that give rise to such solutions have limited applicability. However, computability means that we can synthesize controllers via computable algorithms and simultaneously obtain qualitative information about the solution.
6. *Technological advancement*: Many aspects of technological development will affect the design of control systems. The availability of “cheaper” sensors and actuators that are well-modeled allows for designing control systems with a large number of inputs and outputs. The availability of fast microprocessors, as well as memory, makes it possible to implement more complex feedback systems with high order. The limiting factor in controller implementation is no longer the order of the controller. Instead, it is the computational power and the memory availability.
7. *Available methods*: The available design techniques have concentrated on frequency-domain performance specifications by considering errors in terms of energy rather than peak values. These methods (such as \mathcal{H}_2 and \mathcal{H}_∞) have elegant solutions. However, this elegance is lost if additional time-domain specifications (e.g., overshoot, undershoot, settling time ..) are added. This created a need for a time-domain based computational methodology that can accommodate additional frequency-domain constraints. This design tool aims at achieving this objective.

In the sequel we will summarize the ℓ_1 design tool by discussing the three ingredients, *practicality*, *computability*, and *flexibility*.

19.2 Practicality

19.2.1 Examples

To motivate the formulation of the ℓ_1 problem, we begin with two examples.

The first is the control design for an *Earth Observing System (EOS)*. EOS is a spacecraft that orbits the earth and points in a specific location. It carries on its platform various sensory instruments, with the objective of collecting data from earth. An example of such an instrument is an array of cameras intended to provide images of various points and landscapes on earth. The spacecraft is subjected to various kinds of disturbances: external pressures, noise generated from the instruments on board, and the spacecraft itself. The objective of the control design is to point the spacecraft accurately in a specific direction, otherwise known as attitude control.

The second example is the control design of an active suspension of an automobile. A simplified one-dimensional problem is shown in Figure 19.1.

The objective of the controller design is to maximize ride comfort, while simultaneously maintaining handling (road holding ability) in the presence of bad road conditions.

These examples have several common features:

1. The objectives in both problems are to keep the maximum deviations of signals from set points bounded by some prescribed value to attain uniform tracking or disturbance rejection. In the EOS example, performance is measured in terms of maximum deviations of the attitude angles from a set point. In the active suspension problem, performance is measured in terms of the maximum force acting on the system and the maximum deviation of the distance of the wheel from the ground.

In mathematical terms, both performance specifications are stated in terms of *peak* values of signals, i.e.,

$$\|w\|_\infty = \max_{i=1,\dots,n} \sup_t |w(t)|.$$

FIGURE 19.1 Active suspension.

This is known as the ℓ_∞ -norm of the signal (or its peak value). For the active suspension problem, the performance can be stated as

$$\left\| \begin{pmatrix} x_1 - d \\ u \end{pmatrix} \right\|_\infty \leq \gamma,$$

for some performance bound γ . It is straightforward to incorporate additional scalings and weights into the performance.

2. The disturbances in both examples are unknown, persistent in time, but, bounded in magnitude (peak value). A good model for the disturbance in both cases is given by

$$d = Ww, \quad \|w\|_\infty \leq 1,$$

where W is a linear time-invariant filter that gives information about the frequency content of the disturbance. This model of disturbance accommodates persistent disturbances that are not necessarily periodic. It does not assume that the signal dies out asymptotically.

3. In both problems, saturation constraints are quite important and play a role in limiting the performance. In the active suspension problem, the saturation constraint is given by the maximum deflection of the hydraulic actuator, i.e.,

$$\|x_1 - x_2\|_\infty \leq \gamma_{sat}.$$

These constraints combined with the performance objectives have to be satisfied for all disturbances w such that $\|w\|_\infty \leq 1$.

4. Both examples are difficult to model precisely, and thus the control strategies have to accommodate unmodelled dynamics. In this article, we will not discuss in detail the robust performance problems. We refer the reader to [2] for details.

It is evident from the above discussion that peak values of signals are natural quantities in stating design specifications.

19.2.2 Formulation

Figure 19.2 shows a general setup for posing performance specifications. The variables as defined in the figure are

$$\begin{aligned}
 u &= \text{control inputs} \\
 y &= \text{measured outputs} \\
 w = \text{exogenous Inputs} &= \begin{cases} \text{fixed commands} \\ \text{unknown commands} \\ \text{disturbances} \\ \text{noise} \\ \vdots \end{cases} \\
 z = \text{regulated outputs} &= \begin{cases} \text{tracking Errors} \\ \text{control Inputs} \\ \text{measured Outputs} \\ \text{states} \\ \vdots \end{cases}
 \end{aligned}$$

The operator G is a 2×2 block matrix mapping the inputs w and u to the outputs z and y :

$$\begin{bmatrix} z \\ y \end{bmatrix} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \begin{bmatrix} w \\ u \end{bmatrix}.$$

The actual process or *plant* is the submatrix G_{22} . Both the exogenous inputs and the regulated outputs are auxiliary signals that need not be part of the closed loop system. The feedback controller is denoted by K .

From our discussion above, the set of exogenous inputs consists of unknown, persistent, but bounded, disturbances,

$$\mathcal{D} = \{w \in \ell_\infty \mid \|w\|_\infty \leq 1\}.$$

The performance measure (combined with constraints) is stated as

$$\|z\|_\infty \leq \gamma, \quad \forall w \in \mathcal{D}.$$

FIGURE 19.2 General setup.

If Φ is the linear time-invariant system mapping w to z , then

$$\|z\|_\infty \leq \gamma, \quad \text{for all } w \in \mathcal{D} \iff \|\Phi\|_1 \leq \gamma,$$

where

$$\|\Phi\|_1 = \max_{1 \leq i \leq n_z} \sum_{j=1}^{n_w} \sum_{k=0}^{\infty} |\phi_{ij}(k)|.$$

The latter is the expression for the ℓ_1 norm of the system. In conclusion, the ℓ_1 norm of a system is the *peak-to-peak* gain of the system and can directly describe time-domain performance specifications. The nominal performance problem can be stated as

$$\inf_{K \text{ stabilizing}} (\sup_w \|\Phi\|_1).$$

19.2.3 Comparison to \mathcal{H}_∞

Suppose the exogenous inputs are such that $\|w\|_2 \leq 1$ but are otherwise arbitrary ($\|w\|_2$ is the energy contained in the signal). If the objective is to minimize the energy of the regulated output, then the nominal performance problem is defined as

$$\inf_{K \text{ stabilizing}} (\sup_w \|\Phi w\|_2) = \inf_{K \text{ stabilizing}} \sup_{\theta} \sigma_{\max}[\hat{\Phi}(e^{j\theta})].$$

Both of these norm minimization problems fall under the same paradigm of minimax optimality. Minimizing the \mathcal{H}_∞ norm results in attenuating the energy of the regulated signal but may still result in signals that have large amplitudes. Minimizing the ℓ_1 norm results in attenuating the amplitude of the regulated output, and overbounds the maximum energy due to bounded energy inputs because

$$\|\hat{\Phi}\|_{\mathcal{H}_\infty} \leq \sqrt{m} \|\Phi\|_1,$$

where m is the number of rows in Φ . On the other hand, the following inequality holds:

$$\|\Phi\|_1 \leq 2(N+1)\sqrt{n} \|\hat{\Phi}\|_{\mathcal{H}_\infty},$$

where N is the McMillan degree of the system, and n is the number of columns of Φ . The latter bound is the tightest possible bound (i.e., equality holds for certain classes of systems) and it shows that the gap between these measures can be large if the order of the system is high.

19.2.4 Prototypes

The following prototypes have been discussed in [2]. These are representative problems quite common in applications. We will use these prototypes to illustrate the significance of the ℓ_1 design methodology.

19.2.4.1 Disturbance Rejection

In the context of ℓ_∞ signals, the disturbance rejection problem is defined as follows: Find a feedback controller that minimizes the maximum amplitude of the regulated output over all possible disturbances of bounded magnitude. The two-input two-output system shown in Figure 19.3 depicts the particular case where the disturbance enters the system at the plant output. Its mathematical representation is given by

$$\begin{aligned} z &= P_0 u + W w, \\ y &= P_0 u + W w. \end{aligned}$$

The disturbance rejection problem provides a general enough structure to represent a broad class of interesting control problems.

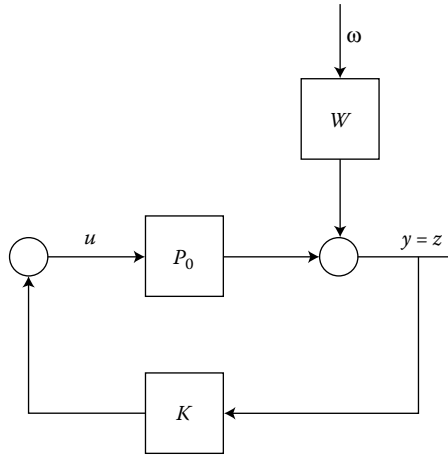

FIGURE 19.3 A disturbance rejection problem.

19.2.4.2 Command Following with Saturation

The command following problem, equivalent to a disturbance rejection problem, is shown in Figure 19.4. We will show how to pose this problem in the presence of saturation nonlinearities at the input of the plant, as an ℓ_1 -optimal control problem.

Define the function

$$\text{Sat}(u) = \begin{cases} u & |u| \leq U_{\max} \\ U_{\max} \text{sgn}(u) & |u| \geq U_{\max} \end{cases}.$$

Let the plant be described as

$$Pu = P_0 \text{Sat}(u)$$

where P_0 is LTI. Let the commands be modeled as

$$r = Ww \quad \text{where } \|w\|_\infty \leq 1.$$

The objective is to find a controller K so that y follows r uniformly in time. Keeping in mind the saturation function, and in order to stay in the linear region of operation, the allowable control inputs must have $\|u\|_\infty \leq U_{\max}$. Let γ be the (tracking) performance level desired, and define

$$z = \begin{bmatrix} (y - r)/\gamma \\ u/U_{\max} \end{bmatrix}$$

with

$$y = P_0 u.$$

FIGURE 19.4 Command following with input saturation.

The problem is equivalent to finding a controller so that

$$\sup_w \|z\|_\infty < 1,$$

which is an ℓ_1 -optimal control problem.

The above closed loop system will remain stable even if the input saturates, as long as it does so infrequently. The solution to the above problem will determine the limits of performance when the system is required to operate in the linear region. Also, the stability for such a system will mean the local stability of the nonlinear system.

19.2.4.3 Saturation and Rate Limits

In the previous example, actuator limitations may require that the rate of change of the control input be bounded. This is captured in the condition

$$\left| \frac{u(k) - u(k-1)}{T_s} \right| \leq U_{\text{der}}$$

where T_s is the sampling period. Let

$$W_{\text{der}} = \frac{1 - \lambda}{T_s U_{\text{der}}}.$$

This condition can be easily incorporated in the objective function by defining z as

$$z = \begin{bmatrix} (y - r)/\gamma \\ u/U_{\text{max}} \\ W_{\text{der}} u \end{bmatrix}.$$

The result is a standard ℓ_1 -optimal control problem.

19.2.5 Stability and Performance Robustness

The power of any design methodology is in its ability to accommodate plant uncertainty. The ℓ_1 norm gives a good measure of performance. Because it is a gain over a class of signals, it will also provide a good measure for robustness. This is a consequence of the small gain theorem which is stated below [2].

Let M be a linear time-invariant system and Δ be a strictly proper ℓ_∞ -stable perturbation. The closed-loop system shown in Figure 19.5 is ℓ_∞ -stable for all Δ with $\|\Delta\|_{\ell_\infty\text{-ind}} \leq 1$ if and only if $\|M\|_1 < 1$.

The above result indicates that the ℓ_1 norm is the exact measure of robustness when the perturbations are known to be BIBO stable, bounded gain, and possibly nonlinear or time-varying. The result can be adapted to derive stability robustness conditions for a variety of plant uncertainty descriptions. We describe one such situation below.

FIGURE 19.5 Stability robustness problem.

19.2.5.1 Unstructured Multiplicative Perturbations

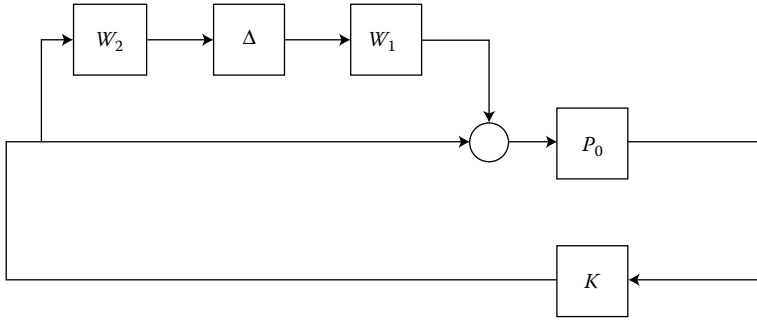

FIGURE 19.6 Multiplicative perturbations.

Consider the case where the system has input uncertainty in a multiplicative form as in Figure 19.6, i.e., let

$$\Omega = \{P \mid P = P_o(I + W_1 \Delta W_2) \text{ and } \|\Delta\|_{\ell_\infty\text{-ind}} \leq 1\}.$$

If a controller is designed to stabilize P_o , under what conditions will it stabilize every system in the set Ω ? By simple manipulations of the closed-loop system, the problem is equivalent to the stability robustness of the feedback system in Figure 19.5, with $M = W_2(I - KP_o)^{-1}KP_oW_1$. In general this manipulation is done in a systematic way: Cut the loop at the inputs and outputs of Δ , and then calculate the map from the output of Δ , w , to the input of Δ , z . A sufficient condition for robust stability is then given by $\|M\|_1 < 1$. The resulting two-input two-output description is given by

$$\begin{aligned} y &= P_o u + P_o W_1 w, \\ z &= W_2 u. \end{aligned}$$

This is a standard ℓ_1 minimization problem.

19.2.5.2 Structured Uncertainty

In many applications, uncertainty is described in a structured fashion where independent perturbations are introduced in various locations of the closed loop system. It turns out that one can derive an exact necessary and sufficient condition in terms of a scaled ℓ_1 norm of the system to guarantee stability robustness in the presence of such structured perturbations. It can also be shown that the problem of achieving robust performance (where performance is measured in terms of the ℓ_1 norm) is equivalent to robustly stabilizing a plant with structured uncertainty. In this article, we will not discuss this problem. Instead, we refer the reader to [2] for more details.

19.3 Computability

Since it is quite hard, in general, to obtain closed form solutions to general optimization problems, we need to be precise about the meaning of a “solution.” A closed form solution has two important features: the first is the ability to compute the optimal solution through efficient algorithms, and the second is to provide a qualitative insight into the properties of the optimal solution. A numerical solution should offer both of these ingredients. In particular, it should provide

1. The exact solution whenever it is possible

2. Upper and lower approximations of the objective function when exact solutions cannot be obtained and a methodology for synthesizing suboptimal controllers
3. Qualitative information about the controller, e.g., the order of the controller

Solutions based on general algorithms even for convex optimization problems offer only approximate upper bounds on the solution. To obtain more information, one needs to invoke duality theory. Duality theory provides a simple reformulation of the optimization problem from which lower bounds on the objective function and, possibly, exact solutions can be found.

19.3.1 Summary of Results

To minimize the ℓ_1 norm, first the Youla parameterization of all stabilizing controllers is invoked. The resulting optimization problem can be stated as an infinite-dimensional linear program in the free parameter. Two cases occur:

1. The infinite dimensional LP is exactly equivalent to a finite-dimensional LP. This happens if the dimension of the control input is at least as large as the dimension of the regulated variables and the dimension of the measured output is at least as large as the exogenous inputs. This means that the controller has a lot of degrees of freedom.
2. If any of the above conditions is violated, then the problem is inherently infinite-dimensional. However, duality theory can be used to provide approximate solutions to this problem with guaranteed performance levels.

The details of the computations for both of the above cases can be found in [2]. The most successful algorithm for computing solutions for the second case is not based on straightforward approximation, but rather on embedding the problem in another that falls under the first case. This procedure generates approximate solutions with converging upper and lower bounds, and also provides information about the order of the actual optimal controller. Other emerging techniques are based on dynamic programming and viability theory and can be found in [1,12].

19.4 Flexibility

Flexibility is the ability to use the design tool to alter a given nominal design so that additional specifications are met with minimal expense. Examples of additional specifications include fixed input constraints and frequency-domain constraints. The computational cost of alteration should be much less than the incorporation of the specification directly in the problem. In addition, it is desirable to maintain the qualitative information of the original solution.

Since the general synthesis problem is equivalent to an infinite dimensional LP, many additional specifications (not directly addressed by ℓ_1 norms) can be incorporated as additional linear constraints. Frequency-domain constraints can be well-approximated by linear constraints. Below we consider an example of adding fixed input constraints to the ℓ_1 problem.

19.4.1 ℓ_1 Performance Objective with Fixed Input Constraints

Consider the case where the specifications given are such that the control signal resulting from a step input must be constrained uniformly in time (e.g., to avoid actuator saturation). We want to bound the controller response to a step input and at the same time minimize the ℓ_1 norm of the transfer functions from the disturbance to both the control signal and plant output. In such a case we augment the basic ℓ_1

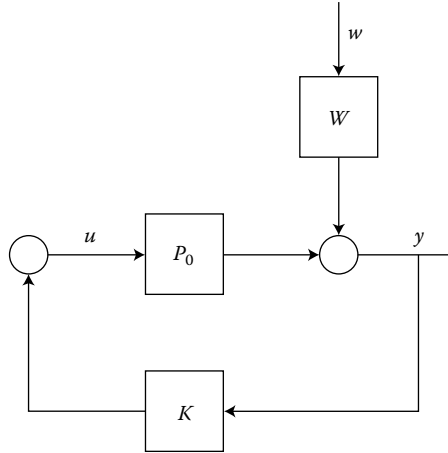

FIGURE 19.7 A disturbance rejection problem.

problem in the following way:

$$\inf_{K \text{ stab.}} \left\| \begin{matrix} K(I + PK)^{-1} W \\ (I + PK)^{-1} W \end{matrix} \right\|_1$$

subject to

$$\|K(I + PK)^{-1} w_f\|_\infty \leq U_{\max}$$

where w_f is a unit step input disturbance and U_{\max} is the specified bound. The above modification results in adding infinitely many constraints on the sequence $K(I + PK)^{-1}$ (i.e., convolution of a unit step with $K(I + PK)^{-1}$). However, since the peak is typically achieved in early samples, only a finite number of constraints must be included (the rest being inactive). This is a particular case of nondecaying template constraints which arise frequently in control system design.

19.4.1.1 Trade-Offs in Design

We take these specifications a step further by asking the following questions: What are the trade-offs in the design? How does the bound on the control signal step response affect the overall performance? And, how does it affect the structure of the optimal solution?

These questions can be readily answered with the ℓ_1 machinery. It amounts to solving a family of mixed ℓ_1 problems parameterized in U_{\max} . Solutions for a range of values of U_{\max} are presented in Figures 19.8 and 19.9 by showing the performance degradation and the controller order growth as U_{\max} decreases. The numerical values are based on a model for the X29 aircraft (for details, see [2]). The following conclusions can be drawn from this analysis:

1. The results present the trade-offs clearly. It is possible to reduce U_{\max} by 50% without losing too much performance in terms of the ℓ_1 norm of the system. This implies that the controller can be altered to satisfy stricter conditions on the step response without losing the nominal performance. The curve in Figure 19.8 also shows the smallest possible achievable U_{\max} .
2. The trade-offs in the order of the controller are valuable. The trade-off curve in Figure 19.9 shows that, by adding two additional states, U_{\max} can be reduced to about 50% of its unconstrained value.
3. To compute such solutions, the unconstrained problem is solved first. The performance for a step input is then checked, and constraints are added only at the time instants where the peak value of

FIGURE 19.8 X29: Trade-offs in performance vs. control signal bound, U_{\max} .

the input u is larger than U_{\max} . This is a simpler problem than incorporating the infinite-horizon constraints at all the time instants of the step response.

Finally, such constraints are hard to deal with by selecting weights and solving an ℓ_1 problem or an \mathcal{H}_∞ problem. The advantage that the ℓ_1 problem has over \mathcal{H}_∞ is that such constraints can be incorporated in the problem, as described earlier, and then solved using the same solution techniques.

FIGURE 19.9 X29: Trade-offs in controller order vs. control signal bound, U_{\max} .

19.5 Conclusions

In this chapter, we gave an overview of the ℓ_1 theory for robust control. The presentation was not detailed. However, it was intended to serve as an introduction to a more detailed account of the theory that can be found in the book, *Control of Uncertain Systems: A Linear Programming Approach*, and references therein.

We highlighted three ingredients of the ℓ_1 design tool, practicality, computability and flexibility. These properties allow for implementing a computer-aided-design environment based on ℓ_1 nominal designs, in which the designer has the flexibility to incorporate frequency-domain and fixed-input constraints, without losing the qualitative information about the structure of the controllers obtained from the nominal designs. Such an environment has proven very powerful in designing controllers for real applications.

20.1 Introduction

This chapter gives a brief overview of the structured singular value (μ). The μ -based methods discussed are useful for analyzing the performance and robustness properties of linear feedback systems. Computational software for μ -based analysis and synthesis is available in commercial software products [2,4]. The interested reader might also consult the tutorials in references [8,14], and application-oriented papers, such as [1,6,13].

20.2 Shortcomings of Simple Robustness Analysis

Many of the theoretical robustness results for single-input, single-output (SISO) systems show that if a single-loop system has good robust stability characteristics, and good nominal performance

characteristics, then, necessarily, it has reasonably good robust performance characteristics. Unfortunately, this “fact” is not, in general, true for multiloop systems. Also, for multiloop systems, checking the robustness via individual loop-at-a-time calculations can be misleading, because the interactions between the deviations are not accounted for in such an analysis. In this chapter, we illustrate these difficulties with examples and introduce the structured singular value as an analytical tool for uncertain, multivariable systems.

The first example concerns control of the angular velocity of a satellite spinning about one of its principal axes. Its mathematical origins are due to Doyle, and are alluded to in [14]. The closed-loop multivariable (MIMO) system is shown in Figure 20.1.

Set $a := 10$, and define

$$G := \frac{1}{s^2 + a^2} \begin{bmatrix} s - a^2 & a(s + 1) \\ -a(s + 1) & s - a^2 \end{bmatrix}, \quad K_1 := \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad K_2 := \frac{1}{1 + a^2} \begin{bmatrix} 1 & -a \\ a & 1 \end{bmatrix}.$$

A minimal, state-space realization for the plant G is

$$G = \left[\begin{array}{cc|cc} A_G & B_G \\ \hline C_G & D_G \end{array} \right] = \left[\begin{array}{cc|cc} 0 & a & 1 & 0 \\ -a & 0 & 0 & 1 \\ \hline 1 & a & 0 & 0 \\ -a & 1 & 0 & 0 \end{array} \right] \tag{20.1}$$

In order to assess the robustness margins to perturbations in the input channels into the plant, consider the four-input, four-output system, denoted by M , in Figure 20.2. The lines from r_1 and r_2 which run above K_2 and G are included to define the tracking error, e_1 and e_2 explicitly.

Some important transfer functions are

$$M_{ry} = \frac{1}{s + 1} I_2, \quad M_{w_1, z_1} = M_{w_2, z_2} = -\frac{1}{s + 1}.$$

These imply that the nominal closed-loop system has decoupled command response, with a bandwidth of 1 rad/s, the crossover frequency in the first feedback loop is 1 rad/s, with phase margin of 90° , the gain margin in the first channel is infinite, the crossover frequency in the second loop is 1 rad/s, with phase margin of 90° , and the gain margin in the second channel is infinite. These suggest that the performance of the closed-loop system is excellent and that it is quite robust to perturbations in each input channel. Yet, consider a 5% variation in each channel at the input to the plant. Referring to Figure 20.3, let $\delta_1 = 0.05$, and $\delta_2 = -0.05$. The output response $y(t)$ to a unit-step reference input in channel 1 is shown in Figure 20.4 (along with the nominal responses). Note that the ideal behavior of the nominal system has degraded sharply despite the seemingly innocuous perturbations and excellent gain/phase margins in the closed-loop system. In fact, for a slightly larger perturbation, $\delta_1 = 0.11$, $\delta_2 = -0.11$, the closed-loop

FIGURE 20.1 Nominal multiloop feedback system.

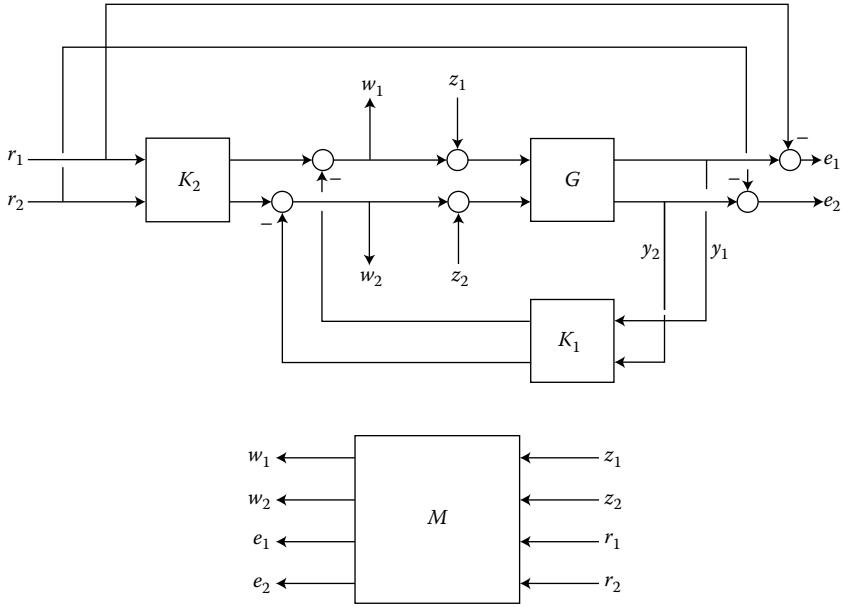

FIGURE 20.2 Closed-loop system with uncertainty model.

system is actually unstable. Why do these small perturbations cause such a significant degradation in performance? To answer this, calculate the 4×4 transfer matrix M represented in Figure 20.2, giving

$$\begin{bmatrix} w_1 \\ w_2 \\ e_1 \\ e_2 \end{bmatrix} = \begin{bmatrix} \frac{1}{s+1} & -\frac{a}{s+1} & \frac{s-a^2}{s+1} & -a \\ \frac{a}{s+1} & -\frac{1}{s+1} & a & \frac{s-a^2}{s+1} \\ \frac{1}{s+1} & \frac{a}{s+1} & -\frac{s}{s+1} & 0 \\ -\frac{a}{s+1} & \frac{1}{s+1} & 0 & -\frac{s}{s+1} \end{bmatrix} \begin{bmatrix} z_1 \\ z_2 \\ r_1 \\ r_2 \end{bmatrix} =: M \begin{bmatrix} z_1 \\ z_2 \\ r_1 \\ r_2 \end{bmatrix}$$

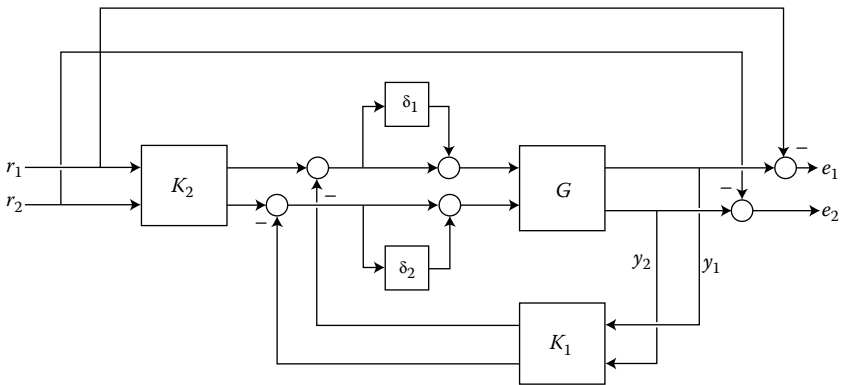

FIGURE 20.3 Satellite: Closed-loop system with uncertain elements, δ_1 and δ_2 .

Note that the earlier calculations about the closed-loop system yielded information only about the (1, 1), (2, 2), and (3 : 4, 3 : 4) entries. The notation (3 : 4, 3 : 4) denotes the 2×2 matrix formed by rows 3 to 4 and columns 3 to 4 of M . In particular, these entries are all small, in some sense. The neglected entries, (1, 2), (2, 1), (1 : 2, 3 : 4), (3 : 4, 1 : 2) are all quite large, because $a = 10$. It is these large off-diagonal entries, and the manner in which they enter, that causes the extreme sensitivity of the closed-loop system's performance to the perturbations δ_1 and δ_2 . For instance, with $\delta_2 \equiv 0$, the perturbation δ_1 can only cause instability by making the transfer function $(1 - M_{w1,z1}\delta_1)^{-1}$ unstable. Similarly, with $\delta_1 \equiv 0$, the perturbation δ_2 can only cause instability by making the transfer function $(1 - M_{w2,z2}\delta_2)^{-1}$ unstable. Because both $M_{w1,z1}$ and $M_{w2,z2}$ are "small", this requires large perturbations, and the single-loop gain/phase margins reported earlier are accurate. However, acting together, the perturbations can cause instability by making

$$\left[\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} - \begin{bmatrix} -\frac{1}{s+1} & -\frac{a}{s+1} \\ \frac{a}{s+1} & -\frac{1}{s+1} \end{bmatrix} \begin{bmatrix} \delta_1 & 0 \\ 0 & \delta_2 \end{bmatrix} \right]^{-1}$$

unstable. The denominator of this multivariable transfer function is

$$s^2 + (2 + \delta_1 + \delta_2)s + [1 + \delta_1 + \delta_2 + (a^2 + 1)\delta_1\delta_2].$$

By choosing $\delta_1 = \frac{1}{\sqrt{a^2+1}} \approx 0.1$, and $\delta_2 = -\delta_1$, the characteristic equation has a root at $s = 0$, indicating marginal stability. For slightly larger perturbations, a root moves into the right half-plane. The simultaneous nature of the perturbations has resulted in a much smaller destabilizing perturbation than predicted by the gain/phase margin calculations.

In terms of robust stability, the loop-at-a-time gain/phase margins only depended on the scalar transfer functions $M_{w1,z1}$ and $M_{w2,z2}$, but the robust stability properties of the closed-loop system to simultaneous perturbations actually depend on the 2×2 transfer function matrix $M_{w,z}$. Similarly, assessing the robust performance characteristics of the closed-loop system involves additional transfer functions ignored in the simple-minded analysis. Consider the perturbed closed-loop system in Figure 20.3. In terms of the

FIGURE 20.4 Satellite: Nominal (solid) and 5% perturbation responses (dashed).

FIGURE 20.5 Perturbed system.

transfer function matrix M , the perturbed $r \rightarrow e$ transfer function can be drawn as shown in Figure 20.5. Partition the transfer function matrix M into four 2×2 blocks, as

$$M = \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix}.$$

Then the perturbed closed-loop transfer function from r to e can be written as

$$e = \left[M_{22} + M_{21} \Delta (I - M_{11} \Delta)^{-1} M_{12} \right] d$$

where Δ is the structured matrix of perturbations, $\Delta = \text{diag} [\delta_1, \delta_2]$. Our initial information about the closed-loop system consisted of the diagonal entries of M_{11} and the entire matrix M_{22} . We have seen that the large off-diagonal entries of M_{11} created destabilizing interactions between the two perturbations. In the robust performance problem, there are additional relevant transfer functions, M_{21} and M_{12} , which were not analyzed in the loop-at-a-time robustness tests, or in the $r \rightarrow y$ nominal command response, though it is clear that these transfer functions may play a pivotal role in the robust performance characteristics of the closed-loop system.

Hence, by calculating the two single loop-at-a-time robustness tests and a nominal performance test, 10 of the 16 elements of the relevant 4×4 transfer function matrix are ignored. Any test which accounts for simultaneous perturbations along with the subsequent degradation of performance must be performed on the whole matrix. The point of this example is to show that there are some interesting issues in multivariable system analysis and standard SISO ideas that cannot be made into useful analytical tools simply by applying loop-at-a-time analysis. The structured singular value (μ), introduced in the next section, is a linear algebra tool useful for these types of MIMO system analyses.

20.3 Complex Structured Singular Value

This section is devoted to defining the structured singular value, a matrix function denoted by $\mu(\cdot)$ [5]. The notation we use is standard from linear algebra and systems theory. \mathbf{R} denotes the set of real numbers, \mathbf{C} denotes the set of complex numbers, $|\cdot|$ is the absolute value of elements in \mathbf{R} or \mathbf{C} , \mathbf{R}^n is the set of real n vectors, \mathbf{C}^n is the set of complex n vectors, $\|v\|$ is the Euclidean norm for $v \in \mathbf{C}^n$, $\mathbf{R}^{n \times m}$ is the set of $n \times m$ real matrices, $\mathbf{C}^{n \times m}$ is the set of $n \times m$ complex matrices, I_n is the $n \times n$ identity matrix, and $0_{n \times m}$ is an entirely zero matrix. For $M \in \mathbf{C}^{n \times m}$, M^T is the transpose of M , M^* is the complex-conjugate transpose of M , and $\bar{\sigma}(M)$ is the maximum singular value of M . For $M \in \mathbf{C}^{n \times n}$, $\lambda_i(M)$ is an eigenvalue of M , $\rho(M) := \max_i |\lambda_i(M)|$ is the *spectral radius* of M , and $\rho_R(M)$ is the real spectral radius

of M , $\rho_R(M) := \max \{ |\lambda| : \lambda \in \mathbf{R}, \det(\lambda I - M) = 0 \}$, with $\rho_R(M) := 0$ if M has no real eigenvalues. If $M \in \mathbf{C}^{n \times n}$ satisfies $M = M^*$, then $M > 0$ denotes that M is positive definite, and $M^{\frac{1}{2}}$ means the unique positive definite Hermitian square root. For $M = M^*$, then $\lambda_{\max}(M)$ denotes the most positive eigenvalue.

We consider matrices $M \in \mathbf{C}^{n \times n}$. In the definition of $\mu(M)$, there is an underlying structure Δ , (a prescribed set of block diagonal matrices) on which everything following depends. This structure may be defined differently for each problem depending on the uncertainty and performance objectives. Defining the structure involves specifying three things: the total number of blocks, the type of each block, and their dimensions.

20.3.1 Purely Complex μ

Two types of blocks—*repeated scalar* and *full* blocks are considered. Two nonnegative integers, S and F , denote the number of *repeated scalar* blocks and the number of *full* blocks, respectively. To track the block dimensions, we introduce positive integers $r_1, \dots, r_S; m_1, \dots, m_F$. The i th repeated scalar block is $r_i \times r_i$, while the j th full block is $m_j \times m_j$. With those integers given, define $\Delta \subset \mathbf{C}^{n \times n}$ as

$$\Delta := \{ \text{diag} [\delta_1 I_{r_1}, \dots, \delta_S I_{r_S}, \Delta_{S+1}, \dots, \Delta_{S+F}] : \delta_i \in \mathbf{C}, \Delta_{S+j} \in \mathbf{C}^{m_j \times m_j}, 1 \leq i \leq S, 1 \leq j \leq F \}. \quad (20.2)$$

For consistency among all the dimensions, $\sum_{i=1}^S r_i + \sum_{j=1}^F m_j$ must equal n . Often, we will need norm bounded subsets of Δ , and we introduce the notation $\mathbf{B}_\Delta := \{ \Delta \in \Delta : \bar{\sigma}(\Delta) \leq 1 \}$. Note that in Equation 20.2 all of the repeated scalar blocks appear first, followed by the full blocks. This is done to simplify the notation and can easily be relaxed. The full blocks are also assumed to be square, but again, this is only to simplify notation.

Definition 20.1:

For $M \in \mathbf{C}^{n \times n}$, $\mu_\Delta(M)$ is defined

$$\mu_\Delta(M) := \frac{1}{\min \{ \bar{\sigma}(\Delta) : \Delta \in \Delta, \det(I - M\Delta) = 0 \}} \quad (20.3)$$

unless no $\Delta \in \Delta$ makes $I - M\Delta$ singular, in which case $\mu_\Delta(M) := 0$.

It is instructive to consider a “feedback” interpretation of $\mu_\Delta(M)$ at this point. Let $M \in \mathbf{C}^{n \times n}$ be given, and consider the loop shown in Figure 20.6. This picture represents the loop equations $u = Mv, v = \Delta u$. As long as $I - M\Delta$ is nonsingular, the only solutions of u, v to the loop equations are $u = v = 0$. However, if $I - M\Delta$ is singular, then there are infinitely many solutions to the equations, and the norms $\|u\|, \|v\|$ of the solutions can be arbitrarily large. Motivated by connections with stability of systems, we call this

FIGURE 20.6 $M - \Delta$ interconnection.

constant matrix feedback system “unstable”. Likewise, the term “stable” will describe the situation when the only solutions are identically zero. In this context then, $\mu_{\Delta}(M)$ provides a measure of the smallest structured Δ that causes “instability” of the constant matrix feedback loop in Figure 20.6. The norm of this “destabilizing” Δ is exactly $1/\mu_{\Delta}(M)$.

Consider $M \in \mathbf{C}^{5 \times 4}$,

$$M := \begin{bmatrix} 0.100 + 0.070i & -0.154 + 0.162i & 0 - 0.560i & 0 + 42.000i \\ 0 - 0.273i & -0.300 - 0.280i & 2.860 + 0.546i & -26.000 + 72.800i \\ 0.100 + 0.175i & 0.077 - 0.108i & -0.400 + 0.210i & 5.000 + 3.500i \\ 0 + 0.002i & -0.004 - 0.002i & 0.006 + 0.011i & 0.200 + 0.420i \\ 0.024 + 0.028i & 0 + 0.027i & -0.066 + 0.042i & 0 + 0.700i \end{bmatrix} \quad (20.4)$$

to show the dependence of $\mu_{\Delta}(M)$ on the set Δ . Two different block structures compatible (in the sense of dimensions) with M are

$$\Delta_1 = \{\text{diag} [\delta_1, \delta_2, \Delta_3] : \delta_1, \delta_2 \in \mathbf{C}, \Delta_3 \in \mathbf{C}^{2 \times 3}\}, \quad \text{and} \quad \Delta_2 = \{\text{diag} [\delta_1, \delta_2, \delta_3, \Delta_4] : \delta_i \in \mathbf{C}, \Delta_4 \in \mathbf{C}^{1 \times 2}\}.$$

The definition yields $\mu_{\Delta_1}(M) \approx 8.32$, while $\mu_{\Delta_2}(M) \approx 2.42$.

An alternative expression for $\mu_{\Delta}(M)$ follows easily from the definition.

Lemma 20.1:

$$\mu_{\Delta}(M) = \max_{\Delta \in \mathbf{B}_{\Delta}} \rho(\Delta M)$$

Continuity of the function $\mu: \mathbf{C}^{n \times n} \rightarrow \mathbf{R}$ is apparent from this lemma. In general, though, the function $\mu: \mathbf{C}^{n \times n} \rightarrow \mathbf{R}$ is not a norm, because it doesn't satisfy the triangle inequality. However, for any $\alpha \in \mathbf{C}$, $\mu(\alpha M) = |\alpha| \mu(M)$, so it is related to how “big” the matrix is.

We can relate $\mu_{\Delta}(M)$ to familiar linear algebra quantities when Δ is one of two extreme sets:

- If $\Delta = \{\delta I : \delta \in \mathbf{C}\}$ ($S=1, F=0, r_1=n$), then $\mu_{\Delta}(M) = \rho(M)$.
Proof: The only Δ 's in Δ which satisfy the $\det(I - M\Delta) = 0$ constraint are reciprocals of nonzero eigenvalues of M . The smallest one of these is associated with the largest (magnitude) eigenvalue, so, $\mu_{\Delta}(M) = \rho(M)$.
- If $\Delta = \mathbf{C}^{n \times n}$ ($S=0, F=1, m_1=n$), then $\mu_{\Delta}(M) = \bar{\sigma}(M)$.
Proof: If $\bar{\sigma}(\Delta) < \frac{1}{\bar{\sigma}(M)}$, then $\bar{\sigma}(M\Delta) < 1$, so $I - M\Delta$ is nonsingular. Applying Equation 20.3 implies $\mu_{\Delta}(M) \leq \bar{\sigma}(M)$. On the other hand, let u and v be unit vectors satisfying $Mv = \bar{\sigma}(M)u$, and define $\Delta := \frac{1}{\bar{\sigma}(M)}vu^*$. Then $\bar{\sigma}(\Delta) = 1/\bar{\sigma}(M)$ and $I - M\Delta$ is obviously singular. Hence, $\mu_{\Delta}(M) \geq \bar{\sigma}(M)$.

Obviously, for a general Δ as in Equation 20.2, $\{\delta I_n : \delta \in \mathbf{C}\}$ must be included in $\Delta \subset \mathbf{C}^{n \times n}$. Hence directly from the definition of μ , and the two special cases above, we conclude that

$$\rho(M) \leq \mu_{\Delta}(M) \leq \bar{\sigma}(M). \quad (20.5)$$

These bounds by themselves may provide little information about the value of μ , because the gap between ρ and $\bar{\sigma}$ can be large. To see this, consider the matrix

$$M = \begin{bmatrix} 0 & \alpha \\ 0 & 0 \end{bmatrix}$$

and two different block structures, $\Delta_1 := \{\delta I_2 : \delta \in \mathbf{C}\}$ and $\Delta_2 := \{\Delta \in \mathbf{C}^{2 \times 2}\}$. μ with respect to Δ_1 , which corresponds to $\rho(M)$, is 0, independent of α . μ with respect to Δ_2 , which corresponds to $\bar{\sigma}(M)$, is $|\alpha|$.

The bounds on μ can be refined with transformations on M that do not affect $\mu_\Delta(M)$, but do affect ρ and $\bar{\sigma}$. To do this, define two subsets, \mathbf{Q}_Δ and \mathbf{D}_Δ of $\mathbf{C}^{n \times n}$,

$$\mathbf{Q}_\Delta = \{Q \in \Delta : Q^*Q = I_n\} \quad (20.6)$$

$$\mathbf{D}_\Delta = \{\text{diag}[D_1, \dots, D_S, d_{S+1}I_{m_1}, \dots, d_{S+F}I_{m_F}]: D_i \in \mathbf{C}^{r_i \times r_i}, D_i = D_i^* > 0, d_{S+j} \in \mathbf{R}, d_{S+j} > 0\} \quad (20.7)$$

For any $\Delta \in \Delta$, $Q \in \mathbf{Q}_\Delta$, and $D \in \mathbf{D}_\Delta$,

$$Q^* \in \mathbf{Q}_\Delta, \quad Q\Delta \in \Delta, \quad \Delta Q \in \Delta \quad \bar{\sigma}(Q\Delta) = \bar{\sigma}(\Delta Q) = \bar{\sigma}(\Delta) \quad (20.8)$$

$$D^{\frac{1}{2}}\Delta = \Delta D^{\frac{1}{2}} \quad (20.9)$$

Theorem 20.1:

For all $Q \in \mathbf{Q}_\Delta$ and $D \in \mathbf{D}_\Delta$

$$\mu_\Delta(MQ) = \mu_\Delta(QM) = \mu_\Delta(M) = \mu_\Delta\left(D^{\frac{1}{2}}MD^{-\frac{1}{2}}\right) \quad (20.10)$$

Proof 20.1. For all $D \in \mathbf{D}_\Delta$ and $\Delta \in \Delta$,

$$\begin{aligned} \det(I - M\Delta) &= \det\left(I - MD^{-\frac{1}{2}}D^{\frac{1}{2}}\Delta\right) \\ &= \det\left(I - MD^{-\frac{1}{2}}\Delta D^{\frac{1}{2}}\right) \\ &= \det\left(D^{-\frac{1}{2}}D^{\frac{1}{2}} - D^{-\frac{1}{2}}MD^{-\frac{1}{2}}\Delta\right) \\ &= \det\left(I - D^{\frac{1}{2}}MD^{-\frac{1}{2}}\Delta\right) \end{aligned}$$

because D commutes with Δ . Therefore $\mu_\Delta(M) = \mu_\Delta\left(D^{\frac{1}{2}}MD^{-\frac{1}{2}}\right)$. Also, for each $Q \in \mathbf{Q}_\Delta$, $\det(I - M\Delta) = 0$ if and only if $\det(I - MQQ^*\Delta) = 0$. Because $Q^*\Delta = \Delta$ and $\bar{\sigma}(Q^*\Delta) = \bar{\sigma}(\Delta)$, $\mu_\Delta(MQ) = \mu_\Delta(M)$ as desired. The argument for QM is the same.

Therefore, the bounds in Equation 20.5 can be tightened to

$$\begin{aligned} \max_{Q \in \mathbf{Q}} \rho(QM) &\leq \max_{\Delta \in \mathbf{B}_\Delta} \rho(\Delta M) \\ &= \mu_\Delta(M) \leq \inf_{D \in \mathbf{D}} \bar{\sigma}\left(D^{\frac{1}{2}}MD^{-\frac{1}{2}}\right) \end{aligned} \quad (20.11)$$

where the equality comes from Lemma 20.1.

The lower bound, $\max_{Q \in \mathbf{Q}} \rho(QM)$, is always an equality [5]. Unfortunately, the quantity $\rho(QM)$ can have multiple local maxima which are not global. Thus local search cannot be guaranteed to obtain μ , but can only yield a lower bound. The upper bound can be reformulated as a convex optimization problem, so that the global minimum can, in principle, be found. Unfortunately, the upper bound is not always equal to μ . For block structures Δ satisfying $2S + F \leq 3$, the upper bound is always equal to $\mu_\Delta(M)$, and for block structures with $2S + F > 3$, matrices exist for which μ is less than the infimum [5,9].

Convexity properties make the upper bound computationally attractive. The simplest convexity property is given in the following theorem, which shows that the function $\bar{\sigma}\left(D^{\frac{1}{2}}MD^{-\frac{1}{2}}\right)$ has convex level sets.

Theorem 20.2:

Let $M \in \mathbf{C}^{n \times n}$ be given, along with a scaling set \mathbf{D}_Δ , and $\beta > 0$. Then the set $\left\{D \in \mathbf{D}_\Delta : \bar{\sigma}\left(D^{\frac{1}{2}}MD^{-\frac{1}{2}}\right) < \beta\right\}$ is convex.

Proof 20.2. The following chain of equivalences comprises the proof:

$$\begin{aligned} \bar{\sigma}\left(D^{\frac{1}{2}}MD^{-\frac{1}{2}}\right) < \beta &\Leftrightarrow \lambda_{\max}\left(D^{-\frac{1}{2}}M^*D^{\frac{1}{2}}D^{\frac{1}{2}}MD^{-\frac{1}{2}}\right) < \beta^2 \\ &\Leftrightarrow D^{-\frac{1}{2}}M^*D^{\frac{1}{2}}D^{\frac{1}{2}}MD^{-\frac{1}{2}} - \beta^2 I < 0 \\ &\Leftrightarrow M^*DM - \beta^2 D < 0 \end{aligned} \quad (20.12)$$

The latter is clearly a convex condition in D because it is linear.

The final condition in Equation 20.12 is called a *Linear Matrix Inequality* (LMI) in the variable D . In [3], a large number of control synthesis and analysis problems are cast as solutions of LMI's.

20.3.2 Mixed μ : Real and Complex Uncertainty

Until this point, this section has dealt with complex-valued perturbation sets. In specific instances, it may be more natural to describe modeling errors with real perturbations, for instance, when the real coefficients of a linear differential equation are uncertain. Although these perturbations can be treated simply as complex, proceeding with a complex μ analysis, the results may be conservative. Hence, theory and algorithms to test for robustness and performance degradation with mixed (real blocks and complex blocks) perturbation have been developed.

Definition 20.1 of μ can be used for more general sets Δ , such as those containing real and complex blocks. There are 3 types of blocks, *repeated real scalar*, *repeated complex scalar*, and *complex full* blocks. As before in Section 20.3, S and F , denote the number of *repeated*, *complex scalar* blocks and the number of *complex full* blocks, respectively. V denotes the number of *repeated*, *real scalar* blocks. The block dimensions of the real block are denoted by the positive integers t_1, \dots, t_V . With these integers given, and r_i and m_j as defined in Section 20.3, define Δ as

$$\begin{aligned} \Delta = \left\{ \text{diag} \left[\delta_1^r I_{t_1}, \dots, \delta_V^r I_{t_V}, \delta_{V+1}^c I_{r_1}, \dots, \delta_{V+S}^c I_{r_S}, \Delta_{V+S+1}, \dots, \Delta_{V+S+F} \right] : \right. \\ \left. \delta_k^r \in \mathbf{R}, \delta_{V+i}^c \in \mathbf{C}, \Delta_{V+S+j} \in \mathbf{C}^{m_j \times m_j}, 1 \leq k \leq V, 1 \leq i \leq S, 1 \leq j \leq F \right\}. \end{aligned} \quad (20.13)$$

For consistency among all the dimensions, $\sum_{k=1}^V t_k + \sum_{i=1}^S r_i + \sum_{j=1}^F m_j$ must equal $= n$.

The mixed μ function inherits many of the properties of the purely complex μ function, [5,7]. However, in some aspects such as continuity, the mixed μ problem can be fundamentally different from the complex μ problem. It is now well-known that real μ problems can be discontinuous in the problem data. Beside adding computational difficulties to the problem, the utility of real μ is doubtful as a robustness measure in such cases, the system model is always a mathematical abstraction from the real world, computed to finite precision. It has been shown that, for many *mixed* μ problems, μ is continuous. The main idea is that, *if a mixed μ problem has complex uncertainty blocks that “count,” then the function is continuous.* From an engineering viewpoint, “count” implies that the complex uncertainty affects the value of μ . This is

the usual case because one is usually interested in robust performance problems (which therefore contain at least one complex block – see Section 20.5.2), or robust stability problems with some unmodeled dynamics, which are naturally covered with complex uncertainty. Purely real problems can be made continuous by adding a small amount of complex uncertainty to each real uncertainty (see [1] for an example). Consequently, a small amount of phase uncertainty is added to the gain uncertainty.

The theory for bounding (both lower and upper) mixed real/complex bounds is much more complicated to describe than the bounding theory for complex μ . The lower bound for the mixed case is a real eigenvalue maximization problem. Techniques to solve approximately for a mixed μ lower bound using power algorithms have been derived, and are similar to those used for a lower bound for complex μ [15]. The mixed μ upper bound takes the form of a more complicated version of the same problem, involving an additional “G scaling matrix” which scales only the real uncertainty blocks. This minimization, involving an LMI expression similar to Equation 20.12, is computed using convex optimization techniques similar to those for the purely complex upper bound. See references [7,15] for more computational details.

20.3.3 Frequency Domain, Robust Stability Tests with μ

The best-known use of μ as a robustness analysis tool is in the frequency domain [5,14]. Suppose $\hat{G}(s)$ is a stable, multi-input, multioutput transfer function of a linear system. For clarity, assume \hat{G} has n_z inputs and n_w outputs. Let Δ be a block structure, as in Equation 20.2, and assume that the dimensions are such that $\Delta \subset \mathbb{C}^{n_z \times n_w}$. We want to consider feedback perturbations to \hat{G} , themselves dynamical systems, with the block-diagonal structure of the set Δ , in Figure 20.7.

Let \mathbf{S} denote the set of real-rational, proper, stable, transfer matrices (of appropriate dimensions, which should be clear from context). Associated with any block structure Δ , let \mathbf{S}_Δ denote the set of all block diagonal, stable rational transfer functions, with diagonal block structure as in Δ .

$$\mathbf{S}_\Delta := \{ \Delta \in \mathbf{S} : \Delta(s_o) \in \Delta \text{ for all } s_o \in \bar{\mathbf{C}}_+ \}.$$

Theorem 20.3:

Let $\beta > 0$. The loop in Figure 20.7 is well-posed and internally stable for all $\Delta \in \mathbf{S}_\Delta$ with $\|\Delta\|_\infty < \frac{1}{\beta}$, where $\|\Delta(s)\|_\infty := \max_{\omega \in \mathcal{R}} \bar{\sigma}(\Delta(j\omega))$ if, and only if,

$$\|G\|_\Delta := \sup_{\omega \in \mathbf{R}} \mu_\Delta(\hat{G}(j\omega)) \leq \beta$$

In summary, the peak value on the μ plot of the frequency response of the known linear system that the perturbation “sees” determines the size of perturbations against which the loop is robustly stable.

FIGURE 20.7 $\hat{G} - \Delta$ feedback loop block diagram.

Remark 20.1

If the peak occurs at $\omega = 0$, there are systems G where the theorem statement needs to be modified to be correct. In particular, it may be impossible to do what the theorem statement implies, that is, construct a real-rational perturbation $\Delta \in \mathbf{S}_\Delta$ with $\|\Delta\|_\infty = (\|G\|_\Delta)^{-1}$ and $(I - G\Delta)^{-1}$ unstable. Rather, for any $\epsilon > 0$, there will be a real-rational perturbation $\Delta \in \mathbf{S}_\Delta$ with $\|\Delta\|_\infty = (\|G\|_\Delta)^{-1} + \epsilon$ and $(I - G\Delta)^{-1}$ unstable. These facts can be ascertained from results in [9,10].

The overall implication of this modification can be viewed in two opposite ways. If the theorem is used for actual robustness analysis, the original viewpoint that $(\|G\|_\Delta)^{-1}$ is the size of the smallest real-rational perturbation causing instability is certainly the “right” mental model to use, because the small correction that may be needed is arbitrarily small, and hence of little engineering relevance. On the other hand, if Theorem 20.3 is being used to prove another theorem, then one needs to be very careful.

In the next section, the linear algebra results which extend μ from a robust stability tool to a robust performance tool are covered. These linear algebra results are then applied to give a frequency-domain robust performance test in Section 20.5.2.

20.4 Linear Fractional Transformations and μ

The use of μ in control theory depends to a great extent on its intimate relationship with a class of general linear feedback loops called *Linear Fractional Transformations* (LFTs) [11]. This section explores this relationship with some simple theorems that can be obtained almost immediately from the definition of μ . To introduce these, consider a complex matrix M partitioned as

$$M = \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} \tag{20.14}$$

and suppose that there is a defined block structure Δ_1 compatible in size with M_{11} (for any $\Delta_1 \in \Delta_1$, $M_{11}\Delta_1$ is square). For $\Delta_1 \in \Delta_1$, consider the loop equations

$$z = M_{11}w + M_{12}d; \quad e = M_{21}w + M_{22}d; \quad w = \Delta_1 z \tag{20.15}$$

which correspond to the block diagram in Figure 20.8 (note the similarity to Figure 20.5 in Section 20.2).

The set of Equations 20.15 is called *well posed* if, for any vector d , unique vectors w , z , and e exist satisfying the loop equations. The set of equations is well-posed if, and only if, the inverse of $I - M_{11}\Delta_1$ exists. If not, then depending on d and M , there is either no solution to the loop equations, or there are an infinite number of solutions. When the inverse does exist, the vectors e and d must satisfy $e = F_u(M, \Delta_1)d$, where

$$F_u(M, \Delta_1) := M_{22} + M_{21}\Delta_1(I - M_{11}\Delta_1)^{-1}M_{12}. \tag{20.16}$$

$F_u(M, \Delta_1)$ is called a Linear Fractional Transformation on M by Δ_1 and, in a feedback diagram, appears as in Figure 20.8. $F_u(M, \Delta_1)$ denotes that the “upper” loop of M is closed by Δ_1 . An analogous formula

FIGURE 20.8 Linear fractional transformation.

describes $F_l(M, \Delta_2)$ which is the resulting matrix obtained by closing the “lower” loop of M with a matrix $\Delta_2 \in \Delta_2$.

In this formulation, the matrix M_{22} is assumed to be something nominal, and $\Delta_1 \in \mathbf{B}_{\Delta_1}$ is viewed as a norm-bounded perturbation from an allowable perturbation class, Δ_1 . The matrices M_{12} , M_{21} , and M_{22} and the formula $F_u(M, \Delta_1)$ reflect prior knowledge showing how the unknown perturbation affects the nominal map, M_{22} . This type of uncertainty, called *linear fractional*, is natural for many control problems and encompasses many other special cases considered by researchers.

20.4.1 Well-Posedness and Performance for Constant LFTs

Let M be a complex matrix partitioned as

$$M = \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} \quad (20.17)$$

and suppose that there are two defined block structures, Δ_1 and Δ_2 , compatible in size with M_{11} and M_{22} respectively. Define a third structure Δ as

$$\Delta = \left\{ \begin{bmatrix} \Delta_1 & 0 \\ 0 & \Delta_2 \end{bmatrix} : \Delta_1 \in \Delta_1, \Delta_2 \in \Delta_2 \right\}. \quad (20.18)$$

Now there are three structures for which we may compute μ . The notation we use to keep track of this is as follows: $\mu_1(\cdot)$ is with respect to Δ_1 , $\mu_2(\cdot)$ is with respect to Δ_2 , $\mu_\Delta(\cdot)$ is with respect to Δ . In view of this, $\mu_1(M_{11})$, $\mu_2(M_{22})$ and $\mu_\Delta(M)$ all make sense, though, for instance, $\mu_1(M)$ does not. For notation, let $\mathbf{B}_1 := \{\Delta_1 \in \Delta_1 : \bar{\sigma}(\Delta_1) \leq 1\}$.

Clearly, the linear fractional transformation $F_u(M, \Delta_1)$ is well-posed for all $\Delta_1 \in \mathbf{B}_{\Delta_1}$ if, and only if, $\mu_1(M_{11}) < 1$. As the “perturbation” Δ_1 deviates from zero, the matrix $F_u(M, \Delta_1)$ deviates from M_{22} . The range of values for $\mu_2(F_u(M, \Delta_1))$ is intimately related to $\mu_\Delta(M)$, as follows:

Theorem 20.4: Main Loop Theorem

The following are equivalent:

$$\mu_\Delta(M) < 1 \quad \iff \quad \begin{cases} \mu_1(M_{11}) < 1, \text{ and} \\ \max_{\Delta_1 \in \mathbf{B}_1} \mu_2(F_u(M, \Delta_1)) < 1 \end{cases}$$

Proof 20.3. The proof of this theorem is based on the definition of μ and Schur formulae for determinants of block partitioned matrices as in [9]. The Main Loop Theorem forms the basis for all uses of μ in linear system robustness analysis, whether from a state-space, frequency-domain, or Lyapunov approach.

20.5 Robust Performance Tests Using μ and Main Loop Theorem

Often, stability is not the only property of a closed-loop system that must be robust to perturbations. Typically there are exogenous disturbances acting on the system (wind gusts, sensor noise) which result in tracking and regulation errors. Under perturbation, the effect of these disturbances on error signals can greatly increase. In most cases, long before the onset of instability, the closed-loop performance will be unacceptably degraded. Hence the need for a “robust performance” test to indicate the worst-case level of performance degradation for a given level of perturbations.

20.5.1 Characterization of Performance in μ Setting

Within the structured singular value setting, the most natural (mathematical) way to characterize acceptable performance is in terms of MIMO $\|\cdot\|_\infty$ (\mathcal{H}_∞) norms, discussed in detail in other Chapters (29 and 40) of this Handbook. In this section, we quickly review the \mathcal{H}_∞ norm, and interpretations.

Suppose T is a MIMO stable linear system, with transfer function matrix $T(s)$. For a given driving signal $\tilde{d}(t)$, define \tilde{e} as the output, as in the left-hand diagram of Figure 20.9.

Assume that the dimensions of T are $n_e \times n_d$. Let $\beta > 0$ be defined as

$$\beta := \|T\|_\infty := \max_{\omega \in \mathbf{R}} \bar{\sigma} [T(j\omega)]. \tag{20.19}$$

A time-domain, sinusoidal, steady-state interpretation of this quantity is as follows:

Fact: For any frequency $\bar{\omega} \in \mathbf{R}$, any vector of amplitudes $a \in \mathbf{R}_{n_d}$, and any vector of phases $\phi \in \mathbf{R}^{n_d}$, with $\|a\|_2 \leq 1$, define a time signal

$$\tilde{d}(t) = \begin{bmatrix} a_1 \sin(\bar{\omega}t + \phi_1) \\ \vdots \\ a_{n_d} \sin(\bar{\omega}t + \phi_{n_d}) \end{bmatrix}.$$

Apply this input to the system T , resulting in a steady-state response \tilde{e}_{ss} of the form

$$\tilde{e}_{ss}(t) = \begin{bmatrix} b_1 \sin(\bar{\omega}t + \psi_1) \\ \vdots \\ b_{n_e} \sin(\bar{\omega}t + \psi_{n_e}) \end{bmatrix}.$$

The vector $b \in \mathbf{R}^{n_e}$ will satisfy $\|b\|_2 \leq \beta$. Moreover, β , as defined in Equation 20.19, is the smallest number for which this fact is true for every $\|a\|_2 \leq 1$, $\bar{\omega}$, and ϕ .

Multivariable performance objectives are represented by a single, MIMO $\|\cdot\|_\infty$ objective on a closed-loop transfer function. Because many objectives are being lumped into one matrix and the associated cost is the norm of the matrix, it is important to use frequency-dependent weighting functions, so that different requirements can be meaningfully combined into a single cost function.

In the weighting function selection, diagonal weights are most easily interpreted. Consider the right-hand diagram of Figure 20.9. Assume that W_L and W_R are diagonal, stable transfer function matrices, with diagonal entries denoted L_i and R_i . Bounds on the quantity $\|W_L T W_R\|_\infty$ will imply bounds about the sinusoidal steady-state behavior of the signals \tilde{d} and $\tilde{e}(= T\tilde{d})$. Specifically, for sinusoidal signal \tilde{d} ,

FIGURE 20.9 Unweighted and weighted MIMO systems.

the steady-state relationship between $\tilde{e}(= T\tilde{d})$, \tilde{d} and $\|W_L TW_R\|_\infty$ follows. The steady-state solution \tilde{e}_{ss} , denoted as

$$\tilde{e}_{ss}(t) = \begin{bmatrix} \tilde{e}_1 \sin(\bar{\omega}t + \psi_1) \\ \vdots \\ \tilde{e}_{n_e} \sin(\bar{\omega}t + \psi_{n_e}) \end{bmatrix},$$

satisfies $\sum_{i=1}^{n_e} |L_i(j\bar{\omega})\tilde{e}_i|^2 \leq 1$ for all sinusoidal input signals \tilde{d} of the form,

$$\tilde{d}(t) = \begin{bmatrix} \tilde{d}_1 \sin(\bar{\omega}t + \phi_1) \\ \vdots \\ \tilde{d}_{n_d} \sin(\bar{\omega}t + \phi_{n_d}) \end{bmatrix},$$

satisfying

$$\sum_{i=1}^{n_d} \frac{|\tilde{d}_i|^2}{|R_i(j\bar{\omega})|^2} \leq 1$$

if, and only if, $\|W_L TW_R\|_\infty \leq 1$.

20.5.2 Frequency-Domain Robust Performance Tests

Recall from Section 20.3.1, that if Δ is a single full complex block, then the function μ_Δ is simply the maximum singular value function. We can use this fact, along with the Main Loop Theorem (Theorem 20.4) and the \mathcal{H}_∞ notion of performance, to obtain the central robust performance theorem for perturbed transfer functions.

Assume G is a stable linear system, with real-rational, proper transfer function \hat{G} . The dimension of G is $n_z + n_d$ inputs and $n_w + n_e$ outputs. Partition G in the obvious manner, so that G_{11} has n_z inputs and n_w outputs, and so on. Let $\Delta \subset \mathbb{C}^{n_w \times n_z}$ be a block structure, as in Equation 20.2. For $\Delta \in \mathbf{S}_\Delta$, consider the behavior of the perturbed system in Figure 20.10.

Define an augmented block structure

$$\Delta_P := \left\{ \begin{bmatrix} \Delta & 0 \\ 0 & \Delta_F \end{bmatrix} : \Delta \in \Delta, \Delta_F \in \mathbb{C}^{n_d \times n_e} \right\}.$$

Δ_F corresponds to the Δ_2 block of the Main Loop Theorem. It is used to compute bounds on $\bar{\sigma}(\cdot)$ of the perturbed transfer function $F_u(\hat{G}, \Delta)$ as Δ takes on values in \mathbf{S}_Δ .

FIGURE 20.10 Robust performance LFT.

Theorem 20.5:

Let $\beta > 0$. For all $\Delta \in \mathbf{S}_\Delta$ with $\|\Delta\|_\infty < \frac{1}{\beta}$, the perturbed system in Figure 20.10 is well-posed, internally stable, and $\|F_u(\hat{G}, \Delta)\|_\infty \leq \beta$ if, and only if,

$$\|G\|_{\Delta_p} := \sup_{\omega \in \mathbf{R}} \mu_{\Delta_p}(\hat{G}(j\omega)) \leq \beta.$$

See [14] for details of the proof. The robust performance theorem provides a test to determine if the performance of the system $F_u(\hat{G}, \Delta)$ remains acceptable for all possible norm-bounded perturbations.

20.5.3 Robust Performance Example

It is instructive to carry out these steps on a simple example. Here, we analyze the robust stability of a simple single-loop feedback regulation system with two uncertainties. The plant is a lightly-damped, nominal two-state system with uncertainty in the (2, 1) entry of the A matrix (the frequency-squared coefficient) and unmodeled dynamics (in the form of multiplicative uncertainty) at the control input. The overall block diagram of the uncertain closed-loop system is shown in Figure 20.11.

The two-state system with uncertainty in the A matrix is represented as an upper linear fractional transformation about a two-input, two-output, two-state system H , whose realization is

$$A = \begin{bmatrix} 0 & 1 \\ -16 & -0.16 \end{bmatrix}, \quad B = \begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 6.4 & 0 \\ 16 & 0 \end{bmatrix}, \quad \text{and} \quad D = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

The resulting second order system takes the form

$$F_u(H, \delta_1) = \frac{16}{s^2 + 0.16s + 16(1 + 0.4\delta_1)}$$

If we assume that δ_1 is unknown, but satisfies $|\delta_1| \leq 1$, then we interpret the second-order system to have 40% uncertainty in the denominator entry of the natural frequency-squared coefficient.

The plant is also assumed to have unmodeled dynamics at the input. This could arise from an unmodeled, or unreliable, actuator, for instance. The uncertainty is assumed to be about 20% at low frequency, rising to 100% at 6.5 rad/s. We model it using the multiplicative uncertainty model, using a first-order weight, $W_u = (6.5s + 8)/(s + 42)$. In the block diagram, this is represented with the simple linear fractional transformation involving δ_2 .

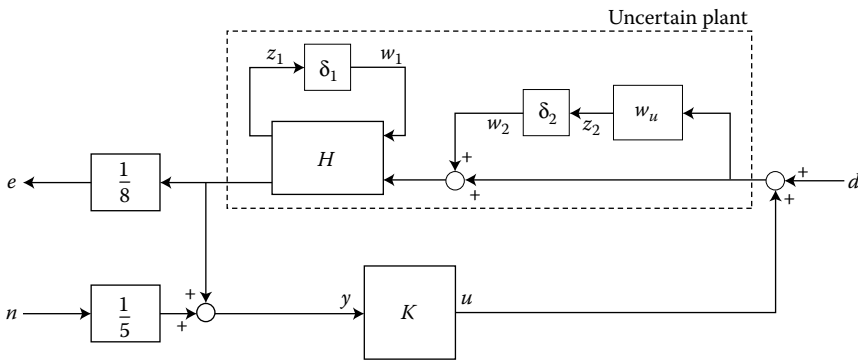

FIGURE 20.11 Robust stability/performance example.

The closed-loop performance objective is $\|T\|_\infty \leq 1$, where T is the transfer function from input disturbance d and sensor noise n to the output error e ,

$$e = T \begin{bmatrix} d \\ n \end{bmatrix} = [T_1 \ T_2] \begin{bmatrix} d \\ n \end{bmatrix}$$

Note that the closed-loop T is a function of both δ_1 and δ_2 . The scalar blocks which weight the error and the noise are used to normalize the two transfer functions that make up T . Finally, for comparison, the open-loop system has $\|T_1\|_\infty \approx 6$, and $\|T_2\|_\infty = 0$.

For this example, the controller is chosen as

$$K = \frac{-12.56s^2 + 17.32s + 67.28}{s^3 + 20.37s^2 + 136.74s + 179.46}$$

Finally, $G(s)$ in Figure 20.12 denotes the closed-loop transfer function matrix from Figure 20.11. The dimensions of G are two states, four inputs and three outputs.

In terms of G , we have

$$T = F_u \left(G, \begin{bmatrix} \delta_1 & 0 \\ 0 & \delta_2 \end{bmatrix} \right)$$

Hence, using Theorems 20.3 and 20.5, the robust stability and robust performance of the closed-loop system can be ascertained by appropriate structured singular value calculations on G (or particular subblocks of G). In the next section, we analyze the robust stability and robust performance of the closed-loop system for a variety of assumptions on the uncertain elements, δ_1 and δ_2 .

20.5.3.1 Analysis

For notational purposes, partition $G(s)$ into

$$G = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \tag{20.20}$$

where $G_{11}(s)$ is 2×2 , and $G_{22}(s)$ is 2×1 . The first two inputs and outputs of G are associated with the perturbation structure and the third and fourth inputs and third output correspond to an exogenous multivariable disturbance signal, and associated error. For robust stability calculations we are only interested in the submatrix G_{11} , and for robust performance calculations the entire matrix G .

Robust stability calculations are performed with respect to two different block structures:

$$\Delta_1 := \{ \text{diag} [\delta_1, \delta_2] : \delta_1, \delta_2 \in \mathbf{C} \},$$

$$\Delta_2 := \{ \text{diag} [\delta_1, \delta_2] : \delta_1 \in \mathbf{R}, \delta_2 \in \mathbf{C} \}$$

For robust performance calculations, a 2×1 full block is appended to Δ_i for the performance calculation, yielding $\Delta_P \subset \mathbf{C}^{4 \times 3}$. The two block structures used to evaluate robust performance are:

$$\Delta_{P_1} := \{ \text{diag} [\delta_1, \delta_2, \Delta_F] : \delta_1, \delta_2 \in \mathbf{C}, \Delta_F \in \mathbf{C}^{2 \times 1} \},$$

$$\Delta_{P_2} := \{ \text{diag} [\delta_1, \delta_2, \Delta_F] : \delta_1 \in \mathbf{R}, \delta_2 \in \mathbf{C}, \Delta_F \in \mathbf{C}^{2 \times 1} \}$$

FIGURE 20.12 Closed-loop interconnection.

All the upper and lower bounds μ calculations are performed using the μ *Analysis and Synthesis Toolbox* [2].

20.5.3.2 Robust Stability

The robustness of the closed-loop system with respect to linear, complex time-invariant structured perturbations, Δ_1 , is a μ test on $G_{11}(j\omega)$. The complex, robust stability bounds from the μ calculation are shown in Figure 20.13 (Note that the upper and lower bounds are identical.). The peak μ value is about 1.29, hence for any $\Delta(s) \in \mathbf{S}_{\Delta_1}$ stability is preserved as long as $\|\Delta(s)\|_\infty < \frac{1}{1.29}$, and there is a perturbation $\Delta_{\text{dest}}(s)$, of the correct structure, with $\|\Delta_{\text{dest}}\|_\infty = \frac{1}{1.29}$ that does cause instability.

The nominal performance of this system is defined by the \mathcal{H}_∞ norm of the transfer function G_{22} is $\|G_{22}\|_\infty = 0.22$. The maximum singular value of G_{22} is plotted across frequency in Figure 20.14. The robustness and performance measures were originally scaled to be less than 1 when they were achieved. Therefore, the system *is not* robustly stabilized with respect to linear, time-invariant structured complex perturbations of size 1, but it achieves the performance objective on the nominal system.

Recall that the first uncertainty, δ_1 , corresponds to uncertainty in the $A(2, 1)$ coefficient and the second uncertainty, δ_2 , corresponds to input multiplicative modeling error. The $A(2, 1)$ coefficient uncertainty can be treated as a real uncertainty. This would imply that the magnitude $A(2, 1)$ varies between 9.6 and 22.4. In the initial robust stability analysis, both of these uncertainties were modeled as complex perturbations, a potentially more conservative representation of the uncertainty. Let us re-analyze the system with respect to Δ_2 where δ_1 is treated as a real perturbation.

We can analyze the robust stability of the system with respect to one of the uncertainties being real and the other uncertainty complex. This is shown in the mixed robust stability plot shown in Figure 20.13. Notice that when the $A(2, 1)$ uncertainty is treated as a real perturbation, and the input multiplicative uncertainty is complex, the mixed robust stability μ value is reduced from 1.29 to 0.84. Hence the

FIGURE 20.13 Complex robust stability (solid) and mixed robust stability (dashed) plots.

FIGURE 20.14 Nominal performance plot.

system *is* robustly stabilized with respect to real uncertainty in the A(2,1) coefficient and complex input multiplicative uncertainty. In this example, it is very conservative to treat the variation in the coefficient, A(2, 1), as a complex uncertainty.

20.5.3.3 Robust Performance

The closed-loop system under perturbations becomes $F_u(G, \Delta)$. To analyze the degradation of performance due to the uncertainty, we use Theorem 20.5, and the augmented block structure Δ_{p_1} . The plot in Figure 20.15 of $\mu_{\Delta_{p_1}}(G(j\omega))$ is shown. The peak is approximately at 1.41. Applying Theorem 20.5 implies that for any structured $\Delta(s) \in \mathbf{S}_{\Delta_{p_1}}$ with $\|\Delta(s)\|_\infty < \frac{1}{1.41}$, the perturbed loop remains stable *and*, the $\|\cdot\|_\infty$ norm of $F_u(G, \Delta)$ is guaranteed to be ≤ 1.41 . Also, the converse of the theorem shows that there is a perturbation Δ , whose $\|\cdot\|_\infty$ is arbitrarily close to $\frac{1}{1.41}$ that causes $\|F_u(\Delta, \hat{G})\|_\infty > 1.41$. Therefore robust performance was not achieved.

Figure 20.15 also shows the results of a mixed μ analysis on $G(j\omega)$ with respect to Δ_{p_2} . The peak value of μ is 0.99. This implies that for a real perturbation δ_1 and a finite dimensional, linear time-invariant complex perturbation $\delta_2(s)$, stability is preserved and the performance objective achieved. Therefore the robust performance objective is achieved when the frequency-squared coefficient is treated as a real perturbation and the input multiplicative uncertainty is treated as a complex perturbation.

20.6 Spinning Satellite: Robust Performance Analysis with μ

Consider the 4×4 transfer function M shown (along with its with internal structure) in Figure 20.2. The perturbations δ_1 and δ_2 enter as shown in Figure 20.3. The appropriate block structure for the robust performance assessment of this example is $\{\text{diag}(\delta_1, \delta_2, \Delta_F) : \delta_i \in \mathbf{C}, \Delta_F \in \mathbf{C}^{2 \times 2}\}$. This implies that there

FIGURE 20.15 Complex (solid) and mixed (dashed) robust performance plots.

is independent uncertainty in each of the actuators but that the rest of the model is accurate. Computing the structured singular value of $\mu_{\Delta}(M)$ across frequency yields a peak of about 11. This implies that a diagonal perturbation $diag[\delta_1, \delta_2]$ of size $1/11$ exists so that the perturbed reference-to-error transfer function has a singular value peak of approximately 11. This μ analysis clearly detects the poor robust performance characteristics of the closed-loop system. In the next section, we turn our attention to design techniques which use the structured singular value as a design objective.

20.7 Control Design via μ Synthesis

Consider the standard linear fractional description of the control problem shown in Figure 20.16. The P block represents the open-loop interconnection and contains all of the known elements including the nominal plant model, uncertainty structure, and performance and uncertainty weighting functions. The Δ_{pert} block represents the structured set of norm-bounded uncertainty being considered and K represents the controller. Δ_{pert} parameterizes all of the assumed model uncertainty in the problem. Three groups of inputs enter P , perturbations z , disturbances d , and controls u , and three groups of outputs are generated, perturbations w , errors e , and measurements y . The set of systems to be controlled is described by the LFT

$$\{F_u(\Delta_{pert}, P) : \Delta_{pert} \in \mathbf{S}_{\Delta_{pert}}\}.$$

The design objective is to find a stabilizing controller K , so that, for all $\Delta_{pert} \in \mathbf{S}_{\Delta_{pert}}$, $\|\Delta_{pert}\|_{\infty} \leq 1$, the closed-loop system is stable and satisfies

$$\|F_u[F_l(P, K), \Delta_{pert}]\|_{\infty} \leq 1.$$

FIGURE 20.16 Linear fractional transformation description of control problem.

The performance objective involves a robust performance test on the linear fractional transformation $F_l(P, K)$. To assess the robust performance of the closed-loop system, define an augmented perturbation structure, Δ ,

$$\Delta = \left\{ \begin{bmatrix} \Delta_{pert} & 0 \\ 0 & \Delta_F \end{bmatrix} : \Delta_{pert} \in \Delta_{pert}, \Delta_F \in \mathbf{C}^{n_d \times n_e} \right\}.$$

The goal of μ synthesis is to minimize overall stabilizing controllers K , the peak value of $\mu_\Delta(\cdot)$ of the closed-loop transfer function $F_l(P, K)$. More formally,

$$\min_{\substack{K \\ \text{stabilizing}}} \max_{\omega} \mu_\Delta [F_l(P, K)(j\omega)] \tag{20.21}$$

For tractability of the μ synthesis problem, $\mu_\Delta[\cdot]$ is replaced by the upper bound for μ , $\bar{\sigma} [D(\cdot)D^{-1}]$. The scaling matrix D is a member of the appropriate set of scaling matrices \mathbf{D} for the perturbation set Δ . One can reformulate this optimization problem as follows:

$$\min_{\substack{K \\ \text{stabilizing}}} \max_{\omega} \min_{D_\omega \in \mathbf{D}} \bar{\sigma} [D_\omega F_l(P, K)(j\omega) D_\omega^{-1}]. \tag{20.22}$$

Here, the D minimization is an approximation to the $\mu_\Delta [F_l(P, K)(j\omega)]$. D_ω is chosen from the set of scalings, \mathbf{D} , independently at every ω . Hence,

$$\min_{\substack{K \\ \text{stabilizing}}} \min_{\substack{D(\cdot) \\ D_\omega \in \mathbf{D}}} \max_{\omega} \bar{\sigma} [D_\omega F_l(P, K)(j\omega) D_\omega^{-1}]. \tag{20.23}$$

The expression $\max_{\omega} \bar{\sigma} [\cdot]$ corresponds to $\|[\cdot]\|_\infty$, leaving

$$\min_{\substack{K \\ \text{stabilizing}}} \min_{D(\cdot) \in \mathbf{D}} \| [D_\omega F_l(P, K)(j\omega) D_\omega^{-1}] \|_\infty. \tag{20.24}$$

Assume, for simplicity, that the uncertainty block Δ_{pert} has only full blocks. Then the set \mathbf{D}_Δ is of the form

$$\mathbf{D} = \{ \text{diag} [d_1 I, d_2 I, \dots, d_{F-1} I, I] : d_i > 0 \}. \tag{20.25}$$

For any complex matrix M , the elements of \mathbf{D}_Δ , which were originally defined as real and positive, can take on any nonzero complex values and without changing the value of the upper bound, $\inf_{D \in \mathbf{D}} \bar{\sigma} (DMD^{-1})$.

Hence, we can restrict the scaling matrix to be a real-rational, stable, minimum-phase transfer function, $\hat{D}(s)$. The optimization is now

$$\min_{\substack{K \\ \text{stabilizing}}} \min_{\substack{\hat{D}(s) \in \mathbf{D} \\ \text{stable, min-phase}}} \|\hat{D}F_l(P, K)\hat{D}^{-1}\|_{\infty}. \quad (20.26)$$

This approximation to μ synthesis, is currently “solved” by an iterative approach, referred to as “ $D - K$ iteration.”

To solve Equation 20.26, first consider holding $\hat{D}(s)$ fixed. Given a stable, minimum-phase, real-rational $\hat{D}(s)$, solve the optimization $\min_{\substack{K \\ \text{stabilizing}}} \|\hat{D}F_l(P, K)\hat{D}^{-1}\|_{\infty}$. This equation is an \mathcal{H}_{∞} optimization control problem. The solution to the \mathcal{H}_{∞} problem is well-known, consisting of solving algebraic Riccati equations in terms of the state-space system.

Now suppose that a stabilizing controller, $K(s)$, is given, we then solve the following minimization corresponding to the upper bound for μ .

$$\min_{D_{\omega} \in \mathbf{D}} \bar{\sigma} [D_{\omega}F_l(P, K)(j\omega)D_{\omega}^{-1}]$$

This minimization is done over the real, positive D_{ω} from the set \mathbf{D}_{Δ} defined in Equation 20.25. Recall that the addition of phase to each d_i does not affect the value of $\bar{\sigma} [D_{\omega}F_l(P, K)(j\omega)D_{\omega}^{-1}]$. Hence, each discrete function, d_i , of frequency is fit (in magnitude) by a proper, stable, minimum-phase transfer function, $\hat{d}_{R_i}(s)$. These are collected together in a diagonal transfer function matrix $\hat{D}(s)$,

$$\hat{D}(s) = \text{diag} [\hat{d}_{R_1}(s)I, \hat{d}_{R_2}(s)I, \dots, \hat{d}_{R_{F-1}}(s)I, I],$$

and absorbed into the original open-loop generalized plant P . Iterating on these two steps comprises the current approach to $D - K$ iteration.

There are several problems with the $D - K$ iteration control design procedure. The first is that we have approximated $\mu_{\Delta}(\cdot)$ by its upper bound. This is not serious because the value of μ and its upper bound are often close. The most serious problem, that the $D - K$ iteration does not always converge to a global, or even, local minimum, [14] is a more severe limitation of the design procedure. However, in practice the $D - K$ iteration control design technique has been successfully applied to many engineering problems such as vibration suppression for flexible structures, flight control, chemical process control problems, and acoustic reverberation suppression in enclosures.

20.8 F-14 Lateral-Directional Control System Design

Consider the design of a lateral-directional axis controller for the F-14 aircraft during powered approach to landing. The linearized F-14 model is found at an angle-of-attack (α) of 10.5 *degs* and airspeed of 140 *knots*. The problem is posed as a robust performance problem with multiplicative plant uncertainty at the plant input and minimization of weighted-output transfer functions as the performance criterion. A diagram for the closed-loop system, which includes the feedback structure of the plant and controller and elements associated with the uncertainty models and performance objectives, is shown in Figure 20.17.

The overall performance objective is to have the “true” airplane, represented by the dashed box in Figure 20.17, respond effectively to the pilot’s lateral stick and rudder pedal inputs. The performance objective includes

1. Decoupled response of the lateral stick, δ_{lstk} , to roll rate, p , and rudder pedals, δ_{rudp} , to side-slip angle, β . The lateral stick and rudder pedals have a maximum deflection of ± 1 *inch*. Therefore they are represented as unweighted signals in Figure 20.17.

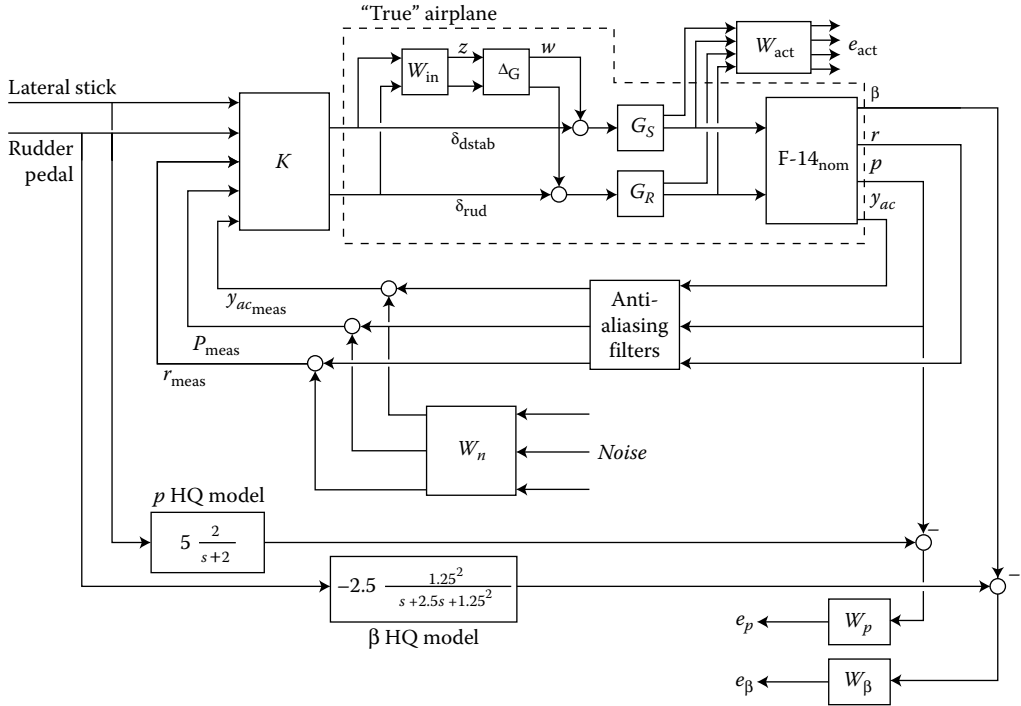

FIGURE 20.17 F-14 control block diagram.

2. The aircraft handling quality (HQ) response from the lateral stick to roll rate should be a first-order system, $5(2)/(s+2) \frac{degs/s}{inch}$. The aircraft handling quality response from the rudder pedals to side-slip angle should be $-2.5 \frac{1.25^2}{s^2+2.5s+1.25^2} \frac{degs/s}{inch}$.
3. The stabilizer actuators have $\pm 20^\circ$ and $\pm 90^\circ/s$ deflection and deflection rate limits. The rudder actuators have $\pm 30^\circ$ and $\pm 125^\circ/s$ deflection and deflection rate limits.
4. The three measurement signals, roll rate, yaw rate and lateral acceleration, are passed through second-order antialiasing filters prior to being fed to the controller. The natural frequency and damping values for the yaw rate and lateral acceleration filters are 12.5Hz and 0.5, respectively and 4.1Hz and 0.7 for the roll rate filter. The antialiasing filters have unity gain at DC (see Figure 20.17). These signals are also corrupted by noise.

The performance objectives are accounted for in this framework via minimizing weight transfer function norms. Weighting functions serve two purposes in the \mathcal{H}_∞ and μ framework: they allow the direct comparison of different performance objectives with the same norm and they allow incorporating frequency information into the analysis. The F-14 performance weighting functions include:

1. Limits on the actuator deflection magnitude and rates are included via the W_{act} weight. W_{act} is a 4×4 constant, diagonal scaling matrix described by $W_{act} = \text{diag}(1/90, 1/20, 1/125, 1/30)$. These weights correspond to the stabilizer and rudder deflection rate and deflection limits.
2. W_n is a 3×3 diagonal, frequency varying weight used to model the magnitude of the sensor noise. $W_n = \text{diag}(0.025, 0.025, 0.0125 \frac{s+1}{s+100})$ which corresponds to the noise levels in the roll rate, yaw rate and lateral acceleration channels.
3. The desired δ_{lstk} -to- p and δ_{rudp} -to- β responses of the aircraft are formulated as a model matching problem in the μ framework. The difference between the ideal response of the transfer functions, δ_{lstk} filtered through the roll rate HQ model and δ_{rudp} filtered through the side-slip angle HQ

model, and the aircraft response, p and β , is used to generate an error that is to be minimized. The W_p transfer function, see Figure 20.17, weights the difference between the idealized roll rate response and the actual aircraft response, p .

$$W_p = \frac{0.05s^4 + 2.90s^3 + 105.93s^2 + 6.17s + 0.16}{s^4 + 9.19s^3 + 30.80s^2 + 18.33s + 3.95}$$

The magnitude of W_p emphasizes the frequency range between 0.06 and 30 rad/s. The desired performance frequency range is limited due to a right half-plane zero in the model at 0.002 rad/s, therefore, accurate tracking of sinusoids below 0.002 rad/s isn't required. Between 0.06 and 30 rad/s, a roll rate tracking error of less than 5% is desired. The performance weight on the β tracking error, W_β , is just $2 \times W_p$. This also corresponds to a 5% tracking error objective.

All the weighted performance objectives are scaled for an \mathcal{H}_∞ less than 1 when they are achieved. The performance of the closed-loop system is evaluated by calculating the maximum singular value of the weighted transfer functions from the disturbance and command inputs to the error outputs, as in Figure 20.18.

20.8.1 Nominal Model and Uncertainty Models

The pilot has the ability to command the lateral directional response of the aircraft with the lateral stick (δ_{lstk}) and rudder pedals (δ_{rped}). The aircraft has two control inputs, differential stabilizer deflection (δ_{dstab} , *degs*) and rudder deflection (δ_{rud} , *degs*), three measured outputs, roll rate (p , *degs/s*), yaw rate (r , *degs/s*) and lateral acceleration (y_{ac} , g^s), and a calculated output side-slip angle (β). Note that β is not a measured variable but is used as a performance measure. The lateral directional F-14 model, F-14_{nom}, has four states, lateral velocity (v), yaw rate (r), roll rate (p) and roll angle (ϕ). These variables are related by the state-space equations

$$\begin{bmatrix} \dot{v} \\ \dot{r} \\ \dot{p} \\ \dot{\phi} \\ \beta \\ p \\ r \\ y_{ac} \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} v \\ r \\ p \\ \phi \\ \delta_{dstab} \\ \delta_{drud} \end{bmatrix}$$

$$A = \begin{bmatrix} -1.16e-1 & -2.27e+2 & 4.30e+1 & 3.16e+1 \\ 2.65e-3 & -2.59e-1 & -1.45e-1 & 0.00e+0 \\ -2.11e-2 & 6.70e-1 & -1.36e+0 & 0.00e+0 \\ 0.00e+0 & 1.85e-1 & 1.00e+0 & 0.00e+0 \end{bmatrix}, B = \begin{bmatrix} 6.22e-02 & 1.01e-1 \\ -5.25e-03 & -1.12e-2 \\ -4.67e-02 & 3.64e-3 \\ 0.00e+00 & 0.00e+0 \end{bmatrix},$$

$$C = \begin{bmatrix} 2.47e-1 & 0.00e+0 & 0.00e+0 & 0.00e+0 \\ 0.00e+0 & 0.00e+0 & 5.73e+1 & 0.00e+0 \\ 0.00e+0 & 5.73e+1 & 0.00e+0 & 0.00e+0 \\ -2.83e-3 & -7.88e-3 & 5.11e-2 & 0.00e+0 \end{bmatrix}, D = \begin{bmatrix} 0.00e+00 & 0.00e+0 \\ 0.00e+00 & 0.00e+0 \\ 0.00e+00 & 0.00e+0 \\ 2.89e-03 & 2.27e-3 \end{bmatrix},$$

FIGURE 20.18 F-14 weighted performance objectives transfer matrix.

The dashed box represents the “true” airplane, corresponding to a set of F-14 plant models define by \mathcal{G} . Inside the box is the nominal model of the airplane dynamics, F-14_{nom}, models of the actuators, G_S and G_R , and two elements, W_{in} and Δ_G , which parameterize the uncertainty in the model. This type of uncertainty is called multiplicative plant input uncertainty. The transfer function W_{in} is assumed known and reflects the amount of uncertainty in the model. The transfer function Δ_G is assumed stable and unknown, except for the norm condition, $\|\Delta_G\|_\infty \leq 1$.

A “first principles” set of uncertainties in the aircraft model would include

1. Uncertainty in the stabilizers and the rudder actuators. The electrical signals that command deflections in these surfaces must be converted to actual mechanical deflections by the electronics and hydraulics of the actuators. Unlike the models, this is not done perfectly in the actual system.
2. Uncertainty in the forces and moments generated on the aircraft, due to specific deflections of the stabilizers and rudder. As a first approximation, this arises from the uncertainties in the aerodynamic coefficients, which vary with flight conditions, as well as uncertainty in the exact geometry of the airplane.
3. Uncertainty in the linear and angular accelerations produced by the aerodynamically generated forces and moments. This arises from the uncertainty in the various inertial parameters of the airplane, in addition to neglected dynamics, such as fuel slosh and airframe flexibility.
4. Other forms of uncertainty that are less well understood.

In this example, we choose not to model the uncertainty in this detailed manner but rather to lump all of these effects together into one, complex full-block, multiplicative uncertainty at the input of the rigid body aircraft nominal model.

The stabilizer and rudder actuators, G_S and G_R , are modeled as first order transfer functions, $25/(s + 25)$. Given the actuator and aircraft nominal models (denoted by $G_{nom}(s)$), we also specify a stable, 2×2 transfer function matrix $W_{in}(s)$ called the uncertainty weight. These transfer matrices parameterize an entire set of plants, \mathcal{G} , which must be suitably controlled by the robust controller K .

$$\mathcal{G} := \{G_{nom} (I + \Delta_G W_{del}) : \Delta_G \text{ stable}, \|\Delta_G\|_\infty \leq 1\}.$$

All of the uncertainty in modeling the airplane is captured in the normalized, unknown transfer function Δ_G . The unknown transfer function $\Delta_G(s)$ is used to parameterize the potential differences between the nominal model $G_{nom}(s)$, and the actual behavior of the real airplane, denoted by \mathcal{G} .

In this example, the uncertainty weight W_{in} is of the form, $W_{in}(s) := \text{diag}(w_1(s), w_2(s))I_2$, for particular scalar valued functions $w_1(s)$ and $w_2(s)$. The $w_1(s)$ weight associated with the differential stabilizer input is selected to be $w_1(s) = \frac{2(s+4)}{s+160}$. The $w_2(s)$ weight associated with the differential rudder input is selected to be $w_2(s) = \frac{1.5(s+20)}{s+200}$. Hence the set of plants that are represented by this uncertainty weight

$$\mathcal{G} := \left\{ \text{F-14}_{nom} \begin{bmatrix} \frac{25}{s+25} & 0 \\ 0 & \frac{25}{s+25} \end{bmatrix} \left(I_2 + \begin{bmatrix} \frac{2(s+4)}{s+100} & 0 \\ 0 & \frac{1.5(s+20)}{s+200} \end{bmatrix} \Delta_G(s) \right) : \Delta_G(s) \text{ stable}, \|\Delta_G\|_\infty \leq 1 \right\}$$

Note that the weighting functions are used to normalize the size of the unknown perturbation Δ_G . At any frequency ω , the value of $|w_1(j\omega)|$ and $|w_2(j\omega)|$ can be interpreted as the percentage of uncertainty in the model at that frequency. The dependence of the uncertainty weight on frequency indicates that the level of uncertainty in the airplane’s behavior depends on frequency.

The particular uncertainty weights chosen imply that, in the differential stabilizer channel at low frequency, there is potentially a 5% modeling error, and at a frequency of 93 rad/s, the uncertainty in channel 1 can be as much as 100%, and can get larger at higher frequencies. The rudder channel has more uncertainty at low frequency, up to 15% modeling error, and at a frequency of 177 rad/s, the uncertainty is at 100%. To illustrate the variety of plants represented by the set \mathcal{G} , some step responses of different systems from \mathcal{G} are shown in Figure 20.19.

FIGURE 20.19 Unit-step responses of the nominal model (+) and 15 perturbed models from \mathcal{G} .

The control design objective is a stabilizing controller K so that for all stable perturbations $\Delta_G(s)$, with $\|\Delta_G\|_\infty \leq 1$, the perturbed closed-loop system remains stable, and the perturbed weighted performance transfer functions has an \mathcal{H}_∞ norm less than 1 for all such perturbations. These mathematical objectives fit exactly into the structured singular value framework.

20.8.2 Controller Design

The control design block diagram shown in Figure 20.17 is redrawn as $P(s)$, shown in Figure 20.20. $P(s)$, the 25-state, six-input, six-output open-loop transfer matrix, corresponds to the P in the linear fractional block diagram in Figure 20.16.

FIGURE 20.20 F-14 generalized plant.

TABLE 20.1 F-14 $D - K$ iteration information

Iteration number	1	2	3	4
Total D -scale order	0	4	4	4
Controller order	25	29	29	29
\mathcal{H}_∞ norm achieved	1.562	1.079	1.025	1.017
Peak μ value	1.443	1.079	1.025	1.017

The first step in the $D - K$ iteration control design procedure is to design an \mathcal{H}_∞ (sub)optimal controller for the open-loop interconnection, P . In terms of the $D - K$ iteration, this amounts to holding the d variable fixed (at 1) and minimizing the $\|\cdot\|_\infty$ norm of $F_l(P, K)$ over the controller variable K . The resulting controller is labeled K_1 .

The second step in the $D - K$ iteration involves solving a μ analysis problem corresponding to the closed-loop system, $F_l(P, K_1)$. This calculation produces a frequency dependent scaling variable d_ω , the (1,1) entry in the scaling matrix. In a general problem (with more than two blocks), there would be several d variables, and the overall matrix is referred to as “the D -scales.” The varying variables in the D -scales are fit (in magnitude) with proper, stable, minimum-phase rational functions and absorbed into the generalized plant for additional iterations. These scalings are used to “trick” the \mathcal{H}_∞ minimization to concentrate more on minimizing μ rather than $\bar{\sigma}$ across frequency. For the first iteration in this example, the d scale data is fit with a first-order transfer function.

The new generalized plant used in the second iteration has 29 states, four more states than the original 25-state generalized plant, P . These extra states are due to the D -scale data being fitted with a rational function and absorbed into the generalized plant for the next iteration. Four $D - K$ iterations are performed until μ reaches a value of 1.02. Information about the $D - K$ iterations is shown in Table 20.1. All the analysis and synthesis results were obtained with *The μ Analysis and Synthesis Toolbox, Version 2.0* [2].

FIGURE 20.21 F-14 robust performance μ plots with K_1 and K_4 implemented.

20.8.2.1 Analysis of the Controllers

The robust performance properties of the controllers can be analyzed using μ analysis. Robust performance is achieved if, and only if, for every frequency, $\mu_{\Delta}(F_l(P, K)(j\omega))$ of the closed-loop frequency response is less than 1. Plots of μ of the closed-loop system with K_1 and K_4 implemented are shown in Figure 20.21.

The controlled system with K_1 implemented *does not* achieve robust performance. This conclusion follows from the μ plot, which peaks to a value of 1.44, at a frequency of 7 rad/s. Because μ is 1.44, there is a perturbation matrix Δ_G , so that $\|\Delta_G\|_{\infty} = \frac{1}{1.44}$, and the perturbed weighted performance transfer functions gets “large.” After four $D - K$ iterations the peak robust performance μ value is reduced to 1.02 (Figure 20.21), thereby, nearly achieving all of our robust performance objectives.

Illustrating the robustness of the closed-loop system in the time domain, time responses of the ideal model, the nominal closed-loop system and the “worst-case” closed-loop system from \mathcal{G} (using perturbations of size 1) are shown in Figure 20.22. Controller K_4 is implemented in the closed-loop simulations.

FIGURE 20.22 Time response plots of the F-14 lateral directional control system.

A 1-inch lateral stick command is given at 9 s, held at 1 inch until 12 s, and then returns to zero. The rudder is commanded at 1 s with a positive 1 inch pedal deflection and held at 1 inch until 4 s. At 4 s a -1 -inch pedal deflection is commanded, held to 7 s, and then returned to zero. One can see from the time responses that the closed-loop response is nearly identical for the nominal closed-loop system and the “worst-case” closed-loop system. The ideal time response for β and p are plot for reference.

20.9 Conclusion

This chapter outlined the usefulness of the structured singular value (μ) analysis and synthesis techniques in designing and analyzing multiloop feedback control systems. Through examples, we have shown some pitfalls with simple-minded analytical techniques, and illustrated the usefulness of the analytic framework provided by the structured singular value. We outlined an approach to robust controller synthesis, the $D - K$ iteration. As an example, these techniques were applied to the design of a lateral directional control system for the F-14 aircraft.

21.1 Introduction

One of the features of modern control theory is the growing presence of algebra. Algebraic formalism offers several useful tools for control system design, including the so-called “factorization” approach.

This approach is based on the input–output properties of linear systems. The central idea is that of “factoring” the transfer matrix of a (not necessarily stable) system as the “ratio” of two *stable* transfer matrices. This is a natural step for the linear systems whose transfer matrices are rational, that is, for the lumped-parameter systems. Under certain conditions, however, this approach is productive also for the distributed-parameter systems.

The starting point of the factorization approach is to obtain a simple parameterization of *all* controllers that stabilize a given plant. One could then, in principle, choose the best controller for various applications. The key point here is that the parameter appears in the closed-loop system transfer matrix in a linear manner, thus making it easier to meet additional design specifications.

The actual design of control systems is an engineering task that cannot be reduced to algebra. Design contains many additional aspects that have to be taken into account: sensor placement, computational constraints, actuator constraints, redundancy, performance robustness, among many others. There is a need for an understanding of the control process, a feeling for what kinds of performance objectives are unrealistic, or even dangerous, to ask for. The algebraic approach to be presented, nevertheless, is an elegant and useful tool for the mathematical part of the controller design.

21.2 Systems and Signals

The fundamentals of the factorization approach will be explained for linear systems with *rational* transfer functions whose input u and output y are scalar quantities. We suppose that u and y live in a space of functions mapping a time set into a value set. The time set is a subset of real numbers bounded on the left, say R_+ (the nonnegative reals) in the case of continuous-time systems and Z_+ (the nonnegative integers) for discrete-time systems. The value set is taken to be the set of real numbers R .

Let the input and output spaces of a continuous-time system be the spaces of locally (Lebesgue) integrable functions f from R_+ into R , and define a p -norm

$$\|f\|_{L_p} = \left[\int_0^{\infty} |f(t)|^p dt \right]^{1/p} \quad \text{if } 1 \leq p < \infty,$$

$$\|f\|_{L_\infty} = \text{ess sup}_{t \geq 0} |f(t)| \quad \text{if } p = \infty.$$

The corresponding normed space is denoted by L_p .

The systems having the desirable property of preserving these functional spaces are called *stable*. More precisely, a system is said to be L_p stable if any input $u \in L_p$ gives rise to an output $y \in L_p$. The systems that are L_∞ stable are also termed to be bounded-input bounded-output (BIBO) stable.

The transfer function of a continuous-time system is the Laplace transform of its impulse response $g(t)$,

$$G(s) = \int_0^{\infty} g(t)e^{-st} dt.$$

It is well known that a system with a rational transfer function $G(s)$ is BIBO stable if and only if $G(s)$ is proper and Hurwitz stable, that is, bounded at infinity with all poles having negative real parts.

In the study of discrete-time systems, we let the input and output spaces be the spaces of infinite sequences $f = (f_0, f_1, \dots)$ mapping Z_+ into R and define a p -norm as follows:

$$\|f\|_p = \left[\sum_{i=0}^{\infty} |f_i|^p \right]^{1/p} \quad \text{if } 1 \leq p < \infty,$$

$$\|f\|_{l_\infty} = \sup_{i \geq 0} |f_i| \quad \text{if } p = \infty.$$

A discrete-time system is said to be l_p stable if it transforms any input $u \in l_p$ to an output $y \in l_p$. The systems that are l_∞ stable are also known as BIBO stable systems.

The transfer function of a discrete-time system is defined as the z -transform of its unit pulse response (h_0, h_1, \dots) ,

$$H(z) = \sum_{i=0}^{\infty} h_i z^{-i},$$

and it is always proper. A system with a proper rational transfer function $H(z)$ is BIBO stable if and only if $H(z)$ is Schur stable, that is, its all poles have modulus less than one.

Of particular interest are discrete-time systems that are finite-input finite-output (FIFO) stable. Such a system transforms finite-input sequences into finite-output sequences, its unit pulse response is finite, and its transfer function $H(z)$ has no poles outside the origin $z = 0$, that is, $H(z)$ is a polynomial in z^{-1} .

21.3 Fractional Descriptions

Consider a rational function $G(s)$. By definition, it can be expressed as the ratio

$$G(s) = \frac{B(s)}{A(s)}$$

of two qualified rational functions A and B .

A well-known example is the *polynomial* description, in which case A and B are coprime polynomials, that is, polynomials having no roots in common.

Another example is to take for A and B two coprime, *proper* and *Hurwitz-stable* rational functions. When $G(s)$ is, say,

$$G(s) = \frac{s+1}{s^2+1},$$

then one can take

$$A(s) = \frac{s^2+1}{(s+\lambda)^2}, \quad B(s) = \frac{s+1}{(s+\lambda)^2},$$

where $\lambda > 0$ is a real number. We recall that two proper and Hurwitz-stable rational functions are coprime if they have no infinite nor unstable zeros in common. Therefore, in the example above, the denominator of A and B can be any strictly Hurwitz polynomial of degree exactly 2; if its degree is lower, then A would not be proper and if it is higher, then A and B would have a common zero at infinity. The set of proper and Hurwitz-stable rational functions is denoted by $R_H(s)$.

The proper rational functions $H(z)$ arising in discrete-time systems can be treated in a similar manner. One can write

$$H(z) = \frac{B(z)}{A(z)},$$

where A and B are coprime, *Schur-stable* (hence proper) rational functions. Coprimeness means having no unstable zeros (i.e., in the closed disc $|z| \geq 1$) in common. For example, if

$$H(z) = \frac{1}{z-1},$$

then one can take

$$A(z) = \frac{z-1}{z-\lambda}, \quad B(z) = \frac{1}{z-\lambda}$$

for any real number λ such that $|\lambda| < 1$. The set of Schur-stable rational functions is denoted by $R_S(z)$.

The particular choice of $\lambda=0$ in the example above leads to

$$A(z) = \frac{z-1}{z} = 1 - z^{-1}, \quad B(z) = \frac{1}{z} = z^{-1}.$$

In this case, A and B are in fact polynomials in z^{-1} .

21.4 Feedback Systems

To control a system means to alter its dynamics so that a desired behavior is obtained. This can be done by feedback. A typical feedback system consists of two subsystems, S_1 and S_2 , connected, as shown in Figure 21.1.

In most applications, it is desirable that the feedback system be BIBO stable in the sense that whenever the exogenous inputs u_1 and u_2 are bounded in magnitude, so too are the output signals y_1 and y_2 .

FIGURE 21.1 Feedback system.

In order to study this property, we express the transfer functions of S_1 and S_2 as ratios of proper stable rational functions and seek for conditions under which the transfer function of the feedback system is proper and stable.

To fix ideas, consider continuous-time systems and write

$$S_1 = \frac{B(s)}{A(s)}, \quad S_2 = -\frac{Y(s)}{X(s)},$$

where A , B and X , Y are two couples of coprime rational functions from $R_H(s)$. The transfer matrix of the feedback system

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} \frac{S_1}{1 - S_1 S_2} & \frac{S_1 S_2}{1 - S_1 S_2} \\ \frac{S_1 S_2}{1 - S_1 S_2} & \frac{S_2}{1 - S_1 S_2} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

is then given by

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \frac{1}{AX + BY} \begin{bmatrix} BX & -BY \\ -BY & -AY \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}.$$

We observe that the numerator matrix has all its elements in $R_H(s)$ and that no infinite or unstable zeros of the denominator can be absorbed in all these elements. We therefore conclude that the transfer functions belong to $R_H(s)$ if and only if the inverse of $AX + BY$ is in $R_H(s)$.

We illustrate with the example where S_1 is a differentiator and S_2 is an inverter such that

$$S_1(s) = s, \quad S_2(s) = -1.$$

We take

$$A(s) = \frac{1}{s + \lambda}, \quad B(s) = \frac{s}{s + \lambda}$$

for any real $\lambda > 0$ and

$$X(s) = 1, \quad Y(s) = 1.$$

Then

$$(AX + BY)^{-1}(s) = \frac{s + \lambda}{s + 1}$$

resides in $R_H(s)$ and hence the feedback system is BIBO stable.

The above analysis applies also to discrete-time systems; the set $R_H(s)$ is just replaced by $R_S(z)$. However, we note that any closed loop around a discrete-time system involves some information delay, no matter how small. Indeed, a control action applied to S_1 cannot affect the measurement from which it was calculated in S_2 . Therefore, either $S_1(z)$ or $S_2(z)$ must be strictly proper; we shall assume that it is $S_1(z)$ that has this property.

To illustrate the analysis of discrete-time systems, consider a summator S_1 and an amplifier S_2 ,

$$S_1(z) = \frac{1}{z-1}, \quad S_2(z) = -k.$$

Taking

$$A(z) = \frac{z-1}{z-\lambda}, \quad B(z) = \frac{1}{z-\lambda}$$

for any real λ in magnitude less than 1 and

$$X(z) = 1, \quad Y(z) = k,$$

one obtains

$$(AX + BY)^{-1}(z) = \frac{z-\lambda}{z-(1-k)}.$$

Therefore, the closed-loop system is BIBO stable if and only if $|1-k| < 1$.

To summarize, the fractional representation used should be matched with the goal of the analysis. The denominators A , X and the numerators B , Y should be taken from the set of stable transfer functions, either $R_H(s)$ or $R_S(z)$, depending on the type of the stability studied. This choice makes the analysis more transparent and leads to a simple algebraic condition: the inverse of $AX + BY$ is stable. Any other type of stability can be handled in the same way, provided one can identify the set of the transfer functions that these stable systems will have.

21.5 Parameterization of Stabilizing Controllers

The design of feedback control systems consists of the following: given one subsystem, say S_1 , we seek to determine the other subsystem, S_2 , so that the resulting feedback system shown in Figure 21.1 meets the design specifications. We call S_1 the *plant* and S_2 the *controller*. Our focus is first on achieving BIBO stability. Any controller S_2 that BIBO stabilizes the plant S_1 is called a *stabilizing* controller for this plant.

Suppose S_1 is a continuous-time plant that gives rise to the transfer function

$$S_1(s) = \frac{B(s)}{A(s)}$$

for some coprime elements A and B of $R_H(s)$. It follows from the foregoing analysis that a stabilizing controller exists and that all controllers that stabilize the given plant are generated by all solution pairs X , Y with $X \neq 0$ of the Bézout equation

$$AX + BY = 1$$

over $R_H(s)$. There is no loss of generality in setting $AX + BY$ to the identity rather than to any rational function whose inverse is in $R_H(s)$: this inverse is absorbed by X and Y and therefore cancels in forming

$$S_2(s) = -\frac{Y(s)}{X(s)}.$$

The solution set of the equation $AX + BY = 1$ with A and B coprimes in $R_H(s)$ can be parameterized as

$$X = X' + BW, \quad Y = Y' - AW,$$

where X' , Y' represent a particular solution of the equation, and W is a free parameter, which is an arbitrary function in $R_H(s)$.

The parameterization of the family of all stabilizing controllers S_2 for the plant S_1 now falls out almost routinely:

$$S_2(s) = -\frac{Y'(s) - A(s)W(s)}{X'(s) + B(s)W(s)},$$

where the parameter W varies over $R_H(s)$ while satisfying $X' + BW \neq 0$.

In order to determine the set of all controllers S_2 that stabilize the plant S_1 , one needs to do two things: (1) express $S_1(s)$ as a ratio of two coprime elements from $R_H(s)$ and (2) find a particular solution in $R_H(s)$ of a Bézout equation, which is equivalent to finding one stabilizing controller for S_1 . Once these two steps are completed, the formula above provides a parameterization of the set of all stabilizing controllers for S_1 . The condition $X' + BW \neq 0$ is not very restrictive, as $X' + BW$ can identically vanish for at most one choice of W .

As an example, we shall stabilize an integrator plant S_1 . Its transfer function can be expressed as

$$S_1(s) = \frac{1/s + 1}{s/s + 1},$$

where $s + 1$ is an arbitrarily chosen Hurwitz polynomial of degree one. Suppose that using some design procedure we have found a stabilizing controller for S_1 , namely

$$S_2(s) = -1.$$

This corresponds to a particular solution $X' = 1$, $Y' = 1$ of the Bézout equation

$$\frac{s}{s+1}X + \frac{1}{s+1}Y = 1.$$

The solution set in $R_H(s)$ of this equation is

$$X(s) = 1 + \frac{1}{s+1}W(s), \quad Y(s) = 1 - \frac{s}{s+1}W(s).$$

Hence, all controllers S_2 that BIBO stabilize S_1 have the transfer function

$$S_2(s) = -\frac{1 - (s/s + 1)W(s)}{1 + (1/s + 1)W(s)},$$

where W is any function in $R_H(s)$.

It is clear that the result is independent of the particular fraction taken to represent S_1 . Indeed, if $s + 1$ is replaced by another Hurwitz polynomial $s + \lambda$ in the above example, one obtains

$$S_2(s) = -\frac{\lambda - (s/s + \lambda)W'(s)}{1 + (1/s + \lambda)W'(s)},$$

which is the same set when

$$W'(s) = \left(\frac{s + \lambda}{s + 1}\right)^2 W(s) + \frac{s + \lambda}{s + 1}(\lambda - 1).$$

21.6 Parameterization of Closed-Loop Transfer Functions

The utility of the fractional approach derives not merely from the fact that it provides a parameterization of all controllers that stabilize a given plant in terms of a free parameter W , but also from the simple manner in which this parameter enters the resulting (stable) closed-loop transfer matrix.

In fact,

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} B(X' + BW) & -B(Y' - AW) \\ -B(Y' - AW) & -A(Y' - AW) \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix},$$

and we observe that all four transfer functions are *affine* in the free parameter W .

This result serves to parameterize the performance specifications, and it is the starting point for the selection of the best controller for the application at hand. The search for S_2 is thus replaced by a search for W . The crucial point is that the resulting selection/optimization problem is linear in W , whereas it is nonlinear in S_2 .

21.7 Optimal Performance

The performance specifications often involve a norm minimization.

Let us consider the problem of *disturbance attenuation*. We are given, say, a continuous-time plant S_1 having two inputs: the control input u and an unmeasurable disturbance d (see Figure 21.2). The objective is to determine a BIBO stabilizing controller S_2 for the plant S_1 such that the effect of d on the plant output y is minimized in some sense.

We describe the plant by two transfer functions

$$S_{1u}(s) = \frac{B(s)}{A(s)}, \quad S_{1d}(s) = \frac{C(s)}{A(s)},$$

where A , B , and C is a triple of coprime functions from $R_H(s)$. The set of stabilizing controllers for S_1 is given by the transfer function

$$S_2(s) = -\frac{Y'(s) - A'(s)W(s)}{X'(s) + B'(s)W(s)},$$

where A' , B' represent a *coprime* fraction over $R_H(s)$ for S_{1u} ,

$$\frac{B(s)}{A(s)} = \frac{B'(s)}{A'(s)}$$

and X' , Y' represent a particular solution over $R_H(s)$ of the equation

$$A'X + B'Y = 1,$$

such that $X' + B'W \neq 0$.

The transfer function, $G(s)$, between d and y in a stable feedback system is

$$G = \frac{S_{1d}}{1 - S_{1u}S_2} = C(X' + B'W)$$

and it is affine in the proper and Hurwitz-stable rational parameter W .

FIGURE 21.2 Disturbance attenuation.

Now suppose that the disturbance d is any function from L_∞ , that is, any essentially bounded real function on R_+ . Then

$$\|y\|_{L_\infty} \leq \|G\|_1 \|d\|_{L_\infty},$$

where

$$\|G\|_1 = \int_0^\infty |g(t)| dt$$

and $g(t)$ is the impulse response corresponding to $G(s)$. The parameter W can be used to minimize the norm $\|G\|_1$ and hence the maximum output amplitude.

If d is a stationary white noise, the steady-state output variance equals

$$Ey^2 = \|G\|_2^2 Ed^2,$$

where

$$\|G\|_2^2 = \int_0^\infty |g(t)|^2 dt = \frac{1}{2\pi j} \oint G(-s)G(s) ds.$$

The last integral is a contour integral up the imaginary axis and then around an infinite semicircle in the left half-plane. Again, W can be selected so as to minimize the norm $\|G\|_2$, thus minimizing the steady-state output variance.

Finally, suppose that d is any function from L_2 , that is, any finite-energy real function on R_+ . Then one obtains

$$\|y\|_{L_2} \leq \|G\|_\infty \|d\|_{L_2},$$

where

$$\|G\|_\infty = \sup_{\text{Re } s > 0} |G(s)|.$$

Therefore, choosing W to make the norm $\|G\|_\infty$ minimal, one minimizes the maximum output energy.

The above system norms provide several examples showing how the effect of the disturbance on the plant output can be measured. The optimal attenuation is achieved by minimizing these norms.

Minimizing the 1-norm involves a linear program while minimizing the ∞ -norm requires a search. The 2-norm minimization has a closed-form solution, which will be now described.

We recall that

$$G(s) = P(s) + Q(s)W(s),$$

where $P = CX'$ and $Q = CB'$. The norm $\|G\|_2$ is finite if and only if G is strictly proper and has no poles on the imaginary axis; hence we assume that Q has no zeros on the imaginary axis. We factorize

$$Q = Q_{ap}Q_{mp},$$

where Q_{ap} satisfies $Q_{ap}(-s)Q_{ap}(s) = 1$ (the so-called all-pass function) and Q_{mp} is such that Q_{mp}^{-1} is in $R_H(s)$ (the so-called minimum-phase function); this factorization is unique up to the sign. Let Q_{ap}^* denote

the function $Q_{ap}^*(s) = Q_{ap}(-s)$. Then

$$\begin{aligned}\|G\|_2^2 &= \|P + QW\|_2^2 \\ &= \|Q_{ap}^*P + Q_{mp}W\|_2^2.\end{aligned}$$

Decompose Q_{ap}^*P as

$$Q_{ap}^*P = (Q_{ap}^*P)_{st} + (Q_{ap}^*P)_{un}$$

where $(Q_{ap}^*P)_{st}$ is in $R_H(s)$ and $(Q_{ap}^*P)_{un}$ is unstable but strictly proper; this decomposition is unique. Then the cross-terms contribute nothing to the norm and

$$\|G\|_2^2 = \|(Q_{ap}^*P)_{un}\|_2^2 + \|(Q_{ap}^*P)_{st} + Q_{mp}W\|_2^2.$$

Since the first term is independent of W ,

$$\min_W \|G\|_2 = \|(Q_{ap}^*P)_{un}\|_2$$

and this minimum is attained by

$$W = -\frac{(Q_{ap}^*P)_{st}}{Q_{mp}}.$$

Here is an illustrative example. The plant is given by

$$S_{1u}(s) = \frac{s-2}{s+1}, \quad S_{1d}(s) = 1$$

and we seek to find a stabilizing controller S_2 such that

$$G(s) = \frac{S_{1d}(s)}{1 - S_{1u}(s)S_2(s)}$$

has minimum 2-norm.

We write

$$A(s) = 1, \quad B(s) = \frac{s-2}{s+1}, \quad C(s) = 1$$

and find all stabilizing controllers first. Since the plant is already stable, these are given by

$$S_2(s) = -\frac{-W(s)}{1 + (s-2)/(s+1)W(s)},$$

where W is a free parameter in $R_H(s)$.

Then

$$G(s) = 1 + \frac{s-2}{s+1}W(s),$$

so that

$$P(s) = 1, \quad Q(s) = \frac{s-2}{s+1}.$$

Clearly,

$$Q_{ap}(s) = \frac{s-2}{s+2}, \quad Q_{mp}(s) = \frac{s+2}{s+1}$$

and

$$Q_{ap}^*(s)P(s) = \frac{s+2}{s-2} = 1 + \frac{4}{s-2}.$$

Therefore,

$$\|G\|_2^2 = \left\| \frac{4}{s-2} \right\|_2^2 + \left\| 1 + \frac{s+2}{s+1} W \right\|_2^2,$$

so that the least norm

$$\min_W \|G\|_2 = \left\| \frac{4}{s-2} \right\|_2 = \left\| \frac{4}{s+2} \right\|_2 = 2$$

is attained by

$$W(s) = -\frac{s+1}{s+2}.$$

21.8 Robust Stabilization

The actual plant can differ from its nominal model. We suppose that a nominal plant description is available together with a description of the plant uncertainty. The objective is to design a controller that stabilizes all plants lying within the specified domain of uncertainty. Such a controller is said to *robustly* stabilize the family of plants.

The plant uncertainty can be modeled conveniently in terms of its fractional description. To fix ideas, we shall consider discrete-time plants factorized over $R_S(z)$ and endow $R_S(z)$ with the ∞ -norm: for any function $H(z)$ from $R_S(z)$,

$$\|H\|_\infty = \sup_{|z|>1} |H(z)|.$$

For any two such functions, $H_1(z)$ and $H_2(z)$, we define

$$\begin{aligned} \|[H_1 H_2]\|_\infty &= \left\| \begin{bmatrix} H_1 \\ H_2 \end{bmatrix} \right\|_\infty \\ &= \sup_{|z|>1} (|H_1(z)|^2 + |H_2(z)|^2)^{1/2}. \end{aligned}$$

Let S_{10} be a nominal plant giving rise to a strictly proper transfer function

$$S_{10}(z) = \frac{B(z)}{A(z)},$$

where A and B are coprime functions from $R_S(z)$. We denote $S_1(A, B, \mu)$ the family of plants having strictly proper transfer functions

$$S_1(z) = \frac{B(z) + \Delta B(z)}{A(z) + \Delta A(z)},$$

where ΔA and ΔB are functions from $R_S(z)$ such that

$$\|[\Delta A \ \Delta B]\|_\infty < \mu$$

for some nonnegative real number μ .

Now, let S_2 be a BIBO stabilizing controller for S_{10} . Therefore,

$$S_2 = -\frac{Y' - AW}{X' + BW},$$

where $AX' + BY' = 1$ and W is an element of $R_S(z)$. Then S_2 will BIBO stabilize all plants from $S_1(A, B, \mu)$ if and only if the inverse of

$$(A + \Delta A)(X' + BW) + (B + \Delta B)(Y' - AW) = 1 + [\Delta A \quad \Delta B] \begin{bmatrix} X' + BW \\ Y' - AW \end{bmatrix}$$

is in $R_S(z)$. This is the case whenever

$$\|[\Delta A \quad \Delta B] \begin{bmatrix} X' + BW \\ Y' - AW \end{bmatrix}\|_\infty < 1;$$

thus, we have the following condition of robust stability:

$$\mu \left\| \begin{bmatrix} X' + BW \\ Y' - AW \end{bmatrix} \right\|_\infty \leq 1.$$

The best controller that robustly stabilizes the plant corresponds to the parameter W that minimizes the ∞ -norm above. This requires a search; closed-form solutions exist only in special cases. One such case is presented next.

Suppose the nominal model

$$S_{10}(z) = \frac{1}{z-1}$$

has resulted from

$$S_1(z) = \frac{z + \delta}{(z-1)(z-\varepsilon)}$$

by neglecting the second-order dynamics, where $\delta \geq 0$ and $0 \leq \varepsilon < 1$. Rearranging,

$$S_1(z) = \frac{(1/z) + (1/z)(\delta + \varepsilon/z - \varepsilon)}{(z-1/z)}$$

and one identifies

$$\Delta A = 0, \quad \Delta B = \frac{1}{z} \frac{\delta + \varepsilon}{z - \varepsilon}.$$

Hence,

$$\|[\Delta A \quad \Delta B]\|_\infty = \frac{\delta + \varepsilon}{1 - \varepsilon}$$

and the true plant belongs to the family

$$S_1 \left(\frac{z-1}{z}, \frac{1}{z}, \frac{\delta + \varepsilon}{1 - \varepsilon} \right).$$

All controllers that BIBO stabilize the nominal plant S_{10} are given by

$$S_2(z) = -\frac{1 - (z-1/z)W(z)}{1 + (1/z)W(z)},$$

where W is a free parameter in $R_S(z)$. Which controller yields the best stability margin against δ and ε ? The one that minimizes the ∞ -norm in

$$\frac{\delta + \varepsilon}{1 - \varepsilon} \left\| \begin{bmatrix} 1 + \frac{1}{z}W \\ 1 - \frac{z-1}{z}W \end{bmatrix} \right\|_\infty < 1.$$

Suppose we wish to obtain a controller of McMillan degree zero, $S_2(z) = -K$. Then

$$W(z) = (1 - K) \frac{z}{z - (1 - K)}$$

and $|1 - K| < 1$. The norm

$$\left\| \begin{bmatrix} 1 + \frac{1}{z} W \\ 1 - \frac{z-1}{z} W \end{bmatrix} \right\|_{\infty} = \sqrt{(1 + K^2)} \left\| \frac{z}{z - (1 - K)} \right\|_{\infty}$$

attains the least value of $\sqrt{2}$ by $K = 1$, which corresponds to $W(z) = 0$. It follows that the controller

$$S_2(z) = -1$$

stabilizes all plants $S_1(z)$ for which

$$\frac{\delta + \varepsilon}{1 - \varepsilon} < \frac{1}{\sqrt{2}}.$$

21.9 Robust Performance

The performance specifications often result in divisibility conditions. A typical example is the problem of *reference tracking*.

Suppose we are given a discrete-time plant S_1 , with transfer function

$$S_1(z) = \frac{B(z)}{A(z)}$$

in coprime fractional form over $R_S(z)$, together with a reference r whose z -transform is of the form

$$r = \frac{E(z)}{D(z)},$$

where only D is specified. We recall that $S_1(z)$ is strictly proper. The objective is to design a BIBO stabilizing controller S_2 such that the plant output y asymptotically tracks the reference r (see [Figure 21.3](#)). The controller can operate on both r (feedforward) and y (feedback), so it is described by two transfer functions

$$S_{2y}(z) = -\frac{Y(z)}{X(z)}, \quad S_{2r}(z) = \frac{Z(z)}{X(z)},$$

where X , Y , and Z are from $R_S(z)$.

FIGURE 21.3 Reference tracking.

The requirement of tracking imposes that the tracking error

$$e = r - y = \left(1 - \frac{BZ}{AX + BY}\right) \frac{E}{D}$$

belong to $R_S(z)$. Since $AX + BY$ has inverse in $R_S(z)$ for every stabilizing controller and E is unspecified, D must divide $1 - BZ$ in $R_S(z)$. Hence, there must exist a function V in $R_S(z)$ such that $1 - BZ = DV$. Therefore, S_2 exists if and only if B and D are coprime in $R_S(z)$, and the two controller transfer functions evolve from solving the two Bézout equations

$$\begin{aligned} AX + BY &= 1, \\ DV + BZ &= 1, \end{aligned}$$

where the function V serves to express the tracking error as

$$e = VE.$$

The reference tracking is said to be *robust* if the specifications are met even as the plant is slightly perturbed. We call S_{10} the nominal plant and $S_1(A, B, \mu)$ the neighborhood of S_{10} defined by

$$S_1 = \frac{B + \Delta B}{A + \Delta A},$$

where ΔA and ΔB are functions of $R_S(z)$, such that

$$\|[\Delta A \ \Delta B]\|_\infty < \mu$$

for some nonnegative real number μ . We recall that all $S_1(z)$ are strictly proper.

Now $A + \Delta A$ and $B + \Delta B$ are not specified, but $(A + \Delta A)X + (B + \Delta B)Y$ still has inverse in $R_S(z)$; call it U . We have

$$e = \left(\frac{A + \Delta A}{U}X + \frac{B + \Delta B}{U}(Y - Z)\right) \frac{E}{D}.$$

Hence, for robust tracking, D must divide both X and $Y - Z$ in $R_S(z)$. But, it is sufficient that D divides X ; this condition already implies the other one as can be seen on subtracting the two Bézout equations above.

We illustrate on a discrete-time plant S_1 given by

$$S_1(z) = \frac{1}{z - 2}$$

whose output is to track every sinusoidal sequence of the form

$$r = \frac{az + b}{z^2 - z + 1},$$

where a, b are unspecified real numbers. Taking

$$A(z) = \frac{z - 2}{z}, \quad B(z) = \frac{1}{z}, \quad D(z) = \frac{z^2 - z + 1}{z^2}$$

and solving the pair of Bézout equations

$$\begin{aligned} \frac{z - 2}{z}X(z) + \frac{1}{z}Y(z) &= 1, \\ \frac{z - z + 1}{z^2}V(z) + \frac{1}{z}Z(z) &= 1 \end{aligned}$$

yields the tracking controllers in parametric form

$$S_{2y}(z) = -\frac{2 - (z - 2/z)W_1(z)}{1 + (1/z)W_1(z)},$$

$$S_{2r}(z) = \frac{(z - 1/z) - (z^2 - z + 1/z^2)W_2(z)}{1 + (1/z)W_1(z)}$$

for any elements W_1, W_2 of $R_S(z)$. The resulting error is

$$e = \left[1 + \frac{1}{z}W_2(z) \right] \frac{az + b}{z^2}.$$

Not all of these controllers, however, achieve a robust tracking of the reference. The divisibility condition is fulfilled if and only if W_1 is restricted to

$$W_1(z) = -\frac{z-1}{z} + \frac{z^2-z+1}{z^2}W(z),$$

where W is free in $R_S(z)$.

It is to be noted that the requirement of asymptotic tracking leaves enough degrees of freedom to meet additional design specifications.

21.10 Finite Impulse Response

Transients in discrete-time systems can settle in finite time. Systems having the property that any input sequence with a finite number of nonzero elements produces an output sequence with a finite number of nonzero elements have been called FIFO stable. We recall that a system with proper rational transfer function $H(z)$ is FIFO stable if and only if $H(z)$ is a polynomial in z^{-1} .

Let us consider the feedback system shown in Figure 21.1 and focus on achieving FIFO stability. To this end, we write the transfer function of the plant as

$$S_1(z) = \frac{B(z)}{A(z)},$$

where this time A and B are coprime polynomials in z^{-1} . We recall that the plant incorporates the necessary delay so that $S_1(z)$ is strictly proper. Repeating the arguments used to design a BIBO stable system, we conclude that all controllers S_2 that FIFO stabilize the plant S_1 have the transfer function

$$S_2(z) = -\frac{Y(z)}{X(z)},$$

where X, Y represent the solution class of the polynomial Bézout equation

$$AX + BY = 1.$$

In particular, if X' and Y' define any FIFO stabilizing controller for S_1 , the set of all such controllers can be parameterized as

$$S_2(z) = -\frac{Y' - AW}{X' + BW},$$

where $W(z)$ is a free polynomial in z^{-1} .

It is a noteworthy fact that the parametric expressions for the sets of BIBO stable and FIFO stable controllers are the same; the only difference is that the free parameter of FIFO stabilizing controllers is

permitted to range over only the smaller set of polynomials in z^{-1} , whereas in BIBO stabilizing controllers it is permitted to range over the larger set of Schur-stable rational functions in z . Indeed, FIFO stability is more restrictive than BIBO stability.

The design options offered by FIFO stability are remarkable. The parameter W can be selected so as to minimize the McMillan degree of S_2 , or to achieve the shortest impulse response of the closed-loop system. Various norm minimizations can also be performed.

A well-known example is the deadbeat controller. We consider a double-sumlator plant with transfer function

$$S_1(z) = \frac{1}{(z-1)^2}$$

and interpret the exogenous inputs u_1 and u_2 as accounting for the effect of the initial conditions of S_1 and S_2 . The requirement of FIFO stability is then equivalent to achieving finite responses y_1 and y_2 for all initial conditions. Since in this case

$$A(z) = (1 - z^{-1})^2, \quad B(z) = z^{-2}$$

and the Bézout equation

$$(1 - z^{-1})^2 X(z) + z^{-2} Y(z) = 1$$

has a particular solution

$$X'(z) = 1 + z^{-1}, \quad Y'(z) = 3 - 2z^{-1},$$

we obtain all deadbeat (or FIFO stabilizing) controllers as

$$S_2(z) = -\frac{3 - 2z^{-1} - (1 - z^{-1})^2 W(z)}{1 + 2z^{-1} + z^{-2} W(z)}.$$

The deadbeat controller of least McMillan degree ($=1$) is obtained for $W(z) = 0$. The choice $W(z) = -3$ leads to a deadbeat controller that rejects step disturbances u_1 (hence, persistent) at the plant output y_1 in finite time. And when u_1 is a stationary white noise, then $W(z) = 2.5$ minimizes the steady-state variance of y_1 among all deadbeat controllers of McMillan degree 2.

21.11 Multivariable Systems

Up until now we have considered only single-input single-output (SISO) plants and controllers. In the case of multiple inputs and/or outputs, the input-output properties of linear systems are represented by a *matrix* of transfer functions. The additional intricacies introduced by these systems stem mainly from the fact that the matrix multiplication is not commutative.

Consider a rational transfer matrix $G(s)$ whose dimensions are, say, $m \times n$. Then it is always possible to factorize G as follows:

$$\begin{aligned} G(s) &= B_R(s)A_R^{-1}(s) \\ &= A_L^{-1}(s)B_L(s), \end{aligned}$$

where the factors B_R, A_R and A_L, B_L are, respectively, $m \times n, n \times n$ and $m \times m, m \times n$ matrices of qualified rational functions, say from $R_H(s)$, such that

$$\begin{aligned} A_R, B_R &\text{ are right coprime,} \\ A_L, B_L &\text{ are left coprime.} \end{aligned}$$

These “matrix fractions” are unique except for the possibility of multiplying the “numerator” and the “denominator” matrices by a matrix whose determinant has inverse in $R_H(s)$. That is, if $G(s)$ can also be

expressed as

$$\begin{aligned} G(s) &= B'_R(s)A_R^{-1}(s) \\ &= A_L^{-1}(s)B'_L(s), \end{aligned}$$

where the factors are matrices of functions from $R_H(s)$, such that

$$\begin{aligned} A'_R, B'_R &\text{ are right coprime,} \\ A'_L, B'_L &\text{ are left coprime,} \end{aligned}$$

then

$$\begin{aligned} A'_R(s) &= A_R(s)U_R(s), & B'_R(s) &= B_R(s)U_R(s), \\ A'_L(s) &= U_L(s)A_L(s), & B'_L(s) &= U_L(s)B_L(s) \end{aligned}$$

for some matrices U_R and U_L over $R_H(s)$, whose determinants have stable inverses in $R_H(s)$.

Analogous results hold for discrete-time systems. To illustrate, consider the transfer matrix

$$G(z) = \begin{bmatrix} \frac{1}{z-1} & \frac{2-z}{z^2-z} \\ \frac{1}{z-1} & \frac{1}{z-1} \end{bmatrix}$$

and determine its left and right coprime factorizations over $R_S(z)$. One obtains, for instance,

$$\begin{aligned} G(z) &= \begin{bmatrix} \frac{1}{z} & \frac{2-z}{z^2-\lambda z} \\ 0 & \frac{1}{z-\lambda} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ -1 & \frac{z-1}{z-\lambda} \end{bmatrix}^{-1} \\ &= \begin{bmatrix} 1 & -1 \\ 0 & \frac{z-1}{z-\mu} \end{bmatrix}^{-1} \begin{bmatrix} 0 & -\frac{2}{z} \\ \frac{1}{z-\mu} & \frac{1}{z-\mu} \end{bmatrix} \end{aligned}$$

for any real λ and μ with modulus less than one.

Let us now consider the feedback system shown in Figure 21.1 where S_1 and S_2 are multivariable systems and analyze its BIBO stability. We therefore factorize the two transfer matrices over $R_H(s)$,

$$\begin{aligned} S_1(s) &= B_R(s)A_R^{-1}(s) = A_L^{-1}(s)B_L(s), \\ S_2(s) &= -X_L^{-1}(s)Y_L(s) = -Y_R(s)X_R^{-1}(s), \end{aligned}$$

where the two pairs A_R, B_R and X_R, Y_R are right coprimes while the two pairs A_L, B_L and X_L, Y_L are left coprimes. The transfer matrix of the feedback system

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} S_1(I - S_2S_1)^{-1} & S_1(I - S_2S_1)^{-1}S_2 \\ S_2(I - S_1S_2)^{-1}S_1 & S_2(I - S_1S_2)^{-1} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

then reads

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} B_R(X_LA_R + Y_LB_R)^{-1}X_L & -B_R(X_LA_R + Y_LB_R)^{-1}Y_L \\ I - A_R(X_LA_R + Y_LB_R)^{-1}X_L & -A_R(X_LA_R + Y_LB_R)^{-1}Y_L \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

or alternatively

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} X_R(A_LX_R + B_LY_R)^{-1}B_L & X_R(A_LX_R + B_LY_R)^{-1}A_L - I \\ -Y_R(A_LX_R + B_LY_R)^{-1}B_L & -Y_R(A_LX_R + B_LY_R)^{-1}A_L \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}.$$

The feedback system is BIBO stable if and only if this transfer matrix has entries in $R_H(s)$. We therefore conclude that the feedback system is BIBO stable if and only if the common denominator $X_LA_R + Y_LB_R$, or alternatively $A_LX_R + B_LY_R$, has inverse with entries in $R_H(s)$.

A parameterization of all controllers S_2 that BIBO stabilize the plant S_1 is now at hand. Given left and right coprime factorizations over $R_H(s)$ of the plant transfer matrix

$$S_1 = B_R A_R^{-1} = A_L^{-1} B_L,$$

we select matrices X'_L , Y'_L and X'_R , Y'_R with entries in $R_H(s)$, such that

$$X'_L A_R + Y'_L B_R = I, \quad A_L X'_R + B_L Y'_R = I.$$

Then the family of all stabilizing controllers has the transfer matrix

$$\begin{aligned} S_2 &= -(X'_L + W_L B_L)^{-1} (Y'_L - W_L A_L) \\ &= -(Y'_R - A_R W_R) (X'_R + B_R W_R)^{-1}, \end{aligned}$$

where W_L is a matrix parameter whose entries vary over $R_H(s)$ such that $X'_L + W_L B_L$ is nonsingular, and W_R is a matrix parameter whose entries vary over $R_H(s)$ such that $X'_R + B_R W_R$ is nonsingular.

As an example, determine all BIBO stabilizing controllers for the discrete-time plant considered earlier, with the transfer matrix

$$S_1(z) = \begin{bmatrix} \frac{1}{z-1} & \frac{2-z}{z^2-z} \\ \frac{1}{z-1} & \frac{1}{z-1} \end{bmatrix}.$$

The left and right coprime factors over $R_S(z)$ can be taken as

$$A_R(z) = \begin{bmatrix} 1 & 0 \\ -1 & \frac{z-1}{z} \end{bmatrix}, \quad B_R(z) = \begin{bmatrix} \frac{1}{z} & \frac{2-z}{z^2} \\ 0 & \frac{1}{z} \end{bmatrix}$$

and

$$A_L(z) = \begin{bmatrix} 1 & -1 \\ 0 & \frac{z-1}{z} \end{bmatrix}, \quad B_L(z) = \begin{bmatrix} 0 & -\frac{2}{z} \\ \frac{1}{z} & \frac{1}{z} \end{bmatrix}.$$

The Bézout equations

$$X'_L A_R + Y'_L B_R = I, \quad A_L X'_R + B_L Y'_R = I$$

have particular solutions

$$X'_L(s) = \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}, \quad Y'_L(s) = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$$

and

$$X'_R(s) = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \quad Y'_R(s) = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}.$$

The set of stabilizing controllers is given by

$$S_2(s) = - \left(\begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix} + W_L \begin{bmatrix} 0 & -2z^{-1} \\ z^{-1} & z^{-1} \end{bmatrix} \right)^{-1} \left(\begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} - W_L \begin{bmatrix} 1 & -1 \\ 0 & 1-z^{-1} \end{bmatrix} \right),$$

where W_L varies over $R_S(z)$, or by

$$S_2(s) = - \left(\begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} - \begin{bmatrix} 1 & 0 \\ -1 & 1-z^{-1} \end{bmatrix} W_R \right) \left(\begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} + \begin{bmatrix} z^{-1} & -z^{-1} + 2z^{-2} \\ 0 & z^{-1} \end{bmatrix} W_R \right)^{-1},$$

where W_R varies over $R_S(z)$ as well.

It is clear that the two parameterizations of S_2 are equivalent. To each controller S_2 there is a unique parameter W_L such that $S_2 = -(X'_L + W_L B_L)^{-1}(Y'_L - W_L A_L)$ as well as a unique parameter W_R such that $S_2 = -(Y'_R - A_R W_R)(X'_R + B_R W_R)^{-1}$, and these two are related by

$$W_R - W_L = X'_L Y'_R - Y'_L X'_R.$$

It is easy to see that the transfer matrix of the closed-loop system is *affine* in the free parameter W_L or W_R . Indeed,

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} B_R(X'_L + W_L B_L) & -B_R(Y'_L - W_L A_L) \\ I - A_R(X'_L + W_L B_L) & -A_R(Y'_L - W_L A_L) \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

or alternatively

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} (X'_R + B_R W_R)B_L & (X'_R + B_R W_R)A_L - I \\ -(Y'_R - A_R W_R)B_L & -(Y'_R - A_R W_R)A_L \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}.$$

Thus, control synthesis problems beyond stabilization can be handled by determining the parameters W_L or W_R as described for SISO systems.

Let us consider the disturbance attenuation problem for the discrete-time plant

$$S_{1u}(z) = \begin{bmatrix} \frac{1}{z-1} & \frac{2-z}{z^2-z} \\ \frac{1}{z-1} & \frac{1}{z-1} \end{bmatrix}, \quad S_{1d}(z) = \begin{bmatrix} \frac{1}{z-1} \\ \frac{1}{z-1} \end{bmatrix},$$

where the disturbance d is assumed to be an arbitrary l_∞ sequence. We seek to find a BIBO stabilizing controller that minimizes the maximum amplitude of the plant output y .

We write

$$\begin{aligned} S_{1u}(z) &= A_L^{-1}(z)B_L(z) = B_R(z)A_R^{-1}(z), \\ S_{1d}(z) &= A_L^{-1}(z)C_L(z), \end{aligned}$$

where

$$\begin{aligned} A_L(z) &= \begin{bmatrix} 1 & -1 \\ 0 & 1-z^{-1} \end{bmatrix}, & B_L(z) &= \begin{bmatrix} 1 & -2z^{-1} \\ z^{-1} & z^{-1} \end{bmatrix}, & C_L(z) &= \begin{bmatrix} 0 \\ z^{-1} \end{bmatrix} \\ A_R(z) &= \begin{bmatrix} 1 & 0 \\ -1 & 1-z^{-1} \end{bmatrix}, & B_R(z) &= \begin{bmatrix} z^{-1} & -z^{-1} + 2z^{-1} \\ 0 & z^{-1} \end{bmatrix}. \end{aligned}$$

The set of BIBO stabilizing controllers has been found to have the transfer matrix

$$S_2(z) = - \left(\begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} - \begin{bmatrix} 1 & 0 \\ -1 & 1-z^{-1} \end{bmatrix} W_R \right) \left(\begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} + \begin{bmatrix} z^{-1} & -z^{-1} + 2z^{-2} \\ 0 & z^{-1} \end{bmatrix} W_R \right)^{-1},$$

where W_R varies over $R_S(z)$.

The disturbance-output transfer matrix equals

$$\begin{aligned} G(z) &= (I - S_{1u}S_2)^{-1}S_{1d} \\ &= (X'_R + B_R W_R)^{-1}C_L. \end{aligned}$$

When

$$W_R = \begin{bmatrix} W_{11} & W_{12} \\ W_{21} & W_{22} \end{bmatrix},$$

one obtains the expression

$$G(z) = \begin{bmatrix} z^{-1} + z^{-2}W_{12} - (z^{-2} - 2z^{-3})W_{22} \\ z^{-1} + z^{-2}W_{22} \end{bmatrix}.$$

The 1-norm of an $m \times n$ matrix $G(z)$ with entries

$$G_{ij}(z) = \sum_{k=0}^{\infty} g_{ij,k} z^{-k}$$

is defined by

$$\|G\|_1 = \max_{i=1,\dots,m} \sum_{j=1}^n \|G_{ij}\|_1,$$

where

$$\|G_{ij}\|_1 = \sum_{k=0}^{\infty} |g_{ij,k}|.$$

In our case

$$\|G\|_1 = \max(\|z^{-1} + z^{-2}W_{12} - (z^{-2} - 2z^{-3})W_{22}\|_1, \|z^{-1} + z^{-2}W_{22}\|_1),$$

and it is clear by inspection that $\|G\|_1$ attains its minimum for $W_{12}(z) = 0$, $W_{22}(z) = 0$ and

$$\min_{W_R} \|G\|_1 = \max(1, 1) = 1.$$

The corresponding optimal BIBO stabilizing controllers are

$$S_2(z) = - \begin{bmatrix} -W_{11} & 1 \\ W_{11} - (1 - z^{-1})W_{21} & 0 \end{bmatrix} \begin{bmatrix} 1 + z^{-1}W_{11} - (z^{-1} - 2z^{-2})W_{22} & 1 \\ z^{-1}W_{21} & 1 \end{bmatrix}^{-1}$$

for any functions W_{11} and W_{21} in $R_S(z)$. The one of least McMillan degree reads

$$S_2(z) = \begin{bmatrix} 0 & -1 \\ 0 & 0 \end{bmatrix}.$$

21.12 Extensions

The factorization approach presented here for linear time-invariant systems with rational transfer matrices can be generalized to extend the scope of the theory to include distributed-parameter systems, time-varying systems, and even nonlinear systems.

The transfer matrices of distributed-parameter systems are no longer rational and coprime factorizations cannot be assumed *a priori* to exist. The coefficients of time-varying systems are functions of time, and the operations of multiplication and differentiation do not commute. In nonlinear systems, transfer matrices are replaced by input–output maps. Suitable factorizations of these maps may not exist and, if they do, they are not commutative in general.

For many systems of physical and engineering interest, these difficulties can be circumvented and the algebraic factorization approach carries over with suitable modifications.

22.1 Introduction

22.1.1 Quantitative Feedback Theory

Quantitative feedback theory (QFT)* is a very powerful design technique for the achievement of assigned performance tolerances over specified ranges of structured plant parameter uncertainties without and with

* The original version of this material was first published by the Advisory Group for Aerospace Research and Development, North Atlantic Treaty Organization (AGARD/NATO) in Lecture Series LS-191 "on Linear Dynamics and Chaos" in June 1993.

control effector failures [9]. It is a frequency domain design technique utilizing the Nichols chart (NC) to achieve a desired robust design over the specified region of plant parameter uncertainty. This chapter presents an introduction to QFT analog and discrete design techniques for both multiple-input single-output (MISO) [1,5,13] and multiple-input multiple-output (MIMO) [3,4,6,7,10–12] control systems. QFT computer-aided design (CAD) packages are readily available to expedite the design process. The purposes of this chapter are (1) to provide a basic understanding of QFT; (2) to provide the minimum amount of mathematics necessary to achieve this understanding; (3) to discuss the basic design steps; and (4) to present a practical example.

22.1.2 Why Feedback?

For the answer to the question of "Why do you need QFT?" consider the following system. The plant P responds to the input $r(t)$ with the output $y(t)$ in the face of disturbances $d_1(t)$ and $d_2(t)$ (see Figure 22.1). If it is desired to achieve a specified system transfer function $T(s)[= Y(s)/R(s)]$, then it is necessary to insert a prefilter whose transfer function is $T(s)/P(s)$, as shown in Figure 22.2. This compensated system produces the desired output as long as the plant does not change and there are no disturbances. This type of system is sensitive to changes in the plant (or uncertainty in the plant), and the disturbances are reflected directly into the output. Thus, it is necessary to feed back the information in the output in order to reduce the output sensitivity to parameter variation and to attenuate the effect of disturbances on the plant output.

In designing a feedback control system, it is desired to utilize a technique that:

- Addresses all known plant variations up front
- Incorporates information on the desired output tolerances
- Maintains reasonably low loop gain (reduce the "cost of feedback")

This last item is important in order to avoid the problems associated with high loop gains such as sensor noise amplification, saturation, and high-frequency uncertainties.

22.1.3 What Can QFT Do?

Assume that the characteristics of a plant that is to be controlled over a specified region of operation vary; that is, a plant with structured parameter uncertainty. This plant parameter uncertainty may be described by the Bode plots of Figure 22.3. This figure represents the range of variation of plant magnitude (dB) and phase over a specified frequency range. The bounds of this variation, for this example, can be described by six linear time-invariant (LTI) plant transfer functions. By the application of QFT for a MISO control system containing this plant, a single compensator and a prefilter may be designed to achieve a specified robust design.

FIGURE 22.1 An open-loop system (basic plant).

FIGURE 22.2 A compensated open-loop system.

FIGURE 22.3 The Bode plots of six LTI plants that represent the range of the plant's parameter uncertainty.

22.1.4 Benefits of QFT

The benefits of QFT may be summarized as follows:

- The result is a robust design that is insensitive to plant variation
- There is one design for the full envelope (no need to verify plants inside templates)
- Any design limitations are apparent up front
- In comparison to other multivariable design techniques there is less development time for a full envelope design
- One can determine what specifications are achievable early in the design process
- One can redesign quickly for changes in the specifications
- The structure of compensator (controller) is determined up front

22.2 The MISO Analog Control System [1]

22.2.1 Introduction

The mathematical proof that an $m \times m$ feedback control system can be represented by m^2 equivalent MISO feedback control systems is given in Section 22.4.2. A 3×3 MIMO control system can be represented by the m^2 MISO equivalent loops shown in Figure 22.4. Thus, this and the next section present an introduction to the QFT technique by considering only a MISO feedback control system.

22.2.2 MISO System

The overview of the MISO QFT design technique is presented in terms of the minimum-phase (m.p.) LTI MISO system of Figure 22.5. The control ratios for tracking ($D = 0$) and for disturbance rejection ($R = 0$)

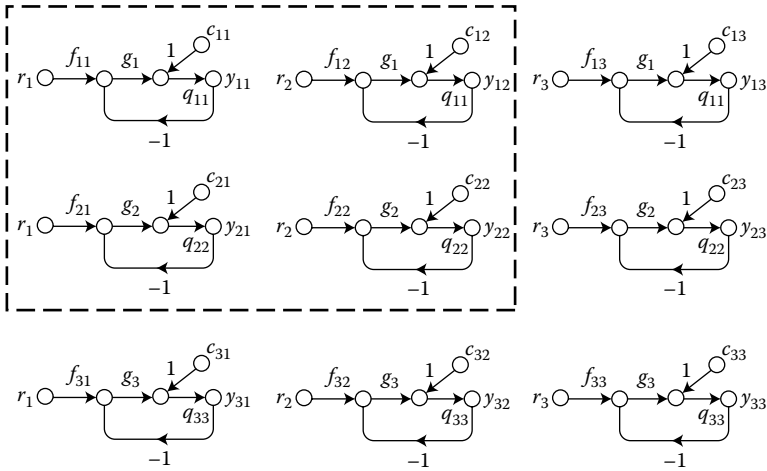

FIGURE 22.4 m^2 MISO equivalent of a 3×3 MIMO feedback control system.

are, respectively,

$$T_R = \frac{F(s)G(s)P(s)}{1 + G(s)P(s)} = \frac{F(s)L(s)}{1 + L(s)} \tag{22.1}$$

$$T_D = \frac{P(s)}{1 + G(s)P(s)} = \frac{P(s)}{1 + L(s)} \tag{22.2}$$

The design objective is to design the prefilter $F(s)$ and the compensator $G(s)$ so the specified robust design is achieved for the given region of plant parameter uncertainty. The design procedure to accomplish this objective is as follows:

- Step 1:** Synthesize the desired tracking model.
- Step 2:** Synthesize the desired disturbance model.
- Step 3:** Specify the J LTI plant models that define the boundary of the region of plant parameter uncertainty.
- Step 4:** Obtain plant templates, at specified frequencies, that pictorially describe the region of plant parameter uncertainty on the NC.
- Step 5:** Select the nominal plant transfer function $P_o(s)$.
- Step 6:** Determine the stability contour (U -contour) on the NC.
- Steps 7–9:** Determine the disturbance, tracking, and optimal bounds on the NC.
- Step 10:** Synthesize the nominal loop transmission function $L_o(s) = G(s)P_o(s)$ that satisfies all the bounds and the stability contour.
- Step 11:** Based upon Steps 1 to 10 synthesize the prefilter $F(s)$.
- Step 12:** Simulate the system in order to obtain the time response data for each of the J plants.

The following sections illustrate this design procedure.

FIGURE 22.5 A MISO plant.

FIGURE 22.6 Desired response characteristic: (a) thumbprint specifications; (b) Bode plots of T_R .

22.2.3 Synthesize Tracking Models

The tracking thumbprint specifications, based upon satisfying some or all of the step-forcing function figures of merit for underdamped (M_p, t_p, t_s, t_r, K_m) and overdamped (t_s, t_r, K_m) responses, respectively, for a simple-second order system, are depicted in Figure 22.6a. The Bode plots corresponding to the time responses $y(t)_U$ (Equation 22.3) and $y(t)_L$ (Equation 22.4) in Figure 22.6b represent the upper bound B_U and lower bound B_L , respectively, of the thumbprint specifications; i.e., an acceptable response $y(t)$ must lie between these bounds. Note that for *m.p.* plants, only the tolerance on $|T_R(j\omega_i)|$ need be satisfied for a satisfactory design. For nonminimum-phase (*n.m.p.*) plants, tolerances on $\angle T_R(j\omega_i)$ must also be specified and satisfied in the design process [4,5]. It is desirable to synthesize the tracking control ratios

$$T_{R_U} = \frac{(\omega_n^2/a)(s+a)}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{22.3}$$

$$T_{R_L} = \frac{K}{(s-\sigma_1)(s-\sigma_2)(s-\sigma_3)} \tag{22.4}$$

corresponding to the upper and lower bounds T_{R_U} and T_{R_L} , respectively, so that $\delta_R(j\omega_i) = B_U - B_L$ increases as ω_i increases above the 0-dB crossing frequency of T_{R_U} . This characteristic of δ_R simplifies the process of synthesizing $L_o(s) = G(s)P_o(s)$. This synthesis process requires the determination of the tracking bounds $B_R(j\omega_i)$ that are obtained based upon $\delta_R(j\omega_i)$. The achievement of the desired performance specification is based upon the frequency bandwidth (BW), $0 < \omega \leq \omega_h$, which is determined by the intersection of the -12-dB line and the B_U curve in Figure 22.6b.

22.2.4 Disturbance Model

The simplest disturbance control ratio model specification is $|T_D(j\omega)| = |Y(j\omega)/D(j\omega)| \leq \alpha_p$ a constant [the maximum magnitude of the output based upon a unit-step disturbance input (d_1 of Figure 22.1)]. Thus, the frequency domain disturbance specification is log magnitude (*Lm*) $T_D(j\omega) \leq Lm \alpha_p$ over the desired specified BW $0 \leq \omega \leq \omega_h$ as defined in Figure 22.6b. Thus, the disturbance specification is represented by only an upper bound on the NC over the specified BW.

22.2.5 J LTI Plant Models

The simple plant

$$P_j(s) = \frac{Ka}{s(s+a)} \tag{22.5}$$

where $K \in \{1, 10\}$ and $a \in \{1, 10\}$, is used to illustrate the MISO QFT design procedure. The region of plant parameter uncertainty is illustrated by Figure 22.7. This region of uncertainty may be described by J LTI

FIGURE 22.7 Region of plant uncertainty characterizing Equation 22.5.

plants, where $j = 1, 2, \dots, J$. These plants lie on the boundary of this region of uncertainty; that is, the boundary points 1 to 6 are utilized to obtain six LTI plant models that adequately define the region of plant parameter uncertainty.

22.2.6 Plant Templates of $P_j(s)$, $\Im P(j\omega_j)$

With $L = GP$, Equation 22.1 yields

$$LmT_R = LmF - Lm \left[\frac{L}{1+L} \right] \tag{22.6}$$

The change in T_R due to the uncertainty in P , since F is LTI, is

$$\Delta(LmT_R) = LmT_R - LmF = Lm \left[\frac{L}{1+L} \right] \tag{22.7}$$

By the proper design of $L_o = GP_o$ and F , this change in T_R is restricted so that the actual value of $Lm T_R$ always lies between B_U and B_L of Figure 22.6b. The first step in synthesizing an L_o is to make NC templates that characterize the variation of the plant uncertainty (see Figure 22.8), as described by $j = 1, 2, \dots, J$ plant transfer functions, for various values of ω_i over a specified frequency range. The boundary of the plant template can be obtained by mapping the boundary of the plant parameter uncertainty region, $Lm P_j(j\omega_i)$ vs. $\angle P_j(j\omega_i)$, as shown on the NC in Figure 22.8. A curve is drawn through the points 1, 2, 3, 4, 5, and 6 where the shaded area is labeled $\Im P(j1)$, which can be represented by a plastic template. Templates for other values of ω_i are obtained in a similar manner. A characteristic of these templates is that, starting

FIGURE 22.8 The template $\Im P(j1)$ characterizing Equation 22.5.

from a “low value” of ω_i , the templates widen (angular width becomes larger) for increasing values of ω_i , then, as ω_i takes on larger values and approaches infinity, they become narrower and eventually approach a straight line of height V dB (see Equation 22.9).

22.2.7 Nominal Plant

While any plant case can be chosen, select whenever possible a plant whose NC template point is always at the lower left corner for all frequencies for which the templates are obtained.

22.2.8 U-Contour (Stability Bound)

The specifications on system performance in the frequency domain (see Figure 22.6b) identify a minimum damping ratio ζ for the dominant roots of the closed-loop system, which becomes a bound on the value $M_p \approx M_m$. On the NC this bound on $M_m = M_L$ (see Figures 22.6b and 22.9) establishes a region that must not be penetrated by the templates and the loop transmission function $L(j\omega)$ for all ω . The boundary of this region is referred to as the universal high-frequency boundary (UHFB) or stability bound—the U-contour, because this becomes the dominating constraint on $L(j\omega)$. Therefore, in Figure 22.9 the top portion, efa , of the M_L contour becomes part of the U-contour. For a large problem class, as $\omega \rightarrow \infty$, the limiting value of the plant transfer function approaches

$$\lim_{\omega \rightarrow \infty} [P(j\omega)] = \frac{K}{\omega^\lambda} \tag{22.8}$$

where λ represents the excess of poles over zeros of $P(s)$. The plant template for this problem class approaches a vertical line of length equal to

$$\Delta \lim_{(\omega \rightarrow \infty)} [LmP_{\max} - LmP_{\min}] = LmK_{\max} - LmK_{\min} = VdB \tag{22.9}$$

If the nominal plant is chosen at $K = K_{\min}$, then measuring VdB down from the bottom portion age of the constraint M_L gives the bcd portion of the U-contour $abcdefa$ of Figure 22.9. The remaining portions, ab and de , of the stability contour are determined during the process of determining the tracking bounds.

22.2.9 Optimal Bounds $B_o(j\omega_i)$ on $L_o(j\omega_i)$

The determination of the tracking $B_R(j\omega_i)$ and the disturbance $B_D(j\omega_i)$ bounds are required in order to yield the optimal bounds $B_o(j\omega_i)$ on $L_o(j\omega_i)$.

22.2.9.1 Tracking Bounds

The solution for $B_R(j\omega_i)$ requires that the condition (actual) $\Delta T_R(j\omega_i) \leq \delta_R(j\omega_i)$ dB (see Figure 22.6b) must be satisfied. Thus, it is necessary to determine the resulting constraint, or bound $B_R(j\omega_i)$, on $L(j\omega_i)$.

FIGURE 22.9 U-contour construction.

The procedure is to pick a nominal plant $P_o(s)$ and to derive tracking bounds on the NC, at specified values of frequency, by use of templates or a CAD package. That is, along a phase angle grid line on the NC, move the nominal point on the template $\Im P(j\omega_i)$ up or down, without rotating the template, until it is tangent to two M -contours whose difference in M values is essentially equal to δ_R . When this condition has been achieved, the location of the nominal point on the template becomes a point on the tracking bound $B_R(j\omega_i)$ on the NC. This procedure is repeated on sufficient angle grid lines on the NC to provide sufficient points to draw $B_R(j\omega_i)$ and for all values of frequency for which templates have been obtained. In general, the templates are moved from right to left starting from a phase angle grid line to the right of the M_L contour. When the templates become tangent to the M_L contour, the nominal point on the templates yields points on the ab and de portions of the stability contour. For m.p. systems, the condition $\Delta T_R(j\omega_i) \leq \delta_R(j\omega_i)$ requires that the synthesized loop transmission must satisfy the requirement that $Lm L(j\omega_i)$ is on or above the corresponding tracking bound $Lm B_R(j\omega_i)$.

22.2.9.2 Disturbance Bounds

The general procedure for determining disturbance bounds for the MISO control system of Figure 22.5 is outlined as follows, but more details are given in [1]. From Equation 22.2 the following equation is obtained:

$$T_D = \frac{P_o}{(P_o/P) + L_o} = \frac{P_o}{W} \tag{22.10}$$

where $W = (P_o/P) + L_o$. From Equation 22.10, setting $Lm T_D = \delta_D = Lm \alpha_p$, the following relationship is obtained:

$$Lm W = Lm P_o - \delta_D \tag{22.11}$$

For each value of frequency for which the NC templates are obtained, the magnitude of $|W(j\omega_i)|$ is obtained from Equation 22.11. This magnitude, in conjunction with the equation $W(j\omega_i) = [P_o(j\omega_i)/P(j\omega_i)]$, is utilized to obtain a graphical solution for $B_D(j\omega_i)$ as shown in Figure 22.10. Note that in this figure the template is plotted in rectangular or polar coordinates.

22.2.9.3 Optimal Bounds

For the case shown in Figure 22.11, $B_o(j\omega_i)$ is composed of those portions of each respective bound $B_R(j\omega_i)$ and $B_D(j\omega_i)$ that have the largest dB values. The synthesized $L_o(j\omega_i)$ must lie on or just above the bound $B_o(j\omega_i)$ of Figure 22.11.

22.2.10 Synthesizing (or Loop-Shaping) $L_o(s)$ and $F(s)$

The shaping of $L_o(j\omega)$ is shown by the dashed curve in Figure 22.11. A point such as $Lm L_o(j2)$ must be on or above $B_o(j2)$. Further, in order to satisfy the specifications, $L_o(j\omega)$ cannot violate the U -contour. In this example, a reasonable $L_o(j\omega)$ closely follows the U -contour up to $\omega = 40$ rad/s and must stay below it above $\omega = 40$, as shown in Figure 22.11. It also must be at least a Type 1 $L_o(s)$ transfer function (one or

FIGURE 22.10 Graphical evaluation of $B_D(j\omega_i)$.

FIGURE 22.11 Bounds $B_o(j\omega_i)$ and loop-shaping.

more poles at the origin) for tracking a step-forcing function with zero steady-state error [1]. Synthesizing a rational function $L_o(s)$ that satisfies the above specification involves building up the function

$$L_o(j\omega) = L_{ok}(j\omega) = P_o(j\omega) \prod_{k=0}^w [K_k G_k(j\omega)] \tag{22.12}$$

where for $k = 0$, $G_0 = 1\angle 0^\circ$ and $K = \prod_{k=0}^w K_k$. In order to minimize the order of the compensator, a good starting point for “building up” the loop transmission function is to assume initially that $L_{o0}(j\omega) = P_o(j\omega)$ as indicated in Equation 22.13. $L_o(j\omega)$ is built up term-by-term or by a CAD loop-shaping routine [8], in order (1) that the point $L_o(j\omega_i)$ lies on or above the corresponding optimal bound $B_o(j\omega_i)$, (2) that it passes close to the trough of the low frequency bounds, for achieving minimal gain, and (3) to stay just outside the U -contour in the NC of Figure 22.11. The design of a proper $L_o(s)$ guarantees only that the variation in $|T_R(j\omega_i)|$ is less than or equal to that allowed; i.e., $\delta_R(j\omega_i)$. The purpose of the prefilter $F(s)$

is to position $Lm [T(j\omega)]$ within the frequency domain specifications; i.e., that it always lies between B_U and B_L (see Figure 22.6b) for all J plants. The method for determining $F(s)$ is discussed in the next section. Once a satisfactory $L_o(s)$ is achieved, then the compensator is given by $G(s) = L_o(s)/P_o(s)$. Note that for this example $L_o(j\omega)$ slightly intersects the U -contour at frequencies above ω_h . Because of the inherent overdress feature of the QFT technique, as a first trial design no effort is made to fine-tune the synthesis of $L_o(s)$. If the simulation results are not satisfactory, then a fine tuning of the design can be made. The available CAD packages simplify and expedite this fine tuning.

22.2.11 Prefilter Design [1,2,4,5]

Design of a proper $L_o(s)$ guarantees only that the variation in $|T_R(j\omega)|$ is less than or equal to that allowed; i.e., $[LmT_R(j\omega)] \leq \delta_R(j\omega)$ The purpose of the prefilter $F(s)$ is to position

$$LmT(j\omega) = Lm \frac{L(j\omega)}{1 + L(j\omega)} \tag{22.13}$$

within the frequency domain specifications. A method for determining the bounds on $F(s)$ is as follows:

- Step 1:** Place the nominal point of the ω_i plant template on the $L_o(j\omega_i)$ point on the $L_o(j\omega)$ curve on the NC (see Figure 22.12).
- Step 2:** Traversing the template, determine the M -contours that yield the maximum LmT_{max} and the minimum LmT_{min} values of Equation 22.13.
- Step 3:** Based upon obtaining sufficient data points, by repeating Step 2 within the desired frequency bandwidth for various values of ω_i , and in conjunction with the data used to obtain Figure 22.6b the plots of Figure 22.13 are obtained.
- Step 4:** Utilizing Figure 22.13, the straight-line Bode technique, and the condition

$$\lim_{s \rightarrow 0} F(s) = 1 \tag{22.14}$$

for a step-forcing function, an $F(s)$ is synthesized that lies within the upper and lower plots in Figure 22.13.

FIGURE 22.12 Prefilter determination.

FIGURE 22.13 Frequency bounds on $F(s)$.

22.2.12 Simulation

The “goodness” of the synthesized $L_o(s)$ and $F(s)$ is determined by simulating the QFT-designed control system for all J plants. MISO QFT CAD packages, as discussed in Section 22.2.4, are available to expedite this simulation phase of the complete design process.

22.2.13 MISO QFT CAD Packages

The first usable MISO QFT CAD package was developed in 1986 for the analog design and in 1991 for the discrete design at the Air Force Institute of Technology (AFIT). These CAD packages have been a catalyst in assisting the newcomer to QFT to understand the fundamentals of this powerful design technique. The QFT CAD package illustrated in Appendix B can be used for both MISO and MIMO control system designs.

22.2.13.1 MISO QFT CAD

The flowchart of the MISO QFT CAD options in the AFIT package called TOTAL-P.C is shown in Appendix A. Those desiring a copy of this package can contact Professor C. H. Houppis, AFIT/ENG, Wright-Patterson AFB, OH 45433. This package has been designed as an educational tool. The QFT CAD package of Appendix B can also be used for the design of a MISO control system.

22.2.13.2 MISO QFT PC CAD

Dr. Yossi Chait, University of Massachusetts, and Dr. Oded Yaniv, Tel-Aviv University, Israel, have developed a MISO QFT PC CAD package for both analog and discrete system design available in MATLAB[®].

22.3 The MISO Discrete Control System [13]

22.3.1 Introduction

The bilinear transformation, z -domain to the w' -domain and vice-versa, is utilized in order to accomplish the QFT design for both MISO and MIMO sampled-data (discrete) control system design in the w' -domain. This transformation enables the MISO QFT analog design technique to be readily used, with minor exceptions, to perform the QFT design for the controller $G(w')$. If the w' -domain simulations satisfy the desired performance specification, then by use of the bilinear transformation the z -domain controller $G(z)$ is obtained. With this z -domain controller, a discrete-time domain simulation is obtained to verify the “goodness” of the design. The QFT technique requires the determination of the minimum sampling frequency $(\omega_s)_{\min}$ BW that is needed for a satisfactory design [13,14]. The larger the plant uncertainty and the narrower the system performance tolerances, the larger must be the value of $(\omega_s)_{\min}$. Henceforth, the prime is omitted from w' ; whenever the symbol w is used it is to be interpreted as w' .

FIGURE 22.14 A MISO sampled-data control system.

22.3.2 The MISO Sampled-Data Control System

Figure 22.14 represents the MISO discrete control system, having plant uncertainty, that is to be designed by the QFT technique. The equations that describe this system are as follows:

$$P_z(z) = G_{zo}P(z) = (1 - z^{-1})Z \left[\frac{P(s)}{s} \right] = (1 - z^{-1})P_e(z) \tag{22.15}$$

$$L(z) = G_{zo}P(z)G_1(z), \quad P_e \equiv \frac{P(s)}{s}, \quad P_e(z) = Z \left[\frac{P(s)}{s} \right] = Z[P_e] \tag{22.16}$$

$$D(s) = \frac{1}{s} P_e(s) = P(s)D(s) \\ P_e(z) = Z[P(s)D(s)] = PD(z) \tag{22.17}$$

$$T_R = \frac{F(z)L(z)}{1 + L(z)} \quad Y_D = \frac{PD(z)}{1 + L(z)} \tag{22.18}$$

$$Y(z) = \left[\frac{L(z)F(z)}{1 + L(z)} \right] R(z) + \frac{PD(z)}{1 + L(z)} = Y_R(z) + Y_D(z) \\ = T_R(z)R(z) + Y_D(z) \tag{22.19}$$

22.3.3 *w*-Domain

The pertinent *s*-, *z*-, and *w*-plane relationships are as follows:

$$\alpha^2 = \left(\frac{\sigma T}{2} \right)^2 < 2, \quad \frac{\omega T}{2} \leq 0.297 \tag{22.20}$$

$$s = \sigma + j\omega, \quad (a)$$

$$w = u + jv = \left(\frac{2}{T} \right) \left[\frac{z - 1}{z + 1} \right] \quad (b) \tag{22.21}$$

$$z = \frac{T\omega + 2}{-T\omega + 2}, \quad v = \frac{2}{T} \tan \left(\frac{\omega T}{2} \right) = \left(\frac{\pi}{\omega_s} \right) \tan \left(\frac{\omega\pi}{\omega_s} \right) \tag{22.22}$$

$$\omega_s = 2\pi/T, \quad z = e^{\sigma T} \angle \omega T = |z| \angle \omega T \tag{22.23}$$

22.3.4 Assumptions

For this chapter, the following assumptions are made:

- Minimum-phase (m.p.) stable plants
- The analog design models, Equations 22.3 and 22.4, yield the desired time response characteristics for the discrete-time system

- The sampling time T is small enough so that over the BW, $0 < \omega < \omega_h$, Equation 22.23 is valid permitting the approximation $s \approx w$ and, in turn,

$$T_R(w) \approx [T_R(s)]_{s=w} \quad (22.24)$$

Both the upper and lower bound w -domain tracking models are obtained in this manner. The disturbance specification is the same as for the analog case.

22.3.5 Nonminimum Phase $L_o(w)$

It is important to note that in the w domain any practical $L(w)$ is n.m.p. containing a zero at $2/T$ (the sampling zero). This result is due to the fact that any practical $L(z)$ has an excess of at least one pole over zeros. Thus, the design technique for a stable uncertain plant is modified [14] to incorporate the allpass filter (apf)

$$A(w) = \frac{w - (2/T)}{w + (2/T)} = -A'(w) = - \left[\frac{(2/T) - w}{(2/T) + w} \right] \quad (22.25)$$

as follows. Let the nominal loop transmission be defined as

$$L_o \equiv -L_{mo}(w)A(w) = L_{mo}(w)A'(w) \quad (22.26)$$

From Equation 22.26 it is seen that

$$\angle L_{mo}(j\nu) = \angle L_o(j\nu) - \angle A'(j\nu) \quad (22.27)$$

where

$$-\angle A'(j\nu) = 2 \tan^{-1} \frac{\nu T}{2} > 0 \quad (22.28)$$

An analysis of Equations 22.26 through 22.28 reveals that the bounds $B'_o(j\nu_i)$ on $L_o(j\nu)$ become the bounds $B_{mo}(j\nu_i)$ on $L_{mo}(j\nu)$ by shifting, over the desired BW, $B'_o(j\nu_i)$ positively (to the right on the NC) by the angle $\angle A'(j\nu_i)$, as shown in Figure 22.15. The U -contour (B'_h) must also be shifted to the right by the same amount, at the specified frequencies ν_i , to obtain the shifted U -contour $B_h(j\nu_i)$. The contour B'_h is shifted to the right until it reaches the vertical line $\angle L_{mo_1}(j\nu_K) = 0^\circ$. The value of ν_K , which is a function of ω_s and the phase margin angle γ as shown in Figure 22.15, [13] is given by

$$2 \tan^{-1} \left(\frac{\nu_K T}{2} \right) = 180^\circ - \gamma \quad (22.29)$$

It should be mentioned that loop-shaping or synthesizing $L_o(w)$ can be done directly without the use of an apf.

22.3.6 Plant Templates $\mathfrak{P}(j\nu_1)$

The plant templates in the w -domain have the same characteristic as those for the analog case (see Section 22.2.4) for the frequency range $0 < \omega_i \leq \omega_s/2$ as shown in Figure 22.16a. In the frequency range $\omega_s/2 < \omega_i < \infty$, the w -domain templates widen once again, then eventually approach a vertical line as shown in Figure 22.16b.

22.3.7 Synthesizing $L_{mo}(w)$

The frequency spectrum can be divided into four general regions for the purpose of synthesizing (loop-shaping) an $L_{mo}(w)$ that satisfies the desired system performance specifications for the plant having plant parameter uncertainty. These four regions are

FIGURE 22.15 The shifted bounds on the NC. Note: Curves drawn approximately to scale.

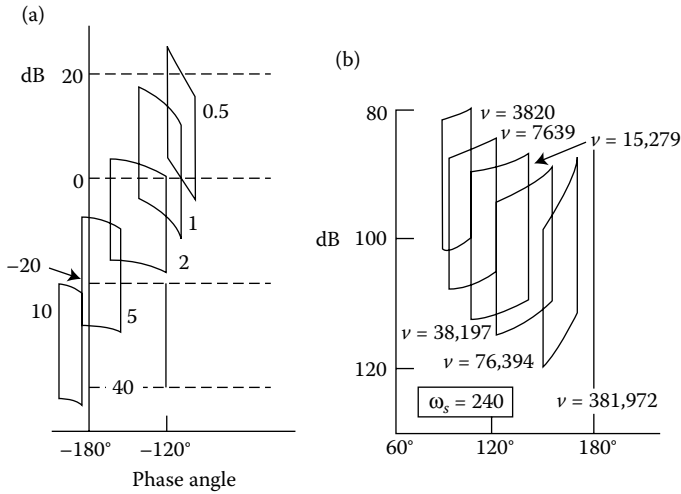

FIGURE 22.16 w -domain plant templates.

Region 1: For the frequency range where Equation 22.20 is essentially satisfied, use the analog templates; i.e., $\Im P(j\omega_i) \approx \Im P(jv_i)$. The w -domain tracking, disturbance, and optimal bounds and the U -contour are essentially the same as those for the analog system. The templates are used to obtain these bounds on the NC in the same manner as for the analog system.

Region 2: For the frequency range $v_{0.25} < v_i \leq v_h$, where $\omega_i \leq 0.25\omega_s$, use the w -domain templates. These templates are used to obtain all three types of bounds, in the same manner as for the analog system, in this region; and the corresponding $B'_h(jv_i)$ contours are also obtained. Depending on the value of T , v_h may be less than $v_{0.25}$.

Region 3: For the frequency range $v_h < v_i \leq v_K$, for the specified value of ω_s , only the B'_h contours are plotted.

Region 4: For the frequency range $v_h > v_K$, use the w -domain templates. Since the templates $\Im P_e(jv_i)$ broaden out again for $v_i > v_K$, as shown in Figure 22.16, it is necessary to obtain the more stringent (stability) bounds B_S shown in Figure 22.17. The templates are used only to determine the stability bounds B_S .

The synthesis (or loop-shaping) of $L_{mo}(w)$ involves the synthesis of the following function:

$$L_{mo}(jv) = P_{eo}(jv) \prod_{k=0}^w [K_k G_k(jv)] \quad (22.30)$$

where the nominal plant $P_{eo}(w)$ is the plant from the J plants that has the smallest dB value and the largest (most negative) phase lag characteristic. The final synthesized $L_{mo}(w)$ function must be one that satisfies the following conditions:

1. In Regions 1 and 2 the point on the NC that represents the dB value and phase angle of $L_{mo}(jv_i)$ must be such that it lies on or above the corresponding $B_{mo}(jv_i)$ bound (see Figure 22.15).
2. The values of Equation 22.30 for the frequency range of region 3 must lie to the right of or just below the corresponding B'_h contour (see Figure 22.15).
3. The value of Equation 22.30 for the frequency range of region 4 must lie below the B_S contour for negative phase angles on the NC (see condition 4 next).
4. In utilizing the bilinear transformation of Equation 22.21, the w -domain transfer functions are all equal order over equal order.
5. The Nyquist stability criterion dictates that the $L_{mo}(jv)$ plot is on the “right side” or the “bottom right side” of the $B_h(jv_i)$ contours for the frequency range of $0 \leq v_i \leq v_K$. It has been shown that [3]
 - a. $L_{mo}(jv)$ must reach the *right-hand bottom* of $B_h(jv_K)$, (i.e., approximately point K in Figure 22.17) at a value of $v \leq v_K$.
 - b. $\angle L_{mo}(jv_K) < 0^\circ$ in order that there exists a practical L_{mo} that satisfies the bounds $B(jv)$ and provides the required stability.
6. For the situation where one or more of the J LTI plants that represent the uncertain plant parameter characteristics represent unstable plants and one of these unstable plants is selected as the nominal plant, *then the apf to be used in the QFT design must include all right half-plane (RHP) zeros of P_{zo}* . This situation is not discussed in this chapter. **Note:** For experienced QFT control system designers, $L_o(v)$ can be synthesized without the use of apf. This approach also is not covered in this chapter.

The synthesized $L_{mo}(w)$ obtained following the guidelines of this section is shown in Figure 22.17.

22.3.8 Prefilter Design

The procedure for synthesizing $F(w)$ is the same as for the analog case (see Section 22.2.11) over the frequency range $0 < v_i \leq v_h$. In order to satisfy condition 4 of Section 22.3.7, a nondominating zero or zeros (“far left” in the w -plane) are inserted so that the final synthesized $F(w)$ is equal order over equal order.

Note: Curves drawn approximately to scale.

FIGURE 22.17 A satisfactory design: $L_{mo}(jv)$ at $\omega_s = 240$.

22.3.9 w -Domain Simulation

The “goodness” of the synthesized $L_{mo}(w)$ [or $L_o(w)$] and $F(w)$ is determined by first simulating the QFT w -domain designed control system for all J plants in the w -domain (an “analog” time domain simulation). See Section 22.2.13 for MISO QFT CAD packages that expedite this simulation.

22.3.10 z -Domain

The two tests of the “goodness” of the w -domain QFT-designed system is a discrete-time domain simulation of the system shown in Figure 22.14. To accomplish this simulation, the w -domain transfer functions $G(w)$ and $F(w)$ are transformed to the z -domain by use of the bilinear transformation of Equation 22.21. This transformation is utilized since the degree of the numerator and denominator polynomials of these functions are equal and the controller and prefilter do not contain a zero-order-hold device.

22.3.10.1 Comparison of the Controller’s w - and z -Domain Bode Plots

Depending on the value of the sampling time T , warping may be sufficient to alter the loop-shaping characteristics of the controller when it is transformed from the w -domain into the z -domain. For the warping effect to be minimal, the Bode plots (magnitude and angle) of the w - and z -domain controllers must essentially lie on top of one another within the frequency range $0 < \omega \leq [(2/3)(\omega_s/2)]$. If the warping is negligible, then a discrete-time simulation can proceed. If not, a smaller value of sampling time needs to be selected.

22.3.10.2 Accuracy

The CAD packages that are available to the designer determines the degree of accuracy of the calculations and simulations. The smaller the value of T , the greater the degree of accuracy that is required to be maintained. The accuracy can be enhanced by implementing $G(z)$ and $F(z)$ as a set of g and f cascaded transfer functions, respectively; that is,

$$\begin{aligned} G(z) &= G_1(z)G_2(z) \cdots G_g(z), \\ F(z) &= F_1(z)F_2(z) \cdots F_f(z) \end{aligned} \quad (22.31)$$

22.3.10.3 Analysis of Characteristic Equation $Q_j(z)$

Depending on the value of T and the plant parameter uncertainty, the pole-zero configuration in the vicinity of the $-1 + j0$ point in the z -plane for one or more of the J LTI plants can result in an unstable discrete-time response. Thus, before proceeding with a discrete-time domain simulation, an analysis of the characteristic equation $Q_j(z)$ for all J LTI plants must be made. If an unstable system exists, an analysis of $Q_j(z)$ and the corresponding root locus may reveal that a slight relocation of one or more controller poles in the vicinity of the $-1 + j0$ point toward the origin may ensure a stable system for all J plants without essentially affecting the desired loop-shaping characteristic of $G(z)$.

22.3.10.4 Simulation and CAD Packages

With the “design checks” of Sections 22.3.10.1 through 22.3.10.3 satisfied, then a discrete-time simulation is performed to verify that the desired performance specifications have been achieved. In order to enhance the MISO QFT discrete control system design procedure that is presented in this chapter, the CAD flow chart of Section 22.2.13.1 is shown in Appendix B.

22.4 MIMO Systems

22.4.1 Introduction

Figure 22.18 represents an $m \times m$ MIMO closed-loop system in which F, G , and P are each $m \times m$ matrices, and $\mathcal{P} = \{P\}$ is a set of J matrices due to plant parameter uncertainty. There are m^2 closed-loop system transfer functions (transmissions) t_{ij} contained within its system transmission matrix (i.e., $T = \{t_{ij}\}$) relating the outputs y_i to the inputs r_j (e.g., $y_i = t_{ij}r_j$). These relationships hold for both the s - and w -domain analysis of a MIMO system. In a quantitative problem statement there are tolerance bounds on each t_{ij} , giving a set of m^2 acceptable regions τ_{ij} that are to be specified in the design; thus, $t_{ij} \in \tau_{ij}$ and $\mathfrak{S} = \{\tau_{ij}\}$. From Figure 22.18 the system control ratio relating r to y is:

$$T = [I + PG]^{-1}PGF \tag{22.32}$$

The t_{ij} expressions derived from this expression are very complex and not suitable for analysis. The QFT design procedure systematizes and simplifies the manner of achieving a satisfactory system design for the entire range of plant uncertainty. In order to readily apply the QFT technique, another mathematical system description is presented in the next section. The material presented in this chapter pertains to both the s - and w -domain analysis of MIMO systems [2,12,16,17].

22.4.2 Derivation of m^2 MISO System Equivalents

The G, F, P and P^{-1} matrices are defined as follows:

$$G = \begin{bmatrix} g_1 & 0 & \cdots & 0 \\ 0 & g_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & g_m \end{bmatrix} \quad F = \begin{bmatrix} f_{11} & f_{12} & \cdots & f_{1m} \\ f_{21} & f_{22} & \cdots & f_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ f_{m1} & f_{m2} & \cdots & f_{mm} \end{bmatrix} \tag{22.33}$$

$$P = \begin{bmatrix} p_{11} & p_{12} & \cdots & p_{1m} \\ p_{21} & p_{22} & \cdots & p_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ p_{m1} & p_{m2} & \cdots & p_{mm} \end{bmatrix} \quad P^{-1} = \begin{bmatrix} p_{11}^* & p_{12}^* & \cdots & p_{1m}^* \\ p_{21}^* & p_{22}^* & \cdots & p_{2m}^* \\ \vdots & \vdots & \ddots & \vdots \\ p_{m1}^* & p_{m2}^* & \cdots & p_{mm}^* \end{bmatrix} \tag{22.34}$$

Although only a diagonal G matrix is considered, the use of a nondiagonal G matrix may allow the designer more design flexibility [2]. The m^2 effective plant transfer functions are based upon defining:

$$q_{ij} \equiv \frac{1}{p_{ij}^*} = \frac{\det P}{\text{adj}P_{ij}} \tag{22.35}$$

FIGURE 22.18 A 3×3 MIMO feedback control system.

There is a requirement that $\det.P$ be m.p. The Q matrix is then formed as:

$$Q = \begin{bmatrix} q_{11} & q_{12} & \cdots & q_{1m} \\ q_{21} & q_{22} & \cdots & q_{2m} \\ \vdots & \vdots & \vdots & \vdots \\ q_{m1} & q_{m2} & \cdots & q_{mm} \end{bmatrix} = \begin{bmatrix} \frac{1}{p_{11}^*} & \frac{1}{p_{12}^*} & \cdots & \frac{1}{p_{1m}^*} \\ \frac{1}{p_{21}^*} & \frac{1}{p_{22}^*} & \cdots & \frac{1}{p_{2m}^*} \\ \vdots & \vdots & \vdots & \vdots \\ \frac{1}{p_{m1}^*} & \frac{1}{p_{m2}^*} & \cdots & \frac{1}{p_{mm}^*} \end{bmatrix} \quad (22.36)$$

The matrix P^{-1} is partitioned to the form:

$$P^{-1} = [P_{ij}^*] = \begin{bmatrix} 1 \\ q_{ij} \end{bmatrix} = \Lambda + B \quad (22.37)$$

where Λ is the diagonal part of P^{-1} and B is the balance of P^{-1} ; thus $\lambda_{ij} = 1/q_{ii} = p_{ii}^*$, $b_{ii} = 0$, and $b_{ij} = 1/q_{ij} = p_{ij}^*$ for $i \neq j$. Premultiplying Equation 22.32 by $[I + PG]$ yields

$$[I + PG]T = PGF \rightarrow [P^{-1} + G]T = GF \quad (22.38)$$

where P is nonsingular. Using Equation 22.37 with G diagonal, Equation 22.38 can be rearranged to the form:

$$T = [\Lambda + G]^{-1}[GF - BT] \quad (22.39)$$

Equation 22.39 is used to define the desired fixed-point mapping where each of the m^2 matrix elements on the right-hand side of this equation can be interpreted mathematically as representing a MISO system. Proof of the fact that design of each MISO system yields a satisfactory MIMO design is based on the Schauder fixed-point theorem [7]. This theorem is described, based upon a *unit impulse input*, by defining a mapping

$$Y(T_i) = [\Lambda + G]^{-1}[GF - BT_i] \equiv T_j \quad (22.40)$$

where each member of T is from the acceptable set \mathfrak{S} . If this mapping has a fixed point [i.e., $T \in \mathfrak{S}$ such that $Y(T_i) = T_j$], then this T is a solution of Equation 22.39. The y_{11} output obtained from Equation 22.40, for the 3×3 case, is given by:

$$y_{11} = \frac{q_{11}}{1 + g_1 q_{11}} \left[g_1 f_{11} - \left(\frac{t_{21}}{q_{12}} + \frac{t_{31}}{q_{13}} \right) \right] \quad (22.41)$$

Based upon the derivation of all the y_{ij} expressions from Equation 22.40 yields the four effective MISO loops (in the boxed area) in Figure 22.4, resulting from a 2×2 system and the nine effective MISO loops resulting from a 3×3 system [4]. The control ratios for the desired tracking inputs r_i by the corresponding outputs y_i for each feedback loop of Equation 22.40 have the form

$$y_{ii} = w_{ij}(v_{ij} + c_{ij}) \quad (22.42)$$

where $w_{ii} = q_{ii}/(1 + g_i q_{ii})$ and $v_{ij} = g_i f_{ij}$. The interaction between the loops has the form

$$c_{ij} = - \sum_{k \neq i} \left[\frac{t_{kj}}{q_{ik}} \right] \quad k = 1, 2, 3, \dots, m \quad (22.43)$$

and appears as a “cross-coupling effect” input in each of the feedback loops. Thus, Equation 22.42 represents the control ratio of the i th MISO system. The transfer function $w_{ii} v_{ij}$ relates the “desired” i th

output to the j th input r_j , and the transfer function $w_{ii}c_{ij}$ relates the i th output to the j th cross-coupling effect input c_{ij} . The outputs given in Equation 22.42 can thus be expressed as

$$y_{ij} = (y_{ij})_{r_i} + (y_{ij})_{c_{ij}} = y_{r_i} + y_{c_{ij}} \quad (22.44)$$

or, based on a *unit impulse input*,

$$t_{ij} = t_{r_{ij}} + t_{c_{ij}} \quad (22.45)$$

where

$$t_{r_{ij}} = y_{r_i} = w_{ii}v_{ij} \quad t_{c_{ij}} = y_{c_{ij}} = w_{ii}c_{ij} \quad (22.46)$$

and where now the upper bound, in the low-frequency range ($0 < \omega \leq \omega_h$), is expressed as b'_{ij} . Thus,

$$\tau_{c_{ij}} = b_{ij} - b'_{ij} \quad (22.47)$$

represents the maximum portion of b_{ij} allocated toward the cross-coupling effect rejection, and b'_{ij} represents the upper bound for the tracking portion, respectively, of t_{ij} . For each MISO system there is a cross-coupling effect input that is a function of all the other loop outputs. The object of the design is to have each loop track its desired input while minimizing the outputs due to the disturbance (cross-coupling effects) inputs.

In each of the nine structures of Figure 22.4 it is necessary that the control ratio t_{ij} must be a member of the acceptable $t_{ij} \in \tau_{ij}$. All the g_i and f_{ij} must be chosen to ensure that this condition is satisfied, thus constituting nine MISO design problems. If all of these MISO problems are solved, there exists a fixed point; then y_{ij} on the left-hand side of Equation 22.40 may be replaced by t_{ij} , and all the elements of T on the right-hand side by t_{kj} . This means that there exist nine t_{ij} and t_{kj} , each in its acceptable set, which is a solution to Figure 22.18. If each element is 1:1, then this solution must be unique. A more formal and detailed treatment is given in [7].

22.4.3 Tracking and Cross-Coupling Specifications

The presentation for the remaining portion of this chapter is based upon not only a diagonal G matrix but also a diagonal F matrix. Thus, in Figure 22.4 the t_{ij} terms, for $i \neq j$, represent disturbance responses due to the cross-coupling effect whereas the t_{ij} terms, for $i = j$ (see Equation 22.45) is composed of a desired tracking term t_r and of an unwanted cross-coupling term t_c . Therefore, the desired tracking specifications for the diagonal MISO systems of Figure 22.4 contain an upper-bound and a lower bound as shown in Figure 22.6. The disturbance specification for all MISO loops is given by only an upper bound. These performance specifications are shown in Figure 22.19 for a 2×2 (in the boxed area) and for a 3×3 MIMO feedback control system.

22.4.3.1 Tracking Specifications

Based upon the analysis of Equations 22.45 through 22.47, the specifications for the t_{ii} responses shown in Figure 22.19 need to be modified as shown in Figure 22.20. As shown in this figure, a portion of $\delta_R(j\omega_i)$ (see Figure 22.6) has been allocated [2,7] for the disturbance (cross-coupling effect) specification. Thus, based upon this modification and given an uncertain plant $\mathcal{P} = \{P_j\} (j = 1, 2, \dots, J)$ and the BW ω_h above which output sensitivity is ignored, it is desired to synthesize G and F such that for all $P \in \mathcal{P}$

$$a'_{ii} \leq |t_{ii}(j\omega)| \leq b'_{ii} \quad \text{for } \omega \leq \omega_h \quad (22.48)$$

A finite ω_h is recommended because, in strictly proper systems, feedback is not effective in the high-frequency range.

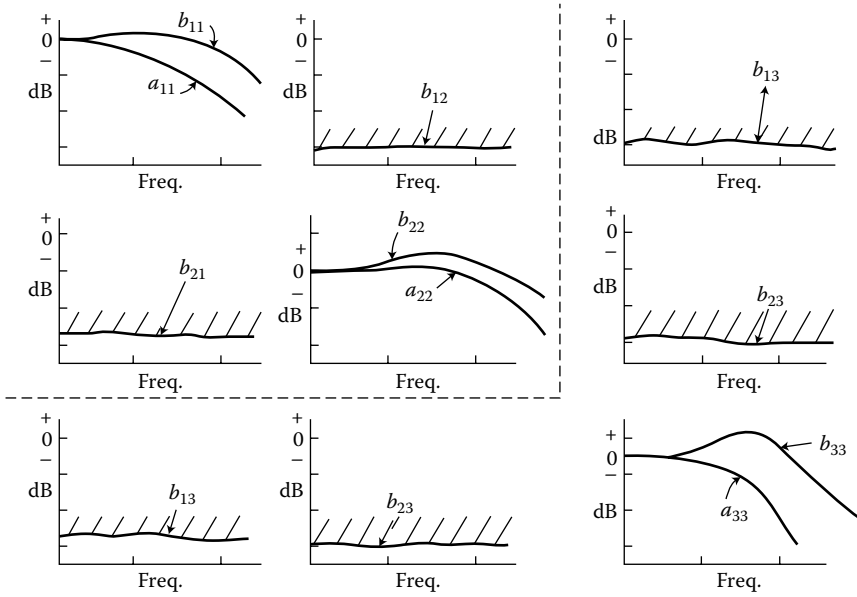

FIGURE 22.19 Tracking and cross-coupling specifications for a 2×2 (in boxed area) and for a 3×3 MIMO system.

22.4.3.2 Disturbance Specification (Cross-Coupling Effect)

Based upon the previous discussion the disturbance specification, an upper bound, is expressed as

$$|t_{c_{ik}}| \leq |b_{ij}| \tag{22.49}$$

Thus, the synthesis of G must satisfy both Equations 22.48 and 22.49.

22.4.4 Determination of Tracking, Cross-Coupling, and Optimal Bounds

The remaining portion of the MIMO QFT approach is confined to a 2×2 system. The reader can refer to the references for higher-order systems ($m > 2$). From Equation 22.39 the following equations are obtained:

$$t_{11} = \frac{L_1 f_{11} + c_{11} q_{11}}{1 + L_1}$$

FIGURE 22.20 Allocation for tracking and cross-coupling specifications for the t_{ii} responses.

where

$$\begin{aligned} c_{11} &= -\frac{t_{21}}{q_{12}}, \quad L_1 = q_{11}g_1 \\ t_{12} &= \frac{c_{12}q_{11}}{1 + L_1} \end{aligned} \quad (22.50)$$

where

$$\begin{aligned} c_{12} &= -\frac{t_{22}}{q_{12}}, \quad f_{12} = 0 \\ t_{21} &= \frac{c_{21}q_{22}}{1 + L_2} \end{aligned} \quad (22.51)$$

where

$$\begin{aligned} c_{21} &= -\frac{t_{11}}{q_{21}}, \quad L_2 = q_{22}g_2, \quad f_{21} = 0, \\ t_{22} &= \frac{L_2 f_{22} + c_{22}q_{22}}{1 + L_2} \end{aligned} \quad (22.52)$$

where

$$c_{22} = -\frac{t_{12}}{q_{21}} \quad (22.53)$$

Equations 22.50 and 22.51 correspond to the MISO systems for the first row of loops in Figure 22.4, and Equations 22.52 and 22.53 correspond to the MISO loops for the second row.

22.4.4.1 Tracking Bounds

The tracking bounds for the ii MISO system is determined in the same manner as for the MISO system of PART II (see Section 22.2.9.1). By use of the templates for the ii loop plant, the value of $\delta_R(j\omega_i)'$, shown in Figure 22.20, is used to satisfy the constraint of Equation 22.48.

22.4.4.2 Cross-Coupling Bounds

From Equations 22.51 and 22.53, considering only the first row of MISO loops in Figure 22.4, the following cross-coupling transfer functions are obtained (see Figures 22.20 and 22.19, respectively):

$$|t_{c_{11}}| = \left| \frac{c_{11}q_{11}}{1 + L_1} \right| \leq \tau_{c_{ij}} \equiv \tau_{c_{11}} \quad \dots \quad (22.54)$$

$$|t_{c_{12}}| = \left| \frac{c_{12}q_{11}}{1 + L_1} \right| \leq b_{ij} \equiv b_{12} \quad \dots \quad (22.55)$$

Substituting for c_{11} and c_{12} into Equations 22.54 and 22.55, respectively, and replacing t_{21} and t_{22} by their respective upper bound values b_{21} and b_{22} , and rearranging these equations yields:

$$\left| \frac{1}{1 + L_1} \right| \leq \left| \frac{q_{12}}{q_{11}} \right| \frac{\tau_{c_{11}}}{b_{21}} = M_{m_{11}} \quad (22.56)$$

$$\left| \frac{1}{1 + L_1} \right| \leq \left| \frac{q_{12}}{q_{11}} \right| \frac{b_{12}}{b_{22}} = M_{m_{12}} \quad (22.57)$$

Substituting into these equations $L_1 = 1/l_1$ yields:

$$\left| \frac{l_1}{1 + l_1} \right| \leq M_{m_{11}} \quad \dots \quad \left| \frac{l_1}{1 + l_1} \right| \leq M_{m_{12}} \quad (22.58)$$

By analyzing these equations for each of the J plants over the desired BW, the maximum value M_m that each of these equations can have, for each value of ω_i (or ν_i), is readily determined by use of a CAD package. Thus, since $L_1 = 1/l_1$, the reciprocals of these values yield the value of the corresponding M -contours or cross-coupling bounds, for $\omega = \omega_i$ (or ν_i), on the NC.

22.4.4.3 Optimal Bounds

The points on the optimal bound for a given value of frequency and for a given row of MISO loops of Figure 22.4 are determined by selecting the largest dB value, for a given NC phase angle, from all the tracking and cross-coupling bounds for these loops at this frequency. The MIMO QFT CAD package is designed to perform this determination of the optimal bounds.

22.4.5 QFT Methods of Designing MIMO Systems

There are two methods of achieving a QFT MIMO design. Method 1 involves synthesizing the loop transmission function L_i and the prefilter f_{ii} independent of the previous synthesized loop transmission functions and prefilters. Method 2 substitutes the synthesized g_i and f_{ii} of the first (or prior) MISO loop(s) that is (are) designed into the equations that describe the remaining loops to be designed. For Method 2, it is necessary to make the decision as to the order that the L_i functions are to be synthesized. Generally, the loops are chosen on the basis of the phase margin frequency ω_ϕ requirements. That is, the loop having the smallest value of ω_ϕ is chosen as the first loop to be designed; the loop having the next smallest value of ω_ϕ is selected as the second loop to be designed; etc. This is an important requirement for Method 2.

22.4.5.1 Method 1

This method involves overdesign (worst-case scenario), i.e., in getting the M_m values of Equations 22.56 and 22.57, for the 2×2 case, the maximum magnitude that q_{12} and the minimum magnitude that q_{11} can have, for each value of ω_i , over the entire J LTI plants are utilized. This method requires that the diagonal dominance condition [2,7] be satisfied. When this condition is not satisfied, then Method 2 needs to be utilized.

22.4.5.2 Method 2

Once the order in which the loops are to be designed is designated accordingly (loop 1, loop 2, etc.), then the compensator g_1 and the prefilter f_{11} are synthesized. These are now known LTI functions, which are utilized to define the loop 2 effective plant transfer function. That is, substitute Equation 22.51 into Equation 22.53, then rearrange the result to obtain a new expression for t_{12} in terms of g_1 and f_{11} as follows:

$$t_{12} = - \left[\frac{f_{11} L_1 q_{22e} / q_{21} (1 + L_1)}{1 + g_2 q_{22e}} \right] \quad (22.59)$$

where the effective loop 2 transfer function is

$$q_{22e} = \frac{q_{22}(1 + L_1)}{(1 + L_1) - \gamma_{12}} \quad \text{where } \gamma_{12} = \frac{q_{11} q_{22}}{q_{12} q_{21}} \quad (22.60)$$

Repeating a similar procedure, the expression for t_{22} is

$$t_{22} = \frac{f_{22} g_2 q_{22e}}{1 + g_2 q_{22e}} \quad (22.61)$$

Remember that a diagonal prefilter matrix has been specified. Note that Equations 22.59 through 22.61 involve the known f_{11} and g_1 , which reduces the overdesign of loop 2.

22.4.6 Synthesizing the Loop Transmission and Prefilter Functions

Once the optimal bound has been determined for each L_i loop, then the synthesis procedures for determining the loop transmission and prefilter functions are the same as for the MISO analog and discrete systems as discussed in Sections 22.2 and 22.3, respectively.

22.4.7 Overview of the MIMO QFT CAD Package

The MIMO QFT CAD package [15], implemented using Mathematica, is capable of carrying an analog or a discrete MISO or MIMO QFT design from problem setup through the design process to a frequency domain analysis of the compensated system. For analog control problems, the design process is performed in the s -plane. The design process is performed in either the w -plane or the s -plane using the pseudo-continuous-time (PCT) representation of the sampled-data system. A flowchart of the CAD package is given in Appendix B.

22.5 QFT Application

A MIMO QFT example, [18] a 2×2 analog flight control system (see the boxed-in loops of [Figure 22.4](#)), is presented to illustrate the power of this design technique. Also, this example illustrates the increased accuracy and efficiency achieved by the MIMO QFT CAD package [15] and the straightforward method for designing an analog MIMO control system. The specifications require a robust analog design for an aircraft that provides stability and meets time domain performance requirements for the specified four flight conditions ([Table 22.1](#)) and the six aircraft failure modes ([Table 22.2](#)). [Table 22.3](#) lists the resulting set of 24 plant cases that incorporate these flight conditions and failure modes. For stability, a 45° phase

TABLE 22.1 Flight Conditions

Flight Condition	Aircraft Parameters

FIGURE 22.21 Open-loop transmissions on NC.

margin is required for each of the two feedback loops. Frequency domain performance specifications, when met, result in the desired closed-loop system performance in the time domain. The frequency domain specifications are shown as dashed lines on the Bode plots of Figure 22.22.

The specifications, the plant models [18] for the 24 cases, and the weighting matrix are entered into the QFT CAD package. The automated features accessed through the designer interface of the CAD package result in synthesizing the compensators $g_1(s)$ and $g_2(s)$ in the manner described in Section 22.2.10. That is, the nominal loop transmission functions $L_{10}(s) = g_1(s)q_{110}(s)$ and $L_{20}(s) = g_2(s)q_{220}(s)$ are synthesized (or shaped) so that they satisfy their respective stability bounds and their respective optimal bounds $B_{10}(j\omega_i)$ and $B_{20}(j\omega_i)$. Note that q_{110} and q_{220} are the nominal plant transfer functions. The first step in a validation check is to plot the loop transmission functions $L_{2\iota}(s)$, where $\iota = 1, \dots, 24$, for all 24 cases on the NC. This is accomplished by a CAD routine, as shown in Figure 22.21 for the purpose of a stability check (m.p. plants). As is seen, none of the cases violate the M_L stability contour (the dark ellipse). In this design, when synthesizing $L_{20}(s)$ a trade-off exists between performance and bandwidth. In this example, the designer chooses to accept the consequences of violating the disturbance bound for $\omega = 2$ rad/s. With $L_{10}(s)$ and $L_{20}(s)$ synthesized, the automated features of the CAD package expedite the design of the prefilters $f_{11}(s)$ and $f_{22}(s)$.

For the second step in the design validation process, the 2×2 array of Bode plots shown in Figure 22.22 is generated, showing on each plot the 24 possible closed-loop transmissions from an input to an output of the completed system. The consequence of violating the channel 2 disturbance bound for $\omega = 2$ rad/s is seen where the closed-loop transmissions violate b_{21} , denoted by dashed line, beginning at $\omega = 2$ rad/s. Violation of performance bounds during loop-shaping may result in violation of the performance specifications for the closed-loop system.

As seen in Figure 22.22, a robust design has been achieved for this 2×2 MIMO analog flight control system. The time domain results, although not drawn, meet all specifications.

23.1 Introduction

The so-called *servomechanism problem* is one of the most basic problems to occur in the field of automatic control, and it arises in almost all application problems of the aerospace and process industries. In the servomechanism problem, it is desired to design a controller for a plant (or “system”) so that the outputs of the plant are independent, as much as possible, from disturbances which may affect the system (i.e., *regulation* occurs), and also such that the outputs asymptotically track any specified reference input signals applied to the system (i.e., *tracking* occurs), subject to the requirements of maintaining closed-loop system stability.

This chapter examines some aspects of controller synthesis for the multivariable servomechanism problem when the plant to be controlled is subject to uncertainty. In this case, a controller is to be designed so that desired regulation and tracking takes place in spite of the fact that the plant dynamics or/and parameters may vary by arbitrary, large amounts, subject only to the condition that the resultant closed-loop perturbed system remains stable. This problem is called the *robust servomechanism problem* (RSP).

23.2 Preliminary Results

23.2.1 Plant Model

The plant to be controlled is assumed to be described by the following linear time-invariant (LTI) model:

$$\dot{x} = Ax + Bu + E\omega$$

$$\begin{aligned}
y &= Cx + Du + F\omega \\
y_m &= C_mx + D_mu + F_m\omega \\
e &= y - y_{\text{ref}}
\end{aligned}
\tag{23.1}$$

where $x \in \mathbb{R}^n$ is the state, $u \in \mathbb{R}^m$ are the inputs that can be manipulated, $y \in \mathbb{R}^r$ are the outputs that are to be regulated and $y_m \in \mathbb{R}^m$ are the outputs which can be measured. Here $\omega \in \mathbb{R}^\Omega$ correspond to the disturbances in the system, which in general cannot necessarily be measured, and $e \in \mathbb{R}^r$ is the error in the system, which is the difference between the output y and the reference input signal y_{ref} , in which it is desired that the outputs y should track.

23.2.2 Class of Tracking/Disturbance Signals

It is assumed that the disturbances ω arise from the following class of systems:

$$\dot{\eta}_1 = \mathcal{A}_1\eta_1, \quad \omega = \mathcal{C}_1\eta_1; \quad \eta_1 \in \mathbb{R}^{n_1} \tag{23.2}$$

and that the reference input signals y_{ref} arise from the following class of systems:

$$\dot{\eta}_2 = \mathcal{A}_2\eta_2, \quad \rho = \mathcal{C}_2\eta_2, \quad y_{\text{ref}} = G\rho; \quad \eta_2 \in \mathbb{R}^{n_2} \tag{23.3}$$

It is assumed for nontriviality that $\text{sp}(\mathcal{A}_1) \subset \mathbb{C}^+$, $\text{sp}(\mathcal{A}_2) \subset \mathbb{C}^+$, where $\text{sp}(\cdot)$ denotes the eigenvalues of (\cdot) and \mathbb{C}^+ denotes the closed right complex half-plane. It is also assumed with no loss of generality that $(\mathcal{C}_1, \mathcal{A}_1)$, $(\mathcal{C}_2, \mathcal{A}_2)$ are observable and that $\text{rank} \begin{pmatrix} E \\ F \end{pmatrix} = \text{rank } \mathcal{C}_1 = \dim(\omega)$, $\text{rank } G = \text{rank } \mathcal{C}_2 = \dim(\rho)$.

This class of signals is quite broad and includes most classes of signals that occur in application problems, e.g., constant, polynomial, sinusoidal, polynomial-sinusoidal, etc.

The following definitions will be used in the development to follow.

Definition 23.1:

Given the systems represented by Equations 23.2, and 23.3, let $\{\lambda_1, \lambda_2, \dots, \lambda_p\}$ be the zeros of the least common multiple of the nominal polynomial of \mathcal{A}_1 and minimal polynomial of \mathcal{A}_2 (multiplicities repeated), and call

$$\Lambda := \{\lambda_1, \lambda_2, \dots, \lambda_p\} \tag{23.4}$$

the disturbances/tracking poles of Equations 23.2 and 23.3.

Definition 23.2:

Given the model represented by Equation 23.1, consider the system

$$\begin{aligned}
\dot{x} &= Ax + Bu; \quad u \in \mathbb{R}^m, \quad y \in \mathbb{R}^r, \quad x \in \mathbb{R}^n \\
y &= Cx + Du
\end{aligned}$$

Then $\lambda \in \mathbb{C}$ is said to be a transmission zero (TZ) [3] of (C, A, B, D) if

$$\text{rank} \begin{bmatrix} A - \lambda I & B \\ C & D \end{bmatrix} < n + \min(r, m)$$

In particular, the transmission zeros are the zeros (multiplicities included) of the greatest common divisor of all $[n + \min(r, m)] \times [n + \min(r, m)]$ minors of $\begin{bmatrix} A - \lambda I & B \\ C & D \end{bmatrix}$.

Definition 23.3:

Given the system (C, A, B, D) , assume that one or more of the transmission zeros of (C, A, B, D) are contained in the closed right complex half-plane; then (C, A, B, D) is said to be a nonminimum-phase system. If (C, A, B, D) is not nonminimum phase, then it is said to be a minimum-phase system.

23.2.3 Robust Servomechanism Problem

The *robust servomechanism problem* (RSP) for Equation 23.1 consists in finding an LTI controller that has inputs y_m, y_{ref} and outputs u for the plant so that:

1. The resultant closed-loop system is asymptotically stable.
2. Asymptotic tracking occurs; that is,

$$\lim_{t \rightarrow \infty} e(t) = 0, \quad \forall x(0) \in \mathbb{R}^n, \quad \forall \eta_1(0) \in \mathbb{R}^{n_1}, \quad \forall \eta_2(0) \in \mathbb{R}^{n_2}$$

for all controller initial conditions.

3. Condition 2 holds for any arbitrary perturbations in the plant model Equation 23.1 (e.g., plant parameters or plant dynamics, including changes in model order) that do not cause the resultant closed-loop system to become unstable.

In this problem statement, there is no requirement made regarding the transient behavior of the closed-loop system; thus, the following problem statement is now made.

Perfect RSP

Given the plant represented by Equation 23.1, it is desired to find a controller such that:

1. It solves the RSP for the class of disturbances/tracking signals given by Equations 23.2 and 23.3.
2. The controller gives *perfect error regulation* when applied to the nominal plant model Equation 23.1, i.e., given $x(0), z_1(0), z_2(0)$, located on the unit sphere, with $\eta(0) = 0$, where $\eta(0)$ is the initial condition of the servo-compensator (see Equation 23.9), then $\forall \epsilon > 0$, there exists a controller (parameterized by ϵ) that satisfies property 1 and has the property that $\int_0^\infty e'(\tau)e(\tau) d\tau < \epsilon$, with no unbounded peaking occurring in the response of e ; i.e., there exists a constant ρ , independent of ϵ , such that $\sup_{t \geq 0} |e(t)| < \rho$.

Thus, in the perfect RSP, arbitrarily good transient error, with no unbounded peaking in the error response of the system, can be obtained for any initial condition of the plant and for any disturbance/tracking signals that belong to Equations 23.2 and 23.3.

23.3 Main Results

The following results are obtained concerning the existence of a solution to the RSP [5,6].

Theorem 23.1:

There exists a solution to the RSP for Equation 23.1, if and only if the following conditions are all satisfied:

1. (C_m, A, B) is stabilizable and detectable.
2. $m \geq r$.

3. The transmission zeros of (C, A, B, D) exclude the disturbance/tracking poles $\lambda_i, i = 1, 2, \dots, p$.
4. $y \subset y_m$; i.e., the outputs y are measurable.

Remark 23.1

The conditions 2 and 3 are equivalent to the condition:

$$\text{rank} \begin{bmatrix} A - \lambda_i I & B \\ C & D \end{bmatrix} = n + r, \quad i = 1, 2, \dots, p \quad (23.5)$$

The following existence results are obtained concerning the existence of a solution to the perfect RSP [12]:

Theorem 23.2:

There exists a solution to the perfect RSP for Equation 23.1, if and only if the following conditions are all satisfied:

1. (C_m, A) is detectable
2. $m \geq r$
3. (C, A, B, D) is minimum phase
4. $y \subset y_m$

Remark 23.2

If $m = r$, the above conditions simplify to just conditions 3 and 4.

The following definitions of a stabilizing compensator and servo-compensator are required in the development to follow.

Definition 23.4:

Given the stabilizable, detectable system (C_m, A, B, D) obtained from Equation 23.1, an LTI stabilizing compensator

$$\begin{aligned} \dot{\xi} &= \Lambda_1 \xi + \Lambda_2 y_m \\ u &= K_1 \xi + K_2 y_m \end{aligned} \quad (23.6)$$

is defined to be a controller that asymptotically stabilizes the resultant closed-loop system, such that “desired” transient behavior occurs.

This compensator is not a unique device and may be designed by using a number of different techniques.

Definition 23.5:

Given the disturbance/reference input poles $\lambda_i, i = 1, 2, \dots, p$, the matrix $C \in R^{p \times p}$ and vector $\gamma \in R^p$ are

defined by

$$\mathcal{C} := \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ -\delta_1 & -\delta_2 & -\delta_3 & \dots & -\delta_p \end{bmatrix}, \quad \gamma := \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix} \quad (23.7)$$

where the coefficients δ_i , $i = 1, 2, \dots, p$ are given by the coefficients of the polynomial $\prod_{i=1}^p (\lambda - \lambda_i)$; i.e.,

$$\lambda^p + \delta_p \lambda^{p-1} + \dots + \delta_2 \lambda + \delta_1 := \prod_{i=1}^p (\lambda - \lambda_i) \quad (23.8)$$

The following compensator, called a *servo-compensator*, is of fundamental importance in the design of controllers to solve the RSP [5].

Definition 23.6:

Consider the class of disturbance/tracking signals given by Equations 23.2 and 23.3, and consider the system of Equation 23.1; then a servo-compensator for Equation 23.1 is a controller with input $e \in R^r$ and output $\eta \in R^{rp}$ given by

$$\dot{\eta} = \mathcal{C}^* \eta + \mathcal{B}^* e \quad (23.9)$$

where

$$\mathcal{C}^* := \text{block diag} \underbrace{(\mathcal{C}, \mathcal{C}, \dots, \mathcal{C})}_r \quad (23.10)$$

$$\mathcal{B}^* := \text{block diag} \underbrace{(\gamma, \gamma, \dots, \gamma)}_r \quad (23.11)$$

where \mathcal{C} , γ are given by Equation 23.7.

The servo-compensator is unique within the class of coordinate transformations and nonsingular input transformations.

Given the servo-compensator of Equation 23.9, now let $\mathcal{D} \in R^{r \times rp}$ be defined by

$$\mathcal{D} := \text{block diag} \underbrace{(\delta, \delta, \dots, \delta)}_r \quad (23.12)$$

where $\delta \in R^{1 \times p}$ is given by:

$$\delta := (1 \ 0 \ 0 \ \dots \ 0) \quad (23.13)$$

The servo-compensator has the following properties:

Lemma 23.1: [12]

Given the plant represented by Equation 23.1, assume that the existence conditions of Theorem 23.1 all hold; then

1. The system

$$\left\{ \begin{pmatrix} C_m & 0 \\ 0 & D \end{pmatrix}, \begin{pmatrix} A & 0 \\ B^*C & c^* \end{pmatrix}, \begin{pmatrix} B \\ B^*D \end{pmatrix} \right\}$$

is stabilizable and detectable and has centralized fixed modes [8] (i.e., those modes of the system that are not both simultaneously controllable and observable) equal to the centralized fixed modes of (C_m, A, B, D_m) .

2. The transmission zeros of

$$\left\{ (0 \ D), \begin{pmatrix} A & 0 \\ B^*C & c^* \end{pmatrix}, \begin{pmatrix} B \\ B^*D \end{pmatrix} \right\}$$

are equal to the transmission zeros of (C, A, B, D) .

23.3.1 Robust Servomechanism Controller

Consider the system of Equation 23.1, and assume that the existence conditions of Theorem 23.1 hold; then any LTI controller that solves the RSP for Equation 23.1 consists of the following structure [6] (see Figure 23.1):

$$u = \xi + K\eta \tag{23.14}$$

where $\eta \in R^{rp}$ is the output of the servo-compensator (Equation 23.9), and ξ is the output of a stabilizing compensator S with inputs y_m, y_{ref}, η, u , where S, K are found to stabilize and give “desired behavior” to the following stabilizable and detectable system:

$$\begin{aligned} \begin{pmatrix} \dot{x} \\ \dot{\eta} \end{pmatrix} &= \begin{bmatrix} A & 0 \\ B^*C & c^* \end{bmatrix} \begin{pmatrix} x \\ \eta \end{pmatrix} + \begin{pmatrix} B \\ B^*D \end{pmatrix} y_{ref} \\ \tilde{y}_m &= \begin{bmatrix} C_m & 0 \\ 0 & I \\ 0 & 0 \end{bmatrix} \begin{pmatrix} x \\ \eta \end{pmatrix} + \begin{pmatrix} D_m \\ 0 \\ I \end{pmatrix} y_{ref} \end{aligned} \tag{23.15}$$

where, from Lemma 23.1, the centralized fixed modes (if any) of

$$\left\{ \begin{pmatrix} C_m & 0 \\ 0 & I \end{pmatrix}, \begin{bmatrix} A & 0 \\ B^*C & c^* \end{bmatrix}, \begin{pmatrix} B \\ B^*D \end{pmatrix} \right\}$$

are equal to the centralized fixed modes of (C_m, A, B) ; i.e., there always exists a coordinate transformation and nonsingular input transformation, by which any controller that solves the RSP for Equation 23.1 can be described by Equation 23.14. It is to be noted that this controller always has order $\geq rp$.

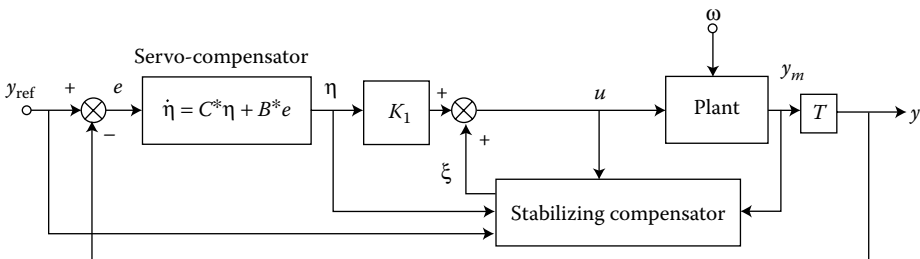

FIGURE 23.1 General controller to solve robust servomechanism problem.

Properties of Robust Servomechanism Controller

Some properties of the robust servomechanism controller (RSC) represented by Equation 23.14 are as follows [5]:

1. In the above controller, it is required to know only the disturbance/reference input poles $\{\lambda_1, \lambda_2, \dots, \lambda_p\}$; i.e., it is not necessary to know E, F of Equation 23.1 nor $\mathcal{A}_1, \mathcal{A}_2, \mathcal{C}_1, \mathcal{C}_2, G$ of Equations 23.2 and 23.3.
2. A controller exists generically [2] for almost all plants described by Equation 23.1, provided that (a) $m \geq r$, and (b) the outputs y can be measured; if either condition (a) or (b) fails to hold, there is no solution to the RSP.

23.3.2 Various Classes of Stabilizing Compensators

Various special classes of stabilizing compensators \mathcal{S} that can be used in the RSC (Equation 23.14) are as follows. It is assumed that the existence conditions of Theorem 23.1 are all satisfied in order to implement these proposed controllers.

Multivariable Three-Term Controller

(See Figure 23.2). In order to use this controller, it is assumed that:

1. The plant of Equation 23.1 is open loop asymptotically stable.
2. The disturbance/tracking poles $\{\lambda_1, \lambda_2, \dots, \lambda_p\}$ are of the polynomial-sinusoidal type; i.e., it is assumed that $\text{Re}(\lambda_i) = 0, i = 1, 2, \dots, p$.

If these assumptions hold, then the following generalized three-term controller solves the RSP [9]:

$$\begin{aligned} u &= (K_0 + K_1s)e + K_2\eta \\ \dot{\eta} &= C^*\eta + B^*e \end{aligned} \tag{23.16}$$

An algorithm is given [7], that shows that a stabilizing K_2 , with $K_0 = 0, K_1 = 0$, can always be found for this controller.

23.3.3 Complementary Controller

(See Figure 23.3) In order to use this controller, it is assumed that the plant of Equation 23.1 is open loop asymptotically stable. If this assumption holds, then the following controller, called a complementary

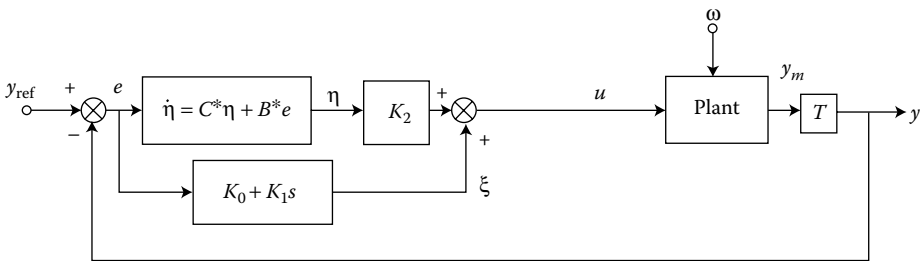

FIGURE 23.2 Generalized three term controller to solve the robust servomechanism problem.

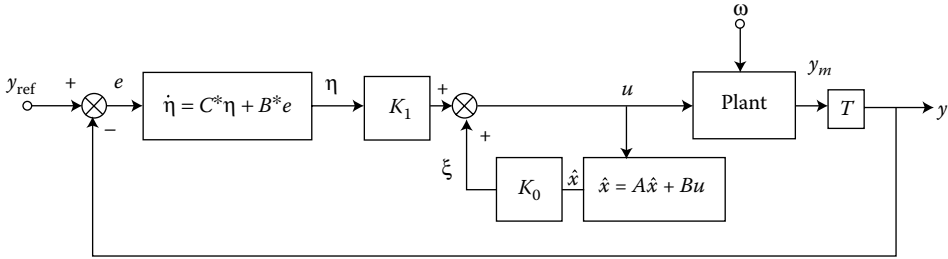

FIGURE 23.3 Complementary controller to solve the robust servomechanism problem.

controller, will solve the RSP [5]:

$$\begin{aligned} u &= K_0\hat{x} + K_1\eta \\ \dot{\eta} &= C^*\eta + B^*e \\ \dot{\hat{x}} &= A\hat{x} + Bu \end{aligned} \tag{23.17}$$

where (K_0, K_1) are found to stabilize the stabilizable system

$$\dot{\tilde{x}} = \begin{bmatrix} A & 0 \\ B^*C & C^* \end{bmatrix} \tilde{x} + \begin{pmatrix} B \\ B^*D \end{pmatrix} u \tag{23.18}$$

using state feedback; i.e., $u = (K_0 \ K_1)\tilde{x}$.

23.3.4 Observer-Based Stabilizing Controller

(See Figure 23.4) No additional assumptions are required in order to implement this controller. The controller is given as follows [9]:

$$\begin{aligned} u &= K_0\hat{x} + K_1\eta \\ \dot{\eta} &= C^*\eta + B^*e \\ \dot{\hat{x}} &= \{A + (B - \Lambda D_m)K_0 - \Lambda C_m\}\hat{x} + (B - \Lambda D_m)K_1\eta + \Lambda y_m \end{aligned} \tag{23.19}$$

where (K_0, K_1) are found to stabilize the system of Equation 23.18, and Λ is an observer gain matrix found to stabilize the system matrix $(A - \Lambda C_m)$ where (C_m, A) is detectable. (A reduced-order observer could also be used to replace the full-order observer in Equation 23.19.)

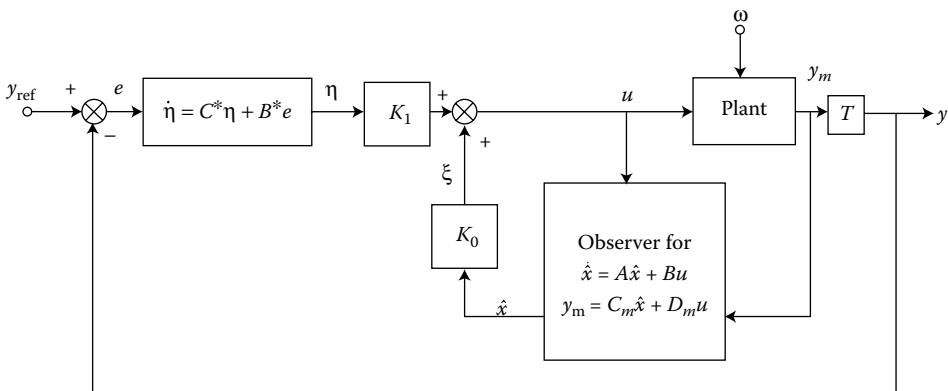

FIGURE 23.4 Observer-based stabilizing compensator to solve the robust servomechanism problem.

23.4 Applications and Example Calculations

We initially demonstrate the theory by considering the design of a controller for a nonminimum-phase plant (Example 23.1), and a minimum-phase plant (Example 23.2), and thence conclude with a case study on the control of a nontrivial distillation column system.

Example 23.1: Nonminimum-Phase System

Consider the following system

$$\begin{aligned}\dot{x} &= \begin{pmatrix} 2 & -1 \\ 0 & 0 \end{pmatrix} x + \begin{pmatrix} 1 \\ 1 \end{pmatrix} u \\ y &= (1 \ 0)x + \omega; \quad y_m = y\end{aligned}\tag{23.20}$$

which is open loop unstable and nonminimum phase (with a transmission zero at 1), and in which it is desired to design a controller to solve the RSP for the case of constant disturbances and constant reference input signals. In this case, the disturbance/tracking poles = {0}, and it can be directly verified that the existence conditions for a solution to the problem are satisfied from Theorem 23.1. In the controller design, it is initially assumed that the control input should not be "excessively large."

Controller Development

On applying the servo-compensator of Equation 23.9 for constant disturbances/reference input signals to Equation 23.20, the following system is obtained:

$$\begin{aligned}\begin{pmatrix} \dot{x} \\ \dot{\eta} \end{pmatrix} &= \begin{pmatrix} 2 & -1 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} \begin{pmatrix} x \\ \eta \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \\ 0 \end{pmatrix} \omega + \begin{pmatrix} 0 \\ 0 \\ -1 \end{pmatrix} y_{\text{ref}} \\ y &= (1 \ 0 \ 0) \begin{pmatrix} x \\ \eta \end{pmatrix} + 1\omega\end{aligned}\tag{23.21}$$

and, on minimizing the performance index [12] for Equation 23.21

$$J_\epsilon = \int_0^\infty (e'e + \epsilon \dot{u}'\dot{u}) d\tau, \quad \epsilon = 1\tag{23.22}$$

the following controller is obtained:

$$u = (k_1 \ k_2)\hat{x} + k \int_0^t (y - y_{\text{ref}}) d\tau\tag{23.23}$$

where

$$k_1 = -13.77, \quad k_2 = 8.721, \quad k = 1.000$$

and where \hat{x} is the output of an observer for Equation 23.20. On using a reduced-order observer with observer pole = -1, the following controller is thence obtained.

Robust Servomechanism Controller

$$\begin{aligned} u &= -22.498y + \eta + 8.7214\sigma \\ \dot{\eta} &= y - y_{\text{ref}} \\ \dot{\sigma} &= 16.443\sigma + 2\eta - 41.996y \end{aligned} \quad (23.24)$$

which, when applied to Equation 23.20, gives the following closed-loop poles:

$$\begin{pmatrix} -0.552 \pm j0.456 \\ -1.00 \\ -1.95 \end{pmatrix}$$

Properties of Controller

On applying the controller of Equation 23.24 to the plant of Equation 23.20, the following closed-loop system is obtained:

$$\begin{aligned} \begin{pmatrix} \dot{x} \\ \dot{\eta} \\ \dot{\sigma} \end{pmatrix} &= \begin{bmatrix} -20.498 & -1 & 1 & 8.7214 \\ -22.498 & 0 & 1 & 8.7214 \\ 1 & 0 & 0 & 0 \\ -41.996 & 0 & 2 & 16.443 \end{bmatrix} \begin{pmatrix} x \\ \eta \\ \sigma \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ -1 \\ 0 \end{pmatrix} y_{\text{ref}} + \begin{pmatrix} -22.49 \\ -22.49 \\ 1 \\ -41.99 \end{pmatrix} \omega \\ y &= [1 \quad 0 \quad 0 \quad 0] \begin{pmatrix} x \\ \eta \\ \sigma \end{pmatrix} + \omega \\ u &= [-22.498 \quad 0 \quad 1 \quad 8.7214] \begin{pmatrix} x \\ \eta \\ \sigma \end{pmatrix} + (-22.498)\omega \end{aligned}$$

which gives the Bode magnitude response between e , u and input y_{ref} in Figure 23.5, e , u and input ω in Figure 23.6, and unit-step responses in y_{ref} in Figure 23.7 and in ω in Figure 23.8, with zero initial conditions. It is seen that satisfactory tracking/regulation occurs using the controller.

Response of Closed-Loop System to Unbounded Reference Input/Disturbance Signals

According to Theorem 3 in [12], the RSC of Equation 23.14 has the property of not only achieving asymptotic tracking/regulation for the class of constant reference input/disturbance signals, but also bringing about *exact* asymptotic tracking/regulation for unbounded signals that have the property that:

$$\begin{aligned} \lim_{t \rightarrow \infty} y_{\text{ref}}(t) &= 0 \\ \lim_{t \rightarrow \infty} \dot{\omega}(t) &= 0 \end{aligned} \quad (23.25)$$

To illustrate this result, Figure 23.9 gives the response of the closed-loop system for the case when the tracking input signal is given by

$$y_{\text{ref}}(t) = t^{1/4}, \quad t \geq 0 \quad (23.26)$$

with zero initial conditions. It is seen that exact asymptotic tracking indeed does take place using this controller.

Optimum Response of Nonminimum-Phase System

The RSC of Equation 23.24 was obtained so that the magnitude of the control input signal is constrained by letting $\epsilon = 1$ in the performance index of Equation 23.22. It is of interest to determine what type of

FIGURE 23.5 Bode plot magnitude of closed-loop system using robust servomechanism controller from reference input signal: (a) to error; (b) to control input.

FIGURE 23.6 Bode plot magnitude of closed-loop system using robust servomechanism controller from disturbance signal: (a) to error; (b) to control input.

FIGURE 23.7 Response of closed-loop system using robust servomechanism controller for unit step in reference input signal: (a) output; (b) input.

FIGURE 23.8 Response of closed-loop system using robust servomechanism controller for unit step in disturbance input signal: (a) output; (b) input.

FIGURE 23.9 Response of closed-loop system using robust servomechanism controller for unbounded reference input signal = $t^{1/4}$: (a) output; (b) input.

transient performance can be obtained for the system if the controller is designed without any regard for the magnitude of the control input signal; i.e., by letting $\epsilon = 10^{-8}$, say, in the performance index (Equation 23.22). According to Theorem 23.2, “perfect control” cannot be achieved for the system; in particular, if the plant’s and controller’s initial conditions are equal to zero and $\omega = 0$, then the limiting performance that can be achieved is given by [13]

$$\lim_{\epsilon \rightarrow 0} J_\epsilon = 2 \sum_{i=1}^l \frac{1}{\lambda_i^*} y_{\text{ref}}^2 \tag{23.27}$$

where $\{\lambda_i^*, i = 1, 2, \dots, l\}$ are the nonminimum TZ of the system, and J_ϵ is given by Equation 23.22. In this case, $l = 1, \lambda_1^* = 1$, so that the limiting performance index is given by $\lim_{\epsilon \rightarrow 0} J_\epsilon = 2y_{\text{ref}}^2$.

The following optimal controller is now obtained on putting $\epsilon = 10^{-8}$ in the performance index of Equation 23.22:

$$\begin{aligned} u &= (-2.043 \times 10^4 \quad 2.029 \times 10^4)x + 10^4 \eta \\ \dot{\eta} &= y - y_{\text{ref}} \end{aligned} \tag{23.28}$$

This controller results in the following closed-loop system poles:

$$\begin{pmatrix} -70.7 \pm j70.7 \\ -1.00 \end{pmatrix}$$

with the following optimal performance index, for $x(0) = 0, \omega = 0$:

$$J = 2.014y_{\text{ref}}^2 \tag{23.29}$$

which is “close” to the optimal limiting performance index of $2y_{\text{ref}}^2$.

FIGURE 23.10 Response of closed-loop system using robust servomechanism controller with high gain for unit step in reference input signal: (a) output; (b) input.

A response of the closed-loop system using the controller of Equation 23.28 for a unit step in y_{ref} , with zero initial conditions for the plant, is given in Figure 23.10. It is seen that the response of the closed-loop system is only about twice as fast as that obtained using the controller of Equation 23.24, in spite of the fact that the control signal is now some 40 times larger than that obtained using Equation 23.24, which confirms the fact that nonminimum-phase systems are fundamentally “difficult to control.”

High-Gain Servomechanism Control

The same example as considered in the previous sections will now be considered, except that a high-gain servomechanism controller (HGSC) [12], which is simpler than an RSC, will now be applied and compared with the RSC of Equation 23.24.

Plant Model

$$\begin{aligned}\dot{x} &= \begin{pmatrix} 2 & -1 \\ 0 & 0 \end{pmatrix} x + \begin{pmatrix} 1 \\ 1 \end{pmatrix} u \\ y &= (1 \quad 0)x + \omega\end{aligned}\tag{23.30}$$

Controller Development

Given the cheap control performance index

$$\tilde{J}_\epsilon = \int_0^\infty (y'y + \epsilon u'u) d\tau\tag{23.31}$$

let $\epsilon = 1$; in this case, the optimal control that minimizes \tilde{J}_ϵ for the system of Equation 23.30 with $\omega = 0$ is given by

$$u = kx, \quad k = (-10.292 \quad 5.6458) \quad (23.32)$$

which results in the closed-loop system of Equations 23.30 and 23.33 having poles given by $(-0.457, -2.19)$.

On letting $\mathcal{K} := -[c(A + Bk)^{-1}B]^{-1} = -1$, the HGSC is now given by [12]:

$$u = \mathcal{K}(y_{\text{ref}} - y) + (k + \mathcal{K}c)\hat{x} \quad (23.33)$$

where \hat{x} is the output of an observer for Equation 23.30. On choosing a reduced-order observer with observer gain $= -1$, and simplifying, the following controller is finally obtained:

High-Gain Servomechanism Controller

$$\begin{aligned} u &= -y_{\text{ref}} - 15.94y - 5.646\xi \\ \dot{\xi} &= 10.29\xi + 28.87y + 2y_{\text{ref}} \end{aligned} \quad (23.34)$$

Properties of HGSC

On applying Equation 23.34 to Equation 23.30, the following closed-loop system is obtained:

$$\begin{aligned} \begin{pmatrix} \dot{x} \\ \dot{\xi} \end{pmatrix} &= \begin{bmatrix} -13.94 & -1 & -5.646 \\ -15.94 & 0 & -5.646 \\ 28.87 & 0 & 10.29 \end{bmatrix} \begin{pmatrix} x \\ \xi \end{pmatrix} + \begin{pmatrix} -1 \\ -1 \\ 2 \end{pmatrix} y_{\text{ref}} + \begin{pmatrix} 0 \\ 0 \\ 28.87 \end{pmatrix} \omega \\ e &= [1 \quad 0 \quad 0] \begin{pmatrix} x \\ \xi \end{pmatrix} - 1y_{\text{ref}} + 1\omega \\ y &= [1 \quad 0 \quad 0] \begin{pmatrix} x \\ \xi \end{pmatrix} + 1\omega \\ u &= [-15.94 \quad 0 \quad -5.646] \begin{pmatrix} x \\ \xi \end{pmatrix} - 1y_{\text{ref}} - 15.94\omega \end{aligned}$$

which has closed-loop poles given by $(-0.457, -1.00, -2.19)$. The Bode magnitude response of this system with respect to output e , u and input y_{ref} is given in Figure 23.11. The unit-step function response of this system for an increase in y_{ref} with zero initial conditions is given in Figure 23.12. It is seen that satisfactory tracking occurs using this controller.

Comparison of Robustness Properties of HGSC to RSP

Although the HGSC of Equation 23.34 is “simpler” than the RSC of Equation 23.24, the outstanding advantage of the RSP is that it is robust; i.e., it provides *exact* asymptotic tracking/regulation for any perturbations of the plant model, that do not destabilize the perturbed closed-loop system. As an example of this behavior, consider the HGSC (Equation 23.34) and RSC (Equation 23.24) controlling the following (slightly) perturbed model of Equation 23.20:

Perturbed Model

$$\begin{aligned} \dot{x} &= \begin{pmatrix} 2 & -1 \\ 0 & -0.1 \end{pmatrix} x + \begin{pmatrix} 1 \\ 1 \end{pmatrix} u \\ y &= (1 \quad 0)x + \omega \end{aligned} \quad (23.35)$$

In this case, the resultant perturbed closed-loop system remains stable for each of the controllers, but the HGSC no longer provides tracking; e.g., $\lim_{t \rightarrow \infty} y(t) = 0.3$ when $y_{\text{ref}} = 1$. In contrast, it may be verified that the RSC (Equation 23.24) still provides exact tracking when applied to Equation 23.35.

FIGURE 23.11 Bode plot magnitude of closed-loop system using high-gain servomechanism controller from reference input signal: (a) to error; (b) to control input.

FIGURE 23.12 Response of closed-loop system using high-gain servomechanism controller for unit step in reference input signal: (a) output; (b) input.

Example 23.2: Minimum-Phase System

Consider the following system, which is a model of a pressurized head box in paper manufacturing:

$$\begin{aligned} \dot{x} &= \begin{pmatrix} 0.395 & 0.01145 \\ -0.011 & 0 \end{pmatrix} x + \begin{pmatrix} 0.03362 & 1.038 \\ 0.000966 & 0 \end{pmatrix} u \\ y &= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} x; \quad y_m = y \end{aligned} \quad (23.36)$$

which has open-loop eigenvalues $= (-3.19 \times 10^{-4}, -3.95 \times 10^{-1})$. In this case, the plant represented by Equation 23.36 has no transmission zeros, which implies that it is minimum phase, and so there exists a solution to the RSP for the class of constant disturbances/reference input signals such that perfect control occurs (see Theorem 23.2).

The following development illustrates how “perfect control” in a minimum-phase system results in *arbitrarily good approximate error regulation* (AGAER) [12] occurring; i.e., although the servo-compensator is designed to give exact asymptotic error regulation for constant disturbances/reference input signals, AGAER will occur for other classes of disturbances/reference input signals, e.g., for the class of sinusoidal signals $y_{\text{ref}} = \bar{y} \sin(\omega t)$.

The following perfect controller is now obtained:

$$u = K_0 y + K \int_0^t (y - y_{\text{ref}}) d\tau \quad (23.37)$$

which, on minimizing the performance index

$$J_\epsilon = \int_0^\infty (\epsilon' e + \epsilon u' u) d\tau \quad (23.38)$$

gives

$$\begin{aligned} K_0 &= \begin{pmatrix} -4.33 & -4549 \\ -138.3 & 158.7 \end{pmatrix}, \quad K = \begin{pmatrix} -371.9 & -10^4 \\ -10^4 & 371.9 \end{pmatrix} \quad \text{for } \epsilon = 10^{-8} \\ K_0 &= \begin{pmatrix} -13.8 & -1.439 \times 10^4 \\ -438.2 & 477.3 \end{pmatrix}, \quad K = \begin{pmatrix} -338.8 & -9.994 \times 10^4 \\ -9.994 \times 10^4 & 3388 \end{pmatrix} \quad \text{for } \epsilon = 10^{-10} \end{aligned} \quad (23.39)$$

It may now be demonstrated that AGAER occurs; e.g., when the reference input signal $y_{\text{ref}} = \bar{y} \sin(\omega t)$, $\omega = 0.1$ is applied, we obtain the following *error coefficient* [12]:

$$\begin{aligned} {}_0K_t^0(j\omega) &= \begin{pmatrix} 1.4 \times 10^{-3} & 1.0 \times 10^{-4} \\ 1.0 \times 10^{-4} & 4.6 \times 10^{-2} \end{pmatrix} \quad \text{for } \epsilon = 10^{-8} \\ &= \begin{pmatrix} 4.4 \times 10^{-4} & 1.0 \times 10^{-5} \\ 1.0 \times 10^{-5} & 1.4 \times 10^{-2} \end{pmatrix} \quad \text{for } \epsilon = 10^{-10} \end{aligned} \quad (23.40)$$

which implies that excellent (but approximate) tracking occurs as $\epsilon \rightarrow 0$ for the tracking signal $y_{\text{ref}} = \bar{y} \sin(\omega t)$, $\omega = 0.1$.

Stability Robustness Concerns

The previous example studies have ignored “stability robust concerns”; i.e., the recognition that any plant model is really only an approximation to a model of the actual physical system, and hence that a given physical system may become unstable under feedback if the model used is sufficiently inaccurate.

The following shows that for some classes of systems, a system may be relatively insensitive to plant perturbations, whereas for other classes of systems, a system may be highly sensitive to plant perturbations. This implies that any controller that is designed to solve the RSP must *always* take into account stability robustness considerations for the particular problem being studied.

Consider the head box example (Equation 23.36) and the controller

$$u = K_0 y + K \int_0^t (y - y_{\text{ref}}) d\tau \tag{23.41}$$

which has been designed for the class of constant disturbances/reference input signals. It is now desired to determine the optimal controller gain matrices K_0, K that minimize the performance index

$$J_\epsilon = \int_0^\infty (e'e + \epsilon \dot{u}'\dot{u}) d\tau \quad \epsilon = 10^{-8} \tag{23.42}$$

with and without a *gain margin* (GM) constraint [10] imposed on the system. This constraint can be imposed by using the computer-aided design (CAD) approach of Davison and Ferguson [9]. Let Γ denote the optimal cost matrix of Equation 23.44, and define $J_{\text{opt}} = \text{trace}(\Gamma)$. The following results are now obtained (see Table 23.1)

In this case, the optimal controller that minimizes J_ϵ (Equation 23.44), subject to a fairly demanding GM constraint of (0.2,2) is only about “two times slower” than the optimal controller, which does not take gain margin into account; i.e., the system is relatively insensitive to plant perturbations.

Consider now, however, the following system:

$$\begin{aligned} \dot{x} &= \begin{pmatrix} -1 & 0 \\ 0 & -2 \end{pmatrix} x + \begin{pmatrix} 7 & 8 \\ 12 & 14 \end{pmatrix} u \\ y &= \begin{pmatrix} 7 & -8 \\ -6 & 7 \end{pmatrix} x; \quad y_m = y \end{aligned} \tag{23.43}$$

and the controller of Equation 23.43. It is desired now to find optimal controller parameters K_0, K so as to minimize the performance index J_ϵ (Equation 23.44) with and without a modest GM of (0.9,1.1) applied. The following results are obtained from Davison and Copeland [10] (see Table 23.2).

In this case, it can be seen that a very modest demand that the controller should have a GM of only 10% has produced a dramatic effect in terms of the controller. The controller obtained with the 10% GM constraint being imposed has a performance index that is some 10^5 times “worse” than the case when no GM constraint is imposed; i.e., the system is extremely sensitive to plant perturbations. Thus, this example emphasizes the need to always apply some type of stability robustness constraint when solving “high-performance controller” problems.

More Complex Tracking/Disturbance Signal Requirements

The following example illustrates the utilization of more complex servo-compensator construction. In this case, the head box problem modeled by Equation 23.36 is to be controlled for the class of disturbance/reference input signals that have the structure:

$$y_{ref} = \bar{y}_1 \sin(\omega_1 t) + \bar{y}_2 \sin(\omega_2 t) + \bar{y}_3 \sin(\omega_3 t) \tag{23.44}$$

where $\omega_1 = \pi$, $\omega_2 = 3\pi$, $\omega_3 = 5\pi$, and $\bar{y}_1, \bar{y}_2, \bar{y}_3$ are arbitrary real two-dimensional vectors.

From Theorem 23.1, there exists a solution to the problem, and the servo-compensator is now given from Equation 23.9 by:

$$\dot{\eta} = \text{block diag} \left[\begin{pmatrix} 0 & I \\ -\omega_1^2 I & 0 \end{pmatrix}, \begin{pmatrix} 0 & I \\ -\omega_2^2 I & 0 \end{pmatrix}, \begin{pmatrix} 0 & I \\ -\omega_3^2 I & 0 \end{pmatrix} \right] \eta + \begin{bmatrix} 0 \\ I \\ 0 \\ I \\ I \\ 0 \\ 0 \\ I \end{bmatrix} (y - y_{ref}) \tag{23.45}$$

and the following controller is now obtained:

$$u = K_0 y + (K_1 \ K_2 \ K_3) \eta \tag{23.46}$$

In this case, the following performance index

$$\bar{J}_\epsilon = \int_0^\infty \left\{ (x' \ \eta') Q \begin{pmatrix} x \\ \eta \end{pmatrix} + \epsilon u' u \right\} d\tau \tag{23.47}$$

where

$$Q := (0 \ I \ 0 \ I \ 0 \ I \ 0 \ I \ 0 \ I \ 0 \ I \ 0) \tag{23.48}$$

$$\epsilon = 10^{-8}$$

is to be minimized in order to determine the optimal controller parameters (K_0, K_1, K_2, K_3) . As before, let Γ denote the optimal cost matrix of Equation 23.47, corresponding to a minimization of \bar{J}_ϵ , and define $\bar{J}_{opt} = \text{trace}(\Gamma)$. The following results are now obtained:

$$\bar{J}_{opt} = 36.3$$

and the optimal K_0, K_1, K_2, K_3 are given in Table 23.3.

The eigenvalues of the resultant closed-loop system using this controller are given in Table 23.4.

In this case, the response of the resultant closed-loop system for a triangular tracking signal of period 4 seconds is given in Figure 23.13. It is seen that the tracking performance of the system is excellent; it is to be noted that the dominant harmonics of this triangular wave are given by $\pi, 3\pi, 5\pi$ rad/s, and thus the servo-compensator is approximating the tracking of a triangular wave, in this case, by tracking/regulating the main harmonic terms of the periodic signal.

23.4.1 CAD Approach

In designing controllers for actual physical systems, it is often important to impose on the controller construction constraints that are related to the specific system being considered. Such constraints can be incorporated directly using a CAD approach (e.g., see [9]). The following example illustrates the type of results that may be obtained.

Consider the head box problem modeled by Equation 23.36, controlled by the controller

$$u = K_0 y + K \int_0^t (y - y_{\text{ref}}) d\tau \tag{23.49}$$

and assume that it is desired to determine the controller gain matrices K_0, K_1 , so as to minimize the performance index:

$$J_\epsilon = \int_0^\infty (\epsilon' e + \epsilon i' \dot{u}) d\tau, \quad \epsilon = 10^{-8} \tag{23.50}$$

such that all elements of K_0, K satisfy the constraint:

$$|k_{ij}| \leq 100$$

This constraint could arise, for example, in terms of attempting to regulate the control signal magnitude level for a system. The following results are obtained in this case [9] (see Table 23.5).

TABLE 23.5 Results Obtained

Constraint	J_{opt}	(K_0, K)	Closed-Loop Poles
None	0.516	$\begin{bmatrix} -4.33 & -4550 & -372 & -9993 \\ -138 & 159 & -9993 & 372 \end{bmatrix}$	$\begin{pmatrix} -2.20 \pm j2.20 \\ -72.1 \pm j72.1 \end{pmatrix}$
$ k_{ij} \leq 100$	22.2	$\begin{bmatrix} -70 & -100 & -100 & -100 \\ -2.6 & 78 & -29 & 22 \end{bmatrix}$	$\begin{pmatrix} -0.157 \pm j0.330 \\ -2.61 \pm j5.62 \end{pmatrix}$

Consider now the following model, which approximately describes the behavior of a DC motor:

$$\dot{x} = \begin{bmatrix} -7.535 \times 10^{-2} & 5.163 \\ -209.4 & -198.1 \end{bmatrix} x + \begin{bmatrix} 0 \\ 188.7 \end{bmatrix} u + \begin{bmatrix} -4.651 \\ 0 \end{bmatrix} \omega \tag{23.51}$$

$$y = [1 \quad 0]x; \quad y_m = x$$

and consider the following controller:

$$u = K_0 y_m + K \int_0^t (y - y_{ref}) d\tau \tag{23.52}$$

where (K_0, K) are to be obtained so as to minimize the performance index

$$J_\epsilon = \int_0^\infty (e'e + u'u) d\tau, \quad \epsilon = 10^{-8} \tag{23.53}$$

subject to the constraint that the damping factor of the closed-loop system should have the property that $\zeta \geq 1$, in order to prevent an excessively oscillatory response, say. The following results are obtained [9] (see Table 23.6).

Discrete Systems

The previous results have considered a continuous system. For discrete-time systems, equivalent conditions for the existence of a solution to the RSP and the necessary controller structure can be obtained (e.g., see [4]). The following example illustrates this point.

Consider the following discrete system:

$$x_{k+1} = \begin{pmatrix} 0.9512 & 0 \\ 0 & 0.09048 \end{pmatrix} x_k + \begin{pmatrix} 4.877 & 4.877 \\ -1.1895 & 3.369 \end{pmatrix} u_k \tag{23.54}$$

$$y_k = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} x_k; \quad y^m = y$$

in which it is desired to solve the RSP for the class of constant disturbances/constant tracking signals. In this case, the above system is controllable and observable and has no transmission zeros, so that there

TABLE 23.6 Results Obtained

Constraint	J_{opt}	(K_0, K)	Closed-Loop Poles
None	9.93_{10}^{-3}	$[-98.1 \quad -1.49 \quad -10000]$	$\begin{pmatrix} -116 \pm j161 \\ -249 \end{pmatrix}$
$\zeta \geq 1$	1.00_{10}^{-2}	$[-109 \quad -1.62 \quad -9480]$	$\begin{pmatrix} -153 \pm j153 \\ -197 \end{pmatrix}$

exists a solution to the RSP; the servomechanism controller becomes in this case:

$$\begin{aligned} u_k &= K_0 y_k + K \eta_k \\ \eta_{k+1} &= \eta_k + y_k - y_{\text{ref}} \end{aligned} \quad (23.55)$$

and, on minimizing the performance index

$$J_\epsilon^* = \sum_{k=1}^{\infty} [e_k' e_k + \epsilon (u_{k+1} - u_k)' (u_{k+1} - u_k)], \quad \epsilon = 10^{-8} \quad (23.56)$$

the following controller gain matrices are obtained:

$$\begin{aligned} J_{opt}^* &= 6.00 \\ (K_0, K)_{opt} &= \begin{bmatrix} -0.296 & 0.239 & -0.152 & 0.219 \\ -0.104 & -0.239 & -0.0535 & -0.219 \end{bmatrix} \end{aligned} \quad (23.57)$$

The closed-loop poles obtained by applying the above controller to the plant modeled by Equation 23.54 are, in this case, given by $-8.4 \times 10^{-10} \pm j1.6 \times 10^{-5}$, $7.2 \times 10^{-11} \pm j8.1 \times 10^{-6}$; i.e., a “dead-beat” closed-loop system time response is obtained.

23.4.2 Case Study Problem—Distillation Column

The following model of a binary distillation column with pressure variation is considered:

$$\begin{aligned} \dot{x} &= Ax + Bu + E\omega \\ y &= Cx \end{aligned} \quad (23.58)$$

where (C, A, B, E) are given in Table 23.7. Here y_1 is the composition of the more volatile component in the bottom of the column, y_2 is the composition of the more volatile component in the top of the column, and y_3 is the pressure in the column; ω_1 is the input feed disturbance in the column; and u_1 the reheater input, u_2 the condensor input, and u_3 the reflux in the system.

Eigenvalues and Transmission Zeros of Distillation Column

The open-loop eigenvalues and transmission zeros of the distillation column are given in Table 23.8, which implies that the system is minimum phase.

It is desired now to find a controller that solves the RSP problem for this system for the case of constant disturbances and constant reference input signals. In this case, the existence conditions of Theorem 23.1 hold, so that a solution to the problem exists; in particular, there exists a solution to the “perfect control robust servomechanism” problem (see Theorem 23.2) for the system.

Perfect Robust Controller

The following controller is obtained from Zhang and Davison [14], and it can be shown to produce “perfect control” (i.e., the transient error in the system can be made arbitrarily small) in the system as $\epsilon \rightarrow 0$:

$$u = \frac{1}{\epsilon} \frac{(s+1)^2}{(\epsilon^2 s + 1)^2} \frac{\Theta}{s} (y - y_{\text{ref}}) \quad (23.59)$$

where

$$\Theta := \begin{bmatrix} 1.7599 \times 10^0 & -3.4710 \times 10^6 & -1.0869 \times 10^3 \\ -1.7599 \times 10^0 & 3.4710 \times 10^6 & -1.0870 \times 10^3 \\ -3.9998 \times 10^2 & -3.0545 \times 10^4 & -7.8258 \times 10^0 \end{bmatrix} \quad (23.60)$$

Properties of Closed-Loop System

In order to determine the potential “speed of response” that may be obtained by the controller modeled by Equation 23.59, the following closed-loop eigenvalues of the system are obtained with $\epsilon = 0.1$ (see Table 23.9).

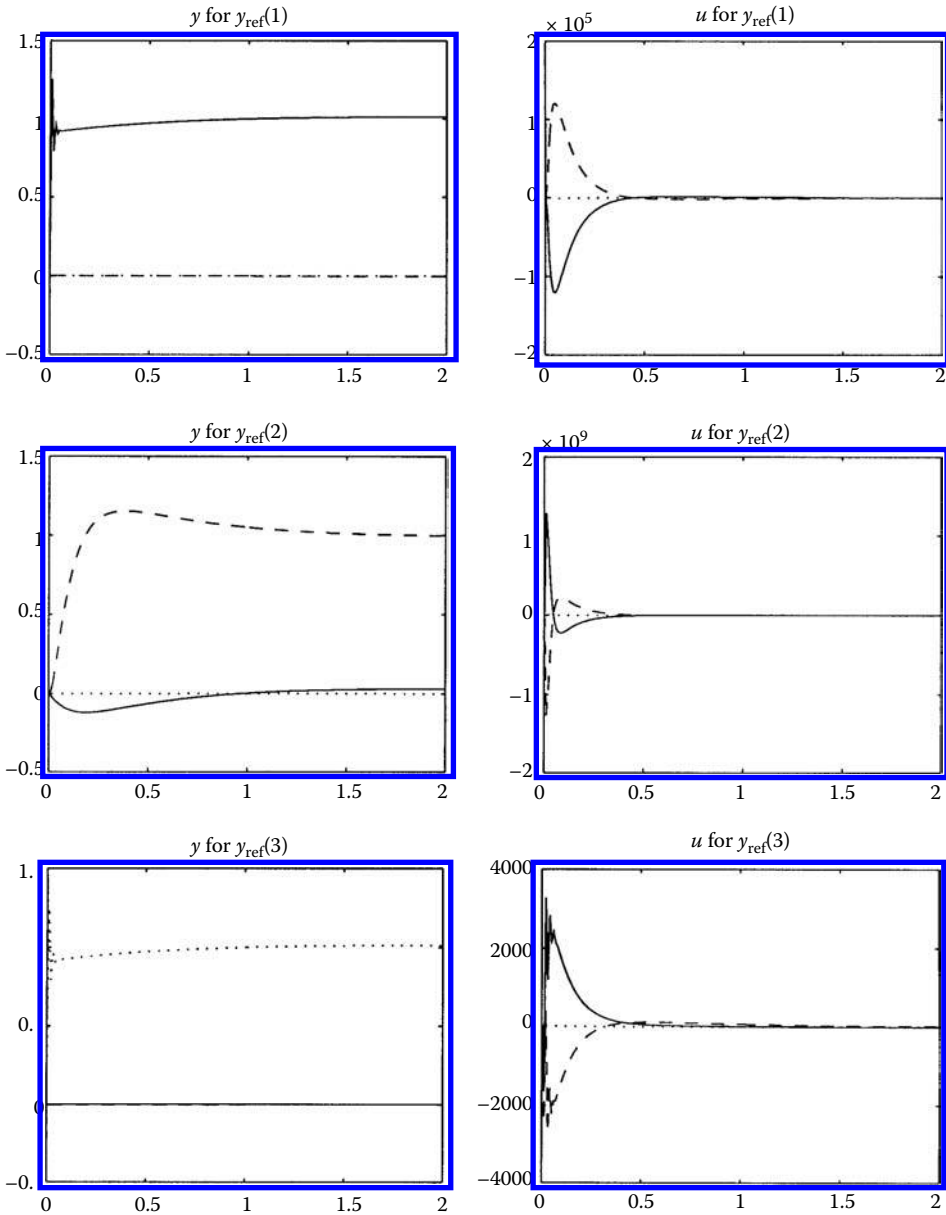

FIGURE 23.14 Response of closed-loop system for distillation column example using perfect robust servomechanism controller for unit step in y_{ref} given by $y_{ref}(1) = (1\ 0\ 0)'$, $y_{ref}(2) = (0\ 1\ 0)'$, $y_{ref}(3) = (0\ 0\ 1)'$.

Using the controller of Equation 23.59 with $\epsilon = 0.1$, the response of Figure 23.14 is then obtained for the case of a unit-step increase in $y_{ref} = (1\ 0\ 0)'$, $(0\ 1\ 0)'$, $(0\ 0\ 1)'$, respectively, with zero initial conditions. It is seen that “perfect control” indeed does take place; i.e., all transients have died down in less than 1 second, the system displays “low interaction,” and no “excessive peaking occurs.” In real life, however, this controller would not be used because the control inputs are excessively large (see Figure 23.14).

The following decentralized controller, obtained by the procedure given in [11], would be quite realistic to implement, however, since the control input signals do not “peak” now as they did in the previous controller.

Properties of Closed-Loop System

The following closed-loop eigenvalues are obtained by applying the controller of Equation 23.61 to Equation 23.58 (see Table 23.11).

Using the controller of Equation 23.61, the response of Figure 23.15 is then obtained for the case of a unit step in $y_{\text{ref}} = (1 \ 0 \ 0)'$, $(0 \ 1 \ 0)'$, $(0 \ 0 \ 1)'$, respectively, and for the case of a unit step in the disturbance term ω with zero initial conditions. It is seen that excellent tracking/regulation takes place; i.e., the output responses obtained show little interaction effects with no peaking occurring, and the control input signals are now quite realistic to implement. In addition, the controller has the additional advantage of being decentralized; i.e., the controller is particularly simple to implement. The time response of the closed-loop system, however, is now much slower compared to the case when perfect control is applied.

23.5 Concluding Remarks

In this overview on the RSP, the emphasis has been placed on the control of LTI continuous systems, and existence conditions and corresponding required controller construction to solve the RSP have been reviewed. To demonstrate the principles involved, various simple nonminimum- and minimum-phase examples were initially considered, and then a case study of a nontrivial system example was studied.

23.6 Defining Terms

Arbitrarily good approximate error regulation (AGAER): The property of a closed-loop system that permits arbitrarily good regulation to occur for arbitrary disturbance/tracking signals of a specified class.

Centralized fixed modes: Those modes of an LTI system that are not both simultaneously controllable and observable.

Decentralized control: Refers to a controller in which the information flow between the inputs and outputs is constrained to be block diagonal.

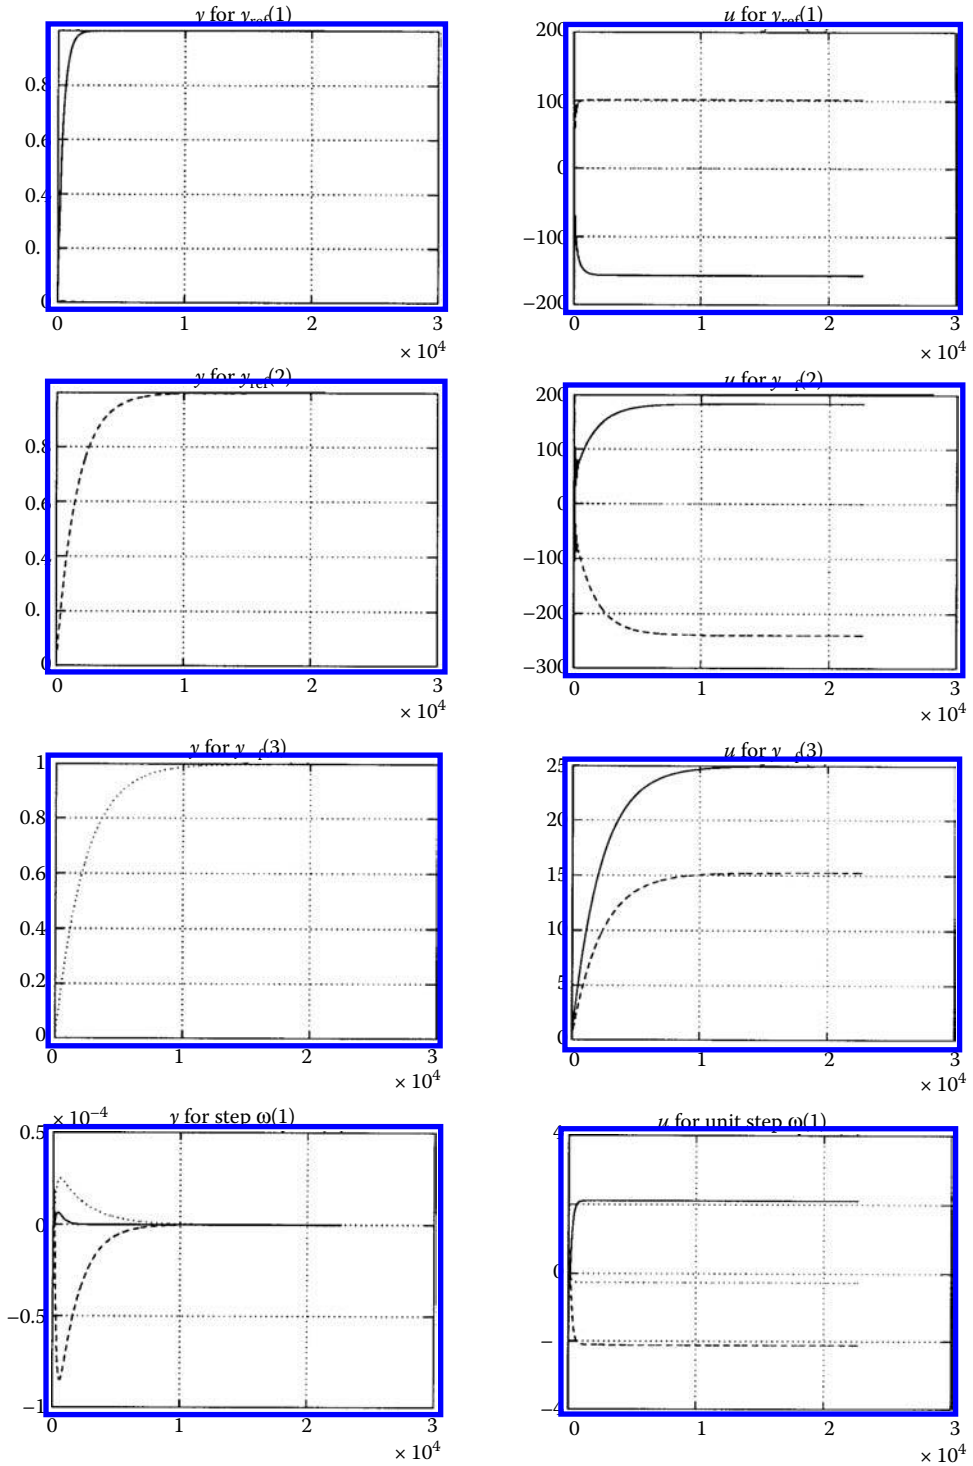

FIGURE 23.15 Response of closed-loop system for distillation column example using decentralized robust servomechanism controller for unit-step in y_{ref} given by $y_{ref}(1) = (1\ 0\ 0)'$, $y_{ref}(2) = (0\ 1\ 0)'$, $y_{ref}(3) = (0\ 0\ 1)'$ and for a unit-step disturbance.

- Error coefficient:** The steady-state error coefficient matrix associated with a closed-loop system for a given class of disturbance or reference input signals.
- Gain margin (GM):** Given a stable closed-loop system, the GM (θ, β) refers to the largest perturbation of gain in the system's transfer function matrix that may occur before instability occurs.
- High-gain servomechanism controller (HGSC):** A controller that gives perfect tracking for continuous minimum-phase systems.
- Minimum phase:** A system whose transmission zeros are all contained in the open left complex half-plane.
- Nonminimum phase:** A system that is not minimum phase.
- Perfect control:** The ability of a controller to provide arbitrarily good transient response in the system.
- Perfect robust controller:** A controller that solves the RSP such that perfect control occurs.
- Robust servomechanism problem (RSP):** The problem of finding a controller to solve the servomechanism problem that has the property of providing exact asymptotic error regulation, independent of any perturbations in the plant that do not destabilize the system.
- Servomechanism problem:** The problem of finding a controller to provide asymptotic error regulation and tracking for a system, subject to a specified class of disturbances and tracking signals.
- Servo-compensator:** A compensator that is used in the construction of a controller to solve the RSP.
- Stabilizing compensator:** A controller that stabilizes a system.
- Transmission zero:** A generalization of the notion of a zero of a single-input/single-output system to multivariable systems.

Further Reading

There are a number of important issues that have not yet been considered in this chapter. For example, when disturbances are measurable, so-called *feedforward control* [1,7] can be highly effective in minimizing the effects of disturbances in the servomechanism problem.

In many classes of problems, the controller must often be constrained to be decentralized, e.g., in process control systems, power system problems, transportation system problems. A treatment of the so-called *decentralized robust servomechanism problem*, which arises in this case, is given in [8] and [11].

The effect of transportation delay in a system is often of critical importance in the design of controllers to solve the servomechanism problem. A treatment of systems that have *time lag* is given in [4].

Finally, it is often the case that no mathematical model is actually available to describe the plant that is to be controlled. In this case, if the plant is open-loop asymptotically stable, so-called *tuning regulator theory* [7] can be applied to obtain existence conditions and to design a controller, which can then be applied to the plant to solve the servomechanism problem.

The above treatment of the servomechanism problem has been carried out in a state-space setting; alternative treatments may be found using other settings such as geometric methods, frequency-domain methods, polynomial matrix representation methods, coprime matrix factorization methods, etc.

24.1 Introduction

Optimization problems and control problems are highly intertwined. If a control configuration has been decided upon, controller parameters or control input signals can be interpreted as decision variables of an optimization problem that reflects the desired specifications and constraints of the controlled system.

In recent years, linear matrix inequalities (LMIs) have emerged as a powerful tool for approaching control problems that appear difficult if not impossible to solve in an analytic fashion. Although the history of LMIs goes back to the 1940s, with a major emphasis on their role in control in the 1960s through the work of Kalman, Yakubovich, Popov, and Willems, only during the last decades have powerful numerical

interior point techniques been developed to solve LMIs in a practical and efficient manner (Nesterov, Nemirovskii). Today, several commercial and noncommercial software packages are available that allow for simple coding of general LMI problems. For example, Yalmip [12] is a very flexible and noncommercial toolbox for defining and solving advanced optimization problems.

Boosted by the availability of fast LMI solvers, research in robust control theory has experienced a significant paradigm shift. Instead of arriving at an analytical solution of an optimal control problem and implementing such a solution in software so as to synthesize optimal controllers, today a substantial body of research is devoted to reformulating a control problem to the question of whether a specific LMI is solvable or, alternatively, to optimizing functionals over LMI constraints. It is the purpose of this chapter to highlight the main role and use of LMIs in solving a large variety of control and estimation problems.

24.1.1 Notation

\mathbb{R} and \mathbb{C} denote the fields of real and complex numbers. Sets of real and complex matrices of dimension $m \times n$ are denoted by $\mathbb{R}^{m \times n}$ and $\mathbb{C}^{m \times n}$. A matrix $A \in \mathbb{C}^{m \times n}$ is Hermitian if it is square ($m = n$) and if $A = A^*$, where the star denotes taking complex conjugate transpose. For real matrices, this amounts to saying that $A = A^\top$ in which case A is said to be symmetric. The vector spaces of all $n \times n$ Hermitian and symmetric matrices will be denoted by \mathbb{H}^n and \mathbb{S}^n , respectively, and we will omit superscript n if the dimension is not relevant for the context. A Hermitian or symmetric matrix A is called negative definite, negative semidefinite, positive definite, or positive semidefinite if $x^*Ax < 0, \leq 0, > 0$ or ≥ 0 for all nonzero complex vectors $x \in \mathbb{C}^n$. We will denote this by $A < 0, A \preceq 0, A \succ 0$, and $A \succeq 0$, and extend this notation to expressions $A \preceq B$ to mean that $A - B \preceq 0$ for any $A, B \in \mathbb{H}^n$. A congruence transformation of a square matrix M is a mapping $M \mapsto T^\top M T$ with some nonsingular T . The operator $\text{col}(\cdot)$ stacks its arguments in a vector, as in $\text{col}(a, b) = \begin{pmatrix} a \\ b \end{pmatrix}$, where a and b are vectors or matrices with the same number of columns.

\mathcal{L}_2^n denotes the space of all signals $x : [0, \infty) \rightarrow \mathbb{R}^n$ with finite energy $\|x\|_{\mathcal{L}_2} := \sqrt{\int_0^\infty \|x(t)\|^2 dt}$, where $\|\cdot\|$ is the Euclidean vector norm. We refer to the appendix for a brief summary on notions of convex sets and convex functions.

24.2 LMIs and Convexity

An LMI is a constraint of the form

$$F(x) := F_0 + x_1 F_1 + \cdots + x_n F_n < 0, \quad (24.1)$$

where F_0, F_1, \dots, F_n are given real symmetric matrices and where $x = \text{col}(x_1, \dots, x_n)$ is a vector of unknown real scalar *decision variables*.

The inequality $F(x) < 0$ means that x should render the symmetric matrix $F(x)$ negative definite, that is, the maximum eigenvalue of $F(x)$ should be negative. The LMI (Equation 24.1) gives rise to two types of questions:

1. The *LMI feasibility problem* amounts to testing whether there exist real variables x_1, \dots, x_n such that Equation 24.1 holds.
2. The *LMI optimization problem* amounts to minimizing a cost function $c(x) = c_1 x_1 + \cdots + c_n x_n$ over all x_1, \dots, x_n that satisfy the constraint (Equation 24.1).

Classical linear programs easily fit in this formalism, but also quadratic programs and some instances of convex quadratically constrained quadratic programs can be reformulated in this setting. In fact, the LMI optimization problem is a natural generalization of a linear program in which inequalities are defined by the cone of positive definite matrices.

In most control applications, LMIs arise with matrix variables rather than vector variables. This means that we consider inequalities of the more general form

$$F(X) \prec 0,$$

in which X is a matrix that belongs to an arbitrary finite-dimensional vector space \mathcal{X} of matrices and where $F : \mathcal{X} \rightarrow \mathbb{S}^m$ is an *affine function*. We recall that affine functions assume the form $F(x) = F_0 + T(x)$, where F_0 is fixed and where T is a linear map. Affine functions are, therefore, linear mappings plus some offset. For this reason, an LMI is actually better called an affine matrix inequality, but the world has decided to accept this erroneous nomenclature.

Example 24.1

A simple example of an LMI in the matrix valued unknown $X = X^\top$ is

$$F(X) = A^\top X + XA + Q \prec 0,$$

where A and $Q = Q^\top$ are given square real matrices. This is a special case of Equation 24.1 by expanding X as $X = \sum_{k=1}^n x_k X_k$, where $X_k = X_k^\top$, $k = 1, \dots, n$, is a basis of the set of symmetric matrices \mathcal{X} . Indeed, F is affine and $F(X) = F(\sum_{k=1}^n x_k X_k) = Q + \sum_{k=1}^n x_k (A^\top X_k + X_k A)$ which is of the form as in Equation 24.1 with $F_0 = Q$ and $F_k = A^\top X_k + X_k A$.

Of course, one is led to wonder what the practical interest in studying constraints of the special form as in Equation 24.1 might be. There are a number of answers to this question. First, Equation 24.1 defines a *convex constraint* on the decision variable. This means that the solution set $\mathcal{S} := \{x \mid F(x) \prec 0\}$ of the LMI $F(x) \prec 0$ is convex. We refer the reader to the appendix for a brief overview of notions and results on convex sets and convex functions. Although the convex constraint $F(x) \prec 0$ on x may seem rather special, many convex sets can be represented in this way and, in fact, have more attractive properties than general convex sets. Second, the solution set of every finite set of LMIs

$$F_1(x) \prec 0, \dots, F_k(x) \prec 0$$

can again be represented as one single LMI $F(x) \prec 0$ by setting $F(x) = \text{diag}(F_1(x), \dots, F_k(x))$. Hence, multiple LMI constraints on a decision variable x is again an LMI constraint. Third, and very importantly, the partitioned LMI

$$F(x) = \begin{pmatrix} F_{11}(x) & F_{12}(x) \\ F_{21}(x) & F_{22}(x) \end{pmatrix} \prec 0$$

is equivalent to

$$\begin{cases} F_{11}(x) \prec 0 \\ S_{22}(x) := F_{22}(x) - F_{21}(x)F_{11}(x)^{-1}F_{12}(x) \prec 0 \end{cases}$$

and at the same time equivalent to

$$\begin{cases} S_{11}(x) := F_{11}(x) - F_{12}(x)F_{22}(x)^{-1}F_{21}(x) \prec 0. \\ F_{22}(x) \prec 0 \end{cases}$$

Since F is affine, this equivalence means that also specific types of quadratic and rational inequalities can be reformulated as Equation 24.1. The expressions $S_{11}(x)$ and $S_{22}(x)$ are called *Schur complements* of $F_{22}(x)$ and $F_{11}(x)$ in $F(x)$. The above equivalences follow from the fact that congruence transformations of symmetric matrices leave the number of positive and negative eigenvalues invariant. In particular, $M \prec 0$, if and only if $T^\top M T \prec 0$ for any nonsingular matrix T . For example, the first follows by taking $M = F(x)$ and $T = \begin{pmatrix} I & -F_{11}(x)^{-1}F_{12}(x) \\ 0 & I \end{pmatrix}$.

24.3 Numerical Solutions of LMIs

Optimization problems over symmetric semidefinite matrix constraints belong to the realm of semidefinite programming or semidefinite optimization. Although we mainly focus on control problems here, semidefinite programs occur in combinatorial optimization, polynomial optimization, topology optimization, and so on. In the last few decades, this research field has witnessed incredible breakthroughs in numerical tools, commercial and noncommercial software developments, and fast solution algorithms. In particular, the introduction of powerful interior point methods allow us to effectively decide about the feasibility of semidefinite programs and to determine their solutions.

This section aims to indicate briefly the main ideas behind interior point solvers of convex optimization programs. Let the solution set $\mathcal{S} := \{x \in \mathbb{R}^n \mid F(x) \prec 0\}$ of the LMI (Equation 24.1) be the domain of a convex function $f : \mathcal{S} \rightarrow \mathbb{R}$ which we wish to minimize. That is, we consider the convex optimization problem

$$v_{\text{opt}} = \inf_{x \in \mathcal{S}} f(x). \quad (24.2)$$

The idea behind interior point methods is to solve this constrained optimization problem by a sequence of unconstrained optimization problems. For this purpose, a *barrier function* ϕ is introduced. This is a function $\phi : \mathbb{R}^n \rightarrow \mathbb{R}$ which is required to

1. be *strictly convex* on the interior of \mathcal{S} and
2. approach $+\infty$ along any sequence of points $\{x_n\}_{n=1}^{\infty}$ in the interior of \mathcal{S} that converges to a boundary point of \mathcal{S} .

Given a barrier function ϕ , the constraint optimization problem is replaced by the *unconstrained optimization problem* to minimize the functional

$$f_t(x) := f(x) + t\phi(x), \quad (24.3)$$

where $t > 0$ is a *penalty parameter*. The main idea is to determine a curve $t \mapsto x(t)$ that associates with any $t > 0$ a minimizer $x(t)$ of f_t . The minimum of f_t is attained in the interior of \mathcal{S} . Subsequently, the behavior of this mapping is considered as the penalty parameter t decreases to zero. In almost all interior point methods, the unconstrained optimization problem is solved with the classical Newton–Raphson iteration technique to approximately determine a local minimizer of f_t . Since f_t is strictly convex on \mathbb{R}^n , every local minimizer of f_t is guaranteed to be the unique global minimizer. Under mild assumptions and for a suitably defined sequence of penalty parameters t_n , $t_n \rightarrow 0$ as $n \rightarrow \infty$, the sequence $x(t_n)$ will converge to a point x^* . That is, the limit $x^* := \lim_{n \rightarrow \infty} x(t_n)$ exists and $v_{\text{opt}} = f(x^*)$. If, in addition, x^* belongs to the interior of \mathcal{S} , then it is an optimal solution to Equation 24.2; otherwise an almost optimal solution of Equation 24.2 can be deduced from the sequence $x(t_n)$.

Interior point methods can be applied to either of the two LMI problems defined in the previous section. If we consider the *feasibility problem* associated with the LMI $F(x) \prec 0$, then (f does not play a role and) one candidate barrier function is the logarithmic function

$$\phi(x) := \begin{cases} \log \det(-F(x)^{-1}) & \text{if } x \in \mathcal{S}, \\ \infty & \text{otherwise.} \end{cases}$$

If \mathcal{S} is bounded and nonempty, ϕ will be strictly convex. This implies the existence of a unique x_{opt} such that $\phi(x_{\text{opt}})$ is the global minimum of ϕ . The point x_{opt} belongs to \mathcal{S} and is called the *analytic center* of the feasibility set \mathcal{S} .

The LMI optimization problem to minimize $c(x)$ subject to the LMI $F(x) < 0$ can be viewed as a feasibility problem for the LMI

$$G_t(x) := \begin{pmatrix} c(x) - t & 0 \\ 0 & F(x) \end{pmatrix} < 0,$$

where $t > t_0 := \inf_{x \in S} c(x)$ is a penalty parameter. Using the same barrier function yields the unconstrained optimization problem to minimize

$$g_t(x) := \log \det(-G_t(x)^{-1}) = \log \frac{1}{t - c(x)} + \log \det(-F(x)^{-1})$$

for a sequence of decreasing positive values of t . Due to the strict convexity of g_t the minimizer $x(t)$ of g_t is unique for all $t > t_0$. Since closed-form expressions for the gradient and Hessian of g_t can be obtained, a Newton iteration is an efficient numerical method to find minimizers of g_t . Currently, much research is devoted to further exploiting the structure of LMIs in order to tailor dedicated solvers for specific semidefinite programs.

24.4 Stability Characterizations with LMIs

Around 1890, Aleksandr Mikhailovich Lyapunov made a systematic study of the local expansion and contraction properties of motions of dynamical systems around an attractor. He worked out the idea that an invariant set of a differential equation attracts all nearby solutions if one can find a function that is bounded from below and decreases along all solutions outside the invariant set. Such functions are called *Lyapunov functions* and they have been used to prove stability of equilibria of differential equations ever since.

Consider the differential equation

$$\dot{x}(t) = f(x(t), t) \tag{24.4}$$

with finite-dimensional state space $X = \mathbb{R}^n$ and where $f : X \times \mathbb{R} \rightarrow X$ is assumed to be sufficiently smooth so as to guarantee existence and uniqueness of the solution $x(t, t_0, x_0)$ that satisfies the initial condition $x(t_0, t_0, x_0) = x_0 \in X$. The differential equation (24.4) is *time-invariant*, if solutions satisfy

$$x(t + \tau, t_0 + \tau, x_0) = x(t, t_0, x_0)$$

for any $\tau \in \mathbb{R}$ with t and $t + \tau$ in the interval of existence. A point $x^* \in X$ is called an *equilibrium* or *fixed point* of the differential equation if $x(t, t_0, x^*) = x^*$ satisfies Equation 24.4 (which implies that $f(x^*, t) = 0$ for all $t \geq t_0$). A wealth of stability concepts associated with fixed points of differential equations exists. Here, we focus on just one.

The equilibrium point x^* of Equation 24.4 is called *exponentially stable* if for all $t_0 \in \mathbb{R}$, positive numbers α, β , and δ exist (all possibly depending on t_0) such that

$$\|x_0 - x^*\| \leq \delta \implies \|x(t, t_0, x_0) - x^*\| \leq \beta \|x_0 - x^*\| e^{-\alpha(t-t_0)} \quad \text{for all } t \geq t_0. \tag{24.5}$$

If α, β , and δ do not depend on t_0 , then x^* is said to be *uniformly exponentially stable*. If δ is arbitrary, x^* is called *globally exponentially stable*.

Hence, a fixed point is exponentially stable if all solutions of the differential equation that initiate nearby x^* converge to x^* with an exponential rate $\alpha > 0$. The following result is standard and relates exponential stability of linear time-invariant differential equations to LMI feasibility.

Theorem 24.1:

Let $A \in \mathbb{R}^{n \times n}$. The following statements are equivalent.

1. The origin is an exponentially stable equilibrium point of $\dot{x} = Ax$.
2. All eigenvalues $\lambda(A)$ of A belong to $\mathbb{C}^- := \{s \in \mathbb{C} \mid \Re(s) < 0\}$ (i.e., A is Hurwitz).
3. The LMIs $A^\top X + XA < 0$ and $X > 0$ are feasible.

Any solution X of the LMIs in item (3) defines the quadratic function $V(x) := x^\top Xx$ that serves as a Lyapunov function for the equilibrium point $x^* = 0$ of the differential equation $\dot{x} = Ax$. Indeed, V achieves its minimum at $x^* = 0$ and its derivative in the direction of the vector field Ax is

$$\frac{d}{dt}x(t)^\top Xx(t) = \dot{x}(t)^\top Xx(t) + x(t)^\top X\dot{x}(t) = x(t)^\top [A^\top X + XA]x(t),$$

and hence nonincreasing by item (3). Rather straightforward arguments lead to Equation 24.5, where δ is arbitrary, $\beta = \sqrt{\lambda_{\max}(X)/\lambda_{\min}(X)}$, and $\alpha > 0$ is any number for which $A^\top X + XA + 2\alpha X < 0$.

For many applications in control and engineering one may be interested in characterizing eigenvalue locations of A in more general stability regions than \mathbb{C}^- .

For a real symmetric matrix $P \in \mathbb{S}^{2m}$, the set of complex numbers

$$\mathcal{L}_P := \left\{ s \in \mathbb{C} \mid \begin{pmatrix} I \\ sI \end{pmatrix}^* P \begin{pmatrix} I \\ sI \end{pmatrix} < 0 \right\}$$

is called an *LMI region*.

Important stability regions such as half-planes $\mathbb{C}_{\text{stab } 1} := \{s \mid \Re(s) < \alpha\}$, circles $\mathbb{C}_{\text{stab } 2} := \{s \mid |s| < r\}$, or conic sectors $\mathbb{C}_{\text{stab } 3} := \{s \mid \Re(s) \tan(\theta) < |\Im(s)|\}$ can be represented by LMI regions \mathcal{L}_{P_1} , \mathcal{L}_{P_2} , and \mathcal{L}_{P_3} , respectively, by taking

$$P_1 = \begin{pmatrix} -2\alpha & 1 \\ 1 & 0 \end{pmatrix}, \quad P_2 = \begin{pmatrix} -r^2 & 0 \\ 0 & 1 \end{pmatrix}, \quad P_3 = \begin{pmatrix} 0 & 0 & \sin(\theta) & \cos(\theta) \\ 0 & 0 & -\cos(\theta) & \sin(\theta) \\ \sin(\theta) & -\cos(\theta) & 0 & 0 \\ \cos(\theta) & \sin(\theta) & 0 & 0 \end{pmatrix}.$$

LMI regions include sets bounded by circles, ellipses, strips, parabolas, and hyperbolas. Since any finite intersection of LMI regions is again an LMI region, one can virtually approximate any convex region in \mathbb{C} as long as it is symmetric with respect to the real axis.

To present the main result of this section, we recall the definition of the *Kronecker product* $A \otimes B$ of two matrices $A \in \mathbb{C}^{m \times n}$, $B \in \mathbb{C}^{k \times \ell}$, which is the $mk \times n\ell$ matrix

$$A \otimes B = \begin{pmatrix} A_{11}B & \dots & A_{1n}B \\ \vdots & & \vdots \\ A_{m1}B & \dots & A_{mn}B \end{pmatrix}.$$

The following result as originating from [4] is an interesting and elegant generalization of the stability characterization in Theorem 24.1.

Theorem 24.2:

Let $A \in \mathbb{R}^{n \times n}$. The following statements are equivalent.

1. All eigenvalues of A are contained in the LMI region

$$\left\{ s \in \mathbb{C} \mid \begin{pmatrix} I \\ sI \end{pmatrix}^* \begin{pmatrix} Q & S \\ S^\top & R \end{pmatrix} \begin{pmatrix} I \\ sI \end{pmatrix} < 0 \right\}.$$

2. There exists $X = X^\top$ such that

$$X \succ 0 \text{ and } \begin{pmatrix} I \\ A \otimes I \end{pmatrix}^* \begin{pmatrix} X \otimes Q & X \otimes S \\ X \otimes S^\top & X \otimes R \end{pmatrix} \begin{pmatrix} I \\ A \otimes I \end{pmatrix} \prec 0.$$

The condition in item (2) is an LMI in X . The result of Theorem 24.1 is recovered by taking $Q = 0, S = 1$, and $R = 0$. With $Q = -1, S = 0$, and $R = 1$, the LMI region corresponds to the open unit disc; hence A has all eigenvalues within the open unit disc iff there exists $X \succ 0$ such that $A^\top X A - X \prec 0$. In turn, this LMI test is equivalent to saying that the discrete-time system $x(k + 1) = Ax(k)$ is exponentially stable.

Example 24.2

Consider the problem to find a stabilizing feedback law $u = Fx$ that simultaneously stabilizes the systems $\dot{x} = A_k x + B_k u$, where $k = 1, \dots, 4$ and

$$\begin{aligned} A_1 &= \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, & B_1 &= \begin{pmatrix} 1 \\ 0 \end{pmatrix}, & A_2 &= \begin{pmatrix} -1 & 2 \\ 1 & 2 \end{pmatrix}, & B_2 &= \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \\ A_3 &= \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, & B_3 &= \begin{pmatrix} 0 \\ 1 \end{pmatrix}, & A_4 &= \begin{pmatrix} 0 & 2 \\ 1 & -1 \end{pmatrix}, & B_4 &= \begin{pmatrix} 2 \\ 1 \end{pmatrix}. \end{aligned}$$

By Theorem 24.1, the equivalent problem is to find $X_k \succ 0$ and F such that $(A_k + B_k F)^\top X_k + X_k (A_k + B_k F) \prec 0$ for $k = 1, \dots, 4$. Since both X_k and F are unknown, this is *not* an LMI constraint. However, assuming $X_1 = \dots = X_4 = X$, a congruence transformation with the matrix $Y := X^{-1}$ transforms the five matrix inequalities to

$$Y \succ 0, \quad A_k Y + Y A_k^\top + B_k M + M^\top B_k \prec 0, \quad k = 1, \dots, 4,$$

where we set $M = FY$. These are LMIs in Y and M . When implemented with the given matrices, this set of LMIs turns out to be feasible and any solution defines a feedback $F = MY^{-1}$ that solves the stabilization problem. One of these feedbacks is computed to be $F = (-4.3874 \quad -10.6332)$. An analogous synthesis strategy can be applied for the *simultaneous pole-placement problem* which amounts to finding F such that eigenvalues of $A_k + B_k F$ belong to an LMI region \mathcal{L}_p for all k . Its solution is then an application of Theorem 24.2.

24.5 Performance Characterizations with LMIs

In this section, we consider a linear system

$$\dot{x} = Ax + Bd, \quad e = Cx + Dd, \quad x(0) = 0, \tag{24.6}$$

in which d is viewed as an undesired external disturbance and e is an error output. Many control synthesis problems can be translated into a question of disturbance attenuation: the controller should reduce the effect of the disturbance d onto the error e as much as possible. In this section we quantify or analyze the effect of d onto e for the system (Equation 24.6) whose transfer function matrix is given by

$$T(s) = C(sI - A)^{-1}B + D.$$

24.5.1 \mathcal{H}_2 -Performance

Let us assume for Equation 24.6 that A is Hurwitz and $D = 0$. If the number of inputs is m then $B = (b_1, \dots, b_m)$ has m columns. If the system is excited with a unit impulse in the v th input, it responds with

the output trajectory $z_v(t) = Ce^{At}b_v$. The energy of this output trajectory equals

$$\int_0^\infty [Ce^{At}b_v]^\top [Ce^{At}b_v] dt = b_v^\top \left(\int_0^\infty e^{A^\top t} C^\top C e^{At} dt \right) b_v = b_v^\top Y_0 b_v \quad (24.7)$$

with Y_0 being the observability Gramian, the unique solution of the Lyapunov equation

$$A^\top Y_0 + Y_0 A + C^\top C = 0. \quad (24.8)$$

If we add the output energies for impulsive inputs in all input components we obtain

$$\sum_{v=1}^m \int_0^\infty z_v(t)^\top z_v(t) dt = \sum_{v=1}^m \text{Trace}(b_v b_v^\top Y_0) = \text{Trace}(B B^\top Y_0) = \text{Trace}(B^\top Y_0 B),$$

where Trace denotes the sum of the diagonal elements of any matrix. In view of the explicit formula for the observability Gramian as used in Equation 24.7 combined with Parseval's theorem, we infer that $\text{Trace}(B^\top Y_0 B)$ actually equals

$$\|T\|_{\mathcal{H}_2}^2 := \frac{1}{2\pi} \text{Trace} \int_{-\infty}^\infty [C(i\omega I - A)^{-1} B]^* [C(i\omega I - A)^{-1} B] d\omega. \quad (24.9)$$

Note that $\|T\|_{\mathcal{H}_2}$ is the so-called \mathcal{H}_2 -norm of the transfer matrix T , the name of which is motivated by the theory of Hardy-spaces in pure mathematics; this relation is not relevant for our purposes.

We have actually derived the *impulse-response performance interpretation* of the \mathcal{H}_2 -norm. Moreover, this interpretation also provides a concise link to classical linear quadratic control, since the impulse response $z_v(\cdot)$ is identical to the output response if the system's state is initialized as $x(0) = b_v$.

Let us briefly touch upon the stochastic interpretation of the \mathcal{H}_2 -norm. If w is white noise with unity covariance, the asymptotic variance of the output process of Equation 24.6 satisfies

$$\lim_{t \rightarrow \infty} E[z(t)^\top z(t)] = \text{Trace} \left(\lim_{t \rightarrow \infty} CE[x(t)x(t)^\top]C^\top \right) = \text{Trace}(CX_0C^\top),$$

where X_0 is the system's controllability Gramian, the unique solution of

$$AX_0 + X_0A^\top + BB^\top = 0. \quad (24.10)$$

Since $T(s)^\top = B^\top(sI - A^\top)^{-1}C^\top$, we can conclude that the asymptotic output variance is equal to $\|T^\top\|_{\mathcal{H}_2}$. Due to Equation 24.9 this is the same as $\|T\|_{\mathcal{H}_2}$, which leads to a dual version for computing $\|T\|_{\mathcal{H}_2}$. Let us summarize our findings as follows: *If $D = 0$ and X_0 and Y_0 are the system's controllability and observability Gramians satisfying Equations 24.10 and 24.8, respectively, then $\|T\|_{\mathcal{H}_2}^2 = \text{Trace}(CX_0C^\top) = \text{Trace}(B^\top Y_0 B)$ is the sum of the energies of the output of Equation 24.6 for impulsive inputs in each input channel, and it also equals the asymptotic output variance if the input is white noise with unity covariance.*

Note that \mathcal{H}_2 -norms can be easily determined by solving linear equations and computing traces. Since these explicit formulas are inadequate for applying the synthesis procedure as developed in the next section, let us provide a genuine characterization of a bound on the \mathcal{H}_2 -norm by LMIs. It is important to stress that this formulation actually combines an LMI characterization of system stability with a bound on system performance.

Theorem 24.3:

A is Hurwitz and $\|T\|_{\mathcal{H}_2} < \gamma$ iff $D = 0$ and there exist $X = X^\top$ and $W = W^\top$ with

$$\begin{pmatrix} A^\top X + XA & XB \\ B^\top X & -\gamma I \end{pmatrix} < 0, \quad \begin{pmatrix} X & C^\top \\ C & W \end{pmatrix} > 0 \quad \text{and} \quad \text{Trace}(W) < \gamma. \quad (24.11)$$

Sketch of proof of “if”

For the general manipulation of performance specifications it is an instructive illustration of how to show that the feasibility of the system of LMIs (Equation 24.11) implies $\|T\|_{\mathcal{H}_2} < \gamma$. Indeed, by taking Schur complements we infer that Equation 24.11 leads to

$$A^\top X + XA + \frac{1}{\gamma} XBB^\top X < 0, \quad X > 0, \quad CX^{-1}C^\top < W, \quad \text{Trace}(W) < \gamma.$$

The first inequality implies $A^\top X + XA < 0$. Together with $X > 0$ this implies (Theorem 24.1) that A is Hurwitz. On the other hand, $\hat{X}_0 = (\gamma X)^{-1}$ satisfies

$$A\hat{X}_0 + \hat{X}_0A^\top + BB^\top < 0 \quad \text{and} \quad \text{Trace}(C\hat{X}_0C^\top) < \text{Trace}(\gamma W) < \gamma^2.$$

Combining the latter inequalities with Equation 24.10, we get $A(\hat{X}_0 - X_0) + (\hat{X}_0 - X_0)A^\top < 0$, which implies, using the stability of A , that $\hat{X}_0 - X_0 > 0$. Consequently, also $\text{Trace}(CX_0C^\top) < \gamma^2$, which yields that $\|T\|_{\mathcal{H}_2} < \gamma$.

24.5.2 \mathcal{H}_∞ -Performance

A different way of quantifying the effect of the disturbance d on the output e in Equation 24.6 is in terms of the so-called energy gain

$$\|T\|_{\mathcal{H}_\infty} := \sup_{0 < \|d\|_{\mathcal{L}_2} < \infty} \frac{\|e\|_{\mathcal{L}_2}}{\|d\|_{\mathcal{L}_2}}.$$

The norm reflects the worst amplification of disturbances on outputs if measuring the sizes of the input and output signals in terms of their \mathcal{L}_2 -norm or energy. Dissipativity theory [19] provides a direct path toward an LMI characterization of an upper bound $\|T\|_{\mathcal{H}_\infty} < \gamma$.

Theorem 24.4:

A is Hurwitz and $\|T\|_{\mathcal{H}_\infty} < \gamma$ iff there exists $X > 0$ with

$$\begin{pmatrix} I & 0 \\ A & B \end{pmatrix}^\top \begin{pmatrix} 0 & X \\ X & 0 \end{pmatrix} \begin{pmatrix} I & 0 \\ A & B \end{pmatrix} + \begin{pmatrix} 0 & I \\ C & D \end{pmatrix}^\top \begin{pmatrix} -\gamma^2 I & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} 0 & I \\ C & D \end{pmatrix} < 0. \quad (24.12)$$

Sketch of proof of “if”

Let us assume that Equation 24.12 holds. Then the left-upper block of Equation 24.12 just reads as $A^\top X + XA + C^\top C < 0$, which implies $A^\top X + XA < 0$. Therefore $X > 0$ guarantees that A is Hurwitz. Since the inequality Equation 24.12 is strict, it continues to hold if we replace $-\gamma^2$ by $-(\gamma - \epsilon)^2$ for some suitably small $\epsilon > 0$. Let us choose any d with $0 < \|d\|_{\mathcal{L}_2} < \infty$ and let e be the output of Equation 24.6. If we right-multiply the perturbed version of Equation 24.12 with $\text{col}(x(t), d(t))$ and left-multiply with its transpose, and if we exploit the relations in Equation 24.6, we obtain

$$\begin{aligned} & \begin{pmatrix} x(t) \\ \dot{x}(t) \end{pmatrix}^\top \begin{pmatrix} 0 & X \\ X & 0 \end{pmatrix} \begin{pmatrix} x(t) \\ \dot{x}(t) \end{pmatrix} + \begin{pmatrix} d(t) \\ e(t) \end{pmatrix}^\top \begin{pmatrix} -(\gamma - \epsilon)^2 I & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} d(t) \\ e(t) \end{pmatrix} \\ & = \frac{d}{dt} x(t)^\top X x(t) + e(t)^\top e(t) - (\gamma - \epsilon)^2 d(t)^\top d(t) \leq 0. \end{aligned}$$

By integration on $[0, T]$ and with $x(0) = 0$ we infer

$$x(T)^\top X x(T) + \int_0^T e(t)^\top e(t) dt \leq (\gamma - \epsilon)^2 \int_0^T d(t)^\top d(t) dt \quad \text{for all } T \geq 0.$$

Since both $x(\cdot)$ and $\dot{x}(\cdot)$ are of finite energy, $x(T) \rightarrow 0$ for $T \rightarrow \infty$. After taking the limit $T \rightarrow \infty$ we hence obtain $\|e\|_{\mathcal{L}_2}^2 \leq (\gamma - \epsilon)^2 \|d\|_{\mathcal{L}_2}^2$ or $\|e\|_{\mathcal{L}_2} / \|d\|_{\mathcal{L}_2} \leq \gamma - \epsilon$. Since this holds for all $0 < \|d\|_{\mathcal{L}_2} < \infty$ we finally arrive at $\|T\|_{\mathcal{H}_\infty} < \gamma$.

We started from the formulation of the LMIs (Equation 24.12), which gives the most insight for a dissipation-based proof of these results. In the literature, more common equivalent representations of the LMI (Equation 24.12) are

$$\begin{pmatrix} A^\top X + XA + C^\top C & XB + C^\top D \\ B^\top X + D^\top C & D^\top D - \gamma^2 I \end{pmatrix} < 0 \quad \text{or (Schur)} \quad \begin{pmatrix} A^\top X + XA & XB & C^\top \\ B^\top X & -\gamma^2 I & D^\top \\ C & D & -I \end{pmatrix} < 0. \quad (24.13)$$

Equivalently, $A^\top X + XA + C^\top C + (XB + C^\top D)(\gamma^2 I - D^\top D)^{-1}(B^\top X + D^\top C) < 0$, and $D^\top D - \gamma^2 I < 0$, which touches upon the relation to Riccati inequalities and equations.

24.5.3 The Kalman–Yakubovich–Popov (KYP) Lemma

We have established the link of Equation 24.12 to the time-domain energy-gain by dissipation arguments. The relation of this LMI to the frequency-domain is the subject of the celebrated KYP lemma. Algebraic arguments proceed as follows. If Equation 24.12 holds with $X = X^\top$, then $A^\top X + XA < 0$ implies that A has no eigenvalues on the imaginary axis. For $\omega \in \mathbb{R}$ let us observe that

$$\begin{aligned} & \begin{pmatrix} (i\omega I - A)^{-1} B \\ I \end{pmatrix}^* \begin{pmatrix} I & 0 \\ A & B \end{pmatrix} \begin{pmatrix} 0 & X \\ X & 0 \end{pmatrix} \begin{pmatrix} I & 0 \\ A & B \end{pmatrix} \begin{pmatrix} (i\omega I - A)^{-1} B \\ I \end{pmatrix} \\ &= [(i\omega I - A)^{-1} B]^* \begin{pmatrix} I & \\ & i\omega I \end{pmatrix}^* \begin{pmatrix} 0 & X \\ X & 0 \end{pmatrix} \begin{pmatrix} I \\ i\omega I \end{pmatrix} (i\omega I - A)^{-1} B \\ &= [(i\omega I - A)^{-1} B]^* [i\omega X - i\omega X] (i\omega I - A)^{-1} B = 0. \end{aligned}$$

Therefore, feasibility of Equation 24.12 implies the validity of the frequency-domain inequality

$$\begin{pmatrix} I \\ T(i\omega) \end{pmatrix}^* \begin{pmatrix} -\gamma^2 I & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} I \\ T(i\omega) \end{pmatrix} < 0 \quad \text{for all } \omega \in \mathbb{R} \cup \{\infty\},$$

which follows for $\omega = \infty$ from the right-lower block of Equation 24.12. Note that this inequality translates into $T(i\omega)^* T(i\omega) - \gamma^2 I < 0$ or $\sigma_{\max}(T(i\omega)) < \gamma$ for all $\omega \in \mathbb{R} \cup \{\infty\}$. In turn, this reveals the relation of the \mathcal{L}_2 -gain bound to the peak of the largest singular value of the system's frequency response, which is simply the classical \mathcal{L}_∞ -norm for transfer matrices without poles on the imaginary axis, or the \mathcal{H}_∞ -norm for transfer matrices whose poles are all contained in the open left-half-plane.

The following result captures a generalization of the strict version of the KYP lemma for an arbitrary symmetric matrix P and without involving any sign-constraint on X .

Theorem 24.5:

In the case that A has no eigenvalues on the imaginary axis then

$$\begin{pmatrix} I \\ T(i\omega) \end{pmatrix}^* P \begin{pmatrix} I \\ T(i\omega) \end{pmatrix} < 0 \quad \text{for all } \omega \in \mathbb{R} \cup \{\infty\}, \quad (24.14)$$

iff there exists some $X = X^\top$ with

$$\begin{pmatrix} I & 0 \\ A & B \end{pmatrix}^\top \begin{pmatrix} 0 & X \\ X & 0 \end{pmatrix} \begin{pmatrix} I & 0 \\ A & B \end{pmatrix} + \begin{pmatrix} 0 & I \\ C & D \end{pmatrix}^\top P \begin{pmatrix} 0 & I \\ C & D \end{pmatrix} < 0. \quad (24.15)$$

The survey article [10] provides a nice historical account of the development around the KYP lemma with many references, also to the Russian literature, and discusses further versions of this result even without any *a priori* hypotheses. In particular [2] is a rich source for the link of the KYP lemma to semidefinite programming duality and the related control theoretic interpretations.

24.5.4 Variants

The books [3,7] contain a whole variety of concrete variations on the theme of formulating performance specifications with LMIs. Let us provide a sample.

24.5.4.1 Generalized \mathcal{H}_2 -Performance

If replacing $\text{Trace}(W) < \gamma$ by $W \prec \gamma I$ in Theorem 24.3, the formulated LMIs characterize that the system gain from finite energy input signals to the peak value of the output signal is bounded by γ :

$$\sup_{0 < \|d\|_{\mathcal{L}_2} < \infty} \frac{\|e\|_{\mathcal{L}_\infty}}{\|d\|_{\mathcal{L}_2}} < \gamma \quad \text{with} \quad \|e\|_{\mathcal{L}_\infty} := \sup_{t \geq 0} \|e(t)\|.$$

This criterion allows to impose time-uniform bounds on the error variable under the assumption that the disturbance has bounded energy.

24.5.4.2 Quadratic Performance

Our discussion of \mathcal{L}_2 -gain performance opens the path toward the following generalization. With a symmetric weighting matrix P , quadratic performance with index P is achieved if an $\epsilon > 0$ exists, such that the following integral quadratic constraint (IQC) on the performance channel $d \rightarrow e$ of the stable system in Equation 24.6 is satisfied:

$$\int_0^\infty \begin{pmatrix} d(t) \\ e(t) \end{pmatrix}^\top P \begin{pmatrix} d(t) \\ e(t) \end{pmatrix} dt \leq -\epsilon \|d\|_{\mathcal{L}_2}^2 \quad \text{for all } d \in \mathcal{L}_2.$$

This time-domain specification directly translates into the frequency-domain inequality in Equation 24.14 and, due to Theorem 24.5, into feasibility of the LMI in Equation 24.15. If the right-lower block of P is positive semidefinite, it is elementary to see that stability of A is guaranteed by imposing the additional positivity constraint $X > 0$.

24.5.4.3 Discrete-Time

All described results have counterparts for discrete-time systems

$$x(t+1) = Ax(t) + Bd(t), \quad e(t) = Cx(t) + Dd(t), \quad x(0) = 0, \quad t = 0, 1, 2, \dots$$

If A has all its eigenvalues in the unit disc (Schur stability), then quadratic performance holds, by definition, if there exists some $\epsilon > 0$ with

$$\sum_{t=0}^\infty \begin{pmatrix} d(t) \\ e(t) \end{pmatrix}^\top P \begin{pmatrix} d(t) \\ e(t) \end{pmatrix} \leq -\epsilon \sum_{t=0}^\infty d(t)^\top d(t).$$

This is equivalent to the frequency-domain inequality

$$\begin{pmatrix} I \\ T(z) \end{pmatrix}^* P \begin{pmatrix} I \\ T(z) \end{pmatrix} \prec 0 \quad \text{for all } z \in \mathbb{C}, \quad |z| = 1$$

on the unit circle, which is, in turn, equivalent to the existence of $X = X^\top$ satisfying the LMI

$$\begin{pmatrix} I & 0 \\ A & B \end{pmatrix}^\top \begin{pmatrix} -X & 0 \\ 0 & X \end{pmatrix} \begin{pmatrix} I & 0 \\ A & B \end{pmatrix} + \begin{pmatrix} 0 & I \\ C & D \end{pmatrix}^\top P \begin{pmatrix} 0 & I \\ C & D \end{pmatrix} < 0.$$

If the right-lower block of P is positive semidefinite, Schur stability of A is once again guaranteed by $X > 0$. We stress the pleasing parallel structure of continuous-time and discrete-time performance formulations, which is even more striking for synthesis since the proposed general procedure applies to both domains without the need for any adaptation.

24.6 Optimal Performance Synthesis

Let us now consider a system

$$\begin{aligned} \dot{x} &= Ax + B_0d + Bu, \\ e &= C_0x + D_0d + Eu, \\ y &= Cx + Fd, \end{aligned} \tag{24.16}$$

where, in addition to the disturbance d and the error e , the signal u is a control input and y is a measured output. In feedback synthesis, the goal is to determine a controller

$$\begin{aligned} \dot{x}_c &= A_c x_c + B_c y, \\ u &= C_c x_c + D_c y, \end{aligned} \tag{24.17}$$

which feeds the measurements y back to u such that the controlled system, the interconnection of Equations 24.16 and 24.17, is internally stable and satisfies a desired performance property (Figure 24.1).

Note that the controlled system with state $\xi = \text{col}(x, x_c)$ is easily seen to be described by

$$\begin{aligned} \dot{\xi} &= \mathcal{A}\xi + \mathcal{B}d \\ e &= \mathcal{C}\xi + \mathcal{D}d \end{aligned} \quad \text{with} \quad \left(\begin{array}{c|c} \mathcal{A} & \mathcal{B} \\ \mathcal{C} & \mathcal{D} \end{array} \right) := \left(\begin{array}{cc|c} A + BD_cC & BC_c & B_0 + BD_cF \\ B_cC & A_c & B_cF \\ \hline C_0 + ED_cC & EC_c & D_0 + ED_cF \end{array} \right). \tag{24.18}$$

In view of the generalized plant framework [18,20], it is essential to understand that this innocent problem formulation comprises surprisingly many specific configurations as they are needed in one- or two-degrees of freedom controller synthesis for reference tracking and disturbance attenuation. In this section, emphasis is put on an \mathcal{H}_∞ -norm bound as a measure of performance.

FIGURE 24.1 Generalized plant configuration.

24.6.1 State-Feedback Synthesis

The simplest control law is state-feedback $u = D_c x$ with a gain D_c , which leads to the controlled system

$$\begin{aligned} \dot{x} &= (A + BD_c)x + B_0 d, \\ e &= (C_0 + ED_c)x + D_0 d. \end{aligned} \quad (24.19)$$

Using Theorem 24.4 and with the LMI expressed as in Equation 24.13, this controller stabilizes the system in Equation 24.19 and renders the \mathcal{H}_∞ -norm of the transfer matrix $d \rightarrow e$ smaller than γ iff there exists some X with

$$X > 0 \quad \text{and} \quad \begin{pmatrix} (A + BD_c)^\top X + X(A + BD_c) & XB_0 & (C_0 + ED_c)^\top \\ B_0^\top X & -\gamma^2 I & D_0^\top \\ (C_0 + ED_c) & D_0 & -I \end{pmatrix} < 0. \quad (24.20)$$

Recall that the first inequality guarantees stability while the second captures performance. We observe that, in synthesis, we need to search for *both* D_c and X in order to satisfy Equation 24.20. The performance inequality is, with some abuse of notation, a so-called bilinear matrix inequality problem since the left-hand side is affine in X (for fixed D_c) and affine in D_c (for fixed X). Actually, a large variety of design problems in control can be easily seen to admit this structure. Unfortunately, however, bilinear matrix inequalities are as hard to handle as general nonlinear programs. Fortunately, for the problem at hand there is a surprisingly simple remedy.

There exists a celebrated procedure that actually turns the nonconvex bilinear matrix inequality (Equation 24.20) into a convex problem of LMIs. This is achieved by applying a nonlinear change of variables $(D_c, X) \rightarrow (M, Y)$ and a congruence transformation to Equation 24.20. Indeed if we transform Equation 24.20 by congruence with X^{-1} and $\text{diag}(X^{-1}, I, I)$, respectively, and if we introduce the new variables

$$Y := X^{-1} \quad \text{and} \quad M := D_c X^{-1}, \quad (24.21)$$

we arrive at

$$Y > 0 \quad \text{and} \quad \begin{pmatrix} (AY + BM)^\top + (AY + BM) & B_0 & (C_0 Y + EM)^\top \\ B_0^\top & -\gamma^2 I & D_0^\top \\ (C_0 Y + EM) & D_0 & -I \end{pmatrix} < 0. \quad (24.22)$$

Obviously the constraints in Equation 24.22 constitute LMIs in (M, Y) whose feasibility can be verified. If (M, Y) is a solution of Equation 24.22, we can solve Equation 24.21 for (D_c, X) as $X = Y^{-1}$ and $D_c = MY^{-1}$ and perform a congruence transformation of Equation 24.22 with Y^{-1} and $\text{diag}(Y^{-1}, I, I)$ which leads back to Equation 24.20. This proves, with X being a certificate, that D_c is indeed stabilizing and achieves the desired performance specification. On the other hand, if the inequalities in Equation 24.22 are not feasible, it is assured that no state-feedback gain can exist for which both these properties are satisfied.

24.6.2 Output-Feedback Synthesis

A general output-feedback controller leads to the controlled system in Equation 24.18. It achieves stability of \mathcal{A} and $\|\mathcal{C}(sI - \mathcal{A})^{-1}\mathcal{B} + \mathcal{D}\|_{\mathcal{H}_\infty} < \gamma$ iff there exists some \mathcal{X} with

$$\mathcal{X} > 0 \quad \text{and} \quad \begin{pmatrix} \mathcal{A}^\top \mathcal{X} + \mathcal{X} \mathcal{A} & \mathcal{X} \mathcal{B} & \mathcal{C}^\top \\ \mathcal{B}^\top \mathcal{X} & -\gamma^2 I & \mathcal{D}^\top \\ \mathcal{C} & \mathcal{D} & -I \end{pmatrix} < 0. \quad (24.23)$$

Due to the affine dependence of $(\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D})$ on the controller matrices (A_c, B_c, C_c, D_c) , this involves again a bilinear matrix inequality.

It is pleasing that one can identify, again, a convexifying controller parameter transformation [13,17]. If we partition

$$\mathcal{X} = \begin{pmatrix} X & U \\ U^\top & * \end{pmatrix} \quad \text{and} \quad \mathcal{X}^{-1} = \begin{pmatrix} Y & V \\ V^\top & * \end{pmatrix} \quad (24.24)$$

according to \mathcal{A} (where X and Y share their dimension with A and the $*$'s denote matrices that are irrelevant for our purposes) it reads as

$$\begin{pmatrix} K & L \\ M & N \end{pmatrix} = \begin{pmatrix} XAY & 0 \\ 0 & 0 \end{pmatrix} + \begin{pmatrix} U & XB \\ 0 & I \end{pmatrix} \begin{pmatrix} A_c & B_c \\ C_c & D_c \end{pmatrix} \begin{pmatrix} V^\top & 0 \\ CY & I \end{pmatrix}. \quad (24.25)$$

We view this as a transformation $(\mathcal{X}, A_c, B_c, C_c, D_c) \rightarrow (X, Y, K, L, M, N) =: v$. This definition is motivated by the following easily verified relations:

$$\text{with } \mathcal{Y} := \begin{pmatrix} Y & I \\ V^\top & 0 \end{pmatrix} \quad \text{we have } \mathcal{Y}^\top \mathcal{X} \mathcal{Y} = \begin{pmatrix} Y & I \\ I & X \end{pmatrix} =: \mathbf{X}(v) \quad \text{and} \quad (24.26)$$

$$\left(\begin{array}{c|c} \mathcal{Y}^\top (\mathcal{X}\mathcal{A}) \mathcal{Y} & \mathcal{Y}^\top (\mathcal{X}\mathcal{B}) \\ \hline C\mathcal{Y} & \mathcal{D} \end{array} \right) = \left(\begin{array}{c|c} AY + BM & A + BNC \\ \hline K & XA + LC \end{array} \middle| \begin{array}{c} B_0 + BNF \\ XB_0 + LF \end{array} \right) =: \left(\begin{array}{c|c} \mathbf{A}(v) & \mathbf{B}(v) \\ \hline \mathbf{C}(v) & \mathbf{D}(v) \end{array} \right). \quad (24.27)$$

Although looking intricate, the key is the affine dependence of the blocks $\mathbf{X}(v)$, $\mathbf{A}(v)$, $\mathbf{B}(v)$, $\mathbf{C}(v)$, and $\mathbf{D}(v)$ on the new variables v . If \mathcal{Y} is nonsingular, a congruence transformation with \mathcal{Y} and $\text{diag}(\mathcal{Y}, I, I)$ on Equation 24.23 leads to

$$\mathcal{Y}^\top \mathcal{X} \mathcal{Y} > 0 \quad \text{and} \quad \begin{pmatrix} \mathcal{Y}^\top (\mathcal{A}^\top \mathcal{X}) \mathcal{Y} + \mathcal{Y}^\top (\mathcal{X}\mathcal{A}) \mathcal{Y} & \mathcal{Y}^\top (\mathcal{X}\mathcal{B}) & \mathcal{Y}^\top \mathcal{C}^\top \\ (\mathcal{B}^\top \mathcal{X}) \mathcal{Y} & -\gamma^2 I & \mathcal{D}^\top \\ C\mathcal{Y} & \mathcal{D} & -I \end{pmatrix} < 0, \quad (24.28)$$

which is, in turn, nothing but the following LMI in v :

$$\mathbf{X}(v) > 0 \quad \text{and} \quad \begin{pmatrix} \mathbf{A}(v)^\top + \mathbf{A}(v) & \mathbf{B}(v) & \mathbf{C}(v)^\top \\ \mathbf{B}(v)^\top & -\gamma^2 I & \mathbf{D}(v)^\top \\ \mathbf{C}(v) & \mathbf{D}(v) & -I \end{pmatrix} < 0. \quad (24.29)$$

This brings us to the following result which is true without any hypothesis on \mathcal{Y} .

Theorem 24.6:

There exists a controller as in Equation 24.17 which stabilizes the system in Equation 24.18 and renders the \mathcal{H}_∞ -norm of the transfer matrix $d \rightarrow e$ smaller than γ iff the LMI's in Equation 24.29 are feasible.

The actual design of a controller proceeds as follows. Find a solution of the LMIs in Equation 24.29; due to the first inequality in Equation 24.29 the matrix $I - XY$ is nonsingular (Schur); therefore, one can find square and nonsingular matrices U and V with $I - XY = UV^\top$; then we can solve Equation 24.25 for (A_c, B_c, C_c, D_c) . This controller does the job since we can define the nonsingular matrix \mathcal{Y} and solve for \mathcal{X} in Equation 24.26, which implies that Equation 24.27 is valid; then Equation 24.29 is nothing but Equation 24.28; since \mathcal{Y} is nonsingular, this transforms into Equation 24.23 by congruence.

In summary, we have reduced the design problem to find a stabilizing controller that establishes a bound on the \mathcal{H}_∞ -norm of the closed-loop system to an equivalent problem that amounts to checking the feasibility of the LMIs in Equation 24.29. Since γ^2 enters these constraints in an affine fashion, one can minimize γ^2 subject to the feasibility of these LMIs in order to directly compute the optimal \mathcal{H}_∞ -attenuation level that is achievable by stabilizing controllers.

24.6.3 General Synthesis Procedure

Although we discussed \mathcal{H}_∞ -synthesis in quite some detail, we can extract the following generic procedure for moving from analysis to synthesis inequalities for a whole variety of other performance specifications that can be expressed by LMIs.

- Rewrite the analysis inequalities in terms of the blocks $\mathcal{X}, \mathcal{XA}, \mathcal{XB}, \mathcal{C}$, and \mathcal{D} .
- Find a formal congruence transformation involving \mathcal{Y} which leads to inequalities in terms of the blocks $\mathcal{Y}^\top \mathcal{X} \mathcal{Y}, \mathcal{Y}^\top (\mathcal{XA}) \mathcal{Y}, \mathcal{Y}^\top (\mathcal{XB}), \mathcal{C} \mathcal{Y}$, and \mathcal{D} .
- Then the synthesis inequalities are obtained by the substitution

$$\mathcal{Y}^\top \mathcal{X} \mathcal{Y} \rightarrow \mathbf{X}(v), \quad \begin{pmatrix} \mathcal{Y}^\top (\mathcal{XA}) \mathcal{Y} & \mathcal{Y}^\top (\mathcal{XB}) \\ \mathcal{C} & \mathcal{D} \end{pmatrix} \rightarrow \begin{pmatrix} \mathbf{A}(v) & \mathbf{B}(v) \\ \mathbf{C}(v) & \mathbf{D}(v) \end{pmatrix}$$

with Equation 24.27 for $v := (X, Y, K, L, M, N)$.

- For state-feedback synthesis one can apply the very same procedure with the formulas $\mathbf{X}(v) = Y, \mathbf{A}(v) = AY + BM, \mathbf{B}(v) = B_0, \mathbf{C}(v) = C_0 Y + EM, \mathbf{D}(v) = D_0$ for $v = (M, Y)$.
- The controller construction is independent from the particular analysis inequalities and remains, both for state-feedback and output-feedback synthesis, unaltered.

This procedure applies to \mathcal{H}_2 -synthesis as well as to the variants of the LMI analysis specification discussed in Section 24.5.4. As an illustration, the discrete-time system $x(t+1) = \mathcal{A}x(t) + \mathcal{B}d(t), e(t) = \mathcal{C}x(t) + \mathcal{D}d(t)$ is Schur-stable and its l_2 -gain is bounded by γ iff there exists some \mathcal{X} with

$$\mathcal{X} \succ 0, \quad \begin{pmatrix} I & 0 \\ \mathcal{A} & \mathcal{B} \end{pmatrix}^\top \begin{pmatrix} -\mathcal{X} & 0 \\ 0 & \mathcal{X} \end{pmatrix} \begin{pmatrix} I & 0 \\ \mathcal{A} & \mathcal{B} \end{pmatrix} + \begin{pmatrix} 0 & I \\ \mathcal{C} & \mathcal{D} \end{pmatrix}^\top \begin{pmatrix} -\gamma^2 I & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} 0 & I \\ \mathcal{C} & \mathcal{D} \end{pmatrix} \prec 0.$$

Since these can also be expressed as

$$\mathcal{X} \succ 0, \quad \begin{pmatrix} \mathcal{X} & 0 \\ 0 & \gamma^2 I \end{pmatrix} - \begin{pmatrix} \mathcal{A} & \mathcal{B} \\ \mathcal{C} & \mathcal{D} \end{pmatrix}^\top \begin{pmatrix} \mathcal{X} & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} \mathcal{A} & \mathcal{B} \\ \mathcal{C} & \mathcal{D} \end{pmatrix} \succ 0,$$

a Schur complement argument reveals that these analysis inequalities can be written as

$$\left(\begin{array}{cc|cc} \mathcal{X} & 0 & \mathcal{A}^\top \mathcal{X} & \mathcal{C}^\top \\ 0 & \gamma^2 I & \mathcal{B}^\top \mathcal{X} & \mathcal{D}^\top \\ \hline \mathcal{XA} & \mathcal{XB} & \mathcal{X} & 0 \\ \mathcal{C} & \mathcal{D} & 0 & I \end{array} \right) \succ 0$$

and thus admit the precise format in order to apply the general synthesis procedure.

Based on the generic dualization and elimination results described in [16], it is often possible to eliminate matrix variables that only appear in one of these synthesis inequalities, with the benefit of reducing computational complexity. For example, one can eliminate all matrices K, L, M , and N from the \mathcal{H}_∞ -synthesis inequalities in order to arrive at the inequalities as proposed in [8,11].

Finally, in many practical problems the disturbance and error signals are partitioned as $d = \text{col}(d_1, \dots, d_p)$ and $e = \text{col}(e_1, \dots, e_q)$ in order to impose multiple individual performance requirements on some of the channels $d_v \rightarrow e_\mu$, possibly with different norms. The general controller synthesis procedure described in this section is applicable for this kind of multiobjective control problems provided that one is willing to allow some level of conservatism by expressing the combined desired specifications with one and the same matrix \mathcal{X} in the closed-loop system. This variant of multiobjective control, which is addressed as a Lyapunov-shaping paradigm in [17] in more detail, even allows the incorporation of pole-placement requirements on \mathcal{A} in terms of general LMI regions. We refer to [17] for an instructive controller design example. The introduction of slack-variables offers a possibility to reduce conservatism as shown for discrete-time systems in [5], while an LMI solution of the general multiobjective control problem based on the Youla-Kucera parameterization of all stabilizing controllers is discussed in [15] and its references.

24.6.4 Observer and Estimator Synthesis

Estimation problems are related to the configuration in Figure 24.2. Based on measurements y , the goal is to determine an estimator whose output approximates the system output z (which can be equal to the state or comprise components of d) as closely as possible, despite the corruption of the system by the disturbance d . If d is white noise with unity covariance, minimization of the asymptotic variance of e amounts to minimizing the \mathcal{H}_2 -norm of $d \rightarrow e$ which results in the classical Kalman filter. Alternatively, using the energy-gain of $d \rightarrow e$ as a performance indicator amounts to considering the \mathcal{H}_∞ -estimation problem. These and many other variants of estimation problems can be rephrased as an output-feedback synthesis problem for a system as described by Equation 24.16 with $B = 0$ and $E = -I$ (which means that u does not excite the system dynamics). Let us stress that in this reformulation u admits the interpretation of the estimator output and e is the estimation error.

If the estimator admits the structure of an observer with a to-be-designed gain D_c ,

$$\dot{x}_c = Ax_c + D_c(Cx_c - y), \quad u = C_0x_c, \tag{24.30}$$

then the dynamics of the state-error $\xi = x - x_c$ is described by

$$\dot{\xi} = (A + D_cC)\xi + (B_0 + D_cF)d, \quad e = C_0\xi + D_0d$$

and defines the transfer matrix $d \rightarrow e$. This representation is dual (transposed) to what we considered for state-feedback synthesis, and only slight modifications are required in order to determine the LMIs for synthesizing observer gains D_c that stabilize the error dynamics and achieve, for example, an \mathcal{H}_∞ - or \mathcal{H}_2 -norm bound γ on $d \rightarrow e$.

Let us now assume that A in Equation 24.16 is stable. Instead of assuming a particular structure, we can then try to find a general estimator Equation 24.17 with stable A_c such that a desired performance level for $d \rightarrow e$ is achieved. In view of Equation 24.18 and the fact that $B = 0$, stability of A_c now boils down to stability of \mathcal{A} , and the very same output-feedback synthesis procedure can be followed in order to design optimal estimators by LMIs.

However, it is interesting to observe that the structural property $B = 0$ allows a simplification of the convexifying controller parameter transformation which will be essential for robust estimator synthesis [9]. Indeed, starting from Equation 24.24 and with $Z = Y^{-1}$ let us define

$$\begin{pmatrix} K & L \\ M & N \end{pmatrix} := \begin{pmatrix} U & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} A_c & B_c \\ C_c & D_c \end{pmatrix} \begin{pmatrix} V^T Z & 0 \\ 0 & I \end{pmatrix} \quad \text{and} \quad \mathcal{Y} := \begin{pmatrix} I & I \\ V^T Z & 0 \end{pmatrix}. \tag{24.31}$$

After a direct computation we obtain

$$\mathcal{Y}^T \mathcal{X} \mathcal{Y} = \begin{pmatrix} Z & Z \\ Z & X \end{pmatrix} =: \mathbf{X}(v) \quad \text{and} \tag{24.32}$$

$$\left(\frac{\mathcal{Y}^T(\mathcal{X}\mathcal{A})\mathcal{Y} \mid \mathcal{Y}^T(\mathcal{X}\mathcal{B})}{\mathcal{C}\mathcal{Y} \mid \mathcal{D}} \right) = \left(\begin{array}{cc|c} ZA & ZA & ZB_0 \\ \hline XA + LC + K & XA + LC & XB_0 + LF \\ \hline C_0 + ENC + EM & C_0 + ENC & D_0 + ENF \end{array} \right) =: \left(\frac{\mathbf{A}(v) \mid \mathbf{B}(v)}{\mathbf{C}(v) \mid \mathbf{D}(v)} \right)$$

with an affine dependence on X, Z, K, L, M , and N . Therefore the general synthesis procedure in Section 24.6.3 does apply, with the only modification being the use of these new substitution formulas and by recalling the relation $Z = Y^{-1}$ for the actual design of the estimator.

FIGURE 24.2 Estimator synthesis.

24.7 Polytopic Uncertainties and Robustness Analysis

First principle models of physical systems are often represented by state-space descriptions in which the various components of the state represent well-defined physical quantities. Variations, perturbations, or uncertainties in physical parameters lead to uncertainty in the model. Often, this uncertainty is reflected by variations in well-distinguished parameters or coefficients in the model, while, in addition, the nature and/or range of the uncertain parameters may be known, or partially known. Since very small parameter variations may have a major impact on the dynamics of a system, it is of evident importance to analyze parametric uncertainties of dynamical systems. Suppose that $\delta = (\delta_1, \dots, \delta_p)$ is the vector that expresses the ensemble of all uncertain quantities in a given dynamical system. Then there are at least two distinct cases that are of independent interest:

- a. *Time-invariant parametric uncertainties:* the vector δ is a fixed but unknown element of an uncertainty set $\delta \subseteq \mathbb{R}^p$.
- b. *Time-varying parametric uncertainties:* the vector δ is an unknown time-varying function $\delta : \mathbb{R} \rightarrow \mathbb{R}^p$ whose values $\delta(t)$ belong to an uncertainty set $\delta \subseteq \mathbb{R}^p$, and possibly satisfy additional constraints.

24.7.1 Time-Invariant Parametric Uncertainty

Consider the uncertain time-invariant system defined by

$$\dot{x} = A(\delta)x, \tag{24.33}$$

where $A(\cdot)$ is a continuous function of the real-valued parameter vector $\delta = \text{col}(\delta_1, \dots, \delta_p)$ which is only known to be contained in an uncertainty set $\delta \subseteq \mathbb{R}^p$. The problem of *robust stability* amounts to characterizing whether the equilibrium point $x^* = 0$ of Equation 24.33 is exponentially stable for all parameters $\delta \in \delta$. With time-invariant uncertainties, Equation 24.33 is robustly stable iff $A(\delta)$ is Hurwitz for all $\delta \in \delta$. Since δ generally consists of infinitely many points, the verification of this condition is rather troublesome from a computational point of view.

The uncertain system (Equation 24.33) is called *quadratically stable* if there exists $X = X^T$ such that

$$X > 0, \quad A(\delta)^T X + X A(\delta) < 0 \quad \text{for all } \delta \in \delta. \tag{24.34}$$

The importance of this definition becomes apparent after observing that $V(x) := x^T X x$ is a quadratic Lyapunov function for Equation 24.33 which, by Theorem 24.1, implies that $A(\delta)$ is Hurwitz for all $\delta \in \delta$. Hence, quadratic stability implies the origin of Equation 24.33 to be robust exponentially stable against time-invariant uncertainties $\delta \in \delta$. Unless δ has a finite number of points, Equation 24.34 cannot be verified easily. Therefore, the following result is of considerable interest.

Theorem 24.7:

If $A(\delta)$ is affine in δ and $\delta = \text{co}\{\delta^1, \dots, \delta^N\}$ then Equation 24.33 is quadratically stable if and only if there exists some X such that

$$X > 0, \quad A(\delta^k)^T X + X A(\delta^k) < 0, \quad k = 1, \dots, N.$$

Hence, for polytopic uncertainty sets and affine parametric dependence in Equation 24.33, quadratic stability can be numerically verified by a feasibility test for a *finite number* of LMIs only. The proof is an illustrative example of the use of convexity. It requires showing that $F(\delta) := A(\delta)^T X + X A(\delta) < 0$ for all $\delta \in \delta$ if $F(\delta^k) < 0$ for $k = 1, \dots, N$. To see this, first observe that $F(\cdot)$ is a convex function on δ whenever $A(\cdot)$ is affine. Second, any $\delta \in \delta$ can be written as a convex combination of the points $\delta^1, \dots, \delta^N$,

say $\delta = \sum_{k=1}^N \alpha_k \delta^k$ with nonnegative coefficients α_k that sum up to 1; hence $F(\delta) = F(\sum_{k=1}^N \alpha_k \delta^k) \preceq \sum_{k=1}^N \alpha_k F(\delta^k) \prec 0$, which gives the result.

24.7.2 Time-Dependent Parametric Uncertainty

Robust stability against time-varying uncertainties is generally a more demanding requirement than robust stability against time-invariant uncertainties. Consider the system

$$\dot{x}(t) = A(\delta(t))x(t), \quad (24.35)$$

which is affected by an uncertain parameter curve $\delta : \mathbb{R} \rightarrow \mathfrak{d}$. Unlike the case with time-invariant uncertainties, robust stability of the origin is now *not implied* by the condition that $A(\delta)$ is Hurwitz for all $\delta \in \mathfrak{d}$. However, the uncertain system with time-varying parametric uncertainties is exponentially stable if there exists $X \succ 0$ such that Equation 24.34 holds. Therefore, quadratic stability does, in fact, imply robust stability against arbitrary fast time-varying parametric uncertainties. This is a nice, but in general conservative, test if additional *a priori* information on the uncertainty is available. For example, the parameter curves $\delta(\cdot)$ are often known to be continuously differentiable and constrained in terms of their values and their rate-of-variation as

$$\delta(t) \in \mathfrak{d}, \quad \dot{\delta}(t) \in \mathfrak{p} \quad \text{for all } t \in \mathbb{R}. \quad (24.36)$$

Less conservative robust stability tests can be inferred by postulating the existence of *parameter-dependent* Lyapunov functions. A popular instance of such functions takes the form $V(x, \delta) := x^\top X(\delta)x$ and requires a search over matrix functions $X(\delta) = X(\delta)^\top$ with $\delta \in \mathfrak{d}$. For notational convenience, let us introduce, for a continuously differentiable matrix function $X(\delta)$, the “derivative”

$$\partial X(\delta, \rho) := \sum_{k=1}^p \partial_k X(\delta) \rho_k, \quad (\delta, \rho) \in \mathfrak{d} \times \mathfrak{p}, \quad (24.37)$$

where $\partial_k X(\cdot)$ denotes the partial derivative of the function $X(\cdot)$ with respect to the k th entry of δ and where ρ_k is the k th component of the vector ρ . (We stress that $\partial X(\delta, \rho)$ is purely a symbolic notation which is not to be confused with the partial derivative of $X(\cdot)$ itself.) The following result provides a sufficient condition for robust stability and actually covers many tests in the literature. The proof provides much insight into the understanding of stability arguments based on parameter-dependent Lyapunov functions.

Theorem 24.8:

Suppose that \mathfrak{d} and \mathfrak{p} are compact subsets of \mathbb{R}^p and suppose that $X(\delta) = X(\delta)^\top$ is a continuously differentiable matrix function that satisfies

$$X(\delta) \succ 0, \quad \partial X(\delta, \rho) + A(\delta)^\top X(\delta) + X(\delta)A(\delta) \prec 0 \quad (24.38)$$

for all $\delta \in \mathfrak{d}$ and $\rho \in \mathfrak{p}$. Then the origin of Equation 24.35 is exponentially stable for all time-varying parametric uncertainties that satisfy Equation 24.36.

Proof. Suppose that $X(\delta)$ satisfies Equation 24.38. Continuity of $X(\cdot)$ and compactness of \mathfrak{d} and \mathfrak{p} guarantee the existence of constants $a, b, c > 0$ such that, for all $\delta \in \mathfrak{d}$ and $\rho \in \mathfrak{p}$,

$$aI \preceq X(\delta) \preceq bI, \quad \partial X(\delta, \rho) + A(\delta)^\top X(\delta) + X(\delta)A(\delta) \preceq -cI. \quad (24.39)$$

Let $\delta(\cdot)$ and $x(\cdot)$ be a parameter curve and a state trajectory that satisfy Equations 24.36 and 24.35, respectively. With $\xi(t) := x(t)^\top X(\delta(t))x(t)$ we clearly have

$$\dot{\xi}(t) = x(t)^\top \left[\sum_{k=1}^p \partial_k X(\delta(t)) \dot{\delta}_k(t) \right] x(t) + x(t)^\top [A(\delta(t))^\top X(\delta(t)) + X(\delta(t))A(\delta(t))]x(t).$$

If we exploit Equation 24.39 we obtain $a\|x(t)\|^2 \leq \xi(t) \leq b\|x(t)\|^2$ and $\dot{\xi}(t) \leq -c\|x(t)\|^2$. This implies that $\dot{\xi}(t) \leq -\frac{c}{b}\xi(t)$ and hence $\xi(t) \leq \xi(t_0) \exp(-\frac{c}{b}(t - t_0))$ for all $t \geq t_0$. In turn, this leads to $\|x(t)\|^2 \leq \frac{b}{a}\|x(t_0)\|^2 e^{-\frac{c}{b}(t-t_0)}$, which is Equation 24.5 for $\alpha = c/(2b)$ and $\beta = \sqrt{b/a}$.

The constraints in Equation 24.38 on $X(\cdot)$ define a purely algebraic test that do not involve the system- or parameter-trajectories. The test is not easy to apply directly because the matrix function $X(\cdot)$ needs to satisfy a partial differential LMI. By considering specific classes of matrix functions $X(\cdot)$, Equation 24.38 can be converted and implemented with LMI solvers. One of these classes is the set of affine symmetric matrix functions $X : \delta \rightarrow \mathbb{S}^n$.

A few special instances are worth mentioning. If the parameters are *time-invariant*, we have $\rho = \{0\}$ and Equation 24.38 simplifies to the conditions $X(\delta) > 0$ and $A(\delta)^\top X(\delta) + X(\delta)A(\delta) < 0$. In that case, Equation 24.38 is also *necessary* for robust stability. If parameters vary *arbitrarily fast*, ρ is unbounded and Equation 24.38 is feasible only if the partial derivatives $\partial_k X(\delta)$ vanish identically. This means that $X(\delta) = X$ is not depending on δ and we recover the quadratic stability test.

24.7.3 Robust Performance

In the previous subsections we have shown how tests for robust stability against parametric uncertainties can be inferred from characterizations of nominal stability. The same generalization applies in order to obtain conditions for verifying robust performance. Consider the uncertain parameter depending system

$$\begin{aligned} \dot{x}(t) &= A(\delta(t))x(t) + B(\delta(t))d(t), \\ e(t) &= C(\delta(t))x(t) + D(\delta(t))d(t), \end{aligned} \tag{24.40}$$

where $\delta(\cdot)$ is a continuously differentiable rate-bounded uncertainty that satisfies Equation 24.36. In the case of \mathcal{H}_∞ -performance, we quantified the effect of d on e in terms of the \mathcal{L}_2 gain of the system. However, the output e of Equation 24.40 not only depends on the input d but also on the uncertainty $\delta(\cdot)$. Hence we say that the *robust \mathcal{L}_2 -gain is smaller than γ* if

- for $d = 0$ and for all parameter curves $\delta(\cdot)$ satisfying Equation 24.36, $x^* = 0$ is an exponentially stable equilibrium of the system in Equation 24.40.
- for $x(0) = 0$ it holds that

$$\sup_{\delta(\cdot) \text{ satisfies Equation 24.36}} \sup_{0 < \|d\|_{\mathcal{L}_2} < \infty} \frac{\|e\|_{\mathcal{L}_2}}{\|d\|_{\mathcal{L}_2}} < \gamma.$$

With some abuse of terminology, robust \mathcal{L}_2 -gain performance is often referred to as *robust \mathcal{H}_∞ -performance*, but it is important to realize that frequency-domain characterizations do not make sense when considering time-dependent parametric uncertainties in Equation 24.40. Only with time-invariant parameter uncertainties ($\rho = \{0\}$) does a robust \mathcal{L}_2 -gain that is smaller than γ imply that $\|T_\delta\|_{\mathcal{H}_\infty} < \gamma$ for all $\delta \in \delta$, where T_δ is the transfer function associated with Equation 24.40 for time-invariant parameters $\delta(t) = \delta$. The following result generalizes Theorem 24.4 to robust \mathcal{L}_2 -gain performance.

Theorem 24.9:

Suppose there exists a continuously differentiable matrix function $X(\delta) = X(\delta)^\top$ such that $X(\delta) \succ 0$ and

$$\begin{aligned} & \begin{pmatrix} \partial X(\delta, \rho) + A(\delta)^\top X(\delta) + X(\delta)A(\delta) & X(\delta)B(\delta) \\ B(\delta)^\top X(\delta) & 0 \end{pmatrix} \\ & + \begin{pmatrix} 0 & I \\ C(\delta) & D(\delta) \end{pmatrix}^\top \begin{pmatrix} -\gamma^2 I & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} 0 & I \\ C(\delta) & D(\delta) \end{pmatrix} < 0 \end{aligned} \quad (24.41)$$

for all $\delta \in \delta$ and $\rho \in \rho$. Then the uncertain system in Equation 24.40 has a robust \mathcal{L}_2 -gain smaller than γ .

The proof of this result is analogous to that of Theorem 24.4. The main merit of Theorem 24.9 is that it converts robust \mathcal{L}_2 -gain performance to an algebraic property. As in Theorem 24.8, the condition in Equation 24.41 requires the numerical search for a matrix function $X(\cdot)$ that needs to satisfy a partial differential LMI. Moreover, the discussion about the extreme cases concerning time-invariant or arbitrary fast time-varying parameters in Section 24.7.2 remains valid for Equation 24.41. Finally, let us remark that Theorem 24.9 extends, mutatis mutandis, to all other performance specifications that have been mentioned in Section 24.5.

24.8 Robust State-Feedback and Estimator Synthesis

Consider the system

$$\begin{aligned} \dot{x}(t) &= A(\delta(t))x(t) + B_0(\delta(t))d(t) + B(\delta(t))u(t), \\ e(t) &= C_0(\delta(t))x(t) + D_0(\delta(t))d(t) + E(\delta(t))u(t), \\ y(t) &= C(\delta(t))x(t) + F(\delta(t))d(t), \end{aligned} \quad (24.42)$$

whose describing matrices are affected by a time-dependent parametric uncertainty $\delta(t) \in \mathbb{R}^p$. Let us also assume that the dependence of the system matrices is actually affine, and that $\delta(t)$ takes values that are, for $t \geq 0$, confined to the polytope

$$\delta := \text{co}\{\delta^1, \dots, \delta^N\} \subset \mathbb{R}^p. \quad (24.43)$$

Robust controller synthesis deals with the problem of determining a feedback controller that processes measurements y to control inputs u , so as to guarantee robust stability and a desired robust performance specification on the mapping from the disturbance d to the output e of the controlled system.

The robust state-feedback synthesis problem is a special case in which the whole state is assumed to be measurable ($y = x$ in Equation 24.42) and the controller is a static feedback law $u = D_c x$ with some gain D_c . In that case, the resulting closed-loop system is described by

$$\begin{aligned} \dot{x}(t) &= [A(\delta(t)) + B(\delta(t))D_c]x(t) + B_0(\delta(t))d(t), \\ e(t) &= [C_0(\delta(t)) + E(\delta(t))D_c]x(t) + D_0(\delta(t))d(t). \end{aligned}$$

If applying Theorem 24.9 for a parameter-independent $X(\delta) = X$ and exploiting affine parameter-dependence as for Theorem 24.7, we infer that the robust \mathcal{L}_2 -gain of the controlled system is smaller than γ if there exists $X = X^\top$ with

$$\begin{aligned} X \succ 0, \quad & \begin{pmatrix} [A(\delta^k) + B(\delta^k)D_c]^\top X + X[A(\delta^k) + B(\delta^k)D_c] & XB_0(\delta^k) & [C_0(\delta^k) + E(\delta^k)D_c]^\top \\ B_0(\delta^k)^\top X & -\gamma^2 I & D_0(\delta^k)^\top \\ C_0(\delta^k) + E(\delta^k)D_c & D_0(\delta^k) & -I \end{pmatrix} < 0 \\ & \text{for all } k = 1, \dots, N. \end{aligned} \quad (24.44)$$

Literally following the nominal synthesis procedure of Section 24.6.1 with the convexifying transformation in Equation 24.21 we infer that there exist (D_c, X) satisfying Equation 24.44 iff there exist (M, Y) satisfying

$$Y > 0, \quad \begin{pmatrix} [A(\delta^k)Y + B(\delta^k)M]^\top + [A(\delta^k)Y + B(\delta^k)M] & B_0(\delta^k) & [C_0(\delta^k)Y + E(\delta^k)M]^\top \\ B_0(\delta^k)^\top & -\gamma^2 I & D_0(\delta^k)^\top \\ C_0(\delta^k)Y + E(\delta^k)M & D_0(\delta^k) & -I \end{pmatrix} < 0$$

for all $k = 1, \dots, N$.

This LMI feasibility problem in (M, Y) can be readily solved. If (M, Y) is a solution, the state-feedback gain $D_c = MY^{-1}$ guarantees a robust \mathcal{L}_2 -gain that is smaller than γ for the closed-loop system.

This procedure works smoothly because the transformation (Equation 24.21) does not involve data matrices that describe the open-loop system (Equation 24.42) and because X is assumed independent of δ . The reduction of conservatism by employing parameter-dependent functions $X(\delta)$ is possible, to a certain extent, by introducing slack variables as discussed in [5].

Unfortunately, robust output-feedback controllers cannot be designed by following the general synthesis procedure of Section 24.6.2 for the parameter-dependent system (Equation 24.42). As the main reason, the convexifying transformation (Equation 24.25) involves the system data while, in addition, the matrix blocks in the corresponding synthesis inequalities are not affine in the parameter vector δ . Similarly, robust observers with the structure appearing in Equation 24.30 cannot be designed, just because the observer is defined in terms of open-loop system data.

In contrast, for the estimation problem we have considered the convexifying transformation in Equation 24.31 of the estimator parameters that does not involve system matrices. Therefore it is possible to design robust estimators in complete analogy to what was discussed for state-feedback synthesis. Specifically, recall from Section 24.6.4 that estimator design involves a system description (Equation 24.42) with $B(\delta) = 0$ and $E(\delta) = E$. Then there exists an estimator (Equation 24.17) that achieves for $d \rightarrow e$ a robust \mathcal{L}_2 -gain performance level smaller than γ (according to the definition in Section 24.7.3) if there exists $v = (X, Z, K, L, M, N)$ such that

$$X(v) > 0, \quad \begin{pmatrix} A(v, \delta^k)^\top + A(v, \delta^k) & B(v, \delta^k) & C(v, \delta^k)^\top \\ B(v, \delta^k)^\top & -\gamma^2 I & D(v, \delta^k)^\top \\ C(v, \delta^k) & D(v, \delta^k) & -I \end{pmatrix} < 0 \quad \text{for all } k = 1, \dots, N,$$

where $X(v)$ is given in Equation 24.32 and

$$\left(\begin{array}{c|c} A(v, \delta^k) & B(v, \delta^k) \\ \hline C(v, \delta^k) & D(v, \delta^k) \end{array} \right) = \left(\begin{array}{cc|c} ZA(\delta^k) & ZA(\delta^k) & ZB_0(\delta^k) \\ \hline XA(\delta^k) + LC(\delta^k) + K & XA(\delta^k) + LC(\delta^k) & XB_0(\delta^k) + LF(\delta^k) \\ \hline C_0(\delta^k) + ENC(\delta^k) + EM & C_0(\delta^k) + ENC(\delta^k) & D_0(\delta^k) + ENF(\delta^k) \end{array} \right)$$

are affine in the design parameters v . This set of $(N + 1)$ LMIs can be readily implemented. If v is a solution, the desired robust estimator is then given by the state-space representation matrices (A_c, B_c, C_c, D_c) that are resolved from Equation 24.31 with nonsingular U, V satisfying $Z - X = UV^T Z$.

24.9 Gain-Scheduling Synthesis

An interesting generalization of the robust controller synthesis problem treated in the previous section amounts to allowing the controller to be dependent on the parameter vector $\delta = \text{col}(\delta_1, \dots, \delta_p)$. This means that the controller has online access to the time-varying parameter $\delta(t)$ through an additional measurement. Hence, the actual parameter value, although not known *a priori*, is used as extra information to control the system.

The classical *gain-scheduling* approach towards control system design fits in this line of reasoning and typically amounts to associating with $\delta(t)$ a specific operating condition of the plant. A (robust)

controller is designed for each operating condition $\delta \in \mathfrak{d}$ and these are *scheduled* by means of switching or interpolation rules inferred from measurement information. This design methodology has found widespread applications, but the assessment of guarantees on robust stability and robust performance in view of time-dependent changes of δ is usually difficult if not impossible.

For the linear parameter-varying (LPV) system in Equation 24.42, an LPV controller is a system of the form

$$\begin{aligned}\dot{x}_c(t) &= A_c(\delta(t))x_c(t) + B_c(\delta(t))y(t), \\ u(t) &= C_c(\delta(t))x_c(t) + D_c(\delta(t))y(t),\end{aligned}\tag{24.45}$$

where $\delta(t)$ satisfies the bound and rate constraints in Equation 24.36. As before, the aim will be to design an LPV controller (Equation 24.45) that renders the controlled system robustly stable and establishes a desired robust performance specification. The controlled system is given by

$$\begin{aligned}\dot{\xi}(t) &= \mathcal{A}(\delta(t))\xi(t) + \mathcal{B}(\delta(t))d(t), \\ e(t) &= \mathcal{C}(\delta(t))\xi(t) + \mathcal{D}(\delta(t))d(t),\end{aligned}$$

where the closed-loop matrix functions are structured as in Equation 24.18.

The synthesis techniques for the construction of LPV controllers closely resemble those for nominal controller design as we have investigated in Section 24.6.2. The LPV synthesis problem to achieve robust stability and a robust \mathcal{L}_2 -gain smaller than γ is then solved if one can find a controller and a smooth function $\mathcal{X}(\delta) = \mathcal{X}(\delta)^\top$ such that for all $(\delta, \rho) \in \mathfrak{d} \times \mathfrak{p}$

$$\mathcal{X}(\delta) > 0 \quad \text{and} \quad \begin{pmatrix} \partial\mathcal{X}(\delta, \rho) + \mathcal{A}(\delta)^\top\mathcal{X}(\delta) + \mathcal{X}(\delta)\mathcal{A}(\delta) & \mathcal{X}(\delta)\mathcal{B}(\delta) & \mathcal{C}(\delta)^\top \\ \mathcal{B}(\delta)^\top\mathcal{X}(\delta) & -\gamma^2 I & \mathcal{D}(\delta)^\top \\ \mathcal{C}(\delta) & \mathcal{D}(\delta) & -I \end{pmatrix} < 0, \tag{24.46}$$

where $\partial\mathcal{X}(\delta, \rho)$ is defined in Equation 24.37. Mutatis mutandis, the convexifying controller transformation $(\mathcal{X}, A_c, B_c, C_c, D_c) \rightarrow (X, Y, K, L, M, N) =: \nu$ from Section 24.6 still works to arrive at a synthesis procedure for LPV output-feedback controllers. However, note that all matrices in the transformed variable ν have become functions of $\delta \in \mathfrak{d}$ or of $(\delta, \rho) \in \mathfrak{d} \times \mathfrak{p}$ now. In fact, finding a controller and a continuously differentiable $\mathcal{X}(\cdot)$ satisfying Equation 24.46 on $\mathfrak{d} \times \mathfrak{p}$ is equivalent to finding $\nu(\cdot)$ such that the synthesis inequalities

$$X(\nu) > 0, \quad \begin{pmatrix} \mathbf{Z}(\nu) + \mathbf{A}(\nu)^\top + \mathbf{A}(\nu) & \mathbf{B}(\nu) & \mathbf{C}(\nu)^\top \\ \mathbf{B}(\nu)^\top & -\gamma^2 I & \mathbf{D}(\nu)^\top \\ \mathbf{C}(\nu) & \mathbf{D}(\nu) & -I \end{pmatrix} < 0 \tag{24.47}$$

hold on all of $\mathfrak{d} \times \mathfrak{p}$, where $\mathbf{Z}(\nu(\delta, \rho)) := \text{diag}(-\partial Y(\delta, \rho), \partial X(\delta, \rho))$. This turns the LPV controller synthesis problem into a linear matrix-function inequality in the decision variable $\nu(\cdot)$. A description of the related design algorithm can be found in [1].

Let us consider a particular popular scenario in more detail. Suppose that the matrices in Equation 24.42 are affine functions of δ and that B, E, C , and F are actually *independent* of δ . Also, suppose that the time-varying parameters $\delta(t)$ assume their values in the polytope (Equation 24.43) without any constraints on their rate-of-variation. We will search for an LPV controller in which the matrix functions in Equation 24.45 are also *affine* in δ . Finally, we let \mathcal{X} in Equation 24.46 be constant, which implies that $\partial\mathcal{X}(\delta, \rho) = 0$.

These assumptions immediately imply that the closed-loop system matrices become affine in δ . Therefore, Equation 24.46 is satisfied for all $\delta \in \mathfrak{d}$ if and only if Equation 24.46 is satisfied for the generators $\delta = \delta^k, k = 1, \dots, N$, of the set \mathfrak{d} . Hence we achieve a robust \mathcal{L}_2 -gain smaller than γ for the controlled system if there exists \mathcal{X} with

$$\mathcal{X} > 0 \quad \text{and} \quad \begin{pmatrix} \mathcal{A}(\delta^k)^\top\mathcal{X} + \mathcal{X}\mathcal{A}(\delta^k) & \mathcal{X}\mathcal{B}(\delta^k) & \mathcal{C}(\delta^k)^\top \\ \mathcal{B}(\delta^k)^\top\mathcal{X} & -\gamma^2 I & \mathcal{D}(\delta^k)^\top \\ \mathcal{C}(\delta^k) & \mathcal{D}(\delta^k) & -I \end{pmatrix} < 0 \quad \text{for } k = 1, \dots, N. \tag{24.48}$$

Under the present structural assumptions, the transformed variables (K, L, M, N) also become affine functions in δ and $\mathbf{Z}(\nu) = 0$. Now apply the general convexifying transformation

$$(\mathcal{X}, A_c(\delta^k), B_c(\delta^k), C_c(\delta^k), D_c(\delta^k)) \rightarrow (X, Y, K_k, L_k, M_k, N_k) := \nu_k$$

with $k = 1, \dots, N$ as in Section 24.6.2. This transforms Equation 24.48 into

$$\begin{pmatrix} Y & I \\ I & X \end{pmatrix} \succ 0, \quad \begin{pmatrix} \mathbf{A}(\nu_k, \delta^k)^\top + \mathbf{A}(\nu_k, \delta^k) & \mathbf{B}(\nu_k, \delta^k) & \mathbf{C}(\nu_k, \delta^k)^\top \\ \mathbf{B}(\nu_k, \delta^k)^\top & -\gamma^2 I & \mathbf{D}(\nu_k, \delta^k)^\top \\ \mathbf{C}(\nu_k, \delta^k) & \mathbf{D}(\nu_k, \delta^k) & -I \end{pmatrix} \prec 0 \quad \text{for } k = 1, \dots, N. \quad (24.49)$$

We end up with a system of genuine LMIs in the parameters ν_1, \dots, ν_N that can be readily solved. In summary, this leads to the following LPV controller design procedure:

- Verify feasibility of (or minimize γ over) the synthesis inequalities (Equation 24.49) in the variables $\nu_k = (X, Y, K_k, L_k, M_k, N_k)$ for $k = 1, \dots, N$.
- If a solution has been found, construct \mathcal{X} as in the standard output-feedback synthesis procedure in Section 24.6.2.
- For this fixed \mathcal{X} , find controller parameters $\begin{pmatrix} A_{c,k} & B_{c,k} \\ C_{c,k} & D_{c,k} \end{pmatrix}$ that render Equation 24.48 satisfied for each $k = 1, \dots, N$. These controller parameters can be obtained by solving Equation 24.25.
- If $\delta \in \mathfrak{D}$ is represented by $\delta = \sum_{k=1}^N \alpha_k \delta^k$ with $\alpha_k \geq 0$, $\sum_{k=1}^N \alpha_k = 1$, then Equation 24.46 holds for

$$\begin{pmatrix} A_c(\delta) & B_c(\delta) \\ C_c(\delta) & D_c(\delta) \end{pmatrix} = \sum_{k=1}^N \alpha_k \begin{pmatrix} A_{c,k} & B_{c,k} \\ C_{c,k} & D_{c,k} \end{pmatrix}$$

with \mathcal{X} independent of δ and, consequently, $\partial \mathcal{X}(\delta, \rho) = 0$.

The actual LPV controller is now obtained by taking time-varying convex combinations of the N controllers defined by the quadruples $(A_{c,k}, B_{c,k}, C_{c,k}, D_{c,k})$. It is given by Equation 24.45 with

$$\begin{pmatrix} A_c(\delta(t)) & B_c(\delta(t)) \\ C_c(\delta(t)) & D_c(\delta(t)) \end{pmatrix} = \sum_{k=1}^N \alpha_k(t) \begin{pmatrix} A_{c,k} & B_{c,k} \\ C_{c,k} & D_{c,k} \end{pmatrix},$$

where the parameter $\delta(t)$ at time t is represented as $\delta(t) = \sum_{k=1}^N \alpha_k(t) \delta^k$ with $\alpha_k(t) \geq 0$, $\sum_{k=1}^N \alpha_k(t) = 1$. It achieves robust stability and a robust \mathcal{L}_2 -gain performance smaller than γ .

24.10 Robustness Analysis and Synthesis with Multipliers

24.10.1 Robustness Analysis with IQCs

Uncertain systems are often described by a feedback interconnection with a stable LTI system in the forward path and some uncertainty in the feedback path as depicted in Figure 24.3. Mathematically, this amounts to

$$\begin{aligned} \dot{x} &= Ax + B_1 w + B_2 d, \\ z &= C_1 x + D_1 w + D_{12} d \quad \text{interconnected with } w = \Delta(z), \\ e &= C_2 x + D_{21} w + D_2 d, \end{aligned} \quad (24.50)$$

where A is Hurwitz and Δ denotes the uncertainty, a map that is supposed to be contained in some class $\mathbf{\Delta}$. We do not intend to include the theory around general systems and their abstract properties as, for example, developed in [6]. Instead we just assume that the interconnection is well-posed: For all $\Delta \in \mathbf{\Delta}$

FIGURE 24.3 Uncertainty system.

and for all initial conditions $x(0)$ as well as arbitrary external signals d that are of finite energy on $[0, T]$ for all $T \geq 0$, the interconnection has unique responses x, z, w , and e that are of finite energy on finite subintervals of $[0, \infty)$.

The interconnection is said to be robustly stable if, for any $\Delta \in \mathbf{\Delta}$, arbitrary finite energy disturbance signals lead to responses of finite energy as well. The uncertain system has robust \mathcal{L}_2 -gain smaller than γ if the interconnection is robustly stable and if there exists some $\epsilon > 0$ such that the \mathcal{L}_2 -gain of $d \rightarrow e$ in Equation 24.50 for zero initial condition is bounded by $\gamma - \epsilon$ for all uncertainties $\Delta \in \mathbf{\Delta}$.

In order to computationally verify robust performance, we need to suitably capture information about the uncertainty set. Suppose, for example, that for all $\Delta \in \mathbf{\Delta}$ and all $z \in \mathcal{L}_2$ the signal $w = \Delta(z)$ satisfies

$$\int_0^T w(t)^\top w(t) dt \leq \int_0^T z(t)^\top z(t) dt \quad \text{for all } T \geq 0.$$

This just means that all uncertainties have an \mathcal{L}_2 -gain bounded by 1. If, in addition, we also know that all uncertainties are passive, we have

$$\int_0^T w(t)^\top z(t) dt \geq 0 \quad \text{for all } T \geq 0.$$

These properties of the uncertainties can be expressed as IQCs on their input and output signals with the help of so-called *multipliers* P :

$$\int_0^T \begin{pmatrix} w(t) \\ z(t) \end{pmatrix}^\top P \begin{pmatrix} w(t) \\ z(t) \end{pmatrix} dt \geq 0 \quad \text{for all } T \geq 0 \quad \text{and} \quad P \in \{P_{\text{gain}}, P_{\text{passive}}\},$$

where the multipliers for the gain and passivity constraints are defined, respectively, as

$$P_{\text{gain}} = \begin{pmatrix} -I & 0 \\ 0 & I \end{pmatrix} \quad \text{and} \quad P_{\text{passive}} = \begin{pmatrix} 0 & I \\ I & 0 \end{pmatrix}. \tag{24.51}$$

With any set of such multipliers one can computationally verify robust performance on the basis of the following result.

Theorem 24.10:

Let \mathbf{P} be a family of symmetric matrices P which satisfy

$$\int_0^T \begin{pmatrix} \Delta(z)(t) \\ z(t) \end{pmatrix}^\top P \begin{pmatrix} \Delta(z)(t) \\ z(t) \end{pmatrix} dt \geq 0 \quad \text{for all } z \in \mathcal{L}_2[0, T], T \geq 0 \quad \text{and} \quad \text{all } \Delta \in \mathbf{\Delta}. \tag{24.52}$$

Then Equation 24.50 is robustly stable and has robust \mathcal{L}_2 -gain performance smaller than γ if there exists $X = X^\top$ and $P = \begin{pmatrix} Q & S \\ S^\top & R \end{pmatrix} \in \mathbf{P}$ that satisfy the LMIs

$$X \succ 0 \quad \text{and} \quad \begin{pmatrix} I & 0 & 0 \\ A & B_1 & B_2 \\ 0 & I & 0 \\ C_1 & D_1 & D_{12} \\ 0 & 0 & I \\ C_2 & D_{21} & D_2 \end{pmatrix}^\top \begin{pmatrix} 0 & X & 0 & 0 & 0 & 0 \\ X & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & Q & S & 0 & 0 \\ 0 & 0 & S^\top & R & 0 & 0 \\ 0 & 0 & 0 & 0 & Q_p & S_p \\ 0 & 0 & 0 & 0 & S_p^\top & R_p \end{pmatrix} \begin{pmatrix} I & 0 & 0 \\ A & B_1 & B_2 \\ 0 & I & 0 \\ C_1 & D_1 & D_{12} \\ 0 & 0 & I \\ C_2 & D_{21} & D_2 \end{pmatrix} < 0 \quad (24.53)$$

for the performance index $P_p = \begin{pmatrix} Q_p & S_p \\ S_p^\top & R_p \end{pmatrix} = \begin{pmatrix} -\gamma^2 I & 0 \\ 0 & I \end{pmatrix}$.

Proof. For some sufficiently small $\epsilon > 0$ we can add ϵI to the left-hand side of Equation 24.53 while keeping the inequality valid. Let us then choose any trajectory of the interconnection Equation 24.50 for an arbitrary uncertainty. Then right-multiply Equation 24.53 with $\text{col}(x(t), w(t), d(t))$ and left-multiply it with its transpose in order to obtain

$$\begin{pmatrix} x(t) \\ \dot{x}(t) \end{pmatrix}^\top \begin{pmatrix} 0 & X \\ X & 0 \end{pmatrix} \begin{pmatrix} x(t) \\ \dot{x}(t) \end{pmatrix} + \begin{pmatrix} w(t) \\ z(t) \end{pmatrix}^\top P \begin{pmatrix} w(t) \\ z(t) \end{pmatrix} + \begin{pmatrix} d(t) \\ e(t) \end{pmatrix}^\top P_p \begin{pmatrix} d(t) \\ e(t) \end{pmatrix} + \epsilon (\|x(t)\|^2 + \|w(t)\|^2 + \|d(t)\|^2) \leq 0.$$

This inequality continues to hold after integration on $[0, T]$. As the key observation, we can exploit Equation 24.52 in order to conclude that one can drop the middle term in the first row without violating the inequality. Since the integral of the left-most term is $\int_0^T (\text{d}/\text{d}t)x(t)^\top Xx(t) \text{d}t = x(T)^\top Xx(T) - x(0)^\top Xx(0)$ and since $x(T)^\top Xx(T) \geq 0$, we obtain

$$\epsilon \int_0^T (\|x(t)\|^2 + \|w(t)\|^2) \text{d}t + \int_0^T (\|e(t)\|^2 - \gamma^2 \|d(t)\|^2) \text{d}t \leq x(0)^\top Xx(0) - \epsilon \int_0^T \|d(t)\|^2 \text{d}t.$$

If d is of finite energy, we infer that $\int_0^T \|x(t)\|^2 \text{d}t$ and $\int_0^T \|w(t)\|^2 \text{d}t$ remain bounded for $T \rightarrow \infty$, which implies that x , w , and hence also z and e (due to Equation 24.50) are of finite energy. This proves stability. If $x(0) = 0$, we conclude that the \mathcal{L}_2 -gain is strictly smaller than γ as for Theorem 24.4.

Clearly the very same result holds (with identical proof) for general robust quadratic performance (Section 24.5.4) with index

$$P_p = \begin{pmatrix} Q_p & S_p \\ S_p^\top & R_p \end{pmatrix} \quad \text{satisfying} \quad R_p \succ 0.$$

In order to verify robust stability and performance one only needs to check feasibility of the LMI in Equation 24.53. This is certainly possible if \mathbf{P} is described by computationally tractable LMI constraints (such as in our example in which \mathbf{P} just consists of two elements).

If Equation 24.52 holds for \mathbf{P} , it persists to hold for all P in the larger convex conic hull

$$\text{cc}(\mathbf{P}) := \left\{ \sum_{v=1}^N \tau_v P_v : P_v \in \mathbf{P}, \tau_v \geq 0, v = 1, \dots, N, N \in \mathbb{N} \right\},$$

which can lead to (sometimes substantially) improved computational results. Note that $\text{cc}(\mathbf{P})$ is a convex cone, since with any two of its elements P_1, P_2 it also contains their positive linear combination $\tau_1 P_1 + \tau_2 P_2$, $\tau_1, \tau_2 \geq 0$. Therefore, in applications, the set \mathbf{P} in Theorem 24.10 is typically assumed to be a convex cone with an LMI representation.

24.10.2 Examples and Extensions

Many classical results on robust performance can be obtained as special cases of Theorem 24.10. Its real power, however, manifests itself in the flexibility to handle mixtures of structured uncertainties beyond such classical cases with ease. Here is a highly nonexhaustive sample.

24.10.2.1 Small-Gain and Passivity Theorems

With $P = \{P_{\text{gain}}\}$ and $P_p = P_{\text{gain}}$ as defined in Equation 24.51, feasibility of Equation 24.53 just means that the \mathcal{L}_2 -gain of the LTI system in Equation 24.50 is strictly smaller than one, while Equation 24.52 translates into $\Delta \in \mathbf{\Delta}$ having \mathcal{L}_2 -gain smaller than one. This is simply the classical small-gain theorem. Similarly, for $P = \{P_{\text{passive}}\}$ and $P_p = P_{\text{passive}}$, we obtain a passivity theorem which says that a passive interconnection in negative feedback with a passive system stays passive.

24.10.2.2 Sector Nonlinearities

As another variant let $\Delta(z)(t) = \phi(z(t))$ with any (Lipschitz-continuous) $\phi : \mathbb{R} \rightarrow \mathbb{R}$ whose graph is located in the conic sector between the lines $\{(x, y) \in \mathbb{R}^2 : y = \alpha x\}$ and $\{(x, y) \in \mathbb{R}^2 : y = \beta x\}$ for some real $\alpha \leq \beta$. For $D_1 = 0$, standard results on the existence of solutions of differential equations imply that Equation 24.50 is well-posed. Moreover, all these uncertainties satisfy the IQC in Equation 24.52 for all $P \in \mathbf{P}$ with \mathbf{P} being equal to

$$\left\{ \begin{pmatrix} -2 & \alpha + \beta \\ \alpha + \beta & -2\alpha\beta \end{pmatrix} \right\} \text{ or its conic hull } \left\{ \tau \begin{pmatrix} -2 & \alpha + \beta \\ \alpha + \beta & -2\alpha\beta \end{pmatrix} : \tau \geq 0 \right\}. \quad (24.54)$$

This holds for example, with $\alpha = 0$ and $\beta > 0$ for the saturation nonlinearity

$$\phi(x) = \begin{cases} bx & \text{for } |x| \leq 1, \\ \beta \text{ sign}(x) & \text{for } |x| > 1. \end{cases}$$

For the interconnection $e = z = Gw + Gd$, $w = \Delta(z)$ with $G(s) = -(12(s + 1)(s + 2)(s + 3))^{-1}$, a plot of the guaranteed \mathcal{L}_2 -gain levels over the saturation slope β is shown in Figure 24.4. It indicates a well-known fundamental trade-off for obtaining less conservative results for larger sets of multipliers at the expense of higher computational complexity.

24.10.2.3 General Structured Uncertainties

Let $w = \text{col}(w_1, \dots, w_q)$, $z = \text{col}(z_1, \dots, z_q)$, and suppose that Δ is diagonally structured and defined by $w_v = \Delta_v(z_v)$, $v = 1, \dots, q$. If Δ_v satisfies an IQC with multiplier class \mathbf{P}_v , then Δ satisfies an IQC for all

FIGURE 24.4 Results for multipliers in Equation 24.54 with $\alpha = 0$: Fixed (dotted); Cone (solid).

$P \in \mathbf{P}$ with

$$P := \left\{ \begin{pmatrix} \text{diag}(Q_1, \dots, Q_q) & \text{diag}(S_1, \dots, S_q) \\ \text{diag}(S_1^\top, \dots, S_q^\top) & \text{diag}(R_1, \dots, R_q) \end{pmatrix} : \begin{pmatrix} Q_v & S_v \\ S_v^\top & P_v \end{pmatrix} \in \mathbf{P}_v, \ v = 1, \dots, q \right\}.$$

If the sets $\mathbf{P}_v, v = 1, \dots, q$, are represented by LMIs, the same is true for \mathbf{P} . Similarly if \mathbf{P}_v are convex cones for $v = 1, \dots, q$, so is the set \mathbf{P} . This diagonal augmentation procedure allows the construction of multipliers for diagonally structured uncertainties of an arbitrary nature. In this fashion, we can handle uncertainties whose diagonals are combinations of \mathcal{L}_2 -gain, passive, sector-bounded static nonlinear, or time-varying parametric elements as discussed below.

24.10.2.4 Time-Varying Parametric Uncertainties

If $\Delta_v(z_v)(t) = \delta_v(t)z_v(t)$ for some $\delta_v(t) \in \mathbb{R}$ with $|\delta_v(t)| \leq 1$ for all $t \geq 0$, it is trivial to check that it satisfies an IQC for the convex cone

$$\mathbf{P}_v = \left\{ \begin{pmatrix} Q_v & S_v \\ S_v^\top & -Q_v \end{pmatrix} : Q_v \preceq 0, \ S_v + S_v^\top = 0 \right\}.$$

Diagonal augmentation leads to a set of diagonally structured multipliers for $\Delta(z)(t) = \Delta(t)z(t)$ with $\Delta(t) = \text{diag}(\delta_1(t)I, \dots, \delta_q(t)I)$ as they are used in (frequency-by-frequency) structured singular value upper bound computations [20].

24.10.2.5 Full Block Multipliers

If $\Delta(z)(t) = \Delta(t)z(t)$ with some time-varying matrix $\Delta(t)$ which satisfies $\Delta(t) \in \text{co}\{\Delta_1, \dots, \Delta_N\}$, a simple convexity argument reveals that Equation 24.52 holds for

$$P \in \left\{ P = P^\top : \begin{pmatrix} I \\ 0 \end{pmatrix}^\top P \begin{pmatrix} I \\ 0 \end{pmatrix} \preceq 0, \ \begin{pmatrix} \Delta_v \\ I \end{pmatrix}^\top P \begin{pmatrix} \Delta_v \\ I \end{pmatrix} \succcurlyeq 0, \ v = 1, \dots, N \right\}.$$

Clearly this set of unstructured multipliers has an LMI description and can be readily implemented. If $\Delta(t)$ admits a diagonal structure as in the previous example, one can compare diagonally structured with full multipliers; the latter often lead to less conservative analysis results at a higher computational cost.

For time-varying parametric uncertainties as considered in the latter two examples, it is remarkable to note that the feasibility of the LMI in Equation 24.53 does actually imply nonsingularity of $I - D_1 \Delta(t)$ and hence well-posedness of the interconnection (Equation 24.50); moreover one can even prove exponential stability of Equation 24.50.

We have only hinted at the power of static IQCs, while the extension to allow for dynamics in the multipliers even further expands the wealth of the applications and their computational power [14].

24.10.3 Robust Synthesis

For the purpose of synthesis, the system (Equation 24.50) is extended with a control channel as

$$\begin{aligned} \dot{x} &= Ax + B_1 w + B_2 d + Bu \\ z &= C_1 x + D_1 w + D_{12} d + E_1 u \\ e &= C_2 x + D_2 w + D_{22} d + E_2 u \\ y &= Cx + F_1 w + F_2 d \end{aligned} \quad \text{interconnected with } w = \Delta(z), \ \Delta \in \mathbf{\Delta}. \quad (24.55)$$

The goal is to design a controller (Equation 24.17) which achieves robust performance for the closed-loop system. With a set \mathbf{P} of IQC multipliers satisfying Equation 24.52, we need to enforce the LMI in Equation 24.53 for the closed-loop system description (after having verified well-posedness). This opens

FIGURE 24.5 Robust estimator design.

up the opportunity to apply the general synthesis procedure from Section 24.6.3. Convex constraints result if \mathbf{P} just consists of one element P whose right-lower block is positive semidefinite, since the problem then boils down to one of quadratic performance synthesis as discussed in Section 24.5.4. Unfortunately, convexification is impossible if \mathbf{P} consists of a whole family of multipliers. This has led to the suggestion of various heuristic algorithms in order to approach the solution of the bilinear matrix inequalities for robust performance synthesis.

A particularly lucky case is the robust estimator synthesis problem for a configuration as depicted in Figure 24.5. Then Equation 24.55 specializes to $B = 0, E_1 = 0,$ and $E_2 = -I.$ After having checked well-posedness (which does not involve the to-be-designed estimator), we can apply the convexifying estimator parameter transformation from Section 24.6.4. The general procedure results in the synthesis inequalities

$$\begin{pmatrix} Z & Z \\ Z & X \end{pmatrix} > 0,$$

$$(\star)^\top \left(\begin{array}{cccc|cccc} 0 & 0 & I & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & I & 0 & 0 & 0 & 0 \\ I & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & I & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & Q & S & 0 & 0 \\ 0 & 0 & 0 & 0 & S^\top & R & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 & 0 & Q_p & S_p \\ 0 & 0 & 0 & 0 & 0 & 0 & S_p^\top & R_p \end{array} \right) \left(\begin{array}{cc|cc} I & 0 & 0 & 0 \\ 0 & I & 0 & 0 \\ ZA & ZA & ZB_1 & ZB_2 \\ \hline XA + LC + K & XA + LC & XB_1 + LF_1 & XB_2 + LF_2 \\ \hline 0 & 0 & I & 0 \\ C_1 & C_1 & D_1 & D_{12} \\ \hline 0 & 0 & 0 & I \\ \hline C_2 - NC - M & C_2 - NC & D_{21} - NF_1 & D_2 - NF_2 \end{array} \right) < 0,$$

which are actually convex in X, Z and $Q, S, R.$ Since $R_p \succcurlyeq 0$ can be factorized as $T_p^\top T_p$ with a full row-rank matrix $T_p,$ one can easily turn the second constraint into a genuine LMI by taking the Schur complement.

Finally, let us stress that dualization arguments allow a similar convexification procedure for the design of robust state-feedback controller gains, as shown for parametric uncertainties in [16].

24.11 Conclusions

We have provided a selective overview on the application of semidefinite programming techniques in control in order to cover the most basic but essential ideas in the analysis and synthesis of nominal and robust controllers. During the last decades this field has grown dramatically and the scope of applications of LMIs in solving complex control problems has widened considerably. Notable activities have been devoted to broadening the LMI stability and performance specifications and to exploring their applicability to time-varying, time-delay, fuzzy and nonlinear systems. Considerable advances have been made in constructing systematic relaxation schemes for handling robust LMIs. Recently emerging applications of convex optimization to the synthesis of distributed controllers for large-scale systems offer exiting new avenues for progress.

Appendix: Convex Sets and Convex Functions

A set S in a linear vector space is said to be *convex* if

$$x_1, x_2 \in S \text{ implies } x = \alpha x_1 + (1 - \alpha)x_2 \in S \text{ for all } \alpha \in (0, 1).$$

Geometrically, this states that the line segment connecting any two points of the set belongs to the set as well. For all $\alpha \in (0, 1)$, the point x defined in the above expression is called a *convex combination* of x_1 and x_2 . More generally, the point $x = \sum_{k=1}^n \alpha_k x_k$ is a *convex combination* of $x_1, \dots, x_n \in S$ if $\alpha_k \geq 0$ for all k and $\sum_{k=1}^n \alpha_k = 1$. Many operations preserve convexity of sets. As the most important one, the intersection of an arbitrary collection of convex sets is convex. Simple examples of convex sets are *hyperplanes* $\{x \in \mathbb{R}^n \mid a^\top x = b\}$ and *half-spaces* $\{x \in \mathbb{R}^n \mid a^\top x \leq b\}$, where $a \in \mathbb{R}^n, b \in \mathbb{R}$. A *polyhedron* is the intersection of finitely many hyperplanes and half-spaces and is hence convex. A *polytope* is a compact polyhedron. It is easy to see that the set of all convex combinations of n points $x_1, \dots, x_n \in S$ is itself convex. For any subset S of a linear vector space the *convex hull* $\text{co}(S)$ is the set of all convex combinations of the elements of S . The convex hull of a finite set of points is always a polytope and, conversely, any polytope is the convex hull of a finite set.

A (Hermitian-valued) function $F : S \rightarrow \mathbb{H}^m$ is *convex* if its domain S is convex and

$$F\left(\sum_{k=1}^n \alpha_k x_k\right) \preceq \sum_{k=1}^n \alpha_k F(x_k) \text{ for all } x_1, \dots, x_n \in S \text{ and } \alpha_k \geq 0 \text{ with } \sum_{k=1}^n \alpha_k = 1.$$

This is referred to as Jensen's inequality. F is *strictly convex* if Jensen's inequality holds with \prec in the case that neither of the α_k 's equals one. If F is real valued, the inequalities are the same as the usual \leq and $<$ for real numbers. Generally it is not easy to verify whether a function is convex. Twice continuously differentiable functions $F : S \rightarrow \mathbb{R}$ on convex sets S with interior points are convex iff their Hessian satisfies $\partial^2 F(x) \succcurlyeq 0$ for all $x \in S$. If F defined on S is convex, then the *sublevel sets* $\{x \in S \mid F(x) \prec H\}$ are convex for any $H \in \mathbb{H}^m$. The most important reason for considering convex functions in optimization is the fact that local minimal points of convex functions are actually global minimal points. Precisely, $x_0 \in S$ is a local minimal point of F if there exists an open neighborhood $\mathcal{N}(x_0)$ of x_0 such that $F(x_0) \preceq F(x)$ for all $x \in \mathcal{N}(x_0) \cap S$. If F is convex one can conclude that $F(x_0) \preceq F(x)$ for all $x \in S$, showing that x_0 is a global minimal point of F . This property is of great interest in numerical optimization. Indeed, many efficient algorithms exist for the numerical computation of local minima of real-valued functions. If these are convex, such algorithms actually determine global minimal points.

25.1 Introduction to Optimal Control Design

Many systems occurring naturally in fields such as biology and sociology use feedback control to achieve homeostasis, or equilibrium conducive to existence. Because the bounds within which life can continue are small (e.g., temperature changes of a few degrees can eliminate populations) and the *resources available* are limited, it is remarkable yet not expected that most of these feedback control systems have evolved

into *optimal* systems where performance objectives are achieved efficiently with a minimum of control effort. Since naturally occurring systems are optimal, it makes sense to design man-made controllers from the view point of optimality.

25.1.1 The Philosophy of Classical Control

Classical control theory, developed in the mid-1900s, imparts a great deal of engineering insight. It was best developed for linear systems. Since computers were not available to solve complex design equations, the design algorithms are heuristic in terms of Bode plots, Nyquist plots, the root locus, and other single-input/single-output (SISO) graphical techniques that offer intuition and rely on the design engineer's expertise. Since most design was in the frequency domain, robustness to unknown disturbances, modeling errors, and noise was automatically built in.

Complex modern systems have multiple inputs and outputs. Examples include aircraft, satellites, and automobile engines, which, though nonlinear, can often be linearized about a desired operating point or trajectory. In such applications, classical design relies on successive loop closures based on *one-loop-at-a-time SISO design*. Unfortunately, using this approach, neither stability nor robustness of the overall system can be guaranteed, since one loop closure can destroy what has been gained in the design of previous loops.

25.1.2 The Philosophy of Optimal Control Design

About 1960, modern optimal control theory began developing for complex multivariable systems. It developed coincidentally with the space age (Sputnik was launched in 1957), the computer age, and the age of robotics. Optimal control is a branch of modern control theory that deals with designing controls for dynamical systems by minimizing a *performance index* that depends on the system variables. The performance index might include, for instance, a measure of operating error, a measure of control "effort," or any other characteristic important to the user of the control system. Under some mild assumptions, making the performance index small also guarantees that the system variables will be small, thus insuring *closed-loop stability*.

Classical design is concerned with directly selecting the feedback gains K in the inner *real-time control loops*. On the other hand, modern control design offers standard algorithms for implementing an *outer design loop* that automatically selects the inner loop feedback gains in such a fashion that *closed-loop stability and performance for MIMO systems is guaranteed*. In contrast to classical one-loop-at-a-time design, in modern control, *all of the feedback loops are closed simultaneously* by computing the feedback gains by solving standard *matrix design equations*. Special purpose software [9,10] is commercially available to solve these equations, so that control design for complex systems is straightforward with a personal computer (PC).

In this chapter, optimal control design is discussed for deterministic systems with a well-known mathematical model. The major emphasis is on linear systems in the state-space form. It will be assumed that *full state-variable feedback* is available; in the event that only partial information is available on the system states, the chapter on "Output Feedback" or the references should be consulted as well. The discussion in this chapter will center around continuous-time systems, with a follow-up discussion on discrete-time (DT) systems. Several design techniques will be covered, including the regulator problem, the tracker problem, minimum-time control, and polynomial design. Robustness of the linear quadratic regulator (LQR) will be discussed using multivariable frequency-domain design techniques, which allow one to draw close connections with classical control theory. This is a condensed version of presentations available in [7,8,11] where derivations and computer software appear. Important key foundation references are [1-6].

There are two basic approaches to optimal control. The Calculus of Variations leads to a formulation of the optimal control solution in terms of partial derivatives of the Hamiltonian, which is an energy-based construct that captures the prescribed optimality criteria in terms of motion along the system trajectories.

This approach leads to optimal control solutions in terms of the state equation, costate equation, and stationarity condition. Bellman's Optimality Principle, on the other hand, leads to Dynamic Programming (DP) solutions, which develop backwards in time. From this, one obtains minimizations with respect to the Hamiltonian, which leads to the Hamilton–Jacobi–Bellman (HJB) equations. First we present the Calculus of Variations results, then the DP results.

25.2 Optimal Control of Continuous-Time Systems

In this section nonlinear control design will be covered for general nonlinear systems. Then, the LQR will be developed for linear systems. The LQR is a cornerstone of modern control theory design.

25.2.1 The General Continuous-Time Optimal Control Problem

A state-variable model for a nonlinear time-varying dynamical system is given by Equation 25.1 in Table 25.1, where $x(t) \in \mathcal{R}^n$ is the vector of internal states and $u(t) \in \mathcal{R}^m$ is the vector of control inputs. This is the plant to be controlled. A broad range of performance objectives may be achieved by selecting the control $u(t)$ to minimize a *performance index* (PI) or a *cost* given by Equation 25.2 with t_0 the initial time and T the final time of interest. The *final-state weighting function* $\phi(x(T), T)$ and weighting function $L(x, u, t)$ are selected depending on the performance objectives.

The *optimal control problem* is to determine a control input $u(t)$ for the system that minimizes the PI and also insures that the *final state constraint* (Equation 25.3) is satisfied for a given function $\psi \in \mathcal{R}^p$. The roles of the final weighting function ϕ and the final constraint ψ should not be confused. The former is a function one would like to minimize, such as the final energy $x^T(T)S(T)x(T)$, with $S(T)$ a specified weighting matrix. On the other hand, $\psi(x(T), T)$ must be exactly equal to zero. A sample problem might be to find the control input $u(t)$ that drives a satellite, with dynamics described by Equation 25.1, from a given initial position $x(t_0)$ to an specified orbit, described by Equation 25.3, while minimizing the expended energy, as described by the PI (Equation 25.2).

25.2.1.1 Solution of the Nonlinear Optimal Control Problem

Using the Calculus of Variations approach to solve the optimal control problem, Lagrange multipliers are used to adjoin the constraints (Equations 25.1 and 25.3) to the performance index (Equation 25.2). Since the system Equation 25.1 is an equality constraint which must hold at each time, an associated multiplier $\lambda(t) \in \mathcal{R}^n$ is required that is a function of time. Thus, the *Hamiltonian function* is defined as Equation 25.4. Using the theory of Lagrange multipliers and the calculus of variations, the solution to the optimal control problem given in Table 25.1 is determined. It is assumed that the initial time t_0 and the initial state $x(t_0)$ are both known and fixed. In the boundary conditions, partial derivatives are denoted by subscripts (e.g., ψ_x represents $\frac{\partial \psi}{\partial x}$).

The equations in the table may be used as *design equations* for determining the control $u(t)$ that minimizes the PI. They are *necessary conditions* for the solution of the nonlinear optimal control problem. Any control $u(t)$ that results in a minimum value of the PI, when it is applied to the system, must satisfy the equations given there. Conditions under which these equations are sufficient as well are addressed in [3,7].

The structure of the equations is worth discussing. According to the table, the Lagrange multiplier $\lambda(t)$ is a dynamical variable that satisfies its own dynamical Equation 25.6; it is called the *costate*. The optimal control $u(t)$ is then generally determined in terms of $x(t)$ and $\lambda(t)$ by using the *stationarity condition* (Equation 25.7) (so named because this is the condition that guarantees a minimum or stationary point with respect to changes in $u(t)$). The value of $\lambda(t)$ is usually of no concern ultimately, but it is an *intermediate variable* which must be determined to solve for the optimal control $u(t)$, that minimizes the PI $J(t_0)$ while insuring that constraints (Equations 25.1 and 25.3) are satisfied. The appearance of

TABLE 25.1 Continuous Nonlinear Optimal Controller

System model:

$$\dot{x} = f(x, u, t), \quad t \geq t_0, \quad t_0 \text{ fixed.} \quad (25.1)$$

Performance index:

$$J(t_0) = \phi(x(T), T) + \int_{t_0}^T L(x, u, t) dt. \quad (25.2)$$

Final state constraint:

$$\psi(x(T), T) = 0. \quad (25.3)$$

Optimal Controller:

Hamiltonian:

$$H(x, u, t) = L(x, u, t) + \lambda^T f(x, u, t). \quad (25.4)$$

State equation:

$$\dot{x} = \frac{\partial H}{\partial \lambda} = f, \quad t \geq t_0. \quad (25.5)$$

Costate equation:

$$-\dot{\lambda} = \frac{\partial H}{\partial x} = \frac{\partial f^T}{\partial x} \lambda + \frac{\partial L}{\partial x}, \quad t \leq T. \quad (25.6)$$

Stationarity condition:

$$0 = \frac{\partial H}{\partial u} = \frac{\partial L}{\partial u} + \frac{\partial f^T}{\partial u} \lambda. \quad (25.7)$$

Boundary conditions:

$$x(t_0) \text{ given, initial condition,} \quad (25.8)$$

$$(\phi_x + \psi_x^T v - \lambda)^T |_{T} dx(T) + (\phi_t + \psi_t^T v + H) |_{T} dT = 0, \quad \text{final condition.} \quad (25.9)$$

intermediate variables, that are required to solve for the variables of interest, is typical of optimal control design.

The dynamical state and costate equations, along with the control specified by the stationarity condition, are called the *Hamiltonian system*. These equations may be used to derive Lagrange's and Hamilton's equations of motion in physics (see Example 25.1). The costate equation and stationarity condition are called *Euler's equations*. In the time-invariant case, f and L are not explicit functions of t , so that neither is H . In this situation

$$\dot{H} = 0. \quad (25.10)$$

Thus for time-invariant systems and cost functions, the Hamiltonian is a *constant* on the optimal trajectory. This is a general statement of the principle of conservation of energy.

25.2.1.2 Two-Point Boundary-Value Problems

The solution for the optimal control $u(t)$ in Table 25.1 depends on solving two coupled differential equations, the state Equation 25.5 and the costate Equation 25.6, each of which is of order n . These two dynamical equations comprise the Hamiltonian system once the stationarity condition has been used to eliminate $u(t)$. The costate equation develops *backward in time* (by defining a backward time

variable $\tau = T - t, d\tau = -dt$), with the final condition $\lambda(T)$ determined by Equation 25.9. The boundary conditions consist of the initial conditions on the state

$$n \text{ conditions: } x(t_0) \text{ given} \tag{25.11}$$

and the final conditions on the costate

$$p \text{ conditions: } \psi(x(T), T) = 0 \tag{25.12}$$

$$n - p \text{ conditions: } (\phi_x + \psi_x^T v - \lambda)^T |_T dx(T) = 0, \tag{25.13}$$

where it has been assumed for simplicity that the final time T is specified and hence fixed, so that $dT = 0$ in condition (Equation 25.9).

Since n boundary conditions are specified at the initial time t_0 and n conditions are specified at the final time T , this is a *two-point boundary-value problem*. There are many methods available for solving such problems, including the *shooting point method* and the *unit solution method*; good software is available for this purpose. The solution of the optimal control problem for nonlinear systems is often difficult, though, for some nonlinear plants, the design equations can be explicitly solved for the optimal control $u(t)$, yielding a great deal of insight. This includes the *Thrust Angle Programming* and *Intercept and Rendezvous* problems. In the special case that the plant is linear and the PI is quadratic, a solution is available, given subsequently.

Example 25.1: Hamilton’s Principle

Both Lagrange’s and Hamilton’s equations of motion may be derived from Table 25.1.

LAGRANGE’S EQUATIONS OF MOTION

Define the generalized coordinate state vector q and the “control input” as the generalized velocities $u = \dot{q}$. Define the Lagrangian $L(q, u) \equiv T(q, u) - U(q)$ as the difference between the kinetic and potential energies. Then the “plant” (Equation 25.1) is

$$\dot{q} = u \equiv f(q, u)$$

where the function $f(\cdot)$ is given by the physics of the problem.

To find the trajectories of the motion, Hamilton’s principle says we may minimize the performance index

$$J = \int_0^T L(q, u) dt,$$

so that the Hamiltonian (Equation 25.4) is $H = L + \lambda^T u$. According to Table 25.1, for a minimum

$$\begin{aligned} -\dot{\lambda} &= \frac{\partial H}{\partial q} = \frac{\partial L}{\partial q} \\ 0 &= \frac{\partial H}{\partial u} = \frac{\partial L}{\partial u} + \lambda. \end{aligned}$$

Combining these equations yields Lagrange’s equations of motion,

$$\frac{\partial L}{\partial q} - \frac{d}{dt} \frac{\partial L}{\partial \dot{q}} = 0.$$

TABLE 25.2 Continuous-Time Linear Quadratic Regulator

System model:

$$\dot{x} = Ax + Bu, \quad t \geq t_0, \quad x(t_0) = x_0 \text{ given.} \quad (25.14)$$

Performance index:

$$J(t_0) = \frac{1}{2}x^T(T)S(T)x(T) + \frac{1}{2} \int_{t_0}^T (x^T Qx + u^T Ru) dt, \quad (25.15)$$

with

$$S(T) \geq 0, \quad Q \geq 0, \quad R > 0.$$

Optimal feedback control:

Riccati equation:

$$-\dot{S} = A^T S + SA - SBR^{-1}B^T S + Q, \quad t \leq T, \quad S(T) \text{ given.} \quad (25.16)$$

Optimal feedback gain:

$$K = R^{-1}B^T S. \quad (25.17)$$

Time-varying feedback:

$$u = -K(t)x. \quad (25.18)$$

Optimal cost:

$$J(t_0) = \frac{1}{2}x_0^T S(t_0)x_0. \quad (25.19)$$

HAMILTON'S EQUATIONS OF MOTION

Defining the generalized momentum vector by $\lambda = -\partial L/\partial \dot{q}$, the equations of motion may be expressed in Hamilton's form as

$$\dot{q} = \frac{\partial H}{\partial \lambda},$$

and

$$-\dot{\lambda} = \frac{\partial H}{\partial q}.$$

25.2.2 Continuous-Time Linear Quadratic Regulator

The nonlinear optimal control design equations in Table 25.1 are not easy to solve, and there is no design algorithm for doing so. In this section the design of optimal controllers for linear systems with quadratic performance indices will be discussed, the so-called LQR *problem*. The LQR is a cornerstone of modern optimal control design consisting of *explicit matrix design equations easily solved on a digital computer*. It has a wide range of relevance, because many systems are linear to begin with, and many nonlinear systems may be considered linear when operating near an equilibrium point. The LQR solution is given as a *closed-loop feedback control*.

Consider the multivariable linear system (Equation 25.14) in Table 25.2 with state $x \in \mathcal{R}^n$ and control input $u \in \mathcal{R}^m$. The plant matrices may be time-varying (e.g., $A(t)$, $B(t)$), though for notational convenience this dependence will not be shown explicitly.

Choose the control that minimizes the quadratic PI (Equation 25.15). The *control weighting* R , *state weighting* Q , and *final state weighting* $S(T)$ are symmetric matrices of design parameters chosen by the

designer depending on the control objectives. For instance, if the elements of $S(T)$ are selected larger, then the control will force the final state $x(T)$ to be smaller to keep the PI small. Weight matrices Q and $S(T)$ are assumed positive-semidefinite ($Q \geq 0, S(T) \geq 0$). Thus Q and $S(T)$ have nonnegative eigenvalues so that $x^T Q x$ and $x^T(T)S(T)x(T)$ are nonnegative for all $x(t)$. Likewise, it will be assumed that R is positive definite ($R > 0$), that is, R has positive eigenvalues so that $u^T R u > 0$ for all $u(t)$. In this case, J is always bounded below by zero, so that a sensible minimization problem results. Since the squares of the states and control inputs occur in Equation 25.15, the PI is a form of generalized energy (consider the case when some of the state components are velocities, or currents and voltages) and minimizing it will keep the states and controls small.

Using the equations in Table 25.1, the solution to the LQR optimal control problem may be derived, as given in Table 25.2. The state and costate equations are

$$\dot{x} = Ax + Bu \tag{25.20}$$

and

$$-\dot{\lambda} = Qx + A^T \lambda, \tag{25.21}$$

where the negative sign indicates that the costate equation must be solved backward in time. The stationarity condition gives the control in terms of the costate as $u(t) = -R^{-1}B^T \lambda(t)$. To find the optimal control, the two-point boundary-value problem associated with the state and costate dynamics is analytically solved using the *sweep method* [3] where it is assumed that $\lambda(t) = S(t)x(t)$ for some unknown auxiliary matrix $S(t)$. The optimal control is given in terms of this intermediate matrix as follows. First, it can be determined that the auxiliary matrix $S(t)$ satisfies the bilinear *matrix Riccati equation* 25.16. In terms of the Riccati solution $S(t)$, the optimal control is given by $u(t) = -R^{-1}B^T S(t)x(t)$. Thus, defining the *optimal feedback gain* by Equation 25.17, one may write the optimal control as the *state-feedback control law* (Equation 25.18).

A block diagram of the LQR is shown in Figure 25.1. It is a *feedback control system* with time-varying feedback gains $K(t)$, and a formal *design outer loop*. Even if the system (A, B) is time-invariant, the optimal control $u(t)$ is a *time-varying state feedback*. This is why the optimal LQ controller may not be determined using classical frequency-domain techniques. If the system model (Equation 25.14) is not an exact description of the plant, the LQR still performs well if it is fairly close. In fact, it will be seen in Section 25.2.4.2 that the LQR has important *guaranteed robustness properties*.

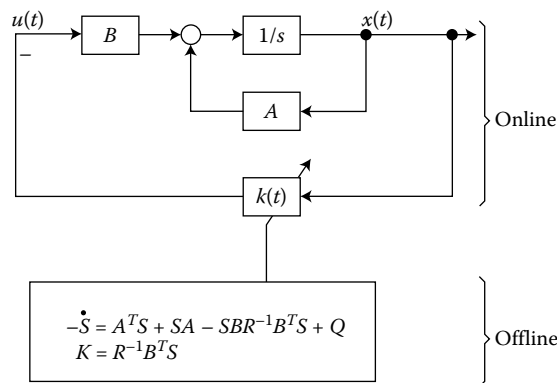

FIGURE 25.1 Linear quadratic regulator.

25.2.2.1 LQR Design

To design the optimal LQR, the design engineer first selects the design parameter weight matrices Q , R , $S(T)$. Then, the Riccati equation (RE) is solved for the auxiliary matrix function $S(t)$, which is used to compute $K(t)$. The RE is solved *backward in time* using, as a final condition, the value of the weighting matrix $S(T)$ selected for the PI. This equation may be solved *off-line* for $S(t)$, and the optimal feedback gain $K(t)$ computed and stored. Next, a *computer simulation* is generally performed to verify the closed-loop performance. If the performance is not suitable, new design matrices Q , R , $S(T)$ are selected and the entire procedure is repeated. With commercially available software, the entire process is fast and convenient. Finally, during the implementation or control run, the states are measured and the feedback control $u(t) = -K(t)x$ applied to the plant.

Thus, by the sweep method, the LQR problem has been decomposed into two stages: offline computation of the optimal gains using a backward differential equation, followed by the actual control of the plant using feedback. Such *hierarchical control schemes*, consisting of an inner linear feedback loop whose gain is computed by an outer quadratic design equation, are typical of modern control schemes. Optimal control is fundamentally a *noncausal design algorithm* requiring future information about the plant and performance objectives.

The LQR design procedure is in stark contrast to classical control design, where the gain matrix K is selected directly. In modern optimal control design, some parameter matrices Q , R , and $S(T)$ are selected by the engineer. Then, the feedback gain K is automatically given by *matrix design equations*. This has the significant advantages of allowing *all the control loops in a multiloop system to be closed simultaneously, while guaranteeing closed-loop stability*.

The optimal cost of using this controller is given in terms of the initial state by Equation 25.19. The initial state of the plant is known. Therefore, this expression allows computation of the optimal cost *before* the control is actually applied to the plant, or even before the optimal gain $K(t)$ is computed and it is simulated on a computer. If the cost is too high, the engineer can select different weighting matrices Q , R , and $S(T)$ in the performance index and try another design. This *preview feature* is typical of optimal control design using state feedback.

Example 25.2: LQR for Armature-Controlled DC Motor

The system equations of an armature-controlled DC motor are

$$\begin{aligned} \dot{i} &= -ai - k'\omega + bu \\ \dot{\omega} &= -\alpha\omega + ki \end{aligned} \quad (25.22)$$

with $i(t)$ the armature current, $\omega(t)$ the motor speed, control input $u(t)$ the armature voltage, $1/a$ the electrical time constant, $1/\alpha$ the mechanical time constant, and the remaining variables other motor parameters.

Defining the state as $x = [i \ \omega]^T$,

$$\dot{x} = \begin{bmatrix} -a & -k' \\ k & -\alpha \end{bmatrix} x + \begin{bmatrix} b \\ 0 \end{bmatrix} u \equiv Ax + Bu. \quad (25.23)$$

It is required to determine $u(t)$ to minimize the PI

$$J = \frac{1}{2}x^T(T) \begin{bmatrix} s_i & 0 \\ 0 & s_\omega \end{bmatrix} x(T) + \frac{1}{2} \int_0^T \left[x^T \begin{bmatrix} q_i & 0 \\ 0 & q_\omega \end{bmatrix} x + ru^2 \right] dt \quad (25.24)$$

with s_i, s_ω the final state weights, q_i, q_ω the (intermediate) state weights, and r the control weight. These are design parameters that may be adjusted or *tuned* using computer simulations to yield suitable closed-loop

behavior, as will be seen in this example. The minimization of J corresponds to the regulation objective of driving the motor to a speed of zero from any initial speed, while keeping the control energy small. If the model represents a linearization of a nonlinear motor about a set point, the control will regulate the motor speed to that set point.

Since the RE solution $S(t)$ is symmetric, one may assume that

$$S = \begin{bmatrix} s_1 & s_2 \\ s_2 & s_3 \end{bmatrix} \tag{25.25}$$

where the scalars $s_i(t)$ are to be determined. Substituting A, B from the state equation and $S(T), Q, R$ from the PI in the RE in Table 25.2 yields the three nonlinear scalar coupled differential equations

$$\begin{aligned} -\dot{s}_1 &= -2as_1 + 2ks_2 - \beta s_1^2 + q_i, \\ -\dot{s}_2 &= -(a + \alpha)s_2 - k's_1 + ks_3 - \beta s_1 s_2, \\ -\dot{s}_3 &= -2\alpha s_3 - 2k's_2 - \beta s_2^2 + q_\omega, \end{aligned} \tag{25.26}$$

where $\beta \equiv b^2/r$.

Writing the feedback gain as $K(t) = [k_i \quad k_\omega]$, the table shows that $K = R^{-1}B^T S$, so that

$$k_i = \frac{b}{r}s_1, \quad k_\omega = \frac{b}{r}s_2. \tag{25.27}$$

Then, the optimal control is given by the time-varying feedback $u = -k_i i - k_\omega \omega$.

Although the equations for $s_i(t)$ are difficult to solve analytically, it is easy to use computer software to solve the RE. Using such software, the optimal state trajectories and control voltage are plotted for $r = 1$ and several values of $q = q_i = q_\omega$. The results are displayed in Figure 25.2. Note that the states go to zero more quickly as q increases, while the controls become larger. Final weights of $s_i = s_\omega = 0$ were used. Based on the simulation results, suitable values for the PI weights can be selected. Then, the associated $K(t)$ may be stored in memory and applied to the actual motor during the control implementation run.

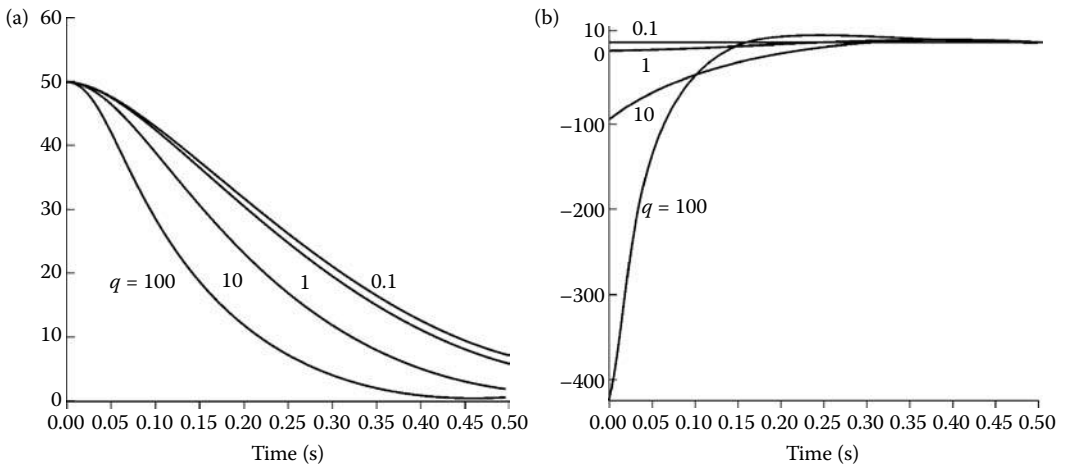

FIGURE 25.2 Results of DC motor simulation. (a) Motor speed. (b) Optimal control voltage.

25.2.3 Steady-State and Suboptimal Control

Even for time-invariant plants, the optimal LQ control is a *time-varying* state-variable feedback. Such feedbacks are inconvenient to implement, because they require the storage in computer memory of time-varying gains. An alternative control scheme will now be given in which the time-varying optimal gain $K(t)$ is replaced by its constant steady-state (e.g., $t \rightarrow \infty$) value. In most practical applications, this use of the steady-state feedback gain is adequate.

The results of this section are important. Showing how to find *multi-loop feedback gains for multi-input systems that are guaranteed to stabilize the closed-loop system*. The gains are determined simply by solving a *matrix design equation* using computer routines available in standard software packages such as MATLAB® and MATRIXx™. This goes far beyond what can be achieved with classical design techniques, which revolve around one-loop-at-a-time procedures offering no stability guarantees.

25.2.3.1 Steady-State Control—Guaranteed Stability of the LQR

Suppose the plant to be controlled has the linear description

$$\dot{x} = Ax + Bu, \quad (25.28)$$

with $x \in \mathcal{R}^n$ and control input $u \in \mathcal{R}^m$. For this section it will be necessary to assume that the plant is time-invariant.

Now, the control should be selected to minimize the quadratic PI

$$J(t_0) = \frac{1}{2} \int_0^{\infty} (x^T Qx + u^T Ru) dt, \quad (25.29)$$

with $Q \geq 0$ and $R > 0$. Since the integration interval is infinite, this is called an *infinite horizon* performance index; the performance objectives are referred to an infinite control interval $[0, \infty)$.

The control law of Table 25.2 still applies; however, because the control horizon is infinite, the RE may reach a steady-state solution where $\dot{S} = 0$. In this case, the RE may be replaced by the *algebraic Riccati equation (ARE)*

$$0 = A^T S + SA - SBR^{-1}B^T S + Q. \quad (25.30)$$

This is a symmetric matrix quadratic equation. $S(T)$ no longer appears in this steady-state formulation.

The ARE can have multiple solutions. However, if certain mild assumptions on the system and PI matrices hold, then there is a single *positive definite* solution S_{∞} , namely, the limiting solution to the time-varying RE for any $S(T)$. Then, the optimal infinite-horizon gain is the *constant* matrix given by

$$K_{\infty} = R^{-1}B^T S_{\infty}. \quad (25.31)$$

Thus, the optimal steady-state control is the *constant state-variable feedback*

$$u(t) = -K_{\infty}x(t). \quad (25.32)$$

Moreover, the optimal cost is given in terms of the initial state by

$$J = \frac{1}{2}x^T(0)S_{\infty}x(0). \quad (25.33)$$

Under the influence of the steady-state control the closed-loop plant has the *time-invariant* dynamics

$$\dot{x} = (A - BK_{\infty})x \equiv A_c x. \quad (25.34)$$

The advantages of this simplified control that uses a constant feedback are clear. The next theorem is vital to modern control theory, and shows that the steady-state LQR is *guaranteed to stabilize the*

system, even if it has multiple inputs, as long as the plant satisfies some basic properties. The system (Equation 25.28) is said to be *stabilizable* if the control input $u(t)$ can be selected to stabilize all the modes in the closed-loop. This is a weaker property than *reachability*, which requires that there is a $u(t)$ that drives any given initial state to any desired final state. These are both controllability properties of the plant. The system is said to be *observable* through the output $y = Cx$ if measurements of only $y(t)$ can be used to reconstruct the entire initial state $x(0)$. This is a stronger condition than *detectability* of (A, C) , which says that if $y(t) \rightarrow 0$ then $x(t) \rightarrow 0$. These are both observability properties of the plant.

Reachability, stabilizability, observability, and detectability are basic *open-loop properties* that hold for any well-behaved system. There are simple tests for reachability and observability. In fact, if n is equal to the number of states, the system is reachable if, and only if, the reachability matrix

$$U = [B \quad AB \quad A^2B \quad \dots \quad A^{n-1}B] \quad (25.35)$$

has rank n . This implies stabilizability as well. The system is observable if, and only if, the observability matrix

$$V = \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{n-1} \end{bmatrix} \quad (25.36)$$

has rank n . This implies detectability as well. Standard software packages such as MATLAB and *MATRIX_X* offer routines to compute these block matrices.

The next result is a cornerstone of LQR theory.

Theorem 25.1: Stability of Closed-Loop System

Let C be any square root of Q so that $Q = C^T C$. Suppose (C, A) is detectable and (A, B) is stabilizable. Then:

1. There is a unique symmetric positive-semidefinite limiting solution S_∞ to the Riccati equation 25.16 independent of the choice of $S(T)$. Furthermore, S_∞ is the unique positive-definite solution of the ARE.
2. The closed-loop plant A_c is asymptotically stable.

This result means that, as long as the system and PI satisfy certain basic controllability and observability requirements, *the steady-state LQ regulator will yield gains that stabilize the system*. Considering the difficulty encountered by classical control techniques in stabilizing multi-input systems, this is a remarkable property. Exactly as in classical control theory, the theorem predicts the *closed-loop* stability properties of the system in terms of *open-loop* system properties that are easily tested using matrix rank techniques.

The detectability of (\sqrt{Q}, A) is needed for the stability result. This property plays out as follows. If the infinite integral cost (Equation 25.29) has been minimized, then it has a finite value so that the integrand goes to zero with time. Then $x^T Q x = \|\sqrt{Q} x\|^2 \rightarrow 0$. Then detectability of (\sqrt{Q}, A) guarantees that $x(t) \rightarrow 0$. Detectability means in fact that all the unstable plant modes should be weighted in the PI, which imposes a design requirement on the engineer as he selects the weighting matrix Q .

The closed-loop poles will depend on the selection of the design matrices Q and R ; however, the poles will always be stable as long as the engineer selects $R > 0$ and $Q \geq 0$ with (\sqrt{Q}, A) observable. Thus, the elements of Q and R may be varied during an interactive computer-aided design procedure to obtain suitable closed-loop performance. The optimal gain K is found for given values of Q and R , and the closed-loop time responses are found by simulation. If these responses are unsuitable, new values for Q and R are selected and the design is repeated. Given good software to solve for K , this procedure is quite convenient. Such software is available, for instance, in MATLAB and *MATRIX_X*.

25.2.3.2 Suboptimal Control—Constant Feedback Gains

Even if the control interval $[0, T]$ is not infinite, the engineer may decide to use the steady-state gain K_∞ instead of the optimal time-varying gain $K(t)$ given in Table 25.2. The theorems guarantee stability of the closed-loop system using the steady-state LQR. On a finite interval $[0, T]$, the constant gain K_∞ is *suboptimal*, but the convenience gained by not having to implement a time-varying gain can more than compensate for the loss of optimality. Moreover, as T becomes large, the optimal gain $K(t)$ tends to K_∞ so that the decision to use the steady-state gain makes more and more sense. In addition to the ease of implementation of constant feedback gains, this suboptimal controller has other important advantages: (1) *it guarantees stability even for complex multi-loop systems*, and (2) there are efficient numerical routines available for the solution of the ARE (e.g., MATLAB and MATRIXx).

Example 25.3: Inverted Pendulum

Figure 25.3 shows a rod attached to a cart through a pivot. A force $u(t)$ is applied to the cart through a motor attached to an axle. The control objective is to use $u(t)$ to balance the pendulum upright while simultaneously keeping the horizontal movement $p(t)$ of the cart small. This is known as the *inverted pendulum problem*.

The state is $x = [\theta \ \dot{\theta} \ p \ \dot{p}]^T$. A force/moment balance approach or a Lagrangian approach may be used to obtain the dynamics. Assuming that $M = 5 \text{ kg}$, $m = 0.5 \text{ kg}$, $L = 1 \text{ m}$, we thus obtain the state equations by linearizing the dynamics about $\theta = \dot{\theta} = p = \dot{p} = 0$:

$$\dot{x} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 10.78 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ -0.98 & 0 & 0 & 0 \end{bmatrix} x + \begin{bmatrix} 0 \\ -0.2 \\ 0 \\ 0.2 \end{bmatrix} u = Ax + Bu. \quad (25.37)$$

The open-loop poles are at $s = 0, 0, \pm 3.283$, so that, with no control input, the rod will clearly fall over due to the unstable pole at $s = 3.283$.

It is desired to select K in

$$u = -Kx = -(k_\theta \theta + k_{\dot{\theta}} \dot{\theta} + k_p p + k_{\dot{p}} \dot{p}) \quad (25.38)$$

to regulate the state x to zero. For this purpose, select the PI (Equation 25.29); then, K is determined by using the matrix design Equations 25.30 and 25.31. Values of $R = 1$ and $Q = \text{diag}\{100, 100, 10, 10\}$ were selected. The motivation for choosing this Q was to place heavy emphasis on keeping the angle $\theta(t)$ small; the cart position control does not matter if the rod falls over. Using MATLAB subroutines from the

FIGURE 25.3 Inverted pendulum on a cart.

FIGURE 25.4 Inverted pendulum response. (a) Angle $\theta(t)$ and position $p(t)$. (b) Control input $u(t)$.

Control System Toolbox, the optimal gain was easily found to be $K = [-156.16 \quad -49.21 \quad -3.16 \quad -8.72]$, which yields closed-loop poles at $s = -0.60 \pm j0.45, -2.48, -4.41$.

Using MATLAB routines, the closed-loop response was *simulated* and plotted. The angle $\theta(t)$ and position $p(t)$ in response to an initial condition offset of $\theta(0) = 0.1\text{rad} \approx 6^\circ, p(0) = 0.1\text{m}$ are shown in Figure 25.4a. The required control force $u(t)$ is shown in Figure 25.4b. These plots are quite interesting and bear discussion. Due to the initial offset of 6° in angle, a large control must be applied immediately to push the cart under the rod to catch it so it does not fall. Subsequent smaller control motions begin to move the cart slowly back to the desired horizontal position of $p = 0$ while balancing the rod. Thus, the fast closed-loop poles correspond to the rod motion. The slow complex pole pair is associated with the cart position. This *two-time scale behavior* was induced by the widely disparate weightings selected in the design matrix Q .

In fact, the value for Q was selected by performing *several design iterations* with different Q until computer simulation finally showed a good time response. Such design iterations, coupled with computer simulation, are common in modern control and are very easy using software like MATLAB.

25.2.3.3 Eigenstructure LQR Design

In most computer software routines for solving for the LQR gains, the ARE solution is determined from the eigenstructure of the Hamiltonian matrix H in the *Hamiltonian system*

$$\begin{bmatrix} \dot{x} \\ \dot{\lambda} \end{bmatrix} = \begin{bmatrix} A & -BR^{-1}B^T \\ -Q & -A^T \end{bmatrix} \begin{bmatrix} x \\ \lambda \end{bmatrix} \equiv H \begin{bmatrix} x \\ \lambda \end{bmatrix} \quad (25.39)$$

which consists of the state Equation 25.20 and the costate Equation 25.21, with $u(t)$ replaced by $-R^{-1}B^T\lambda(t)$.

The Hamiltonian matrix H enjoys the special property of having n stable poles and n unstable poles (their images in the $j\omega$ axis), where n is the dimension of the state vector x . If (A, B) is stabilizable, and (\sqrt{Q}, A) is observable, so that the conditions of Theorem 25.1 hold, then the stable eigenvalues of H are also the poles of the optimal closed-loop system

$$\dot{x} = (A - BK_\infty)x \equiv A_c x, \quad (25.40)$$

with K_∞ the steady-state feedback gain. This provides an alternative proof of the stability of the optimal closed-loop system.

Select the eigenvectors of the stable eigenvalues of H , and partition them as $[X_i^T \ \Lambda_i^T]^T$. Let X be an $n \times n$ matrix whose columns are X_i , and Λ be an $n \times n$ matrix whose columns are Λ_i . Then the solution to the ARE is given in terms of the eigenstructure of H by

$$S_\infty = \Lambda X^{-1}, \quad (25.41)$$

and the steady-state gain is given by

$$K_\infty = R^{-1} B^T \Lambda X^{-1}. \quad (25.42)$$

(If the eigenvalues are complex, then, in the definitions of X and Λ , it is necessary to use the real and imaginary parts of the associated vectors X_i and Λ_i instead of the complex conjugate vectors themselves.)

25.2.4 Frequency-Domain Results and Robustness of the LQR

It is possible to discuss the LQR from the view point of the frequency domain. Classical frequency-domain results are given in terms of scalar SISO systems and involve notions like the loop gain, return difference, sensitivity, and so on. Such ideas are extended in modern optimal design using multivariable transfer functions and the notions of the *singular value* and the *multivariable Bode plot*. For more details, see Chapter 8 or the references. An important property of any closed-loop system is *robustness* to uncertainties, including modeling errors, disturbances, and noise. The LQR has some important robustness properties that are detailed here.

25.2.4.1 LQR Frequency-Domain Relationships

Suppose that the plant is time-invariant and, in Figure 25.1, K is the constant optimal LQ state-feedback gain determined using the LQR ARE as in Section 25.2.3.1. Define the plant transfer function as $G(s) \equiv (sI - A)^{-1}B$. Then, the *loop gain* referred to the input is

$$KG(s) = K(sI - A)^{-1}B = KG(s) \quad (25.43)$$

and the *closed-loop return difference* is $[I + K(sI - A)^{-1}B] = I + KG(s)$.

25.2.4.1.1 Optimal Return Difference Relationship

Two key results are the following. The *optimal characteristic polynomial relationship* is

$$\Delta_c(s) = |I + K(sI - A)^{-1}B| \Delta(s) \quad (25.44)$$

where the open-loop characteristic polynomial is $\Delta(s) = |sI - A|$ and the closed-loop characteristic polynomial is $\Delta_c(s) = |sI - (A - BK)|$. The *optimal return difference relationship* is

$$[I + K(-sI - A)^{-1}B]^T R [I + K(sI - A)^{-1}B] = R + B^T (-sI - A)^{-T} Q (sI - A)^{-1} B. \quad (25.45)$$

These are extremely important because, exactly as in classical control theory, they express *closed-loop properties* in terms of *open-loop properties* that can be computed before the optimal controller is designed. They allow, for instance, the development of the *Chang-Letov design approach for LQR* which is an extension of root locus design to MIMO systems.

25.2.4.1.2 Optimal Singular Value Relationships

Select the control weighting matrix as $R = \rho I$, with ρ a positive design parameter. Denoting the i th singular value of a matrix M as $\sigma_i(M)$, Equation 25.45 yields the *optimal singular value relationship* of

the LQR

$$\sigma_i[I + KG(j\omega)] = \left[1 + \frac{1}{\rho} \sigma_i^2[H(j\omega)] \right]^{\frac{1}{2}} \tag{25.46}$$

with

$$H(s) \equiv C(sI - A)^{-1}B \tag{25.47}$$

and matrix C defined by $Q = C^T C$. This is important because the right-hand side is known in terms of *open-loop* quantities before the optimal feedback gain is found by solution of the ARE, while the left-hand side is the closed-loop return difference.

According to this relationship, for all ω , the minimum singular value, denoted $\underline{\sigma}$, satisfies the *LQ optimal singular value constraint*

$$\underline{\sigma}[I + KG(j\omega)] \geq 1. \tag{25.48}$$

Thus, the LQ regulator always results in a *decreased sensitivity*.

25.2.4.2 Guaranteed Robustness of the Linear-Quadratic Regulator

The linear-quadratic regulator using full state feedback has many useful properties, including guaranteed closed-loop stability and ease of design by solving matrix design equations. It will now be shown that the steady-state LQR has certain *guaranteed robustness properties* that make it even more useful. These conclusions may be discovered using the *multivariable Nyquist criterion*, which shall be referred to the polar plot of the return difference $I + KG(s)$, where the origin is the critical point. A typical polar plot of $\underline{\sigma}[I + KG(j\omega)]$ is shown in Figure 25.5, where the optimal singular value constraint appears as the condition that *all the singular values remain outside the unit disc*.

25.2.4.2.1 Guaranteed Stability

The multivariable Nyquist criterion says that (as long as the open-loop system $G(s)$ is stable) the closed-loop system is stable if none of the singular value plots of $I + KG(j\omega)$ encircle the origin in the figure. Due to the optimal singular value constraint, no encirclements are possible. This constitutes a proof of the *guaranteed stability* of the LQR discussed in Section 25.2.3.1.

25.2.4.2.2 Gain Margin

Multiplying the optimal feedback K by any positive scalar gain $k > 1$ results in a loop gain of $kKG(s)$, which has a minimum singular value plot identical to the one in Figure 25.5 except that it is scaled outward; that is, the $\omega \rightarrow 0$ limit (i.e., the DC gain) will be larger, but the $\omega \rightarrow \infty$ limit will still be 1.

FIGURE 25.5 Typical polar plot for optimal LQ return difference.

FIGURE 25.6 Definition of multivariable phase margin.

Thus, the closed-loop system will still be stable. In classical terms, the LQ regulator with full state feedback has an *infinite gain margin*.

25.2.4.2.3 Phase Margin

For multivariable systems the *phase margin* may be defined as the angle marked “PM” in Figure 25.6. As in the classical case, it is the angle through which the polar plot of $\underline{\sigma}[I + KG(j\omega)]$ must be rotated (about the point 1) clockwise to make the plot go through the critical point. By combining Figure 25.5 with Figure 25.6, it can be determined that, due to the LQ singular value constraint, the plot of $\underline{\sigma}[I + KG(j\omega)]$ must be rotated through at least 60° to make it pass through the origin. The LQR with full state feedback thus has a *guaranteed phase margin of at least 60°* . This means that a phase shift of up to 60° may be introduced in any of the m paths in Figure 25.1, or in all paths simultaneously, as long as the paths are not coupled to each other in the process. (Here, m is the number of control inputs, i.e., the number of control loops.)

This phase margin is excessive; it is higher than that normally required in classical control system design. This overdesign means that, in other performance aspects, the LQ regulator may have some deficiencies. One of these is that, at the *crossover frequency* (loop gain = 1), the slope of the *multivariable Bode plot* is -20 dB/decade, a relatively slow attenuation rate. (By allowing a Q weighting matrix in the PI that is not positive semidefinite, it is possible to obtain better LQ designs that have higher roll-off rates at high frequencies.)

25.2.4.2.4 Stability with Multiplicative Uncertainty

It can be shown that Equation 25.48 implies that

$$\underline{\sigma}[I + (KG(j\omega))^{-1}] \geq \frac{1}{2}. \quad (25.49)$$

This corresponds to the fact that the LQR with state feedback remains stable for all *multiplicative uncertainties* in the plant transfer function which satisfies $m(\omega) < \frac{1}{2}$.

25.3 The Tracker Problem

The function of the LQ regulator is to hold the states near zero, that is, to guarantee closed-loop stability. Another fundamental design problem in systems engineering is to control a system so that a specified output follows a given nonzero *reference trajectory* $r(t)$. An example is controlling an aircraft to follow a desired step input command (e.g., change in altitude). This is called the *tracking or servodesign* problem. For this purpose, the regulator control law must be modified. The fundamental issue here is that for optimal tracking some additional *feedforward terms* must be added to the control input besides the basic LQR feedback loop that gives closed-loop stability.

Consider the linear system given by Equation 25.51, with $z(t)$ in Equation 25.52 a *performance output* that should track the given reference input $r(t)$. In contrast to classical control, it is easy to include here the case where both $z(t)$ and $r(t)$ are vectors, that is, the case of multivariable tracking. The control input is given by

$$u = -Kx + v, \tag{25.50}$$

where $v(t)$ is a feedforward signal required for good tracking performance. The feedback gain K and feedforward signal $v(t)$ are determined so as to keep the *tracking error* (Equation 25.53) small.

The solution to the tracking problem is significantly more involved than the regulator problem. It is now discussed from three points of view. In this section, full state-variable feedback is assumed. In actual applications, only *output feedback* is allowed. In that case refer to Chapter 5.1 or to [8,11], where these techniques are extended.

25.3.1 Optimal LQ Tracker

The optimal LQ tracker can be derived along the same lines as the Hamiltonian approach in Section 25.2.2. The result is given in Table 25.3. The feedback structure is basically the same as the LQ regulator in

TABLE 25.3 Optimal Continuous-Time Linear Quadratic Tracker

System model:

$$\dot{x} = Ax + Bu, \quad t \geq t_0, \quad x(t_0) = x_0 \text{ given.} \tag{25.51}$$

Performance output and tracking error:

$$z = Hx, \tag{25.52}$$

$$e = r - z. \tag{25.53}$$

Performance index:

$$J(t_0) = \frac{1}{2} e^T(T) P e(T) + \frac{1}{2} \int_{t_0}^T (e^T Q e + u^T R u) dt, \tag{25.54}$$

with

$$P \geq 0, \quad Q \geq 0, \quad R > 0.$$

Optimal tracking controller:

Riccati equation:

$$-\dot{S} = A^T S + SA - SBR^{-1}B^T S + H^T QH, \quad t \leq T, \quad S(T) = H^T P H. \tag{25.55}$$

Optimal feedback gain:

$$K = R^{-1}B^T S. \tag{25.56}$$

Feedforward system:

$$-\dot{w} = (A - BK)^T w + H^T Qr, \quad t \leq T, \quad w(T) = H^T P r(T). \tag{25.57}$$

Feedback plus feedforward control:

$$u(t) = -K(t)x(t) + R^{-1}B^T w(t). \tag{25.58}$$

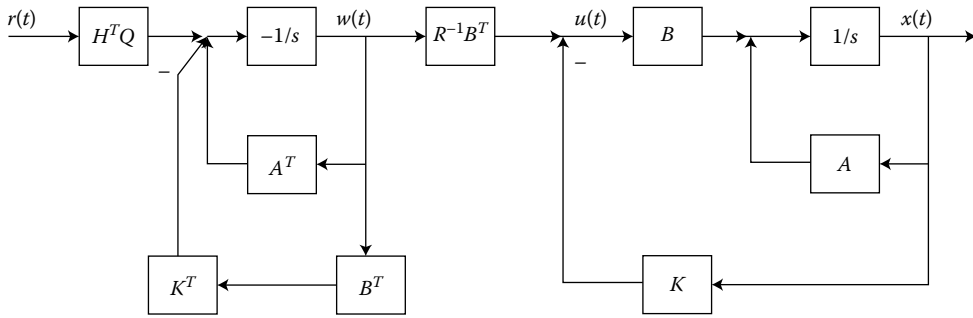

FIGURE 25.7 Optimal LQ tracker.

Table 25.2, but now the PI contains the tracking error, not the state, because $e(t)$ is to be small in this application. The presence of $e(t)$ in the PI has the effect of adding a feedforward term $v(t)$ to the control signal. The tracker gain K and signal $v(t)$ determined with the LQ optimal approach are given in the table. The feedback gain K is found in the same manner as in the LQR case. The structure of the LQ optimal tracker is given in Figure 25.7.

The feedforward signal is computed using the dynamical system (Equation 25.57), which is called the *adjoint system*; like the RE, it is integrated *backward* in time. Thus, the RE and the adjoint system must be integrated off-line before the control run. In fact, the optimal LQ tracker is *noncausal*, because future values of the reference input $r(t)$ are needed to compute $w(t)$. The ramifications of this noncausal nature of the optimal tracker are illustrated in Figure 25.8, which shows the optimal tracker response for a scalar system using control weighting $R = 1$ and different values of the error weighting Q . The system output begins to change *before* the reference $r(t)$ does, so that the system anticipates the changes in $r(t)$. This *anticipatory behavior* is an important feature of the optimal tracker.

The noncausal nature of the optimal LQ tracker means that it cannot be implemented in practice when $r(t)$ is not predetermined. Therefore, two suboptimal strategies are now outlined that yield implementable tracking systems.

FIGURE 25.8 Anticipatory response of the optimal LQ tracker.

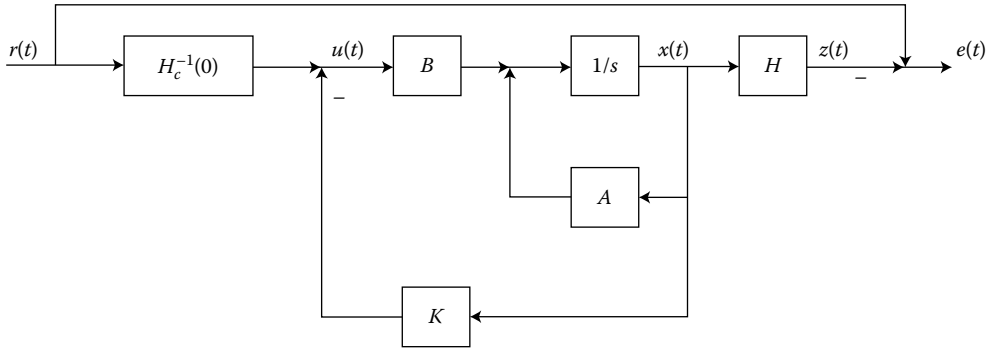

FIGURE 25.9 Tracker based on DC gain.

25.3.2 Conversion of an LQR to an LQ Tracker

As an alternative to the optimal tracking solution just presented, a causal tracker can be obtained as follows. First, the LQ regulator is designed using Table 25.2. Then, it is converted to an LQ tracker by adding a feedforward term. In the case where the reference signal $r(t)$ is a constant (i.e., step function) with magnitude r_0 , the tracking control with state feedback is given by

$$u = -Kx + H_c^{-1}(0)r_0, \tag{25.59}$$

where the closed-loop transfer function is

$$H_c(s) = H(sI - (A - BK))^{-1}B \tag{25.60}$$

and $H_c(0)$ is the DC gain of the closed-loop system $(A - BK)$. The control gain K is found using the LQR design equations in Table 25.2. The structure of this suboptimal tracker is shown in Figure 25.9. Unfortunately, if the DC gain is not well known this tracker structure does not perform well, that is, this tracker is not *robust*.

25.3.3 A Practical Suboptimal Tracker

This section shows how to design a suboptimal tracker that works well for practical applications and is robust to uncertainties and disturbances. The key is in the use of engineering design insight and common sense to formulate the problem. One uses a *unity feedback gain outer loop*, which has proven effective in classical control approaches. This technique also relies on converting an LQR to a tracker, but differs from the work in the previous section.

25.3.3.1 Problem Formulation

A general class of systems is described by the equations

$$\begin{aligned} \dot{x} &= Ax + Bu + Er \\ z &= Hx \end{aligned} \tag{25.61}$$

which can contain both the plant plus some desirable *compensator dynamics*. The control input is allowed to have the form

$$u = -Kx - KFr, \tag{25.62}$$

which consists of state feedback plus a feedforward term of a special composition. Placing the control into the system yields the closed-loop system

$$\dot{x} = (A - BK)x + (E - BKF)r \equiv A_c x + B_c r. \tag{25.63}$$

Matrices E and F are chosen to have a structure that is sensible from a design point of view. Specifically, it is very desirable to incorporate a unity-gain outer tracking loop in the controller, as shown in Example 25.4.

25.3.3.2 Deviation System and LQR Design Step

Assume that the reference input is a unit step of magnitude r_0 . Then, the *steady-state* system is

$$0 = A_c \bar{x} + B_c r_0,$$

where overbars denote steady-state values, so that the steady-state value of the state is $\bar{x} = -A_c^{-1} B_c r_0$. Though the reference input is assumed constant for design purposes, this is to allow good closed-loop rise time and overshoot qualities. Then, the designed controller works for *any reference input* $r(t)$, *even though time-varying*.

Define the *deviations*

$$\begin{aligned} \tilde{x} &= x - \bar{x}, & \tilde{z} &= z - \bar{z}, \\ \tilde{u} &= u - \bar{u}, & \tilde{e} &= e - \bar{e}. \end{aligned} \quad (25.64)$$

Then, the deviations satisfy the dynamics of the *deviation system*

$$\dot{\tilde{x}} = A \tilde{x} + B \tilde{u} \quad (25.65)$$

$$\tilde{z} = H \tilde{x} \quad (25.66)$$

$$\tilde{u} = -K \tilde{x}. \quad (25.67)$$

Because $e = r - z$, the tracking error deviation is $\tilde{e} = -\tilde{z}$. To induce tracking behavior, define the performance index

$$J(t_0) = \frac{1}{2} \int_0^{\infty} (\tilde{x}^T Q \tilde{x} + \tilde{u}^T R \tilde{u}) dt, \quad (25.68)$$

which makes the entire deviation state, and therefore \tilde{e} , small.

25.3.3.3 Tracker Design

The tracking problem may now be solved as follows. First, solve the LQ regulator problem for the deviation system using Table 25.2. Then, the tracking control input is given by Equation 25.62. This tracker has a much different structure than the DC-gain-based tracker in Figure 25.9. The next example shows that a sensible choice for matrices E and F based on classical control notions gives a robust tracker with a unity gain outer loop. Then, a sensible choice for the PI design matrices Q and R gives good control gains and *guaranteed stability*, even for complex multiloop tracking systems.

Note that $e = \tilde{e} + \bar{e}$, where \bar{e} is the steady-state value of the tracking error. Because this technique only guarantees that \tilde{e} is small, special steps must be taken to guarantee that \bar{e} is also small. One way to do this is to include *integrators in all the feedforward loops*, as in the next example. As an alternative, a term involving \bar{e} can be added to the PI (Equation 25.68). This gives more involved design equations, which are nevertheless still easily solved by digital computer. The details are in [8]. Finally, although the gain determined in this fashion is optimal for the deviation system, it is not optimal for the tracking problem in terms of the original dynamics (Equation 25.61). In practical applications, however, it is suitable provided that the design matrices are sensibly selected.

Example 25.4: Aircraft Pitch-Rate Control System

This example illustrates the tracker design procedure just presented. Good tracker system design relies on a sensible selection of the structure matrices E and F , and good feedback gains rely on a sensible selection of the design weighting matrices Q, R . *Compensator dynamics* can be accounted for using this procedure. Because this is an LQ-based approach, a reasonable formulation of the

problem should result in *guaranteed closed-loop stability*. This is an important feature of modern control design techniques, and is in complete contrast to classical techniques where stability in multi-loop systems can be difficult to achieve.

AIRCRAFT AND CONTROL SYSTEM DYNAMICS

In a pitch-rate control system, the control input is elevator actuator voltage $u(t)$ and r is a reference step input corresponding to the desired pitch command. The performance output $z(t)$ is the pitch rate q . To ensure zero steady-state error, an integrator is added in the feedforward channel; this corresponds to *compensator dynamics*, and is easily dealt with in this approach. The integrator output is ϵ . It is assumed here that all states are available as measurements for feedback purposes; in practice, the output-feedback design technique in [11] will be required.

The design is based on a short period approximation to the F-16 dynamics linearized about a nominal flight condition of 502 ft/s, 0 ft altitude, level flight, with the center of gravity at 0.35. The basic aircraft states of interest are q and angle of attack α . An additional state is introduced by the elevator actuator, whose deflection is δ_e . The states of the plant plus compensator are $x = [\alpha \ q \ \delta_e \ \epsilon]^T$ and the system dynamics are described by Equation 25.61 with

$$A = \begin{bmatrix} -1.01887 & 0.90506 & -0.00215 & 0 \\ 0.82225 & -1.07741 & -0.17555 & 0 \\ 0 & 0 & -20.2 & 0 \\ 0 & -57.2958 & 0 & 0 \end{bmatrix}, \tag{25.69}$$

$$B = \begin{bmatrix} 0 \\ 0 \\ 20.2 \\ 0 \end{bmatrix}, \quad E = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}, \tag{25.70}$$

and

$$H = [0 \ 57.2958 \ 0 \ 0] \tag{25.71}$$

The factor of 57.2958 is added to convert angles from radians to degrees. The last line of the state equation using this A and E matrix describes the integrator, $\dot{\epsilon} = -57.2958q + r$.

CONTROL DESIGN

Select the control input $u(t)$ to yield good closed-loop response to a step input at r , which corresponds to a SISO tracker design problem. Since the integrator makes the system Type I, the steady-state error \bar{e} is equal to zero and $e(t) = \bar{e}(t)$. Thus, the design method just described is appropriate.

The control input is

$$u = -Kx = -[k_\alpha \ k_q \ k_{\delta_e} \ k_I]x = -k_\alpha\alpha - k_qq - k_{\delta_e}\delta_e - k_I\epsilon. \tag{25.72}$$

Therefore, referring to Equation 25.62 it is evident that $F = 0$; however, including the integrator output as a state variable in the dynamics (1) adds the feedforward path required for tracking behavior, that is, element k_I of the feedback matrix K is actually a “feedforward” gain.

To determine the gain matrix K , select the PI (Equation 25.68), and try weighting matrices $R = 1, Q = \text{diag}\{1, 10, 1, 1\}$. Now use the LQR routine from the MATLAB Control Systems Toolbox to determine the optimal gain $K = [-0.046 \ -1.072 \ 0 \ 3.381]$. Using MATLAB routines, the corresponding closed-loop poles are $s = -8.67 \pm j9.72, -9.85, -4.07, -1.04$. The resulting step response is shown in Figure 25.10, which displays good performance.

FIGURE 25.10 Pitch-rate step response.

25.4 Minimum-Time and Constrained-Input Design

An important class of control problems is concerned with achieving the performance objectives in *minimum time*. A suitable performance index for these problems is

$$J = \int_{t_0}^T 1 \, dt = T - t_0. \quad (25.73)$$

Several sorts of minimum-time problems are now discussed.

25.4.1 Nonlinear Minimum-Time Problems

Suppose the objective is to drive the system

$$\dot{x} = f(x, u) \quad (25.74)$$

from a given initial state $x(t_0) \in \mathcal{R}^n$ to a specified final state $x(T)$ in minimum time. Then, from Table 25.1 the Hamiltonian is

$$H = 1 + \lambda^T f \quad (25.75)$$

and the Euler equations are the costate equation

$$-\dot{\lambda} = \frac{\partial f^T}{\partial x} \lambda \quad (25.76)$$

plus the stationarity condition

$$0 = \frac{\partial f^T}{\partial u} \lambda. \quad (25.77)$$

Since the final state is fixed (so that $dx(T) = 0$) but the final time is free, the final condition in Table 25.1 says that

$$0 = H(T) = 1 + \lambda^T(T) f[x(T), u(T)]. \quad (25.78)$$

If $f(x, u)$ is not an explicit function of time, then according to the conservation principle (Equation 25.10), $H(t)$ is zero for all time.

The stationarity condition (Equation 25.77) may often be used to solve for $u(t)$ in terms of $\lambda(t)$. Then, $u(t)$ may be eliminated in the state and costate equations to obtain the Hamiltonian system. To solve this,

we require n initial conditions ($x(t_0)$ given) and n final conditions ($x(T)$ specified). However, the final time T is now unknown. The function of Equation 25.78 is to provide one more equation so that T can be solved for. Several nonlinear design problems can be explicitly solved, yielding great insight into the minimum-time control structure. Examples include *Zermelo's Problem* and the *Brachistochrone Problem*.

25.4.2 Linear Quadratic Minimum-Time Design

The general solution procedure given in the previous section for the nonlinear minimum-time problem is difficult to apply. Moreover, a reasonable solution may not exist. A general class of practical problems is covered by the case where it is required to find an optimal control for the linear system

$$\dot{x} = Ax + Bu \quad (25.79)$$

that minimizes the performance index

$$J = \frac{1}{2}x^T(T)S_Tx(T) + \frac{1}{2} \int_{t_0}^T (1 + x^TQx + u^TRu) dt \quad (25.80)$$

with $S_T \geq 0, Q \geq 0, R > 0$, and the final time T free. There is no constraint on the final state; thus, the control objective is to make the final state sufficiently small. Due to the term $\frac{1}{2}(T - t_0)$ arising from the integral, this must be accomplished in a short time period. This is a general sort of PI that allows for a trade-off between the minimum-time objective and a desire to keep the states and the controls small. Thus, if the engineer selects smaller Q and R , the term $\frac{1}{2}(T - t_0)$ in the PI dominates, and the control tries to make the transit time smaller. This is called the *LQ minimum-time problem*.

The solution for this problem is the same as in Table 25.2. The control is a linear time-varying state feedback given by

$$u = -K(t)x \quad (25.81)$$

with optimal gain

$$K = R^{-1}B^TS \quad (25.82)$$

and $S(t)$ the solution determined by integrating the RE backward from time T . Unfortunately, there is a problem in that the final time T is unknown.

To determine the value of T that minimizes the PI, an *extra condition* is needed, given by Equation 25.78, which yields

$$x^T(t_0)\dot{S}x(t_0) = 1, \quad (25.83)$$

with $x(t_0)$ the specified initial condition of the plant. The solution procedure for the LQ minimum-time problem is to integrate the RE

$$-\dot{S} = A^TS + SA + Q - SBR^{-1}B^TS \quad (25.84)$$

backward from some time τ using $S(\tau) = S_T$ as the final condition. At each time t , the left-hand side of Equation 25.83 is computed using the known initial state and $\dot{S}(t)$. Then, the minimum interval $(T - t_0)$ is equal to $(\tau - t)$ where t is the time for which Equation 25.83 first holds. This specifies the minimum final time T , and then allows the computation of the optimal feedback gain $K(t)$ on the interval $[t_0, T]$.

The Riccati derivative \dot{S} is used to determine the optimal time interval, while S is used to determine the optimal feedback gain $K(t)$.

More details on this control scheme may be found in [12]. It is important to note that condition (Equation 25.83) may never hold. Then, the optimal solution is $T - t_0 = 0$, that is, the PI is minimized by using *no control*. Roughly speaking, if $x(t_0)$ and/or Q and $S(T)$ are selected large enough, then it makes sense to apply a nonzero control $u(t)$ to make $x(t)$ decrease. On the other hand, if Q and $S(T)$ are selected too small for the given initial state $x(t_0)$, then it is not worthwhile to apply any control to decrease $x(t)$, because a nonzero control and a nonzero time interval will increase the PI.

25.4.3 Constrained-Input Design and Bang-Bang Control

Up to this point minimum-time control has been presented based on the conditions of Table 25.1, which were derived using the calculus of variations. Under some smoothness assumptions on $f(x, u, t)$ and $L(x, u, t)$, the resulting controls are also smooth. Here, a fundamentally different sort of control strategy will be presented.

If the linear system

$$\dot{x} = Ax + Bu \quad (25.85)$$

with $x \in \mathcal{R}^n$, $u \in \mathcal{R}^m$ is prescribed, there are problems with using the pure minimum-time PI,

$$J(t_0) = \int_{t_0}^T 1 \, dt, \quad (25.86)$$

where T is free. The way to minimize the time is to use infinite control energy! Since this optimal strategy is not acceptable, it is necessary to find a way to reformulate the minimum-time problem for linear systems.

Therefore, the control input now must satisfy the *magnitude constraint*

$$\|u(t)\| \leq 1 \quad (25.87)$$

for all $t \in [t_0, T]$. This constraint means that *each component* of the m -vector $u(t)$ must be no greater than 1. Thus, the control is constrained to an *admissible region* (in fact, a hypercube) of \mathcal{R}^m . If the constraints on the components of $u(t)$ have a value different from 1, then one may appropriately scale the corresponding columns of the B matrix to obtain the constraints in the form of Equation 25.87. A requirement like Equation 25.87 arises in many problems where the control magnitude is limited by physical considerations; for instance, the thrust of a rocket certainly has a maximum possible value, as has the armature voltage of a DC motor.

Referring to Table 25.1, the optimal control problem posed here is to find a control $u(t)$ that drives a given $x(t_0)$ to a final state $x(T)$ satisfying the final state constraint, minimizes the PI, and satisfies Equation 25.87 at all times. Intuitively, to minimize the time, the optimal control strategy appears to be to apply maximum effort (i.e., plus or minus 1) over the entire time interval. This idea will now be formalized. When a control component takes on a value at the boundary of its admissible region (i.e., ± 1), it is said to be *saturated*. Pontryagin and coworkers have shown that, in the case of constrained control, Table 25.1 still applies if the stationarity condition is replaced by the more general condition, known as *Pontryagin's Minimum Principle*,

$$H(x^*, u^*, \lambda^*, t) \leq H(x^*, u, \lambda^*, t), \quad \text{all admissible } u. \quad (25.88)$$

This is an extremely powerful result which can be employed to derive the following solution to the linear constrained-input minimum-time problem.

Define the *signum function* for scalar w as

$$\text{sgn}(w) = \begin{cases} 1, & w > 0 \\ \text{indeterminate}, & w = 0 \\ -1, & w < 0. \end{cases} \quad (25.89)$$

If w is a vector, define $v = \text{sgn}(w)$ as $v_i = \text{sgn}(w_i)$ for each i , where v_i, w_i are the components of v and w . Then, in terms of the costate, the optimal control is given by

$$u^*(t) = -\text{sgn}[B^T \lambda(t)]. \quad (25.90)$$

This may be interpreted as follows. For each column b_i of B , if $\lambda^T(t)b_i$ is positive, we should select $u_i(t) = -1$ to get the largest possible negative value of $\lambda^T(t)b_i u_i(t)$. On the other hand, if $\lambda^T(t)b_i$ is

FIGURE 25.11 Sample switching function and associated optimal control.

negative, we should select $u_i(t)$ as its maximum admissible value of 1 to make $\lambda^T(t)b_i u_i(t)$ as negative as possible. If $\lambda^T(t)b_i$ is zero at a single point t in time, then $u_i(t)$ can be assigned any value at that time, because then $\lambda^T(t)b_i u_i(t)$ is zero for all values of $u(t)$.

The quantity $B^T \lambda(t)$ is called the *switching function*. A sample switching function and the optimal control it determines are shown in Figure 25.11. When the switching function changes sign, the control switches from one of its extreme values to another. The control in the figure switches four times. The optimal linear minimum-time control is always saturated since it switches back and forth between its extreme values, so it is called *bang-bang control*. In some problems, a component $b_i^T \lambda(t)$ of the switching function $B^T \lambda(t)$ can be zero over a finite time interval. If this happens, component $u_i(t)$ of the optimal control is not well-defined by Equation 25.90. This is called a *singular condition*. If this does not occur, the time-optimal problem is called *normal*.

The time-invariant plant (Equation 25.85) is reachable if, and only if, the reachability matrix (Equation 25.35) has full rank n . If b_i is the i th column of $B \in \mathcal{R}^{n \times m}$, then the plant is *normal* if

$$U_i = [b_i \quad Ab_i \quad \dots \quad A^{n-1}b_i] \tag{25.91}$$

has full rank n for each $i = 1, 2, \dots, m$, that is, if the plant is reachable by each separate component u_i of $u \in \mathcal{R}^m$. Normality of the plant and normality of the minimum-time control problem are equivalent. Let the plant be normal (and hence reachable), and suppose it is desired to drive a given $x(t_0)$ to a desired fixed final state $x(T)$ in minimum time with a control satisfying Equation 25.87. Then, the following results have been achieved for time-invariant plants by Pontryagin and coworkers:

1. If the desired final state $x(T)$ is equal to zero, then a minimum-time control exists if the plant has no poles with positive real parts (i.e., no poles in the open right half plane).
2. For any fixed $x(T)$, if a solution to the minimum-time problem exists, then it is unique.
3. Finally, if the n plant poles are all real and if the minimum-time control exists, then each component $u_i(t)$ of the time-optimal control can switch at most $n - 1$ times.

In both its computation and its final appearance, bang-bang control is fundamentally different from the smooth controls seen previously. The minimum principle leads to the expression (Equation 25.90) for $u^*(t)$, but it is difficult to solve explicitly for the optimal control. Instead, this condition specifies several different control laws, and it is necessary to select which among these is the optimal control. Thus, the minimum principle keeps one from having to examine all possible control laws for optimality, giving a small subset of potentially optimal controls to be investigated. In many cases, it is still possible to express $u^*(t)$ as a state-feedback control law.

Example 25.5: Bang-Bang Control

Any system obeying Newton's laws for point-mass motion is described by

$$\begin{aligned}\dot{y} &= v, \\ \dot{v} &= u,\end{aligned}\tag{25.92}$$

with $y(t)$ the position, $v(t)$ the velocity, and $u(t)$ the input acceleration. The state is $x = [y \ v]^T$.

Let the acceleration input u be constrained in magnitude by

$$|u(t)| \leq 1.\tag{25.93}$$

The control objective is to bring the state from any initial point (y_0, v_0) to the origin in the minimum time T . The final state must be fixed at

$$\psi(x(T), T) = \begin{bmatrix} y(T) \\ v(T) \end{bmatrix} = 0.\tag{25.94}$$

Using Equation 25.88 the minimum-time control takes on only values of $u = \pm 1$. Moreover, there is at most one control switching because the maximum number of switchings is $n - 1$ when the plant poles are all real. The *phase plane* is a coordinate system whose axes are the state variables. Phase-plane plots of the state trajectories of (1) for $u = 1$ and for $u = -1$ are parabolas in the phase plane as shown in Figure 25.12. These parabolas represent minimum-time trajectories. The arrows indicate the direction of increasing time. For example, if the initial state (y_0, v_0) is as shown in Figure 25.12, then, under the influence of the control $u = -1$, the state will develop downward along the parabola, eventually passing through the point $(y = 0, v = -2)$. On the other hand, if a control of $u = 1$ is applied, the state will move upward and to the right.

It will now be argued that this figure represents a *state-feedback control law*, which brings any state to the origin in minimum time. Suppose the initial state is as shown in Figure 25.12. Then the only way to arrive at the origin, while satisfying the Pontryagin conditions, is to apply $u = -1$ to move the state

FIGURE 25.12 Phase plane trajectories for $u = 1$ and $u = -1$.

along a parabola to the dashed curve. At this point (labeled “a”), the control is switched to $u = 1$ to drive the state into the origin. Hence, the resulting seemingly roundabout trajectory is in fact a minimum-time path to the origin. The dashed curve is known as the *switching curve*. For initial states on this curve, a control of $u = 1$ (if $v_0 < 0$) or $u = -1$ (if $v_0 > 0$) for the entire control interval will bring the state to zero. For initial states off this curve, the state must first be driven onto the switching curve, and then the control must be switched to its other extreme value to bring the final state to zero. The switching curve is described by the equation $y = -\frac{1}{2}v |v|$.

Simply put, for initial states above the switching curve, the optimal control is $u = -1$, followed by $u = 1$, with the switching occurring when $y(t) = \frac{1}{2}v^2(t)$. For initial states below the switching curve, the optimal control is $u = 1$, followed by $u = -1$, with the switching occurring when $y(t) = -\frac{1}{2}v^2(t)$. Because the control at each time t is completely determined by the state (i.e., by the phase plane location), Figure 25.12 yields a feedback control law. This feedback law, represented graphically in the figure, can be stated as

$$u = \begin{cases} -1 & \text{if } y > -\frac{1}{2}v |v| \\ & \text{or if } y = -\frac{1}{2}v |v| \text{ and } y < 0 \\ 1 & \text{if } y < -\frac{1}{2}v |v| \\ & \text{or if } y = -\frac{1}{2}v |v| \text{ and } y > 0. \end{cases} \quad (25.95)$$

which makes it clear that the minimum-time control is indeed a state-feedback.

25.5 Optimal Control of Discrete-Time Systems

The discussion so far has applied to continuous-time (analog) systems. The discussion of the LQR problem for DT systems

$$x_{k+1} = Ax_k + Bu_k, \quad (25.96)$$

is identical in form, though more complicated in its details. The problem is to select the state-feedback matrix K in

$$u_k = -Kx_k \quad (25.97)$$

to minimize a performance index specified by the design engineer.

25.5.1 Discrete-Time LQR

In general the optimal DT linear quadratic regulator is a time-varying matrix gain sequence K_k . However, the practically useful solution is the optimal steady-state feedback gain obtained by using the infinite horizon PI (Equation 25.99). The design equations for the DT LQR are given in Table 25.4. The DT LQR equations are more complicated than the continuous-time equivalents; however, commercially available software (e.g., MATLAB) makes this irrelevant to the control designer. In practice, DT design is as straightforward as continuous-time design.

All the results discussed for continuous-time systems in Section 25.2 have their DT counterparts (see the references). Thus, as long as (A, B) is stabilizable and (A, \sqrt{Q}) observable, the discrete LQR has guaranteed properties of stability and robustness. Discrete versions of the tracker design problem are also given in the references.

25.5.2 Digital Control of Continuous-Time Systems

Using the DT LQR design equations in Table 25.4, optimal digital controllers may be designed for continuous-time systems. In fact, standard techniques are available for determining a DT description

TABLE 25.4 Discrete-Time Linear Quadratic Regulator.

System model:	$x_{k+1} = Ax_k + Bu_k, \quad x_0 \text{ given.}$	(25.98)
Performance index:	$J = \frac{1}{2} \sum_0^{\infty} (x_k^T Q x_k + u_k^T R u_k)$	(25.99)
with	$Q \geq 0, \quad R > 0.$	
Optimal feedback control:	<i>Discrete-time algebraic Riccati equation:</i>	
	$0 = S - A^T S A + A^T S B (B^T S B + R)^{-1} B^T S A - Q.$	(25.100)
<i>Optimal feedback gain:</i>	$K = (B^T S B + R)^{-1} B^T S A.$	(25.101)
<i>Feedback control:</i>	$u_k = -K x_k.$	(25.102)
Optimal cost:	$J = \frac{1}{2} x_0^T S x_0.$	(25.103)

given the continuous-time dynamics $\dot{x} = Ax + Bu$ and a specified sampling period T . Then, the table allows the design of digital controllers, because the feedback gain Equation 25.102 is expressed in DT, meaning that it can be directly programmed on a microprocessor or digital signal processor (DSP) and applied every T seconds to the plant. The next example shows some of the issues involved in digital control design, including selection of the sampling period and discretization of the plant.

Example 25.6: Digital Inverted Pendulum Controller

In Example 25.3 a continuous-time controller was designed for an inverted pendulum on a cart; it is now desired to design a digital controller.

DISCRETE INVERTED PENDULUM DYNAMICS

The continuous-time inverted pendulum dynamics are given in Example 25.3. Standard techniques for system discretization are covered in the chapter on Digital Control. The time histories and closed-loop poles in Example 25.3 reveal that a sampling period of $T = 0.1$ sec is very small compared to the speed of the plant response (e.g., about 1/10 of the smallest plant time constant). Therefore, this sampling period is selected.

Using the MATLAB Control System Toolbox to compute the zero-order-hold/step-invariant sampled dynamics yields the system

$$x_{k+1} = \begin{bmatrix} 1.054386 & 0.101806 & 0 & 0 \\ 1.097473 & 1.054386 & 0 & 0 \\ -0.004944 & -0.000164 & 1 & 0.1 \\ -0.099770 & -0.004944 & 0 & 1 \end{bmatrix} x_k + \begin{bmatrix} -0.001009 \\ -0.020361 \\ 0.001001 \\ 0.020033 \end{bmatrix} u_k = Ax_k + Bu_k \quad (25.104)$$

where the state is $x_k = [\theta_k \quad \dot{\theta}_k \quad p_k \quad \dot{p}_k]^T$.

FIGURE 25.13 Response of inverted pendulum digital controller. (a) Rod angle $\theta(t)$ and cart position $p(t)$. (b) Control input $u(t)$.

The continuous system has poles at $s = 0, 0, 3.28, -3.28$. The discrete system has poles at $z = 1, 1, 1.3886, 0.7201$ which corresponds to the sampling transformation $z = e^{sT}$.

DIGITAL CONTROLLER DESIGN

To determine stabilizing control gains in

$$u_k = -Kx_k = -(k_\theta \theta_k + k_{\dot{\theta}} \dot{\theta}_k + k_p p_k + k_{\dot{p}} \dot{p}_k), \quad (25.105)$$

we may use the DT LQR in Table 25.4. Note that this is a *multiloop design problem*, yet the LQR approach easily deals with it. Trying weighting matrices of $R = 1, Q = \text{diag}\{10, 10, 1, 1\}$ and using the discrete ARE solver in MATLAB yields the gains $K = [-1.294 \quad -10.02 \quad 3.648 \quad 16.94]^T$ and corresponding closed-loop poles at $z = 0.37, 0.72, 0.82 \pm j.029$.

A simulation is easily performed to obtain the closed-loop response shown in Figure 25.13. It is very instructive to compare this with the response obtained in Example 25.3. The advantage of DT design is that the control input (2) may be computed every $T = 0.1$ s on a microprocessor and applied to the plant for real time control. The continuous-time feedback law needs to be applied using analog techniques or a very high sampling rate.

25.6 Optimal LQ Design for Polynomial Systems

The discussion thus far has focused on the state-space formulation. A dynamical system may be equally well described in transfer function or *polynomial form* as

$$A(z^{-1})y_k = z^{-d}B(z^{-1})u_k, \quad (25.106)$$

with y_k the output and u_k the control input. The *system delay* is denoted d . This is a DT formulation with z^{-1} denoting the unit delay. For simplicity we discuss the SISO case; these notions may be extended to multivariable polynomial systems using the *matrix fraction descriptions* of the plant. The

denominator polynomial

$$A(z^{-1}) = 1 + a_1 z^{-1} + a_2 z^{-2} + \dots + a_n z^{-n} \quad (25.107)$$

has roots specifying the system poles, and the numerator

$$B(z^{-1}) = b_0 + b_1 z^{-1} + \dots + b_m z^{-m} \quad (25.108)$$

has roots at the system zeros.

In contrast to the PI selected for state-space systems, which is a sum of squares, for polynomial systems, it is more convenient to select the *square of sums* PI

$$J_k = \left[\sum_{i=0}^{n_p} p_i y_{k+d-i} - \sum_{i=0}^{n_Q} q_i y_{k-i} \right]^2 + \left[\sum_{i=0}^{n_R} r_i u_{k-i} \right]^2. \quad (25.109)$$

The constants p_i, q_i, r_i are weighting coefficients (design parameters) selected by the engineer and w_k is a reference or command signal. Defining the *weighting polynomials*

$$\begin{aligned} P(z^{-1}) &= 1 + p_1 z^{-1} + \dots + p_{n_p} z^{-n_p}, \\ Q(z^{-1}) &= q_0 + q_1 z^{-1} + \dots + q_{n_Q} z^{-n_Q}, \\ R(z^{-1}) &= r_0 + r_1 z^{-1} + \dots + r_{n_R} z^{-n_R}, \end{aligned} \quad (25.110)$$

the PI may be written in the streamlined form

$$J_k = (P y_{k+d} - Q w_k)^2 + (R u_k)^2. \quad (25.111)$$

This is a very general sort of PI. For instance, the tracking problem may be solved if we select $P = Q = 1$, $R = r_0$, for then

$$J_k = (y_{k+d} - w_k)^2 + (r_0 u_k)^2 \quad (25.112)$$

and a delayed version of the output y_k tries to follow a reference input w_k . The system delay d is explicitly accounted for. Thus, the polynomial tracker is very easy to compute and implement. In fact, it is *causal*, in contrast to the state-space LQR tracker where a noncausal feedforward signal was needed.

As another example, the regulator problem results if the weights are selected as $P = 1, Q = 0, R = r_0$, for then

$$J_k = (y_{k+d})^2 + (r_0 u_k)^2 \quad (25.113)$$

and the control tries to hold the output at zero without using too much energy.

The optimal control u_k that minimizes the PI is straightforward to determine. In the minimum-phase core (e.g., all roots of $B(z^{-1})$ stable), one solves the *Diophantine equation*

$$1 = AF + z^{-d}G \quad (25.114)$$

for the intermediate polynomials $F(z^{-1})$ and $G(z^{-1})$. Well-known routines are available for this. In fact, one may simply divide $A(z^{-1})$ into 1 until the remainder has a multiplier of z^{-d} . Then the quotient is $F(z^{-1})$ and the remainder yields $G(z^{-1})$. In terms of the Diophantine equation solution, the optimal control sequence is then given by the equation

$$\left(PBF + \frac{r_0}{b_0} R \right) u_k = -PG y_k + Q w_k. \quad (25.115)$$

This is nothing but a *difference equation* that gives the current control u_k in terms of y_k, w_k , and previous values of the control; it is easily implemented using a digital computer or microprocessor. Figure 25.14

FIGURE 25.14 Optimal polynomial LQ regulator drawn as a two-degrees-of-freedom regulator.

shows the structure of the optimal LQ polynomial controller. Because it has a feedback and a feedforward component, it is called a *two-degrees-of-freedom regulator*. Such a controller can influence the closed-loop poles *as well as zeros*. Note that this controller actually requires full state feedback because the complete state is given by $y_k, y_{k-1}, \dots, y_{k-n}, u_{k-d}, u_{k-d-1}, \dots, u_{k-d-m}$.

Some fundamental points in polynomial LQ design, as contrasted to state-space design, are (1) the PI is a square of sums, (2) the role of the RE in state-space design is played by the Diophantine equation in polynomial design, and (3) the optimal tracker problem is easy to solve and implement since it is *causal*.

Example 25.7: Polynomial LQ Tracker

It is desired for the plant

$$y_k - 2y_{k-1} + \frac{3}{4}y_{k-2} = u_{k-1} - \frac{1}{2}u_{k-2} \tag{25.116}$$

to follow a given reference signal w_k using a fairly smooth control signal u_k . The control delay is $d = 1$. To accomplish the design, select the PI

$$J_k = (y_{k+1} - w_k)^2 + r^2(u_k - u_{k-1})^2. \tag{25.117}$$

This PI is motivated by Equation 25.112, but the *first difference* of the control is weighted to keep u_k smooth, as per the specifications. The scalar r is a *design parameter* used to tune the closed-loop performance at the end of the design (e.g., for suitable damping ratio, overshoot, etc.).

Inspecting the plant and PI, the polynomials defined in the discussion are

$$\begin{aligned} A(z^{-1}) &= 1 - 2z^{-1} + 0.75z^{-2}, & B(z^{-1}) &= 1 - 0.5z^{-1}, \\ P(z^{-1}) &= Q(z^{-1}) = 1, & R(z^{-1}) &= r(1 - z^{-1}). \end{aligned} \tag{25.118}$$

To find the required tracking controller, the Diophantine equation is easily solved (simply perform long division of $A(z^{-1})$ into 1 to obtain the quotient $F(z^{-1})$ and remainder $z^{-1}G(z^{-1})$), resulting in the intermediate quantities

$$\begin{aligned} F(z^{-1}) &= 1, \\ G(z^{-1}) &= 2 - 0.75z^{-1}. \end{aligned} \tag{25.119}$$

According to Equation 25.115, therefore, the control is given by

$$[(1 + r^2) - z^{-1}(0.5 + r^2)]u_k = -(2 - 0.75z^{-1})y_k + w_k. \tag{25.120}$$

The variable r is a *design parameter* that can be varied by the engineer as he performs computer simulations of the closed-loop system (1), (5). Then, based on the simulations, the best value of r is

selected and the resulting controller is applied to the actual plant. Selecting, for instance, $r = \frac{1}{2}$, yields the difference equation

$$1.25u_k = 0.75u_{k-1} - 2y_k + 0.75y_{k-1} + w_k, \quad (25.121)$$

which is easily solved for the current control input u_k in terms of u_{k-1} , current and previous values of y_k , and the current w_k . The controller is of the form shown in Figure 25.14.

25.7 Dynamic Programming and the HJB Equation

The Calculus of Variations approach to optimal control design yields the state equation, costate equation, and stationarity condition in Table 25.1. A second approach to optimal control is through Bellman's Optimality Principle. This principle is a cornerstone of optimal control theory and states:

“An optimal policy has the property that no matter what the previous decisions (i.e. controls) have been, the remaining decisions must constitute an optimal policy with regard to the state resulting from those previous decisions.”

We shall apply this to solve the optimal control problem, first for DT systems, then continuous-time systems.

25.7.1 Dynamic Programming for DT Systems

Consider the nonlinear DT plant

$$x_{k+1} = f(x_k) + g(x_k)u_k \quad (25.122)$$

with performance index over the time interval $[k, N]$ given by

$$J(x_k) = \phi(x_N, N) + \sum_{i=k}^{N-1} L(x_i, u_i) \quad (25.123)$$

It is desired to find a state variable feedback policy

$$u_k = h(x_k) \quad (25.124)$$

that minimizes the PI. The optimal cost is

$$J^*(x_k) = \min_{\bar{u}(k:N-1)} \left(\phi(x_N, N) + \sum_{i=k}^{N-1} L(x_i, u_i) \right) \quad (25.125)$$

where $\bar{u}(k : N - 1) = \{u_k, u_{k+1}, \dots, u_{N-1}\}$. The optimal control is

$$\bar{u}^* = \arg \min_{\bar{u}(k:N-1)} \left(\phi(x_N, N) + \sum_{i=k}^{N-1} L(x_i, u_i) \right) \quad (25.126)$$

These equations are very difficult to solve.

One can write (Equation 25.123) as

$$J(x_k) = L(x_k, u_k) + \phi(x_N, N) + \sum_{i=k+1}^{N-1} L(x_i, u_i) \quad (25.127)$$

or

$$J(x_k) = L(x_k, u_k) + J(x_{k+1}) \quad (25.128)$$

which is a difference equation equivalent to (Equation 25.123). That is, given a stabilizing policy $u_k = h(x_k)$, one can find its associated cost either by computing the infinite sum (Equation 25.123) or by solving the difference equation 25.128. The latter is far easier.

Equation 25.128 is known as the Bellman Equation and is the basis for a host of reinforcement learning methods that learn the optimal cost and feedback policy online in real-time by observing data along the system trajectories. See the Chapter 6.

In terms of the Bellman equation, one can write the optimal cost as

$$J^*(x_k) = \min_{\bar{u}(k:N-1)} (L(x_k, u_k) + J(x_{k+1})) \quad (25.129)$$

The importance of Bellman's Optimality Principle is that one may write this is as

$$J^*(x_k) = \min_{u_k} (L(x_k, u_k) + J^*(x_{k+1})) \quad (25.130)$$

with $J^*(x_{k+1})$ the optimal cost from time $k+1$ on.

This is known as the Bellman optimality equation or the HJB equation. This equation yields the optimal cost at time k in terms of the optimal cost at time $k+1$. Therefore, it leads to a backwards-in-time solution procedure for the optimal control problem. This procedure leads to a host of methods for solution collected under the general name of Dynamic Programming. DP leads to tractable solutions in many situations, particularly if there are control constraints; See [7]. Since it proceeds backwards in time, DP is an off-line planning method for solving the optimal control problem.

To solve the DT optimal control problem, one first solves the HJB, then finds the optimal control using

$$u_k^* = \arg \min_{u_k} (L(x_k, u_k) + J^*(x_{k+1})) \quad (25.131)$$

which is far simpler to effect than Equation 25.126.

Let us show what this boils down to in the DT LQR case. Consider the linear time-invariant DT system (Equation 25.96) with associated cost (Equation 25.99). For the LQR, it is known that the cost for any stabilizing state variable feedback (Equation 25.97) is quadratic in the state so that

$$J(x_k) = \frac{1}{2} \sum_{i=k}^{\infty} x_i^T Q x_i + u_i^T R u_i = \frac{1}{2} \sum_{i=k}^{\infty} x_i^T (Q + K^T R K) x_i = \frac{1}{2} x_k^T S x_k \quad (25.132)$$

For some matrix $S = S^T > 0$ to be determined. The closed-loop system is

$$x_{k+1} = (A - BK)x_k \equiv A_c x_k \quad (25.133)$$

For the DT LQR, Bellman's equation 25.128 is

$$x_k^T S x_k = x_k^T Q x_k + u_k^T R u_k + x_{k+1}^T S x_{k+1} \quad (25.134)$$

or

$$x_k^T S x_k = x_k^T Q x_k + u_k^T R u_k + (A x_k + B u_k)^T S (A x_k + B u_k) \quad (25.135)$$

whence the minimization (Equation 25.131) is easily performed by differentiating with respect to u_k to obtain

$$Ru_k + B^T S(Ax_k + Bu_k) = 0 \quad (25.136)$$

or

$$u_k = -(R + B^T SB)^{-1} B^T SAx_k \quad (25.137)$$

so the optimal feedback gain is

$$K = (R + B^T SB)^{-1} B^T SA. \quad (25.138)$$

Substituting this into the Bellman equation 25.135 and simplifying yields the DT HJB equation

$$A^T SA - S + Q - A^T SB(R + B^T SB)^{-1} B^T SA = 0. \quad (25.139)$$

This is exactly the DT ARE in Equation 25.100!

25.7.2 Dynamic Programming for Continuous-Time Systems

Consider the nonlinear dynamical system

$$\dot{x} = f(x, u) \quad (25.140)$$

with associated cost

$$J(x(t)) = \int_t^{\infty} L(x(\tau), u(\tau)) d\tau \quad (25.141)$$

To apply Bellman's optimality principle write this in the form

$$J(x(t)) = \int_t^{t+T} L(x(\tau), u(\tau)) d\tau + J(x(t+T)) \quad (25.142)$$

For any $T > 0$. This is exactly in the form of the DT Bellman equation. According to Bellman's principle, the optimal value is given in terms of this construction as

$$J^*(x(t)) = \min_{\bar{u}(t:t+T)} \left(\int_t^{t+T} L(x(\tau), u(\tau)) d\tau + J^*(x(t+T)) \right) \quad (25.143)$$

where $\bar{u}(t : t+T) = \{u(\tau) : t \leq \tau < t+T\}$. The optimal control is

$$u^*(x(t)) = \arg \min_{\bar{u}(t:t+T)} \left(\int_t^{t+T} L(x(\tau), u(\tau)) d\tau + J^*(x(t+T)) \right) \quad (25.144)$$

Let $J^*(x(t+T), t+T) = J^*(x(t) + \Delta x, t+T)$ and perform a Taylor series expansion of Equation 25.143 and approximate the integral to obtain

$$J^*(x(t)) = \min_{\bar{u}(t:t+T)} \left(LT + J^*(x(t)) + \left(\frac{\partial J^*}{\partial x} \right)^T \Delta x + \left(\frac{\partial J^*}{\partial t} \right)^T T \right) \quad (25.145)$$

However, from Equation 25.140 $\Delta x = f(x, u)T$ so that, manipulating the terms that do not depend on $u(t)$ one has

$$-\left(\frac{\partial J^*}{\partial t}\right)^T T = \min_{\bar{u}(t:t+T)} \left(LT + \left(\frac{\partial J^*}{\partial x}\right)^T f(x, u)T \right) \quad (25.146)$$

whence, letting $T \rightarrow 0$ one obtains

$$-\left(\frac{\partial J^*}{\partial t}\right)^T = \min_{u(t)} \left(L + \left(\frac{\partial J^*}{\partial x}\right)^T f(x, u) \right) \quad (25.147)$$

This is the CT HJB equation. In terms of the Hamiltonian function (Equation 25.4) one may write it as

$$-\left(\frac{\partial J^*}{\partial t}\right)^T = \min_{u(t)} \left(H(x, u, \frac{\partial J^*}{\partial x}, t) \right) \quad (25.148)$$

It is easily shown that, in the CT LQR case, this is exactly the CT RE (Equation 25.16).

26.1 Introduction

The complexity and high performance requirements of present-day industrial processes place increasing demands on control technology. The orthodox concept of driving a large system by a central computer has become unattractive for either economic or reliability reasons. New emerging notions are subsystems, interconnections, distributed computing, parallel processing, and information constraints, to mention a few. In complex systems, where databases are developed around the plants with distributed sources of data, a need for fast control action in response to local inputs and perturbations dictates the use of distributed (that is, decentralized) information and control structures.

The accumulated experience in controlling complex industrial processes suggests three basic reasons for using decentralized control structures:

1. Dimensionality
2. Information structure constraints
3. Uncertainty

Because the amount of computation required to analyze and control a system of large dimension grows faster than its size, it is beneficial to decompose the system into subsystems, and design controls for each subsystem independently based on the local subsystem dynamics and its interconnections. In this way, special structural features of a system can be used to devise feasible and efficient decentralized strategies for solving large control problems previously impractical to solve by “one-shot” centralized methods.

A restriction on what and where the information is delivered in a system is a standard feature of interconnected systems. For example, the standard automatic generation control in power systems is

decentralized because of the cost of excessive information requirements imposed by a centralized control strategy over distant geographic areas. The structural constraints on information make the centralized methods for control and estimation design difficult to apply, even to systems with small dimensions.

It is a common assumption that neither the internal nor the external nature of complex systems can be known precisely in deterministic or stochastic terms. The essential uncertainty resides in the interconnections between different parts of the system (subsystems). The local characteristics of each individual subsystem can be satisfactorily modeled in most practical situations. Decentralized control strategies are inherently robust with respect to a wide variety of structured and unstructured perturbations in the interconnections. The strategies can be made reliable to both interconnection and controller failures involving individual subsystems.

In decentralized control design, it is customary to use a wide variety of disparate methods and techniques that originated in system and control theory. Graph-theoretic methods have been devised to identify the special structural features of the system, which may help us cope with dimensionality problems and formulate a suitable decentralized control strategy. The concept of vector Lyapunov functions, each component of which determines the stability of a part of the system where others do not, is a powerful method for the stability analysis of large interconnected systems. Stochastic modeling and decentralized control have been used in a broad range of situations, involving LQG design, Kalman filtering, Markov processes, and stability analysis and design. Robustness considerations of decentralized control have been carried out since the early stages of its evolution, often preceding a similar development in the centralized control theory. Especially popular have been the adaptive decentralized schemes because of their flexibility and ability to cope efficiently with perturbations in both the interactions and the subsystems of a large system.

The objective of this chapter is to introduce the concept and methods of decentralized control. Due to a large number of results and techniques available, only the basic theory and practice of decentralized control will be reviewed. At the end of the chapter is a discussion of the larger background listing the books and survey papers on the subject. References related to more sophisticated treatment of decentralized control and the relevant applications are also discussed.

26.2 The Decentralized Control Problem

To introduce the decentralized control problem, consider two inverted penduli coupled by a spring as shown in Figure 26.1. The control objective is to keep the penduli in the upright position by applying feedback control via the inputs u_1 and u_2 . The linearized equations of motion in the vicinity of $\theta_1 = \theta_2 = 0$ are

$$\begin{aligned} m\ell^2\ddot{\theta}_1 &= mg\ell\theta_1 - ka^2(\theta_1 - \theta_2) + u_1, \\ m\ell^2\ddot{\theta}_2 &= mg\ell\theta_2 - ka^2(\theta_2 - \theta_1) + u_2. \end{aligned} \quad (26.1)$$

By choosing the state vector $x = (\theta_1, \dot{\theta}_1, \theta_2, \dot{\theta}_2)^T$ and the input vector $u = (u_1, u_2)^T$, the state space representation of the system is

$$\mathbf{S}: \dot{x} = \left[\begin{array}{cc|cc} 0 & 1 & 0 & 0 \\ \frac{g}{\ell} - \frac{ka^2}{m\ell^2} & 0 & \frac{ka^2}{m\ell^2} & 0 \\ \hline 0 & 0 & 0 & 1 \\ \frac{ka^2}{m\ell^2} & 0 & \frac{g}{\ell} - \frac{ka^2}{m\ell^2} & 0 \end{array} \right] x + \left[\begin{array}{c|c} 0 & 0 \\ \frac{1}{m\ell^2} & 0 \\ \hline 0 & 0 \\ 0 & \frac{1}{m\ell^2} \end{array} \right] u. \quad (26.2)$$

The fundamental restriction in choosing the feedback laws to control the system \mathbf{S} is that each input u_1 and u_2 can depend only on the local states $x_1 = (\theta_1, \dot{\theta}_1)^T$ and $x_2 = (\theta_2, \dot{\theta}_2)^T$ of the corresponding penduli,

FIGURE 26.1 Inverted penduli.

that is, $u_1 = u_1(x_1)$ and $u_2 = u_2(x_2)$. This restriction is called the *decentralized information structure constraint*.

Since the system S is linear, a natural choice is the linear control laws

$$u_1 = k_1^T x_1, \quad u_2 = k_2^T x_2 \tag{26.3}$$

where the feedback gain vectors $k_1 = (k_{11}, k_{12})^T$ and $k_2 = (k_{21}, k_{22})^T$ should be selected to *stabilize* the system S , that is, hold the penduli in the upright position.

In control design, it is fruitful to recognize the structure of the system S as an interconnection

$$\begin{aligned} S : \dot{x}_1 &= \begin{bmatrix} 0 & 1 \\ \alpha & 0 \end{bmatrix} x_1 + \begin{bmatrix} 0 \\ \beta \end{bmatrix} u_1 + e \begin{bmatrix} 0 & 0 \\ -\gamma & 0 \end{bmatrix} x_1 + e \begin{bmatrix} 0 & 0 \\ \gamma & 0 \end{bmatrix} x_2, \\ \dot{x}_2 &= \begin{bmatrix} 0 & 1 \\ \alpha & 0 \end{bmatrix} x_2 + \begin{bmatrix} 0 \\ \beta \end{bmatrix} u_2 + e \begin{bmatrix} 0 & 0 \\ \gamma & 0 \end{bmatrix} x_1 + e \begin{bmatrix} 0 & 0 \\ -\gamma & 0 \end{bmatrix} x_2, \end{aligned} \tag{26.4}$$

of two subsystems

$$\begin{aligned} S_1 : \dot{x}_1 &= \begin{bmatrix} 0 & 1 \\ \alpha & 0 \end{bmatrix} x_1 + \begin{bmatrix} 0 \\ \beta \end{bmatrix} u_1, \\ S_2 : \dot{x}_2 &= \begin{bmatrix} 0 & 1 \\ \alpha & 0 \end{bmatrix} x_2 + \begin{bmatrix} 0 \\ \beta \end{bmatrix} u_2, \end{aligned} \tag{26.5}$$

where $\alpha = g/l$, $\beta = 1/ml^2$, $\gamma = \bar{a}^2 k/ml^2$, and $e = (a/\bar{a})^2$. One reason is that, in designing control for interconnected systems, the designer has to account for essential *uncertainty* in the interconnections among the subsystems. Though models of the subsystems are commonly available with sufficient accuracy, the shape and size of the interconnections cannot be predicted satisfactorily either for modeling or operational reasons. In the example, the interconnection parameter $e = a/\bar{a}$ is the uncertain height of the spring which is normalized by its nominal value \bar{a} .

An equally important reason for decomposition is present when controlling large dynamic systems. In complex systems with many variables, most of the variables are *weakly coupled*, if coupled at all, and the behavior of the overall system is dominated by strongly connected variables. Considerable conceptual and numerical simplification can be gained by controlling the strongly coupled variables with decentralized control.

26.3 Plant and Feedback Structures

Consider a linear constant system

$$\begin{aligned} \mathbf{S}: \dot{x} &= Ax + Bu, \\ y &= Cx, \end{aligned} \quad (26.6)$$

as an interconnected system

$$\begin{aligned} \mathbf{S}: \dot{x}_i &= A_i x_i + B_i u_i + \sum_{j \in \mathcal{N}} (A_{ij} x_j + B_{ij} u_j), \\ y_i &= C_i x_i + \sum_{j \in \mathcal{N}} C_{ij} x_j, \quad i \in \mathcal{N}, \end{aligned} \quad (26.7)$$

which is composed of N subsystems

$$\begin{aligned} \mathbf{S}_i: \dot{x}_i &= A_i x_i + B_i u_i, \\ y_i &= C_i x_i, \quad i \in \mathcal{N}, \end{aligned} \quad (26.8)$$

where $x_i(t) \in \mathbb{R}^{n_i}$, $u_i(t) \in \mathbb{R}^{m_i}$, $y_i(t) \in \mathbb{R}^{\ell_i}$ are the state, input, and output of the subsystem \mathbf{S}_i at a fixed time $t \in \mathbb{R}$. All matrices have proper dimensions, and $\mathcal{N} = \{1, 2, \dots, N\}$. At present we are interested in *disjoint* decompositions, that is,

$$\begin{aligned} x &= (x_1^T, x_2^T, \dots, x_N^T)^T, \\ u &= (u_1^T, u_2^T, \dots, u_N^T)^T, \\ y &= (y_1^T, y_2^T, \dots, y_N^T)^T, \end{aligned} \quad (26.9)$$

and where $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, and $y(t) \in \mathbb{R}^\ell$ are the state, input, and output of the overall system \mathbf{S} , so that

$$\begin{aligned} \mathbb{R}^n &= \mathbb{R}^{n_1} \times \mathbb{R}^{n_2} \times \dots \times \mathbb{R}^{n_N}, \\ \mathbb{R}^m &= \mathbb{R}^{m_1} \times \mathbb{R}^{m_2} \times \dots \times \mathbb{R}^{m_N}, \\ \mathbb{R}^\ell &= \mathbb{R}^{\ell_1} \times \mathbb{R}^{\ell_2} \times \dots \times \mathbb{R}^{\ell_N}. \end{aligned} \quad (26.10)$$

A compact description of the interconnected system \mathbf{S} is

$$\begin{aligned} \mathbf{S}: \dot{x} &= A_D x + B_D u + A_C x + B_C u \\ y &= C_D x + C_C x, \end{aligned} \quad (26.11)$$

where

$$\begin{aligned} A_D &= \text{diag}\{A_1, A_2, \dots, A_N\}, \\ B_D &= \text{diag}\{B_1, B_2, \dots, B_N\}, \\ C_D &= \text{diag}\{C_1, C_2, \dots, C_N\}, \end{aligned} \quad (26.12)$$

and the coupling block matrices are

$$A_C = (A_{ij}), \quad B_C = (B_{ij}), \quad C_C = (C_{ij}). \quad (26.13)$$

The collection of N decoupled subsystems is described by

$$\begin{aligned} \mathbf{S}_D: \dot{x} &= A_D x + B_D u \\ y &= C_D x, \end{aligned} \quad (26.14)$$

obtained from (Equation 26.11) by setting the coupling matrices to zero.

Important special classes of interconnected systems are input ($B_C = 0$) and output ($C_C = 0$) decentralized systems, where inputs and outputs are not shared among the subsystems. Input–output decentralized systems are described as

$$\begin{aligned} \mathbf{S} : \dot{x} &= A_D x + B_D u + A_C x \\ y &= C_D x, \end{aligned} \quad (26.15)$$

where both B_C and C_C are zero. This structural feature helps to a great extent when decentralized controllers and estimators are designed for large plants.

A *static decentralized state feedback*,

$$u = -K_D x, \quad (26.16)$$

is characterized by a block-diagonal gain matrix,

$$K_D = \text{diag}\{K_1, K_2, \dots, K_N\}, \quad (26.17)$$

which implies that each subsystem \mathbf{S}_i has its individual control law,

$$u_i = -K_i x_i, \quad i \in \mathcal{N}, \quad (26.18)$$

with a constant gain matrix K_i . The control law u of Equation 26.16, which is equivalent to the totality of subsystem control laws (Equation 26.18), obeys the decentralized information structure constraint requiring that each subsystem \mathbf{S}_i is controlled on the basis of its locally available state x_i . The closed-loop system is described as

$$\hat{\mathbf{S}} : \dot{x} = (A_D - B_D K_D C_D) x + A_C x. \quad (26.19)$$

When *dynamic output feedback* is used under decentralized constraints, then controllers of the following type are considered:

$$\begin{aligned} \mathbf{C}_i : \dot{z}_i &= F_i z_i + G_i y_i, \\ u_i &= -H_i z_i - K_i y_i, \quad i \in \mathcal{N}, \end{aligned} \quad (26.20)$$

which can be written in a compact form as a single decentralized controller defined as

$$\begin{aligned} \mathbf{C}_D : \dot{z} &= F_D z + G_D y, \\ u &= -H_D z - K_D y, \end{aligned} \quad (26.21)$$

where

$$\begin{aligned} z &= (z_1^T, z_2^T, \dots, z_N^T)^T, \quad y = (y_1^T, y_2^T, \dots, y_N^T)^T, \\ u &= (u_1^T, u_2^T, \dots, u_N^T)^T, \end{aligned} \quad (26.22)$$

are the state $z \in \mathbb{R}^r$, input $y \in \mathbb{R}^\ell$, and output $u \in \mathbb{R}^m$ of the controller \mathbf{C}_D . By combining the system \mathbf{S} and the decentralized dynamic controller \mathbf{C}_D , we get the composite closed-loop system as

$$\mathbf{S} \& \mathbf{C}_D : \begin{bmatrix} \dot{x} \\ \dot{z} \end{bmatrix} = \begin{bmatrix} A_D - B_D K_D C_D + A_C & -B_D H_D \\ G_D C_D & F_D \end{bmatrix} \begin{bmatrix} x \\ z \end{bmatrix}. \quad (26.23)$$

26.4 Decentralized Stabilization

The fundamental problem in decentralized control theory and practice is choosing individual subsystem inputs to stabilize the overall interconnected system. In the previous section, the plant structures have been described, where the plant, inputs and outputs are all decomposed with each local controller responsible for the corresponding subsystem. While this is the most common situation in practice, it is by no means all inclusive. It is often advantageous, and sometime necessary, to decentralize the inputs and outputs without decomposing the plant. This is the situation that we consider first.

26.4.1 Decentralized Inputs and Outputs

Suppose that only the inputs and outputs, but not states, of system \mathbf{S} in Equation 26.6 are partitioned as in Equation 26.9, and \mathbf{S} is described as

$$\begin{aligned} \mathbf{S} : \dot{x} &= Ax + \sum_{i \in \mathcal{N}} \tilde{B}_i u_i, \\ y_i &= \tilde{C}_i x, \quad i \in \mathcal{N}. \end{aligned} \quad (26.24)$$

Then, the controllers C_i of Equation 26.20 still operate on local measurements y_i to generate local controls u_i , but now they are collectively responsible for the whole system. In this case,

$$\mathbf{S} \& \mathbf{C}_D : \begin{bmatrix} \dot{x} \\ \dot{z} \end{bmatrix} = \begin{bmatrix} A - BK_D C & -BH_D \\ G_D C & F_D \end{bmatrix} \begin{bmatrix} x \\ z \end{bmatrix}. \quad (26.25)$$

It is well-known that without the decentralization constraint on the controller, the closed-loop system of Equation 26.25 can be stabilized if, and only if, the uncontrollable or unobservable modes of the open-loop system \mathbf{S} are stable; or equivalently, the set of (centralized) fixed modes of \mathbf{S} , which is defined as

$$\Lambda_C = \bigcap_K \sigma(A - BKC) \quad (26.26)$$

is included in the open left half plane, where $\sigma(\cdot)$ denotes the set of eigenvalues of the indicated matrix. This basic result has been extended in [34] to decentralized control of \mathbf{S} , where it was shown that the closed-loop system Equation 26.25 can be made stable with suitable choice of the decentralized controllers C_i if, and only if, the set of decentralized fixed modes

$$\Lambda_D = \bigcap_{K_D} \sigma(A - BK_D C) = \bigcap_{K_1, \dots, K_N} \sigma(A - \sum_{i \in \mathcal{N}} \tilde{B}_i K_i \tilde{C}_i) \quad (26.27)$$

is included in the open left half plane.

The result of [34] has been followed by extensive research on the following topics:

- State space and frequency domain characterization of decentralized fixed modes
- Development of various techniques for designing decentralized controllers (e.g., using static output feedback in all but one channel, distributing the control effort among channels, sequential stabilization, etc.)
- Generalization of the concept of decentralized fixed modes to arbitrary feedback structure constraints
- Formulation of the concept of structurally fixed modes, and their algebraic and graph-theoretical characterization

A useful and simple characterization of decentralized fixed modes was provided in [1]. For any subset $\mathcal{I} = \{i_1, \dots, i_p\}$ of the index set \mathcal{N} , let $\mathcal{I}^C = \{j_1, \dots, j_{N-p}\}$ denote the complement of \mathcal{I} in \mathcal{N} , and define

$$\begin{aligned} \tilde{B}_{\mathcal{I}} &= [\tilde{B}_{i_1}, \tilde{B}_{i_2}, \dots, \tilde{B}_{i_p}], \\ \tilde{C}_{\mathcal{I}^C} &= \begin{bmatrix} \tilde{C}_{j_1} \\ \tilde{C}_{j_2} \\ \vdots \\ \tilde{C}_{j_{N-p}} \end{bmatrix}. \end{aligned} \quad (26.28)$$

Then a complex number $\lambda \in \mathbb{C}$ is a decentralized fixed mode of \mathbf{S} if, and only if,

$$\text{rank} \begin{bmatrix} A - \lambda I & \tilde{B}_{\mathcal{I}} \\ \tilde{C}_{\mathcal{I}^c} & 0 \end{bmatrix} < n \quad (26.29)$$

for some $\mathcal{I} \subset \mathcal{N}$. This result relates decentralized fixed modes to transmission zeros of the systems $(A, \tilde{B}_{\mathcal{I}}, \tilde{C}_{\mathcal{I}^c})$, called the complementary subsystems. Thus, appearance of a fixed mode corresponds to a special pole-zero cancellation, which can not be removed by constant decentralized feedback. However, under mild conditions, such fixed modes can be eliminated by time-varying decentralized feedback.

The characterization of decentralized fixed modes above prompts a generalization of the concept to arbitrary feedback structures. Let $\bar{K} = (\bar{k}_{ij})$ be an $m \times l$ binary matrix such that $\bar{k}_{ij} = 1$ if, and only if, a feedback link from output y_j to input u_i is allowed. Thus \bar{K} specifies a constraint on the feedback structure, a special case of which is decentralized feedback. In this case, permissible controllers have the structure

$$\begin{aligned} \mathbf{C}_{\bar{K}} : \dot{z}_i &= F_i z_i + \sum_{j \in \mathcal{J}_i} g_{ij} y_j \\ u_i &= -h_i^T z_i - \sum_{j \in \mathcal{J}_i} k_{ij} y_j \end{aligned} \quad (26.30)$$

where $\mathcal{J}_i = \{j : \bar{k}_{ij} = 1\}$.

Let K denote any feedback matrix conforming to the structure of \bar{K} , that is, one with $k_{ij} = 0$ whenever $\bar{k}_{ij} = 0$. Then, the set

$$\Lambda_{\bar{K}} = \bigcap_K \sigma(A - BKC) \quad (26.31)$$

can conveniently be defined as the set of fixed modes with respect to the decentralized feedback structure constraint specified by \bar{K} . Then the closed-loop system consisting of \mathbf{S} and the constrained controller $\mathbf{C}_{\bar{K}}$ can be stabilized if, and only if, $\Lambda_{\bar{K}}$ is included in the open left half-plane. Finally, it remains to characterize $\Lambda_{\bar{K}}$ as in Equation 26.29. This, however, is quite automatic; consider the index sets $\mathcal{I} \subset \mathcal{M} = \{1, 2, \dots, M\}$ and replace \mathcal{I}^c by $\mathcal{J} = \cup_{i \in \mathcal{I}^c} \mathcal{J}_i$, where now \mathcal{I}^c refers to the complement of \mathcal{I} in \mathcal{M} .

26.4.2 Structural Analysis

Structural analysis of large scale systems via graph-theoretic concepts and methods offers an appealing alternative to quantitative analysis which often faces difficulties due to high dimensionality and lack of exact knowledge of system parameters. Equipped with the powerful tools of graph theory, structural analysis provides valuable information concerning certain qualitative properties of the system under study by practical tests and algorithms [30].

One of the earliest problems of structural analysis is the graph-theoretic formulation of controllability [20]. Consider an uncontrollable pair (A, B) . Loss of controllability is either due to a perfect matching of system parameters or due to an insufficient number of nonzero parameters, indicating a lack of sufficient linkage among system variables. In the latter case, the pair (A, B) is structurally uncontrollable in the sense that all pairs having the same structure as (A, B) are uncontrollable. Since the structure of (A, B) can be described by a directed graph (as explained below for a more general case), structural controllability can be checked by graph-theoretic means. Indeed, (A, B) is structurally controllable if, and only if, the system graph is input reachable (that is, each state variable is affected directly or indirectly by at least one input variable), and contains no dilations (that is, no subset of state variables exists whose number exceeds the total number of all state and input variables directly affecting these variables). These two conditions are equivalent to the spanning of the system graph by a minimal subgraph, called a cactus, which has a special structure.

The idea of treating controllability in a structural framework has led to formulation and graph-theoretic characterization of *structurally fixed modes* under constrained feedback [26]. Let $\mathbf{D} = (\mathcal{V}, \mathcal{E})$

be a directed graph associated with the system \mathbf{S} of Equation 26.6, where $\mathcal{V} = \mathcal{U} \cup \mathcal{X} \cup \mathcal{Y}$ is a set of vertices corresponding to inputs, states, and outputs of \mathbf{S} , and \mathcal{E} is a set of directed edges corresponding to nonzero parameters of the system matrices A, B , and C . To every nonzero a_{ij} , there corresponds an edge from vertex x_j to vertex x_i , to every nonzero b_{ij} , an edge from u_j to x_i , and to every nonzero c_{ij} , one from x_j to y_i . Given a feedback pattern \bar{K} and adding to \mathbf{D} a feedback edge from y_j to u_i for every $\bar{k}_{ij} = 1$, one gets a digraph $\mathbf{D}_{\bar{K}} = (\mathcal{V}, \mathcal{E} \cup \mathcal{E}_{\bar{K}})$ completely describing the structure of both the system \mathbf{S} and the feedback constraint specified by \bar{K} .

Two systems are said to be structurally equivalent if they have the same system graphs. A system \mathbf{S} is said to have structurally fixed modes with respect to a given \bar{K} if every system structurally equivalent to \mathbf{S} has fixed modes with respect to \bar{K} . Having structurally fixed modes is a common property of a class of systems described by the same system graph; if a system has no structurally fixed modes, then either it has no fixed modes, or if it does, arbitrarily small perturbations of system parameters can eliminate the fixed modes. As a result, if a system has no structurally fixed modes with respect to \bar{K} , then generically it can be stabilized by a constrained controller of the form defined in Equation 26.30.

It was shown in [26] that a system \mathbf{S} has no structurally fixed modes with respect to a feedback pattern \bar{K} if, and only if

1. all state vertices of $\mathbf{D}_{\bar{K}}$ are covered by vertex disjoint cycles, and
2. no strong component of $\mathbf{D}_{\bar{K}}$ contains only state vertices, where a strong component is a maximal subgraph whose vertices are reachable from each other.

This simple graph-theoretic criterion has been used in an algorithmic way in problems such as choosing a minimum number of feedback links (or, if each feedback link is associated with a cost, choosing the cheapest feedback pattern) that avoid structurally fixed modes. As an example, consider a system with a system graph as in Figure 26.2. Let the costs of setting up feedback links (dotted lines) from each output to each input be given by a matrix

$$\begin{bmatrix} 6 & 2 \\ 3 & 7 \end{bmatrix}.$$

FIGURE 26.2 System graph.

It can easily be verified that any feedback pattern of the form

$$\begin{bmatrix} 1 & * \\ * & * \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} * & 1 \\ 1 & * \end{bmatrix},$$

where $*$ stands for either a 0 or a 1, avoids structurally fixed modes. Clearly, the feedback patterns which contain the least number of links and which cost the least are, respectively,

$$\bar{K}_1 = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \quad \text{or} \quad \bar{K}_2 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}.$$

26.4.3 Decentrally Stabilizable Structures

Consider an interconnected system

$$\begin{aligned} \mathbf{S} : \dot{x}_i &= A_i x_i + B_i (u_i + \sum_{j \in \mathcal{N}} D_{ij} x_j) \\ y_i &= x_i \quad i \in \mathcal{N} \end{aligned} \quad (26.32)$$

which is a special case of the system \mathbf{S} in Equation 26.7 in that $A_{ij} = B_i D_{ij}$, $B_{ij} = 0$, $C_i = I$, and $C_{ij} = 0$. Assuming that the decoupled subsystems described by the pairs (A_i, B_i) are controllable, it is easy to verify that \mathbf{S} has no decentralized fixed modes. Thus \mathbf{S} can be stabilized using a decentralized dynamic feedback controller of the form (Equation 26.21). However, because the subsystem outputs are the states, there should be no need to use dynamic controllers.

Choose the decentralized constant state feedbacks in Equation 26.18 to place the subsystem poles at $-\mu_{il}\rho$, $i \in \mathcal{N}$, $l = 1, 2, \dots, n_i$, where $-\mu_{il}$ are distinct negative real numbers, and ρ is a parameter. Then a suitable change of coordinate frame transforms the closed-loop system of Equation 26.19 into the form

$$\hat{\mathbf{S}} : \dot{x} = (-\rho M + \hat{A}_C)x, \quad (26.33)$$

where $M = \text{diag}\{M_1, M_2, \dots, M_N\}$, with $M_i = \text{diag}\{\mu_{i1}, \mu_{i2}, \dots, \mu_{in_i}\}$, and \hat{A}_C is independent of the parameter ρ . Clearly, $\hat{\mathbf{S}}$ is stable for a sufficiently large ρ .

The success of this high-gain decentralized stabilization technique results from the special structure of the interconnections among the subsystems. The interconnections from other subsystems affect a particular subsystem in the same way its local input does. This makes it possible to neutralize potentially destabilizing effects of the interconnections by a local state feedback and provide a high degree of stability to the decoupled subsystems. This special interconnection structure is termed the “matching conditions” [18].

Decentralized stabilizability of interconnected systems satisfying the matching conditions has motivated research in characterizing other decentrally stabilizable interconnection structures. Below, another such interconnection structure is described, where single-input subsystems are considered for convenience.

Let the interconnected system be described as

$$\mathbf{S} : \dot{x}_i = A_i x_i + b_i u_i + \sum_{j \in \mathcal{N}} A_{ij} x_j, \quad i \in \mathcal{N} \quad (26.34)$$

where, without loss of generality, the subsystem pairs (A_i, b_i) are assumed to be in controllable canonical form. For each interconnection matrix A_{ij} , define an integer m_{ij} as

$$m_{ij} = \begin{cases} \max\{q - p : a_{pq}^{ij} \neq 0\}, & A_{ij} \neq 0, \\ -n, & A_{ij} = 0, \end{cases} \quad (26.35)$$

Thus, m_{ij} is the distance between the main diagonal and a line parallel to the main diagonal which borders all nonzero elements of A_{ij} .

For an index set $\mathcal{I} \subset \mathcal{N}$, let \mathcal{I}_p denote any permutation of \mathcal{I} . Then, the system \mathbf{S} in Equation 26.34 is stabilizable by decentralized constant state feedback if

$$\sum_{\substack{i \in \mathcal{I} \\ j \in \mathcal{I}_p}} (m_{ij} - 1) < 0 \quad (26.36)$$

for all \mathcal{I} and all permutations \mathcal{I}_p [14,30]. In the case of matching interconnections, $m_{ij} = n_j - n_i$, so that Equation 26.36 guarantees decentralized stabilizability even when the elements of the interconnection matrices A_{ij} are bounded nonlinear, time-varying functions of the state variables. Therefore, the condition (Equation 26.36) and, thus, the matching conditions, are indeed structural conditions.

26.4.4 Vector Lyapunov Functions

A general way to establish the stability of nonlinear interconnected systems is to apply the Matrosov–Bellman concept of vector Lyapunov functions [17]. The concept has been developed to provide an efficient method of checking the stability of linear interconnected systems controlled by decentralized feedback [30]. First, each subsystem is stabilized using local state or output feedback. Then, for each stable closed-loop (but decoupled) subsystem, a Lyapunov function is chosen using standard methods. These functions are stacked to form a vector of functions, which can then be used to form a single scalar Lyapunov function for the overall system. The function establishes stability if we show positivity of the leading principal minors of a constant aggregate matrix whose dimension equals the number of subsystems.

Consider the linear interconnected system of Equation 26.7,

$$\mathbf{S} : \dot{x}_i = A_i x_i + B_i u_i + \sum_{j \in \mathcal{N}} e_{ij} A_{ij} x_j, \quad i \in \mathcal{N}, \quad (26.37)$$

where the output y_i is not included and $B_{ij} = 0$. We inserted the elements of $e_{ij} \in [0, 1]$ of the $N \times N$ interconnection matrix $E = (e_{ij})$ to capture the presence of uncertainty in coupling between the subsystems

$$\mathbf{S}_i : \dot{x}_i = A_i x_i + B_i u_i, \quad (26.38)$$

as illustrated by the example of the two penduli above.

We assume that each pair (A_i, B_i) is controllable and assign the eigenvalues $-\sigma_1^i \pm j\omega_1^i, \dots, -\sigma_{p_i}^i \pm j\omega_{p_i}^i, \dots, -\sigma_{2p_i+1}^i, \dots, -\sigma_{n_i}^i$ to each closed-loop subsystem

$$\hat{\mathbf{S}}_i : \dot{x}_i = (A_i - B_i K_i) x_i \quad (26.39)$$

by applying decentralized feedback

$$u_i = -K_i x_i. \quad (26.40)$$

Using a nonsingular transformation,

$$x_i = T_i \tilde{x}_i, \quad (26.41)$$

we can obtain the closed-loop subsystems as

$$\tilde{\mathbf{S}}_i : \dot{\tilde{x}}_i = \Lambda_i \tilde{x}_i, \quad (26.42)$$

where the matrix $\Lambda_i = T_i^{-1}(A_i - B_i K_i)T_i$ has the diagonal form

$$\Lambda_i = \text{diag} \left\{ \begin{bmatrix} -\sigma_1^i & \omega_1^i \\ -\omega_1^i & -\sigma_1^i \end{bmatrix}, \dots, \begin{bmatrix} -\sigma_{p_i}^i & \omega_{p_i}^i \\ -\omega_{p_i}^i & -\sigma_{p_i}^i \end{bmatrix}, -\sigma_{2p_i+1}^i, \dots, -\sigma_{n_i}^i \right\}. \quad (26.43)$$

For each transformed subsystem, there exists a suitable Lyapunov function $v : \mathbb{R}^{n_i} \rightarrow \mathbb{R}_+$ of the form

$$v_i(\tilde{x}_i) = (\tilde{x}_i^T H_i \tilde{x}_i)^{\frac{1}{2}}, \quad (26.44)$$

where $H_i = I_i$ is the solution of the Lyapunov matrix equation

$$\Lambda_i H_i + H_i \Lambda_i = -G_i \quad (26.45)$$

for $G_i = \text{diag}\{\sigma_1^i, \sigma_1^i, \dots, \sigma_{p_i}^i, \sigma_{2p_i+1}^i, \dots, \sigma_{n_i}^i\}$.

To determine the stability of the overall interconnected closed-loop system

$$\tilde{\mathbf{S}} : \dot{\tilde{x}}_i = \Lambda_i \tilde{x}_i + \sum_{j \in \mathcal{N}} e_{ij} \Delta_{ij} \tilde{x}_j \quad (26.46)$$

from the stability of the decoupled closed-loop subsystems $\tilde{\mathbf{S}}_i$, we consider subsystem functions v_i as components of a *vector Lyapunov function* $v = (v_1, v_2, \dots, v_N)^T$, and form a candidate Lyapunov function $V : \mathbb{R}^n \rightarrow \mathbb{R}_+$ for the overall system $\tilde{\mathbf{S}}$ as

$$V(\tilde{x}) = \sum_{i \in \mathcal{N}} d_i v_i(\tilde{x}_i), \quad (26.47)$$

where the existence of positive numbers d_i for stability of $\tilde{\mathbf{S}}$ has yet to be established, and $\Delta_{ij} = T_i^{-1} A_{ij} T_j$.

Taking the total time derivative of $V(\tilde{x})$ with respect to $\tilde{\mathbf{S}}$, after lengthy but straightforward computations [30],

$$\dot{V}(\tilde{x}) \leq -d^T \bar{W} z, \quad (26.48)$$

with $d = (d_1, d_2, \dots, d_N)^T$, $z = (\|\tilde{x}_1\|, \|\tilde{x}_2\|, \dots, \|\tilde{x}_N\|)^T$, and $\bar{W} = (\bar{w}_{ij})$ is the $N \times N$ aggregate matrix defined as

$$\bar{w}_{ij} = \begin{cases} \frac{1}{2} \sigma_m^i - \bar{e}_{ii} \lambda_M^{1/2}(\Delta_{ii}^T \Delta_{ii}), & i = j \\ -\bar{e}_{ij} \lambda_M^{1/2}(\Delta_{ij}^T \Delta_{ij}), & i \neq j \end{cases} \quad (26.49)$$

where σ_m^i is the minimal value of all σ_k^i , and $\lambda_M(\cdot)$ is the maximal eigenvalue of the indicated matrix.

The elements \bar{e}_{ij} of the fundamental interconnection matrix $\bar{E} = (\bar{e}_{ij})$ are binary numbers defined as

$$\bar{e}_{ij} = \begin{cases} 1, & \mathbf{S}_j \text{ acts on } \mathbf{S}_i \\ 0, & \mathbf{S}_j \text{ does not act on } \mathbf{S}_i. \end{cases} \quad (26.50)$$

In this way, the binary matrix describes the basic interconnection structure of the system \mathbf{S} . In the case of two penduli,

$$\bar{E} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}. \quad (26.51)$$

It has been shown in [30] that stability of $-\bar{W}$ (all eigenvalues of $-\bar{W}$ have negative real parts) implies stability of the closed-loop system $\tilde{\mathbf{S}}$ and, hence, $\hat{\mathbf{S}}$. To explain this fact, we note first that $w_{ii} > 0$, $w_{ij} \leq 0$ ($i \neq j$), which makes \bar{W} an M -matrix (e.g., [30]) if, and only if, there exists a positive vector d ($d_i > 0$, $i \in \mathcal{N}$), so that the vector

$$c^T = d^T \bar{W} \quad (26.52)$$

is a positive vector as well. Positivity of c and d imply $V(\tilde{x}) > 0$ and $\dot{V}(\tilde{x}) < 0$ and, therefore, stability of $\hat{\mathbf{S}}$ by the standard Lyapunov argument. Finally, the M -matrix property of \bar{W} is equivalent to stability of $-\bar{W}$.

Several comments are in order. First, we note that the M -matrix property of \bar{W} can be tested by a simple determinantal condition

$$\begin{vmatrix} \bar{w}_{11} & \bar{w}_{12} & \cdots & \bar{w}_{1k} \\ \bar{w}_{21} & \bar{w}_{22} & \cdots & \bar{w}_{2k} \\ \cdots & \cdots & \cdots & \cdots \\ \bar{w}_{k1} & \bar{w}_{k2} & \cdots & \bar{w}_{kk} \end{vmatrix} > 0, \quad k \in \mathcal{N}. \quad (26.53)$$

Another important feature of the concept of vector Lyapunov functions is the *robustness* information about decentrally stabilized interconnected system \hat{S} . The determinantal condition (Equation 26.53) is equivalent to the quasidominant diagonal property of \bar{W} ,

$$\bar{w}_{ii} > d_i^{-1} \sum_{j \neq i}^N d_j |\bar{w}_{ij}|, \quad i \in \mathcal{N}. \quad (26.54)$$

where the d_i 's are positive numbers. From Equation 26.54, it is obvious that, if \bar{W} is an M -matrix, so is W for any $E \leq \bar{E}$, where the inequality is taken element by element; the system \hat{S} is *connectively stable* [30]. When a system is connectively stabilized by decentralized feedback, stability is robust and can tolerate variations in coupling among the subsystems. When the two penduli are stabilized for any given position \bar{a} of the spring, including the entire length ℓ of the penduli, the penduli are stable for any position $a \leq \bar{a}$. In other words, if the penduli are stabilized for the fundamental interconnection matrix \bar{E} of (51), they are stabilized for any interconnection matrix

$$E = \begin{bmatrix} e & e \\ e & e \end{bmatrix}, \quad (26.55)$$

whenever $e \in [0, 1]$.

Finally, the decentrally stabilized system can tolerate nonlinearities in the interconnections among the subsystems. The nonlinear interconnections need not be known since only their size is required to be limited. Once the closed-loop system \hat{S} is shown to be stable, it follows [30] that a nonlinear time-varying version

$$\hat{S}_N : \dot{\tilde{x}}_i = (A_i - B_i K_i) \tilde{x}_i + h_i(t, \tilde{x}), \quad i \in \mathcal{N} \quad (26.56)$$

of \hat{S} is connectively stable, provided the conical constraints

$$\|h_i(t, \tilde{x})\| \leq \sum_{j=1}^N \bar{e}_{ij} \xi_{ij} \|\tilde{x}_j\|, \quad i \in \mathcal{N} \quad (26.57)$$

on interconnection functions $h_i : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^{n_i}$ hold, where the nonnegative numbers ξ_{ij} do not exceed $\lambda_M^{1/2}(\Delta_{ij}^T \Delta_{ij})$. This robustness result is useful in practice because, typically, interconnections are poorly known, or they are changing during operation of the controlled system.

26.5 Optimization

There is no general method for designing optimal decentralized controls for interconnected systems, even if they are linear and time invariant. For this reason, standard design practice is to optimize each decoupled subsystem using linear quadratic (LQ) control laws. Then, suboptimality of the interconnected closed-loop system, which is driven by the union of the locally optimal LQ control laws, is determined with respect to the sum of the quadratic costs chosen for the subsystems. The suboptimal decentralized control design is attractive because, under relatively mild conditions, suboptimality implies stability.

Furthermore, the degree of suboptimality can serve as a measure of robustness with respect to a wide spectrum of uncertainties residing in both the subsystems and their interactions.

Consider again the interconnected system

$$\mathbf{S} : \dot{x}_i = A_i x_i + B_i u_i + \sum_{j \in \mathcal{N}} A_{ij} x_j, \quad i \in \mathcal{N} \quad (26.58)$$

in the compact form

$$\mathbf{S} : \dot{x} = A_D x + B_D u + A_C x. \quad (26.59)$$

We assume that the subsystems

$$\mathbf{S}_i : \dot{x}_i = A_i x_i + B_i u_i \quad (26.60)$$

or, equivalently, their union

$$\mathbf{S} : \dot{x} = A_D x + B_D u, \quad (26.61)$$

is controllable, that is, all pairs (A_i, B_i) are controllable.

With \mathbf{S}_D we associate a quadratic cost

$$J_D(x_0, u) = \int_0^\infty (x^T Q_D x + u^T R_D u) dt, \quad (26.62)$$

where $Q_D = \text{diag}\{Q_1, Q_2, \dots, Q_N\}$ is a symmetric nonnegative definite matrix, $R_D = \text{diag}\{R_1, R_2, \dots, R_N\}$ is a symmetric positive definite matrix, and the pair $(A_D, Q_D^{1/2})$ is observable. The cost J_D can be considered as a sum of subsystem costs

$$J_i(x_{i0}, u_i) = \int_0^\infty (x_i^T Q_i x_i + u_i^T R_i u_i) dt. \quad (26.63)$$

In order to satisfy the decentralized constraints on the control law, we solve the standard LQ optimal control problem (\mathbf{S}_D, J_D) to get

$$u_D^\circ = -K_D x, \quad (26.64)$$

where $K_D = \text{diag}\{K_1, K_2, \dots, K_N\}$ is given as

$$K_D = R_D^{-1} B_D^T P_D,$$

and $P_D = \text{diag}\{P_1, P_2, \dots, P_N\}$ is the unique symmetric positive definite solution of the algebraic Riccati equation

$$A_D^T P_D + P_D A_D - P_D B_D R_D^{-1} B_D^T P_D + Q_D = 0. \quad (26.65)$$

The control u_D° , when applied to \mathbf{S}_D , results in the closed-loop system

$$\hat{\mathbf{S}}_D^\circ : \dot{x} = (A_D - B_D K_D) x, \quad (26.66)$$

which is optimal and produces the optimal cost

$$J_D^\circ(x_0) = x_0^T P_D x_0. \quad (26.67)$$

The important fact about the locally optimal control u_D° is that it is decentralized. Each component

$$u_i^\circ = -K_i x_i \quad (26.68)$$

of u_D° uses only the local state x_i . Generally, the proposed control strategy is not globally optimal, but we can proceed to determine if the cost $J_D^\circ(x_0)$ corresponding to the closed-loop interconnected system

$$\hat{\mathbf{S}}^\oplus : \dot{x} = (A_D - B_D K_D + A_C) x \quad (26.69)$$

is finite. If it is, then \mathbf{S}^\oplus is suboptimal and a positive number μ exists such that

$$J_D^\oplus(x_0) \leq \mu^{-1} J_D^\circ(x_0) \quad (26.70)$$

for all $x_0 \in \mathbb{R}^n$. The number μ is called the degree of suboptimality of u_D° .

We can determine the index μ by first computing the performance index

$$J_D^\oplus(x_0) = x_0^T H x_0, \quad (26.71)$$

where

$$\begin{aligned} H &= \int_0^\infty \exp(\hat{A}^T t) G_D \exp(\hat{A} t) dt, \\ G_D &= Q_D + P_D B_D R_D^{-1} B_D^T P_D, \end{aligned} \quad (26.72)$$

and the closed-loop matrix is

$$\hat{A} = A_D - B_D K_D + A_C. \quad (26.73)$$

It is important to note that u_D^\ominus is suboptimal if, and only if, the symmetric matrix H exists. The existence of H is guaranteed by the stability of \hat{S} , in which case we can compute H as the unique solution of the Lyapunov matrix equation

$$\hat{A}^T H + H \hat{A} = -G_D. \quad (26.74)$$

The degree of suboptimality, which is the largest we can obtain in this context, is given as

$$\mu^* = \lambda_M^{1/2}(H P_D^{-1}). \quad (26.75)$$

Details of this development, as well as the broad scope of suboptimality, were described in [30], where special attention was devoted to the robustness implications of suboptimality. First, we can explicitly characterize suboptimality in terms of the interconnection matrix A_C . The system \hat{S}^\oplus is suboptimal with degree μ if the matrix

$$F(\mu) = A_C^T P_D + P_D A_C - (1 - \mu)(Q_D + P_D B_D R_D^{-1} B_D^T P_D) \quad (26.76)$$

is nonpositive definite. This is a sufficient condition for suboptimality, but one that implies stability if the pair $\{A_D + A_C, Q_D^{1/2}\}$ is detectable.

Another important aspect of nonpositivity of $F(\mu)$ is that it implies stability even if each control u_i^\ominus is replaced by a nonlinearity $\phi_i(u_i^\ominus)$, which is contained in a sector, or by a linear time-invariant dynamic element. Furthermore, if the subsystems are single-input systems, then each subsystem feedback loop has infinite gain margin, at least $\pm \cos^{-1}(1 - \frac{1}{2}\mu)$ phase margin, and at least 50% gain reduction tolerance. These are the standard robustness characteristics of an optimal LQ control law, which are modified by the degree of suboptimality. It is interesting to note that the optimal robustness characteristics can be recovered by solving the inverse problem of optimal decentralized control. The matching conditions are one of the conditions that guarantee the solution of the problem.

The concept of suboptimality extends to the case of *overlapping subsystems*, when subsystems share common parts, and control is required to conform with the *overlapping information structure constraints*. By expanding the underlying state space, the subsystems become disjoint and decentralized control can be designed for the expanded system by standard techniques. Finally, the control laws obtained are contracted for implementation in the original system. This expansion–contraction framework is known as the *inclusion principle*. For a comprehensive presentation of this principle, see [30].

26.6 Adaptive Decentralized Control

As mentioned in the section on decentrally stabilizable structures, many large scale interconnected systems with a good interconnection structure can be stabilized by a high-gain type decentralized control. How high the gain should be depends on how strong the interconnections are. If a bound on the interconnections is known, then stability can be guaranteed by a fixed high-gain controller. However, if such a

bound is not available, then one has to use an adaptive controller which adjusts the gain to a value needed for overall stability.

Consider an interconnected system consisting of single-input subsystems

$$\mathbf{S} : \dot{x}_i(t) = A_i x_i(t) + b_i [u_i(t) + h_i(t, x(t))], \quad i \in \mathcal{N} \quad (26.77)$$

where, without loss of generality, the pairs (A_i, b_i) are assumed to be in controllable canonical form, and the nonlinear matching interconnections $h_i : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}$ are assumed to satisfy

$$|h_i(t, x)| \leq \sum_{j \in \mathcal{N}} \alpha_{ij} \|x_j\| \quad (26.78)$$

for some *unknown* constants $\alpha_{ij} \geq 0$. Let a decentralized state feedback

$$u_i(t) = -\rho(t) k_i^T R_i(\rho(t)), \quad i \in \mathcal{N} \quad (26.79)$$

be applied to \mathbf{S} , where $R_i(\rho) = \text{diag}\{\rho^{n_i-1}, \dots, \rho, 1\}$, with $\rho(t)$ being a time-varying gain, and k_i^T are such that the matrices $\hat{A}_i = A_i - b_i k_i^T$ have distinct eigenvalues λ_{il} , $i \in \mathcal{N}$, $l = 1, 2, \dots, n_i$. Let T_i denote the modal matrices of \hat{A}_i , i.e., $T_i \hat{A}_i T_i^{-1} = M_i = \text{diag}\{\lambda_{i1}, \lambda_{i2}, \dots, \lambda_{in_i}\}$. Then a time-varying coordinate transformation $z_i(t) = T_i R_i(\rho(t)) x_i(t)$ transforms the closed-loop system $\hat{\mathbf{S}}$ into

$$\hat{\mathbf{S}} : \dot{z}_i(t) = \rho(t) M_i z_i(t) + g_i(t, z(t)), \quad i \in \mathcal{N}, \quad (26.80)$$

where, provided $0 \leq \dot{\rho}(t) \leq 1 \leq \rho(t)$,

$$\|g_i(t, z)\| \leq \sum_{j \in \mathcal{N}} \beta_{ij} \|z_j\| \quad (26.81)$$

for some *unknown* constants $\beta_{ij} \geq 0$. From Equations 26.80 and 26.81 it follows that there exists a $\rho^* > 0$ so that $\hat{\mathbf{S}}$ is stable for all $\rho(t)$ satisfying $0 \leq \dot{\rho}(t) \leq 1 \leq \rho^* \leq \rho(t)$, as can be shown by the vector Lyapunov approach. However, the crucial point is that ρ^* depends on the unknown bounds β_{ij} . Fortunately, the difficulty can be overcome by increasing $\rho(t)$ adaptively until it is high enough to guarantee stability of $\hat{\mathbf{S}}$. A simple adaptation rule that serves the purpose is

$$\dot{\rho}(t) = \min\{1, \gamma \|x(t)\|\} \quad (26.82)$$

where $\gamma > 0$ is arbitrary. Although the control law is decentralized, $\rho(t)$ is adjusted based on complete state information.

The same idea can also be used in constructing adaptive decentralized dynamic output feedback controllers for various classes of large scale systems with structured nonlinear, time-varying interconnections. A typical example is a system described by

$$\begin{aligned} \mathbf{S} : \dot{x}_i(t) &= A_i x_i(t) + b_i u_i(t) + h_i(t, x(t)), \\ y_i(t) &= c_i^T x_i(t), \quad i \in \mathcal{N} \end{aligned} \quad (26.83)$$

where

1. The decoupled subsystems described by the triples (A_i, b_i, c_i^T) are controllable and observable.
2. The transfer functions $G_i(s) = c_i^T (sI - A_i)^{-1} b_i$ of the decoupled systems are minimum phase, have *known* relative degree q_i and *known* high frequency gain $\kappa_i = \lim_{s \rightarrow \infty} s^{q_i} G_i(s)$.

3. The nonlinear interconnections $h_i : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^{n_i}$ are of the form $h_i(t, x) = b_i f_i(t, x) + g_i(t, y)$ where $f_i : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}$ and $g_i : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^{n_i}$ satisfy

$$\begin{aligned} |f_i(t, x)| &\leq \sum_{j \in \mathcal{N}} \alpha_{ij}^f \|x_j\| \\ \|g_i(t, x)\| &\leq \sum_{j \in \mathcal{N}} \alpha_{ij}^g \|y_j\| \end{aligned} \quad (26.84)$$

for some *unknown* constants $\alpha_{ij}^f, \alpha_{ij}^g$ where $x(t) = [x_1^T(t), x_2^T(t), \dots, x_N^T(t)]^T$ and $y(t) = [y_1(t), y_2^T(t), \dots, y_N(t)]^T$ are the state and the output of the overall system.

Finally, suitable adaptive decentralized control schemes can be developed by forcing an interconnected system of the form (Equation 26.83) to track a decoupled stable linear reference model described as

$$\begin{aligned} \mathbf{S}_M : \dot{x}_{Mi}(t) &= A_{Mi} x_{Mi}(t) + b_{Mi} r_i(t), \\ y_{Mi}(t) &= c_{Mi}^T x_{Mi}(t), \quad i \in \mathcal{N}, \end{aligned} \quad (26.85)$$

under reasonable assumptions on \mathbf{S} and \mathbf{S}_M .

26.7 Discrete and Sampled-Data Systems

Most of the results concerning the stability and stabilization of continuous-time interconnected systems can be carried over to the discrete case with suitable modifications. Yet, there is a distinct approach to the stability analysis of discrete systems, which is to translate the problem in to that of a continuous system for which abundant results are available. For an idea of this approach, consider a system

$$\mathbf{S}_{SD} : x(t+1) = (A_0 + \sum_{k \in \mathcal{K}} p_k A_k) x(t) \quad (26.86)$$

where A_0 is a stable matrix additively perturbed by $p_k A_k$, $k \in \mathcal{K} = \{1, 2, \dots, K\}$ with p_k standing for one of K perturbation parameters. The purpose is to find the largest region in the parameter space within which \mathbf{S}_{SD} remains stable. By choosing a Lyapunov function $v(x) = x^T P x$, where P is the positive definite solution of the discrete Lyapunov equation,

$$A_0^T P A_0 - P = -I, \quad (26.87)$$

it can be shown that \mathbf{S}_{SD} is stable, provided $I - W(p)$ is positive definite, where

$$W(p) = \sum_{k \in \mathcal{K}} p_k (A_k^T P A_0 + A_0^T P A_k) + \sum_{k, l \in \mathcal{K}} p_k p_l A_k^T P A_l. \quad (26.88)$$

Since the perturbation parameters appear nonlinearly in $W(p)$, characterization of a stability region in the parameter space is not easy. However, $I - W(p)$ is positive definite if the continuous system

$$\dot{\xi}(t) = (-I + \sum_{k \in \mathcal{K}} p_k E_k) \xi(t) \quad (26.89)$$

is stable, where

$$E_k = \begin{bmatrix} 0 & p^{1/2} A_k \\ E_k^T p^{1/2} & A_k^T P A_0 + A_0^T P A_k \end{bmatrix}. \quad (26.90)$$

An analysis of the stability of the perturbed continuous system in Equation 26.89 provides a sufficient condition for the stability of the discrete system in Equation 26.86. This idea can be generalized to the

stability analysis of discrete interconnected systems by treating the interconnections as perturbations to nominal stable decoupled subsystems.

A major difference between discrete and continuous systems is that characterizing decentrally stabilizable interconnections for discrete systems is not as easy as for continuous systems. For example, there is no discrete counterpart to the matching conditions. On the other hand, most existing control schemes for continuous systems seem applicable to sampled-data systems provided the sampling rate is sufficiently high. To illustrate this observation, consider the decentralized control of an interconnected system,

$$\mathbf{S} : \dot{x}_i(t) = A_i x_i(t) + b_i [u_i(t) + \sum_{j \in \mathcal{N}} d_{ij}^T x_j(t)], \quad i \in \mathcal{N}, \quad (26.91)$$

using sampled-data feedback of the form

$$u_i(t) = -k_i^T(t - t_m)x_i(t_m), \quad t_m \leq t < t_{m+1}, \quad (26.92)$$

where t_m are the sampling instants, and $k_i(t)$ are time-varying local feedback gains. With $T_m = t_{m+1} - t_m$ denoting the m th sampling period, it can be shown that the choice of

$$k_i^T(t) = [\delta^{n_i}(t) \dots \delta'(t) \delta(t)] \quad (26.93)$$

or similar feedback gains having impulsive behavior, stabilize \mathbf{S} provided T_m are sufficiently small. How small the sampling periods should be requires knowledge of the bounds on the interconnections. If these bounds are not available, then a simple centralized adaptation scheme, such as

$$T_{m+1}^{-1} = T_m^{-1} + \sum_{j \in \mathcal{N}} \gamma_j \|x_j(t_{m-m_j})\|, \quad (26.94)$$

with $\gamma_j > 0$, decreases T_m to the value needed for stability. Clearly, this is a high-gain stabilization scheme coupled with fast sampling, owing its success to the matching structure of the interconnections [36]. Similar adaptive sampled-data control schemes are available for more general classes of interconnected systems.

26.8 Graph-Theoretic Decompositions

Decomposition of large scale systems and their associated problems is often desirable for computational reasons. In such cases, decentralization or any other structural constraints on the controllers, estimators, or the design process itself, is preferred rather than necessary. Depending on the particular problem in hand, one may be interested in obtaining lower block triangular (LBT) decompositions, input and/or output reachable acyclic decompositions, ϵ -decompositions, overlapping decompositions, etc. [30]. In all of these decomposition schemes, the problem is to find a suitable partitioning and reordering of the input, state, or output variables so that the resulting decomposed system has some desirable structural properties. As expected, the system graph plays the key role, with graph-theory providing the tools.

26.8.1 LBT Decompositions

LBT decompositions are used to reorder the states of system \mathbf{S} in Equation 26.6, so that the subsystems have a hierarchical interconnection pattern as

$$\begin{aligned} \mathbf{S} : \dot{x}_i &= \sum_{j=1}^i A_{ij} x_j + B_i u, \quad i \in \mathcal{N}, \\ y &= \sum_{i \in \mathcal{N}} C_i x_i. \end{aligned} \quad (26.95)$$

Such a decomposition corresponds to transforming the A matrix into a Lower Block-Triangular form by symmetric row and column permutations (hence the name LBT decomposition). In terms of system graph, LBT decomposition is the almost trivial problem of identifying the strong components of the truncated digraph $\mathbf{D}_x = (\mathcal{X}, \mathcal{E}_x)$, where $\mathcal{E}_x \subset \mathcal{E}$ contains only the edges connecting state vertices.

LBT decompositions offer computational simplification in the standard state feedback or observer design problems. For example, the problem of designing a state feedback

$$u = -Kx = - \sum_{i \in \mathcal{N}} K_i x_i \quad (26.96)$$

for arbitrary pole placement, can be reduced to computation of the individual blocks K_i of K in a recursive scheme involving the subsystems only.

26.8.2 Acyclic IO Reachable Decompositions

In acyclic input-output (IO) reachable decompositions, the purpose is to decompose \mathbf{S} into the form

$$\begin{aligned} \mathbf{S} : \dot{x}_i &= \sum_{j=1}^i A_{ij} x_j + \sum_{j=1}^i B_{ij} u_j, \\ y_i &= \sum_{j=1}^i C_{ij} x_j, \quad i \in \mathcal{N}. \end{aligned} \quad (26.97)$$

That is, in addition to the A matrix, the B and C matrices must have LBT structure. In addition to the desired structure of the system matrices, it is also necessary that the decoupled subsystems represented by (A_{ii}, B_{ii}, C_{ii}) are at least structurally controllable and observable, and that none is further decomposable.

Because the LBT structure is concerned with the reachability properties of the system, both this structure and input and/or output reachability requirements for the subsystems, which are necessary for structural controllability and/or observability, can be taken care of by a suitable decomposition scheme based on binary operations on the reachability matrix of the system digraph. The requirement that the subsystems be dilation free, which is the second condition for structural controllability and/or observability, is of a different nature, however, and should be checked separately after the input-output reachability decomposition has been obtained.

When outputs are of no concern, it is easy to identify all possible acyclic, irreducible, input reachable decompositions of a given system. If some of the resulting decoupled subsystems turn out to contain dilations (destroying structural controllability), then they can suitably be combined with one or more subsystems at a higher level of hierarchy to eliminate the dilations without destroying the LBT structure. Provided that the overall system is structurally controllable, this process eventually gives an acyclic, irreducible decomposition in which all subsystems are structurally controllable. Of course, dual statements are valid for acyclic output reachable decompositions.

Once an acyclic decomposition into controllable subsystems is obtained, many design problems can be decomposed accordingly. An obvious example is the state feedback structure in Equation 26.96. A more complicated problem is the suboptimal state feedback design discussed in the section on optimization. For the system in Equation 26.97, the test matrix $F(\mu)$, with the inclusion of the input coupling terms B_{ij} , becomes

$$F(M_D) = F_D(M_D) + F_C(M_D) + F_C^T(M_D), \quad (26.98)$$

where $M_D = \text{diag}\{\mu_1, \mu_2, \dots, \mu_N\}$, allowing different μ_i 's for \mathbf{S}_i 's, $F_D(M_D) = [(1 - \mu_i^{-1})(Q_i + K_i^T R_i K_i)]$, and $F_C(M_D) = [F_{ij}(\mu_i)]$ with

$$F_{ij}(\mu_i) = \begin{cases} \mu_i^{-1} P_i (A_{ij} - B_{ij} K_j), & i > j \\ 0, & i \leq j. \end{cases} \quad (26.99)$$

From the structure of $F(M_D)$ it is clear that the choice $\mu_i = \epsilon^{N+1-i}$, $i \in \mathcal{N}$, results in a negative definite $F(M_D)$ for sufficiently small ϵ . This guarantees existence of a suboptimal state feedback control law with the degree of suboptimality $\mu = \epsilon^N$. In practice, it is possible to achieve a much better μ by a careful choice of the weight matrices Q_i and R_i .

In a similar way, acyclic, structurally observable decompositions can be used to design suboptimal state estimators, which are discussed below in the context of sequential optimization for acyclic IO decompositions.

To illustrate the use of acyclic IO decompositions in a standard LQG optimization problem, it suffices to consider decomposition of a discrete-time system into only two subsystems as

$$\begin{aligned} \mathbf{S}_1 : x_1(t+1) &= A_{11}x_1(t) + B_{11}u_1(t) + w_1(t), \\ y_1(t) &= C_{11}x_1(t) + v_1(t), \\ \mathbf{S}_2 : x_2(t+1) &= A_{21}x_1(t) + A_{22}x_2(t) + B_{21}u_1(t) + B_{22}u_2(t) + w_2(t), \\ y_2(t) &= C_{21}x_1(t) + C_{22}x_2(t) + v_2(t), \end{aligned} \quad (26.100)$$

with the usual assumptions on the input and measurement noises ω_i and v_i , $i = 1, 2$. Let each subsystem be associated with a performance criterion

$$\mathcal{E}J_i = \mathcal{E} \left\{ \lim_{T \rightarrow \infty} T^{-1} \sum_{t=0}^{T-1} \left[x_i^T(t) Q_i x_i(t) + u_i^T(t) R_i u_i(t) \right] \right\}, \quad i = 1, 2 \quad (26.101)$$

where \mathcal{E} denotes expectation.

The sequential optimization procedure consists of minimizing $\mathcal{E}J_1$ and $\mathcal{E}J_2$ subject to the dynamic equations for the systems \mathbf{S}_1 and $(\mathbf{S}_1, \mathbf{S}_2)$, respectively. The first problem has the standard solution $u_1^*(t) = -K_1 \hat{x}_1(t)$, where K_1 is the optimal control gain found from the solution of the associated Riccati equation, and $\hat{x}_1(t)$ is the best estimate of $x_1(t)$ given the output information $\mathcal{Y}_1^{t-1} = \{y_1(0), \dots, y_1(t-1)\}$. The estimate $\hat{x}_1(t)$ is generated by the Kalman filter

$$\hat{x}_1(t+1) = A_{11}\hat{x}_1(t) + B_{11}u_1^*(t) + L_1[y_1(t) - c_{11}\hat{x}_1(t)] \quad (26.102)$$

where L_1 is the steady-state estimator gain. With the control u_1^* applied to \mathbf{S}_1 , the overall system becomes

$$\mathbf{S} : \begin{bmatrix} \hat{x}_1(t+1) \\ x_1(t+1) \\ x_2(t+1) \end{bmatrix} = \begin{bmatrix} A_{11} - B_{11}K_1 - L_1C_{11} & L_1C_{11} & 0 \\ -B_{11}K_1 & A_{11} & 0 \\ -B_{21}K_1 & A_{21} & A_{22} \end{bmatrix} \begin{bmatrix} \hat{x}_1(t) \\ x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ B_{22} \end{bmatrix} u_2(t) + \begin{bmatrix} L_1v_1(t) \\ w_1(t) \\ w_2(t) \end{bmatrix} \quad (26.103)$$

which preserves the LBT structure of the original system. Assuming that both \mathcal{Y}_1^{t-1} and $\mathcal{Y}_2^{t-1} = \{y_2(0), \dots, y_2(t-1)\}$ are available for constructing the control u_2^* (which is consistent with the idea of sequential optimization), the problem reduces to minimization of $\mathcal{E}J_2$ subject to (103). An analysis of the standard solution procedure reveals that the optimal control law can be expressed as

$$u_2^*(t) = -K_2 \hat{\xi}(t) \quad (26.104)$$

where $K = [K_{21} \ K_{22}]$ is the optimal control gain, and $\hat{\xi}(t)$ is the optimal estimate of $x(t) = [x_1^T(t) \ x_2^T(t)]^T$, given \mathcal{Y}_1^{t-1} and \mathcal{Y}_2^{t-1} . Furthermore, the $2n_1 + n_2$ -dimensional Riccati equation, from which K is constructed, can be decomposed into an n_2 -dimensional Riccati equation involving the parameters of the second isolated subsystem and a Lyapunov equation corresponding to an $n_2 \times 2n_1$ dimensional matrix. This results in considerably simplifying the solution of the optimal control gain. However, the Kalman filter for $\hat{\xi}(t)$ still requires the solution of an $(n_1 + n_2)$ -dimensional Riccati equation.

Other sequential optimization schemes based on various information structure constraints can be analyzed similarly; for details, see [30].

26.8.3 Nested Epsilon Decompositions

Epsilon decomposition of a square matrix M is concerned with transforming M by symmetric row and column permutations into a form

$$P^T M P = M_D + \epsilon M_C \tag{26.105}$$

where M_D is block diagonal, and ϵ is a prescribed small number [27]. The problem is equivalent to identifying the connected components of a subgraph \mathbf{D}^ϵ of the digraph \mathbf{D} associated with M , which is obtained by deleting all edges of \mathbf{D} corresponding to those elements of M with magnitude smaller than ϵ . All of the vertices of a connected component of \mathbf{D}^{ϵ_1} appear in the same connected component of \mathbf{D}^{ϵ_2} for any $\epsilon_2 < \epsilon_1$. Thus one can identify a number of distinct values $\epsilon_1 > \epsilon_2 > \dots > \epsilon_K$ such that

$$P^T M P = (\dots ((M_0 + \epsilon_1 M_1) + \epsilon_2 M_2) + \dots + \epsilon_K M_K), \tag{26.106}$$

which is a *nested epsilon decomposition* of M as illustrated in Figure 26.3.

As seen from the figure, a large ϵ results in a finer decomposition than a small ϵ does. Thus the choice of ϵ provides a compromise between the size and the number of components and the strength of the interconnections among them. A nice property of nested epsilon decompositions is that once the decomposition corresponding to some ϵ_k is obtained, the decomposition corresponding to ϵ_{k+1} can be found by working with a smaller digraph obtained by condensing \mathbf{D}^{ϵ_k} with respect to its components.

An immediate application of the nested epsilon decompositions is the stability analysis of a large scale system via vector Lyapunov functions, where the matrix M is identified with the matrix A of the system in Equation 26.6. Provided the subsystems resulting from the decomposition are stable, the stability of the overall system can easily be established by means of the aggregate matrix W in Equation 26.49, whose off-diagonal elements are of the order of ϵ .

The nested epsilon decomposition algorithm can also be applied with some modifications to decompose a system with inputs as

$$\dot{x}_i = A_{ii}x_i + B_{ii}u_i + \epsilon \sum_{j \neq i} (A_{ij}x_j + B_{ij}u_j), \quad i \in \mathcal{N}. \tag{26.107}$$

If each decoupled subsystem identified by a pair (A_{ii}, B_{ii}) is stabilized by a local state feedback of the form $u_i = -K_i x_i$, $i \in \mathcal{N}$, with the local gains not excessively high, then the closed-loop system preserves the

FIGURE 26.3 Nested epsilon decompositions.

weak-coupling property of the open-loop system, providing an easy way to stabilize the overall system. The same idea can also be employed in designing decentralized estimators [30] based on a suitable epsilon decomposition of the pair (A, C) .

26.8.4 Overlapping Decompositions

Consider a system

$$\tilde{\mathbf{S}}: \dot{\tilde{x}}(t) = \tilde{A}\tilde{x}(t) \tag{26.108}$$

with an \tilde{n} -dimensional state vector \tilde{x} . Let columns of the matrix $V \in \mathbb{R}^{\tilde{n} \times n}$ form a basis for an n -dimensional A -invariant subspace of $\mathbb{R}^{\tilde{n}}$, and let A be the restriction of \tilde{A} to $\text{Im}V \simeq \mathbb{R}^n$, that is, $\tilde{A}V = VA$. Then the smaller order system

$$\mathbf{S}: \dot{x}(t) = Ax(t) \tag{26.109}$$

is called a restriction of $\tilde{\mathbf{S}}$. Conversely, starting with the system \mathbf{S} , one can obtain an expansion $\tilde{\mathbf{S}}$ of \mathbf{S} by defining $\tilde{A} = VAV^L + M$, where V^L is any left inverse of V , and M is any complementary matrix satisfying $MV = 0$. The very definition of a restriction implies that \mathbf{S} is stable if $\tilde{\mathbf{S}}$ is.

In many problems associated with large scale systems, it may be desirable to expand a system \mathbf{S} to a larger dimensional one which possess some nice structural properties. The increase in dimensionality of the problem may very well be offset by the nice structure of the expansion. As an example, consider a system \mathbf{S} with

$$A = \left[\begin{array}{cc|c} A_{11} & A_{12} & \epsilon A_{13} \\ \epsilon A_{21} & A_{22} & \epsilon A_{23} \\ \epsilon A_{31} & A_{32} & A_{33} \end{array} \right] \tag{26.110}$$

where ϵ is a small parameter. Letting

$$V = \left[\begin{array}{ccc} I_1 & 0 & 0 \\ 0 & I_2 & 0 \\ 0 & I_2 & 0 \\ 0 & 0 & I_3 \end{array} \right] \tag{26.111}$$

where I_k denotes an identity matrix of order n_k , one obtains an expansion $\tilde{\mathbf{S}}$ with

$$\tilde{A} = \left[\begin{array}{cc|cc} A_{11} & A_{12} & 0 & \epsilon A_{13} \\ \epsilon A_{21} & A_{22} & 0 & \epsilon A_{23} \\ \epsilon A_{21} & 0 & A_{22} & \epsilon A_{23} \\ \epsilon A_{31} & 0 & A_{32} & A_{33} \end{array} \right]. \tag{26.112}$$

Since $\tilde{\mathbf{S}}$ has an obvious decomposition into two weakly coupled subsystems, one can take advantage of this structural property in stability analysis, which is not available for the original system \mathbf{S} .

One can easily notice from the structure of V in Equation 26.114 that the expansion $\tilde{\mathbf{S}}$ of \mathbf{S} is obtained simply by repeating the equation for the middle part x_2 of the state vector $x = [x_1^T \ x_2^T \ x_3^T]^T$. In some sense, x_2 is treated as common to two overlapping components $\tilde{x}_1 = [x_1^T \ x_2^T]^T$ and $\tilde{x}_2 = [x_2^T \ x_3^T]^T$ of x . Thus the partitioning of the A matrix in Equation 26.113 is termed the *overlapping decomposition*.

Although the expansion matrix V can be any matrix with full column rank, if it is restricted to contain one and only one unity element in each row (which corresponds, as in the case above, to repeating some of the state equations in the expanded domain), then one can develop a suitable graph-theoretic algorithm to find the smallest expansion which has a disjoint decomposition (into decoupled or ϵ -coupled components) with the property that no component is further decomposable.

The idea of overlapping decompositions via expansions can be extended to systems with inputs. A system

$$\tilde{\mathbf{S}} : \dot{\tilde{x}}(t) = \tilde{A}\tilde{x}(t) + \tilde{B}u(t) \quad (26.113)$$

is said to be an expansion of

$$\mathbf{S} : \dot{x}(t) = Ax(t) + Bu(t) \quad (26.114)$$

if $\tilde{B} = VB$ in addition to $\tilde{A}V = VA$. Consider the optimal control problems of minimizing the performance criteria

$$\begin{aligned} J &= \int_0^\infty [x^T(t)Qx(t) + u^T(t)Ru(t)] dt \\ \tilde{J} &= \int_0^\infty [\tilde{x}^T(t)\tilde{Q}\tilde{x}(t) + u^T(t)Ru(t)] dt \end{aligned} \quad (26.115)$$

associated with \mathbf{S} and $\tilde{\mathbf{S}}$. The optimal solutions are

$$u(t) = -Kx(t), \quad \text{and} \quad u(t) = -\tilde{K}\tilde{x}(t), \quad (26.116)$$

respectively, resulting in closed-loop systems

$$\begin{aligned} \hat{\mathbf{S}} : \dot{x}(t) &= (A - BK)x(t), \\ \hat{\tilde{\mathbf{S}}} : \dot{\tilde{x}}(t) &= (\tilde{A} - \tilde{B}\tilde{K})\tilde{x}(t). \end{aligned} \quad (26.117)$$

Thus, $\hat{\mathbf{S}}$ is a restriction of $\hat{\tilde{\mathbf{S}}}$ if $(\tilde{A} - \tilde{B}\tilde{K})V = V(A - BK)$, or equivalently, if $\tilde{K} = KV$. The last condition is satisfied if \tilde{Q} and Q are related as $Q = V^T\tilde{Q}V$, in which case the optimal cost matrices are also related as $P = V^T\tilde{P}V$. This analysis shows that, if the cost matrices \tilde{Q} and R of the expanded system are chosen to be block diagonal with diagonal blocks associated with the decoupled expanded subsystems, then its optimal (in case of complete decoupling) or suboptimal (in case of weak decoupling) solution can be contracted back to an optimal or suboptimal solution of the original system with respect to a suitably chosen performance criterion.

Further Reading

There is a number of survey papers on decentralized control and large scale systems [3,14,24]. The books on the subject are [10,15,19,29,31]. For a comprehensive treatment of decentralized control theory, methods, and applications, with a large number of references, see [30].

For further information on vector Lyapunov functions and stability analysis of large scale interconnected systems, see the survey papers [22,33], and books [16,17].

Adaptive decentralized control has been of widespread recent interest, see [2,9,21,23,28,30,36].

Robustness of decentralized control to both structured and unstructured perturbations has been one of the central issues in the control of large scale systems. For the background of robustness issues in control, which are relevant to decentralized control, see [18,30]. For new and interesting results on the subject, see [4–6,8].

There is a number of papers devoted to design of decentralized control via parameter space optimization, which rely on powerful convex optimization methods. For recent results and references, see [11].

Overlapping decentralized control and the inclusion principle are surveyed in [30]. Useful extensions were presented in [13]. The concept of overlapping is basic to reliable control under controller failures using multiple decentralized controllers [30]. For more information about this area, see [7,12,32,35].

In a recent development [25], it has been shown how optimal decentralized control of large scale interconnected systems can be obtained in the classical optimization framework of Lagrange. Both sufficient and necessary conditions for optimality are derived in the context of Hamilton–Jacobi equations and Pontryagin’s maximum principle.

27.1 Introduction

Multi-input/multi-output systems are usually difficult for human operators to control directly, since changing any one input generally affects many, if not all, outputs of the system. As an example, consider the vertical landing of a vertical take off and landing jet or of a lunar landing rocket. Moving to a desired landing point to the side of the current position requires tilting the thrust vector to the side; but this reduces the vertical thrust component, which was balancing the weight of the craft. The aircraft therefore starts to descend, which is not desired. To move to the side at a constant height thus requires smooth, simultaneous use of both attitude control and throttle. It would be simpler for the pilot if a single control existed to do this maneuver; hence the interest in control methods that make the original system behave in a way that is easier to control manually. One example of such technique is when a compensator is sought that makes the compensated system diagonally dominant. If this can be achieved, it is then possible to regard the system as, to first order, a set of independent single-input/single-output systems, which is far easier to control than the original plant. Another approach is that of decoupling, where the system transfer matrix is made to be exactly diagonal. Each output variable is therefore affected by only one input signal, and each input/output pair can then be controlled by an easier-to-design single-input/single-output controller or manually by a human operator.

This chapter studies the problem of making the transfer function matrix of the system diagonal using feedback control and, in particular, state feedback, state feedback with dynamic precompensation, and constant output feedback control laws. This problem is referred to as the *dynamical decoupling* problem, as it leads to a compensated system where the input actions are decoupled; it is also called a noninteracting control problem for similar reasons. Stability is an important issue and it also is examined here. Conditions for decoupling with stability and algorithms to determine such control laws are described. The problems of block diagonal or triangular decoupling are also addressed. They are of interest when full diagonal decoupling using a particular form of feedback control, typically state feedback, is not possible. Note that the approach taken in this chapter follows the development in [14]. Static decoupling is also briefly discussed; references for approximate diagonal decoupling are provided in “Further Reading.”

27.1.1 Diagonal Decoupling

Diagonal decoupling of a system with equal numbers of inputs and outputs is the most straightforward type of problem in the field of noninteracting control. The goal is to apply some form of control law to the system so as to make the i th output of the closed-loop system independent of all but the i th closed-loop input signal. Each output can then be controlled by a dedicated simpler single-input/single-output controller, or by a human operator. The main questions to be answered when investigating diagonal decoupling of a given system are

- Can it be decoupled at all?
- If so, what form of controller is required to achieve this?

Three classes of controllers that are customarily considered are

1. Constant output feedback $u = Hy + Gr$, where the output y of the system is simply multiplied by a constant gain matrix H and this is fed back as the control signal u , with r the new external input to the system and G a constant gain matrix
2. Linear state feedback $u = Fx + Gr$, where the control signal consists of a constant matrix F multiplying the internal state variable vector x of the system
3. State feedback plus precompensation, where a feedforward dynamic control system is added to the state feedback controller

Note that the compensator in class 3 corresponds to dynamic output feedback, where the input and output signal vectors r and y are multiplied by dynamic transfer function gain matrices rather than constant ones.

The problem of diagonally decoupling a square system was the first decoupling question to be studied, and it can be answered in a fairly straightforward fashion. First of all, diagonal decoupling by state feedback plus precompensation, or by dynamic output feedback, amounts to finding a transfer matrix that, when the open-loop transfer matrix is multiplied by it, produces a diagonal closed-loop transfer matrix. This problem is therefore closely related to the problem of finding an inverse for the open-loop plant. As a result of this, any square plant that has a full rank transfer matrix can be diagonally decoupled by this type of control. This result was proved by Rekasius [10]. A system that does not satisfy this condition does not have linearly independent outputs, so it follows that it is impossible to decouple by any form of controller. It is of great practical interest to establish whether a given plant can actually be decoupled by a simpler type of controller than this. Falb and Wolovich [3] established the necessary and sufficient condition under which diagonal decoupling by state feedback alone is possible. This condition, which can be easily tested from either a state-space or a transfer matrix model of the plant, can be expressed as follows.

A square system can be diagonalized by state feedback alone if and only if the constant matrix B^* is nonsingular, where this matrix is defined below first from the state-space and then from the transfer matrix description of the system.

State-space representation. Let the given system be $\dot{x} = Ax + Bu, y = Cx + Du$ in the continuous-time case, or $x(k+1) = Ax(k) + Bu(k), y(k) = Cx(k) + Du(k)$ in the discrete-time case; let A, B, C, D be $n \times n, n \times p, p \times n, p \times p$ real matrices, respectively; and assume for simplicity that the system is controllable and observable. Then the $p \times p$ matrix B^* is constructed as follows: If the i th row of the direct feedthrough matrix D is nonzero, this becomes the i th row of the constant matrix B^* . Otherwise, find the lowest integer, f_i , for which the i th row of $CA^{f_i-1}B$ is nonzero. This then becomes the i th row of the constant matrix B^* .

Transfer matrix representation. Let $T(s)$, with s the Laplace transform variable, be the $p \times p$ transfer function matrix of the continuous-time system; or $T(z)$, with z the Z-transform variable, be the transfer function matrix of the discrete-time system. Let $D(s)$ [or $D(z)$] be the diagonal matrix $D(s) = \text{diag}(s^{f_i})$ where the nonnegative integers $\{f_i\}$ are so that all rows of $\lim_{s \rightarrow \infty} D(s)T(s)$ are constant and nonzero.

This limit matrix is B^* ; that is,

$$\lim_{s \rightarrow \infty} D(s)T(s) = B^* \quad (27.1)$$

The integers $\{f_i\}$ are known as the decoupling indices of the system. They can be determined from either the state-space or the transfer function descriptions as described above; note that $f_i = 0$ corresponds to the i th row of D being nonzero. In either case, of course, the resulting matrix B^* is the same. It should be noted that systems will generically satisfy the decoupling condition; that is, if all entries of the A , B , C (and D) matrices are chosen at random, the resulting B^* will have full rank. Diagonal decoupling by state feedback is therefore likely to be feasible for a wide variety of systems.

Example 27.1:

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -6 & -11 & -6 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ -1 & 2 \end{pmatrix}, \quad C = \begin{pmatrix} 3 & 6 & 1 \\ 2 & 0 & 0 \end{pmatrix}, \quad D = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$$

This gives $f_1 = 1$, $f_2 = 3$, and $B^* = \begin{pmatrix} -1 & 2 \\ -2 & 4 \end{pmatrix}$. This matrix is clearly singular; therefore, the system cannot be decoupled by state feedback.

Example 27.2:

$$T(s) = \begin{pmatrix} \frac{1}{s} & \frac{2}{s+1} \\ \frac{4}{s+3} & \frac{8s}{s+4} \end{pmatrix}$$

This gives $B^* = \begin{pmatrix} 1 & 2 \\ 0 & 8 \end{pmatrix}$, with decoupling indices $f_1 = 1$, $f_2 = 0$. This system can therefore be diagonally decoupled by state feedback.

Example 27.3:

$$T(s) = \begin{pmatrix} \frac{1}{s} & \frac{2}{s+1} \\ \frac{4}{s+3} & \frac{8}{s+4} \end{pmatrix}$$

The same as previously, but with the (2,2) entry divided by s . We now obtain $B^* = \begin{pmatrix} 1 & 2 \\ 4 & 8 \end{pmatrix}$, with decoupling indices $f_1 = 1$, $f_2 = 1$. B^* is now singular, so this system cannot be diagonally decoupled by state feedback alone.

27.1.2 Diagonal Decoupling with Internal Stability

A question of great practical interest is whether the closed-loop system that is obtained after decoupling can be made stable. It can be shown constructively (for instance, by use of the algorithm given below) that all of the poles that are evident from the diagonal closed-loop transfer matrix can be assigned any desired values. The question therefore becomes: Can the closed-loop system be made internally stable,

where there are no “hidden” cancellations between unstable poles and zeros? Such unstable modes are particularly dangerous in practice, as they will not be revealed by an examination of the transfer matrix. However, the hidden unstable state behavior they represent will very likely cause problems, such as burnout of internal electronic components of the system. It was shown by Gilbert [5] that a given plant may indeed have hidden fixed modes when it is diagonally decoupled by state feedback, with or without precompensation. Wolovich and Falb [15] then showed that these modes are the same for both cases; furthermore, they are a subset of the transmission zeros of the plant. In fact, they are those transmission zeros z_i that do not make any of the rows of the transfer matrix $T(s)$ equal to zero when evaluating $T(z_i)$; they are called *diagonal coupling zeros*. Thus, any plant with square, full-rank transfer matrix for which all the diagonal coupling zeros are in the left half-plane can be diagonally decoupled with internal stability by state feedback plus precompensation; or by state feedback alone if B^* is nonsingular. Therefore, there will never be any problems with internal stability when decoupling a minimum-phase system, as all of its transmission zeros are in the left half-plane.

An algorithm to diagonally decouple a system, when B^* has full rank, using state feedback is now presented. This algorithm is based on a procedure to obtain a stable inverse of a system that is described below. This procedure is applied to the system $D(s)T(s) = \hat{T}(s)$, where $D(s) = \text{diag}(s^{f_i})$ as in Equation 27.1, that can be shown to have a state-space realization $\{A, B, \hat{C}, \hat{D}\}$. In fact $\hat{D} = B^*$, which is assumed to have full rank p ; and this implies that a proper right inverse of the system $\hat{T}(s)$ exists. Here it is assumed that the system has the same number of inputs and outputs, and this simplifies the selection of F, G as in this case they are unique; see the algorithm for the inverse below for the nonsquare case. In particular, if the state feedback $u = Fx + Gr$ with

$$F = -(B^*)^{-1}\hat{C}, \quad G = (B^*)^{-1} \quad (27.2)$$

is applied to the system $\dot{x} = Ax + Bu, y = \hat{C}x + B^*u$, then it can be shown that $\hat{T}_{F,G}(s) = D(s)T_{F,G}(s) = I_p$. This implies that if the state feedback $u = Fx + Gr$ with F, G as in Equation 27.2 is applied to the given system $\dot{x} = Ax + Bu, y = Cx + Du$ with transfer matrix $T(s)$, then

$$T_{F,G}(s) = D^{-1}(s) \quad (27.3)$$

which is diagonal with entries s^{-f_i} . Note that here the state feedback matrix F assigns all the n closed-loop eigenvalues at the locations of the n zeros of $\hat{T}(s)$; that is, at the zeros of $T(s)$ and of $D(s)$. The closed-loop eigenvectors are also appropriately assigned so the eigenvalues cancel all the zeros to give $D(s)T_{F,G}(s) = I_p$. This explains the control mechanism at work here and also makes quite apparent the changes necessary to ensure internal stability. Simply instead of $D(s)$ use $\hat{D}(s) = \text{diag}\{p_i(s)\}$ with $p_i(s)$ stable polynomials of degree s^{f_i} ; that is, $p_i(s) = s^{f_i} + \text{lower-degree terms}$. Then it can be shown that $\lim_{s \rightarrow \infty} \hat{D}(s)T(s) = B^*$ and that $\{A, B, \tilde{C}, B^*\}$ is a realization of $\hat{D}(s)T(s) = \tilde{T}(s)$. State feedback with

$$F = -(B^*)^{-1}\tilde{C}, \quad G = (B^*)^{-1} \quad (27.4)$$

gives

$$T_{F,G}(s) = \hat{D}^{-1}(s) = \text{diag}\{p_i^{-1}(s)\} \quad (27.5)$$

which is stable. Note that in this case the closed-loop eigenvalues are at the assumed stable zeros of $T(s)$ and at the selected stable zeros of the polynomials $p_i(s)$, $i = 1, \dots, p$.

Example 27.4:

$$\text{Let } T(s) = \begin{pmatrix} \frac{s+1}{s^2} & 0 \\ 1 & \frac{-1}{s-1} \end{pmatrix}.$$

Here

$$\lim_{s \rightarrow \infty} D(s)T(s) = \lim_{s \rightarrow \infty} \text{diag}(s, s)T(s) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = B^*.$$

Since B^* has full rank, the system can be decoupled using state feedback $u = Fx + Gr$. The system has one transmission zero at -1 and there are no diagonal coupling zeros, so it can be decoupled with internal stability. Let $\hat{D}(s) = \begin{pmatrix} s+1 & 0 \\ 0 & s+2 \end{pmatrix}$. A minimal (controllable and observable) realization of $\tilde{T}(s) = \hat{D}(s)T(s)$ is $\{A, B, \tilde{C}, B^*\}$ where

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \tilde{C} = \begin{pmatrix} 1 & 2 & 0 \\ 3 & 1 & -3 \end{pmatrix}.$$

In view now of Equations 27.4 and 27.5, for

$$F = -(B^*)^{-1}\tilde{C} = \begin{pmatrix} -1 & -2 & 0 \\ 3 & 1 & -3 \end{pmatrix}$$

and

$$G = (B^*)^{-1} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

$$T_{F,G}(s) = \hat{D}(s)^{-1} = \begin{pmatrix} \frac{1}{s+1} & 0 \\ 0 & \frac{1}{s+2} \end{pmatrix}.$$

The closed-loop eigenvalues are in this case located at the transmission zero of the plant at -1 and at the selected locations -1 and -2 , the poles of $\hat{D}(s)^{-1}$. Note that it is not necessary to cancel the transmission zero at -1 in order to decouple the system since it is not a coupling zero; it could appear as a zero in the decoupled system instead. To illustrate this, consider Example 27.5 where $T(s)$ is the same except that the zero is now unstable at $+1$.

Example 27.5:

$$\text{Let } T(s) = \begin{pmatrix} \frac{s-1}{s^2} & 0 \\ 1 & \frac{-1}{s-1} \end{pmatrix} \text{ where again}$$

$$\lim_{s \rightarrow \infty} D(s)T(s) = \lim_{s \rightarrow \infty} \text{diag}(s, s)T(s) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = B^*.$$

Since B^* has full rank, the system can be decoupled using state feedback. Since there are no diagonal coupling zeros, the system can be decoupled with internal stability. Write $T(s) = \begin{pmatrix} s-1 & 0 \\ 0 & 1 \end{pmatrix} T_N(s)$

and apply the algorithm to diagonally decouple $T_N(s)$. Now $D_N(s) = \begin{pmatrix} s^2 & 0 \\ 0 & s \end{pmatrix}$ and take

$$\hat{D}_N(s) = \begin{pmatrix} (s+2)(s+3) & 0 \\ 0 & s+1 \end{pmatrix}.$$

A minimal (controllable and observable) realization of $\tilde{T}_N(s) = \hat{D}_N(s)T_N(s)$ is $\{A, B, \tilde{C}_N, B_N^*\}$ where

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \tilde{C}_N = \begin{pmatrix} 6 & 5 & 0 \\ 2 & 1 & -2 \end{pmatrix}$$

and

$$B_N^* = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = B^*.$$

In view now of Equations 27.4 and 27.5, for $F = -(B^*)^{-1}\tilde{C}_N = \begin{pmatrix} -6 & -5 & 0 \\ 2 & 1 & -2 \end{pmatrix}$ and

$$G = (B_N^*)^{-1} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

$$(T_N)_{F,G}(s) = \hat{D}_N(s)^{-1} = \begin{pmatrix} \frac{1}{(s+2)(s+3)} & 0 \\ 0 & \frac{1}{s+1} \end{pmatrix}.$$

If now this state feedback is applied to the minimal realization $\{A, B, C\}$ of $T(s)$ —note that A, B are the same as above—then $T_{F,G}(s) = \begin{pmatrix} s-1 & 0 \\ 0 & 1 \end{pmatrix} \hat{D}_N^{-1} = \begin{pmatrix} \frac{s-1}{(s+2)(s+3)} & 0 \\ 0 & \frac{1}{s+1} \end{pmatrix}$. Note that the unstable noncoupling transmission zero at $+1$ appears on the diagonal of the compensated system; the closed-loop eigenvalues are at the arbitrarily chosen stable locations $-1, -2$ and -3 .

Algorithm to Obtain a Proper Stable Right Inverse Using State Feedback

Let $\dot{x} = Ax + Bu$, $y = Cx + Du$ with A, B, C, D $n \times n$, $n \times m$, $p \times n$, $p \times m$ real matrices, respectively, and assume that the system is controllable and observable. Let $T(s)$ be its transfer function matrix. It is known that there exists a proper right inverse $T_R(s)$, such that $T(s)T_R(s) = I_p$, if and only if $\text{rank} D = p$. If, in addition, all the zeros of $T(s)$ (that is, the transmission zeros of the system) are stable, then a stable right inverse of order n can be constructed with $k (< n)$ of its poles equal to the k stable zeros of $T(s)$ with the remaining $n - k$ poles arbitrarily assignable. This can be accomplished as follows:

Let $T_{eq} = F[sI - (A + BF)]^{-1}BG + G$ where F, G are $n \times m$, $m \times p$, respectively, and note that

$$\begin{aligned} T(s)T_{eq}(s) &= [C(sI - A)^{-1}B + D][F[sI - (A + BF)]^{-1}BG + G] \\ &= (C + DF)[sI - (A + BF)]^{-1}BG + DG = T_{F,G}(s) \end{aligned} \quad (27.6)$$

which is the transfer matrix one obtains when the state feedback control law $u = Fx + Gr$ is applied to the given system. Note that the second line of Equation 27.6 results from application of a well-known formula for the matrix inverse. If now F, G are such that

$$C + DF = 0, \quad DG = I_p \quad (27.7)$$

then $T_{F,G}(s) = I_p$ and T_{eq} is a proper right inverse $T_R(s)$. The additional freedom in the choice of F when $p < m$ is now used to derive a stable inverse; when $p = m$, F, G are uniquely determined from $F = -D^{-1}C$, $G = D^{-1}$.

If the nonsingular $m \times m$ matrix M is such that $DM = (I_p \ 0)$, then $C + DF = C + DMM^{-1}F = C + (I_p \ 0) \begin{pmatrix} \hat{F}_1 \\ \hat{F}_2 \end{pmatrix} = 0$ from which $F = M \begin{pmatrix} -C \\ \hat{F}_2 \end{pmatrix}$ with \hat{F}_2 arbitrary. Also, from $DG = DMM^{-1}G = I_p$, $G = M \begin{pmatrix} I_p \\ \hat{G}_2 \end{pmatrix}$ with \hat{G}_2 arbitrary. The eigenvalues of $A + BF = A + BM \begin{pmatrix} -C \\ \hat{F}_2 \end{pmatrix} = A + (\hat{B}_1 \ \hat{B}_2) \begin{pmatrix} -C \\ \hat{F}_2 \end{pmatrix} = A - \hat{B}_1 C + \hat{B}_2 \hat{F}_2$ are the poles of $T_R(s)$. It can be shown that the uncontrollable eigenvalues of $(A - \hat{B}_1 C \ \hat{B}_2)$ are exactly the (k) zeros of the system; they cannot be changed via \hat{F}_2 . The remaining $n - k$ controllable eigenvalues can be arbitrarily assigned using \hat{F}_2 . In summary, the steps to derive a stable proper inverse are

Step 1. Find nonsingular $m \times m$ matrix M such that $DM = (I_p \ 0)$.

Step 2. Calculate $(\hat{B}_1 \ \hat{B}_2) = BM$, and $A - \hat{B}_1 C$.

Step 3. Find \hat{F}_2 that assigns the controllable eigenvalues of $(A - \hat{B}_1 C \ \hat{B}_2)$ to the desired locations. The remaining uncontrollable eigenvalues are the stable zeros of the system.

Step 4.

$$\left\{ A + BM \begin{pmatrix} -C \\ \hat{F}_2 \end{pmatrix}, BM \begin{pmatrix} I_p \\ \hat{G}_2 \end{pmatrix}, M \begin{pmatrix} -C \\ \hat{F}_2 \end{pmatrix}, M \begin{pmatrix} I_p \\ \hat{G}_2 \end{pmatrix} \right\} \quad (27.8)$$

where \hat{G}_2 , a $(m - p) \times p$ arbitrary real matrix, is a stable right inverse.

$T_{eq}(s)$ above is the open-loop equivalent to the state feedback control law. In view of Equations 27.6 and 27.7 the above algorithm selects F, G in a state feedback control law $u = Fx + Gr$ so that the closed-loop transfer matrix $T_{F,G}(s) = I_p$ and the closed-loop system is internally stable; that is, all the n eigenvalues of $A + BF$ are stable. Note that when $p = m$, then F, G are uniquely given by $F = -D^{-1}C$, $G = D^{-1}$; the eigenvalues of $A + BF$ are then the n zeros of the system. In this development of stable inverses via state feedback, the approach in [1] was taken; see also [7,12].

In order to implement decoupling by state feedback in practice, it is often necessary to estimate the internal state variables by means of an observer. Certain plants can be decoupled by *constant output feedback*, avoiding the need for an observer. The necessary and sufficient conditions under which this is possible were proved by Wolovich [18]: it is that B^* not only be nonsingular, but also that the modified inverse transfer matrix $B^*T^{-1}(s)$ have only constant off-diagonal elements. This appears to be a very stringent condition, so diagonal decoupling by means of constant output feedback is not likely to be possible for any but a relatively small class of plants. This is in clear contrast with the state feedback case, as mentioned previously. If diagonal decoupling by output feedback is possible, any gain matrix H that achieves it must give all off-diagonal entries of B^*H equal to those of $B^*T^{-1}(s)$. It can therefore be seen that any constant matrix of the form $(B^*)^{-1}Z$ can be added to H , where Z is an arbitrary diagonal matrix, and still give a gain matrix that satisfies the required condition. There is thus a small amount of controller design freedom available, which can be used, for instance, to assign closed-loop poles to some extent. However, it does not appear possible to quantify this pole-placement freedom in any straightforward manner.

27.1.3 Block Decoupling

If diagonal decoupling by linear state feedback is not possible, an alternative to applying precompensation may still exist. It may be possible to use state feedback, or perhaps even output feedback, to reduce the system to a set of smaller subsystems that are independent; that is, decoupled. Controlling each of these small systems can then be performed in isolation from all the others, thus reducing the original plant control problem to several simpler ones. This is the idea behind block decoupling, where the goal is to transform the plant transfer matrix to one that is block diagonal rather than strictly diagonal. For square

plants, each of these k diagonal blocks will also be square: the i th will be taken to have p_i inputs and p_i outputs, with $\sum p_i = p$.

One question associated with block decoupling can be answered immediately: namely, any plant with nonsingular transfer matrix can be block decoupled by linear state feedback plus precompensation. This follows from the fact that any such system can be diagonally decoupled by this form of compensation and so is trivially of any desired block diagonal form. The two types of compensation that have to be addressed here are therefore state feedback and constant output feedback.

If we are interested in block decoupling a given system by state feedback, this implies that it was not fully diagonalizable by state feedback. Hence, the matrix B^* must have been singular. As the inverse of this matrix played a significant role in the development of diagonal decoupling compensators, it seems likely that overcoming this singularity may lead toward designing block decoupling compensators for systems that cannot be diagonalized by state feedback. An equivalent way of stating that B^* is singular is to note that, although all rows of $\lim_{s \rightarrow \infty} D(s)T(s)$ are certainly finite and nonzero, some of these rows must have been linearly dependent on the preceding ones. Suppose the i th row is one such. It is then possible to add multiples of rows $1, \dots, i-1$ to row i in order to zero out the i th row in B^* ; that is, to make what had been the leading coefficient vector of this row of $D(s)T(s)$ zero. If the new leading term in this row is now of order s^{-k} , multiplying the row by s^k yields a new finite and nonzero limit as s goes to infinity. If this row vector is independent of the preceding ones, we have now increased the rank of the modified B^* -like matrix; if not, the same process can be repeated until successful. This basic procedure leads to the following definition, which has proved to be very useful for studying block decoupling problems.

The interactor $X_T(s)$ of $T(s)$ is the unique polynomial matrix of the form $X_T(s) = H(s)\Delta(s)$, where $\Delta(s) = \text{diag}(s^{f_i})$ and $H(s)$ is a lower triangular polynomial matrix with 1s on the diagonal and the nonzero off-diagonal elements divisible by s , for which

$$\lim_{s \rightarrow \infty} X_T(s)T(s) = K_T \quad (27.9)$$

is finite and full rank. The interactor can be found from the transfer matrix of the system [16]; from a state-space representation [4]; or from a polynomial matrix fraction description for it [13]. The basic procedure can be illustrated by applying it to two examples discussed previously.

Example 27.6:

$$T(s) = \begin{pmatrix} \frac{1}{s} & \frac{2}{s+1} \\ \frac{4}{s+3} & \frac{8s}{s+4} \end{pmatrix}.$$

This gives $B^* = \begin{pmatrix} 1 & 2 \\ 0 & 8 \end{pmatrix}$, with decoupling indices $f_1 = 1, f_2 = 0$. B^* is nonsingular, so it satisfies the definition of the desired matrix K_T . Thus, $K_T = B^* = \begin{pmatrix} 1 & 2 \\ 0 & 8 \end{pmatrix}$ here, and $X_T(s) = \text{diag}(s^{f_1}, s^{f_2}) = \begin{pmatrix} s & 0 \\ 0 & 1 \end{pmatrix}$.

Example 27.7:

$$T(s) = \begin{pmatrix} \frac{1}{s} & \frac{2}{s+1} \\ \frac{4}{s+3} & \frac{8}{s+4} \end{pmatrix}$$

$B^* = \begin{pmatrix} 1 & 2 \\ 4 & 8 \end{pmatrix}$, which is singular, with decoupling indices $f_1 = 1, f_2 = 1$. Subtracting 4 times row 1 of $\text{diag}(s^{f_i})T(s)$ from row 2 eliminates the linearly dependent leading coefficient vector. The resulting lower-degree polynomial row vector can then be multiplied by s , so as to again obtain a finite limit as s goes to infinity. We then have

$$\hat{T}_1(s) = \begin{pmatrix} 1 & 0 \\ 0 & s \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -4 & 1 \end{pmatrix} \begin{pmatrix} s & 0 \\ 0 & s \end{pmatrix}$$

$$T(s) = \begin{pmatrix} 1 & \frac{2s}{s+1} \\ -12s & \frac{-24s^2}{(s+1)(s+4)} \end{pmatrix}.$$

Unfortunately, $\hat{T}_1(s)$ has limit as s goes to infinity of

$$\begin{pmatrix} 1 & 2 \\ -12 & -24 \end{pmatrix},$$

which is still singular. We therefore have to repeat the procedure, this time adding 12 times row 1 to row 2 to eliminate the leading coefficients and multiplying the resulting row by s to give it a finite

limit. We then obtain $\begin{pmatrix} 1 & 0 \\ 0 & s \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 12 & 1 \end{pmatrix} \hat{T}_1(s) = \begin{pmatrix} 1 & \frac{2s}{s+1} \\ \frac{36s}{s+3} & \frac{2s}{96s^2} \end{pmatrix}$, which has limit as s goes

to infinity of $\begin{pmatrix} 1 & 2 \\ 36 & 96 \end{pmatrix}$. This is clearly nonsingular, so $K_T = \begin{pmatrix} 1 & 2 \\ 36 & 96 \end{pmatrix}$ for this system. The interactor is then

$$X_T(s) = \begin{pmatrix} 1 & 0 \\ 0 & s \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 12 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & s \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -4 & 1 \end{pmatrix} \begin{pmatrix} s & 0 \\ 0 & s \end{pmatrix}$$

$$= \begin{pmatrix} s & 0 \\ -4s^3 + 12s^2 & s^3 \end{pmatrix}$$

$$= \begin{pmatrix} 1 & 0 \\ -4s^2 + 12s & 1 \end{pmatrix} \begin{pmatrix} s & 0 \\ 0 & s^3 \end{pmatrix}$$

which is of the desired form $H(s)\Delta(s)$.

It can be seen that, if B^* is nonsingular, no additional row operations are needed to modify it to give the nonsingular K_T . Thus, in this case $B^* = K_T$ and $D(s) = X_T(s)$. But we already know that diagonal decoupling by state feedback is possible in this case; that is, diagonalization by state feedback is possible if and only if the interactor of the system is diagonal. This suggests the following general result.

A square system can be block decoupled by state feedback if and only if its interactor is of this same block diagonal structure.

A proof of this result is based on the fact that state feedback matrices F, G can always be found that make the closed-loop transfer matrix equal to the inverse of its interactor; see the algorithms discussed previously and [2,6]. Thus, if this matrix is block diagonal, so is the closed-loop transfer matrix. The state feedback that achieves this form can be found in an analogous manner to the state feedback matrices determined above that diagonally decouple the system.

Note that the structure algorithm of Silverman [11] is quite closely related to the interactor. This method determines a polynomial matrix $X(s)$ such that $\lim_{s \rightarrow \infty} X(s)T(s)$ is finite and nonsingular; however, $X(s)$ is not of any particular structure, unlike the interactor. This makes $X_T(s)$ better suited to obtaining clear block decoupling results.

Another question that generalizes naturally from the diagonal case is that of stability. The only fixed modes when diagonalizing were the diagonal coupling zeros, which were all zeros of the original plant that were not also zeros of any of the rows of the plant transfer matrix. In the case of block decoupling, the only fixed poles are the block coupling zeros, which are all zeros of the plant that are not also zeros of one of the $(p_i \times m)$ row blocks of $T(s)$. As in the diagonal case, these zeros must be cancelled by closed-loop poles in the decoupled transfer matrix, so creating unobservable modes; all other poles can be assigned arbitrarily.

Finally, it may be possible to achieve block decoupling by the simpler constant output feedback compensation. It can be shown that the interactor also allows a simple test for this question. In fact, block decoupling by constant output feedback is possible if and only if the interactor of the system is block diagonal and the modified inverse system $K_T T^{-1}(s)$ has only constant entries outside the diagonal blocks. The output feedback gain matrix H that achieves block decoupling is such that $K_T H$ is equal to the constant term in $K_T T^{-1}(s)$ outside the diagonal blocks. This is very similar to the diagonal decoupling result. As there, a certain degree of flexibility exists in the design of H , due to the fact that the diagonal blocks of $K_T T^{-1}(s)$ are essentially arbitrary; this can be used to provide a small amount of pole assignment flexibility when decoupling.

27.1.4 Decoupling Nonsquare Systems

The previous development has been primarily for plants with equal numbers of inputs and outputs. Plants that are not square present additional complications when studying decoupling. For instance, if there are more outputs than inputs, it is clearly impossible to assign a separate input to control each output individually; diagonal decoupling in its standard form is therefore not feasible. Similarly, decoupling the system into several independent square subsystems is also impossible. On the other hand, plants with more inputs than outputs present the opposite difficulty: there are now more input variables than are required to control each output individually.

Fortunately, the classical decoupling problem can be generalized in a straightforward fashion to cover nonsquare plants as well as square ones. In view of the preceding remarks, it is clear that systems with more outputs than inputs ($p > m$) must be analyzed separately from those with more inputs than outputs ($p < m$). The former case leads to decoupling results that are barely more complicated than those for the square case; the additional design freedom available in the latter case means that conditions that were necessary and sufficient for $p = m$ become only sufficient for $p < m$.

Taking the case of more inputs than outputs ($p < m$), the following results can be shown to hold for diagonal decoupling. First, any such plant that is right-invertible (that is, for which the transfer matrix is of full rank, p) can be decoupled by state feedback plus precompensation; this follows from the close connections between this type of decoupling control law and finding a right inverse of the system. If we restrict ourselves to state feedback, two sufficient conditions for diagonal decoupling can be stated. First, the plant can be diagonalized by state feedback if its matrix B^* is of full row rank, p . This is extremely easy to test, but can be somewhat conservative. A tighter sufficient condition is as follows: The plant can be diagonalized by state feedback if a constant $(m \times p)$ matrix G can be found for which the B^* matrix of the square-modified transfer matrix $T(s)G$ is nonsingular.

It may be thought that these two sufficient conditions are identical. To see that they are not, consider the following simple example: $T(s) = \begin{pmatrix} 1/s & 1/s^2 & 1/s \\ (s+2)/s^2 & 1/s^2 & 1/s \end{pmatrix}$ has $B^* = \begin{pmatrix} 1 & 0 & 1 \\ 1 & 0 & 1 \end{pmatrix}$, which has only rank 1. The first sufficient condition for diagonal decoupling is therefore violated. However, post-multiplying $T(s)$ by the matrix

$$G = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ -1 & 0 \end{pmatrix}$$

gives

$$T(s)G = \frac{1}{s^2} \begin{pmatrix} 0 & 1 \\ 2 & 1 \end{pmatrix},$$

which clearly has nonsingular B^* matrix of $\begin{pmatrix} 0 & 1 \\ 2 & 1 \end{pmatrix}$. The role of the G matrix is basically to cancel those higher-power terms in s in $T(s)$ that give rise to linearly dependent rows in B^* ; in the example, the first column of G , $(1 \ 0 \ -1)^T$, can be seen to be orthogonal to the repeated row vector $[1 \ 0 \ 1]$ in the original B^* . Lower-power terms in $T(s)$ then become the leading terms, so their coefficients contribute to the new B^* ; these terms may well be independent of the first ones. An algorithm that goes into the details of constructing such a G , if it exists, for any right-invertible $T(s)$ is given by Williams [13].

Very similar results apply to the problem of block decoupling a system with more inputs than outputs ($p < m$) by means of state feedback. The more conservative sufficient condition states that the plant can be block decoupled if its interactor matrix has the desired block diagonal structure. This can then be tightened somewhat by proving that the plant $T(s)$ can be block decoupled if there exists some $(m \times p)$ constant matrix G that has interactor of the desired block diagonal form. Furthermore, the algorithm described previously for block decoupling of square plants can be applied equally in this case, either to $T(s)$ or $T(s)G$. The only distinction of significance between the square case and $p < m$ is that the algorithm was proved to use decoupling precompensation of lowest possible order in the square case; for nonsquare plants, minimality of this order cannot be proven.

In the case of plants with more outputs than inputs ($p > m$), the main complication is in modifying the definition of a “decoupled” closed-loop structure. Once this is done, the actual technical results are rather straightforward. As already noted, it is no longer possible to assign a single input to each individual output, as is required in the classical diagonal decoupling problem. The closest analog to this problem is one where the closed-loop system is decoupled into a set of m independent single-input/multi-output subsystems; each closed-loop control input influences a set of outputs, but does not affect any of the others. Similarly, it is not possible to assign equal numbers of independent inputs and outputs to each decoupled subsystem, as holds for square block decoupling. What we must do instead is to define decoupled subsystems that generally have more outputs than inputs; that is, they are of dimensions $p_i \times m_i$, where $p_i \leq m_i$; of course, $\sum p_i = p \leq \sum m_i = m$.

It can be shown that a very simple rank condition on the plant transfer matrix determines whether or not these decoupling problems have a solution. The simplest question to answer is whether the desired decoupled structure is achievable by means of a combination of state feedback and precompensation. The test is as follows:

Take the p_i rows of the plant transfer function corresponding to the outputs that are to be assigned to the i th decoupled subsystem. If this $p_i \times m$ transfer matrix has rank m_i , and this holds for each i , then the plant can be decoupled into $p_i \times m_i$ subsystems by means of state feedback plus precompensation.

The significance of this result is easiest to see for the special case where $m_i = 1$ for each i , the closest analog to diagonal decoupling for systems with $p > m$. If decoupling is to be possible, we must have that each $p_i \times m$ transfer matrix of the i th subsystem is of rank 1. This implies that the rows of this transfer matrix are all polynomial multiples of some common factor row vector. In other words, the p_i outputs of this subsystem are all made up of combinations of derivatives of a single “underlying” output variable. Similarly, decoupling into $p_i \times m_i$ subsystems is possible if and only if the p_i outputs making up the i th subsystem are actually made up of some combinations of m_i “underlying” output variables.

In practice, applying these rank conditions to the plant transfer matrix dictates what block dimensions are possible as closed-loop block decoupled structure. They also show which outputs must be taken as members of the same decoupled subsystem. For instance, if we wish to achieve $p_i \times 1$ decoupling and two rows of the plant transfer matrix are linearly dependent, the corresponding outputs must clearly be placed in the same subsystem.

But this approach also has one further very important implication. Consider a system that satisfies these submatrix rank conditions. If we take the m_i “underlying” output variables for each of the r subsystems, write down the corresponding $m_i \times m$ transfer matrix, and then concatenate these, we obtain a new $m \times m$ transfer matrix, denoted by $T_m(s)$. It can then be shown (see [13]) that a controller will decouple $T(s)$ into $p_i \times m_i$ blocks if and only if it also decouples $T_m(s)$ into square $m_i \times m_i$ blocks. We can therefore take all of the decoupling results derived previously for square plants and use them to solve the problem of decoupling systems with more outputs than inputs. In particular, $T(s)$ can be decoupled into $p_i \times m_i$ blocks by state feedback if and only if it satisfies the submatrix rank conditions and the interactor matrix of $T_m(s)$ is $m_i \times m_i$ block diagonal. Also, it can be shown that $T_m(s)$ has precisely the same zeros as $T(s)$. The two systems therefore clearly also have the same coupling zeros, so the fixed poles when decoupling $T(s)$ are the same as the fixed poles when decoupling $T_m(s)$. Finally, decoupling by means of output feedback can also be studied by applying the existing results for square systems to the associated $T_m(s)$.

Example 27.8:

The state-space model

$$A = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 1 \end{pmatrix}, \quad C = I_3$$

has transfer matrix

$$T(s) = \frac{1}{(s+1)(s^2-s-1)} \begin{pmatrix} s(s+1) & s \\ (s+1)^2 & s+1 \\ (s+1)^2 & s^2 \end{pmatrix}.$$

Clearly, the first two rows are linearly dependent, so this system can be decoupled into the block diagonal form $\begin{pmatrix} * & 0 \\ * & 0 \\ 0 & * \end{pmatrix}$ by state feedback plus precompensation. In fact, the associated invertible transfer function for this system is

$$T_m(s) = \frac{1}{(s+1)(s^2-s-1)} \begin{pmatrix} s+1 & 1 \\ (s+1)^2 & s^2 \end{pmatrix},$$

which has interactor $\begin{pmatrix} s^2 & 0 \\ 0 & s \end{pmatrix}$ diagonal [with $K_T = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$]. Thus, block decoupling is actually possible for this system using state feedback alone.

As a final point on general block decoupling, note that this problem can also be studied using the geometric approach; see [19]. This state-space technique is based on considering the supremal (A, B) -invariant subspaces contained in the kernels of the various subsystems formed by deleting the outputs corresponding to each desired block in turn. The ranges of these subspaces determine whether decoupling is possible by state feedback. If it is not, the related “efficient extension” approach allows a precompensator of relatively low order to be found that will produce the desired block diagonal structure. This approach is somewhat involved, and the interested reader is referred to Morse and Wonham [8] for further details.

27.1.5 Triangular Decoupling

There is a form of “partially decoupled” system that can be of particular value for certain plants. This is the triangularized form, where all entries of the closed-loop transfer matrix above its leading diagonal are made zero. The first closed-loop output, y_1 , is therefore affected only by the first input r_1 ; the second, y_2 , is influenced only by inputs r_1 and r_2 ; etc. This type of transfer matrix can be used in the following sequential control scheme. First, input r_1 is adjusted until output y_1 is as desired, and the control is then

frozen. Output variable y_2 is then affected only by r_2 and the fixed r_1 , so r_2 can be adjusted until this output is also as desired. The third input, r_3 , can then be used to set output y_3 , etc. This scheme can be seen to be less powerful than diagonal decoupling, as the outputs must be adjusted sequentially rather than fully independently. However, it has one strong point in its favor: *any right-invertible plant can be triangularized by state feedback alone*, regardless of whether additional precompensation is required to make it diagonally decoupled. Proof of this follows directly from the fact that there always exists some state feedback gains F, G for which $T_{F,G}(s) = X_T^{-1}(s)$, and the interactor is, by definition, lower triangular. Of course, similar results apply for generalized rather than standard interactors also. Therefore, it can be shown, as originally proved by Morse and Wonham [9], that all closed-loop poles of the triangularly decoupled system can be arbitrarily assigned.

Finally, it may also be possible to triangularize a system by means of the simpler constant output feedback. If the original plant is square and strictly proper ($D = 0$), it can be shown that this is possible if and only if all entries of the modified inverse transfer matrix $K_T T^{-1}(s)$ that lie above the leading diagonal are constant. This is quite a simple condition to test and is very similar to the test for diagonal decoupling by output feedback. The required gain matrix H is given from the fact that the upper triangular part of $K_T H$ is precisely the upper triangular constant part of $K_T T^{-1}(s)$. It can be noted that there is therefore some non-uniqueness in the choice of the gain H : in particular, we can add a term of the form $K_T^{-1} Z$ to H , where Z is any lower triangular constant matrix, and still get a suitable output gain matrix. If it is possible to triangularize a given system by output feedback, there is consequently some freedom to assign closed-loop poles also. However, it is difficult to quantify this freedom in any concrete way.

27.1.6 Static Decoupling

Static decoupling, as opposed to dynamic decoupling already described, is much easier to achieve. A system is statically decoupled if a step change in the (static) steady-state level of the i th input is reflected by a change in the steady-state level of the i th output and only that output. To derive the conditions for static decoupling, assume that the system is described by a $p \times p$ transfer matrix $T(s)$ that is bounded-input/bounded-output stable; that is, all of its poles are in the open left half of the s -plane and none is on the imaginary axis. Note that stability is necessary for the steady-state values of the outputs to be well defined. Assume now that the p inputs are step functions described by $u_i(s) = \frac{k_i}{s}$, $i = 1, \dots, p$. The steady-state value of the output vector y , y_{ss} , can then be found using the final value theorem, as follows:

$$y_{ss} = \lim_{s \rightarrow \infty} y(t) = \lim_{s \rightarrow 0} s T(s) \frac{1}{s} \begin{pmatrix} k_1 \\ k_2 \\ \vdots \\ k_p \end{pmatrix} = T(0) \begin{pmatrix} k_1 \\ k_2 \\ \vdots \\ k_p \end{pmatrix} \quad (27.10)$$

It is now clear that $T(s)$ is statically decoupled if and only if $T(0)$ is a diagonal nonsingular matrix; that is, all the off-diagonal entries of $T(s)$ must be divisible by s , while the entries on the diagonal should not be divisible by s . It can be shown easily that a system described by a $p \times p$ transfer matrix $T(s)$ that is bounded-input/bounded-output stable can be statically decoupled, via $u = Gr$, if and only if

$$\text{rank } T(0) = p \quad (27.11)$$

that is, if and only if there is no transmission zero at $s = 0$. Note that this condition, if a controllable and observable state-space description is given, is

$$\text{rank} \begin{pmatrix} A & B \\ C & D \end{pmatrix} = n + p \quad (27.12)$$

If this is the case, any feedforward constant gain G , in $u = Gr$, such that $T(0)G$ is a diagonal and nonsingular matrix will statically decouple the system. To illustrate, consider the following example:

Example 27.9:

$$T(s) = \begin{pmatrix} \frac{s+2}{s+1} & \frac{2}{s+3} \\ \frac{s(s+1)}{(s+3)^2} & \frac{1}{s+1} \end{pmatrix}$$

Here $T(0) = \begin{pmatrix} 2 & 2/3 \\ 0 & 1 \end{pmatrix}$, which has full rank; therefore, it can be statically decoupled. Let $T(0)G = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}$; then $G = \begin{pmatrix} 1 & -1/3 \\ 0 & 1 \end{pmatrix}$. Note that

$$T(s)G = \begin{pmatrix} \frac{s+2}{s+1} & \frac{-s(s-1)}{3(s+1)(s+3)} \\ \frac{s(s+1)}{(s+3)^2} & \frac{-s^3 + s^2 + 17s + 27}{3(s+1)(s+3)^2} \end{pmatrix}$$

where all the off-diagonal entries of $T(s)$ are divisible by s , while the entries on the diagonal are not divisible by s . If now the input $\frac{1}{s} \begin{pmatrix} k_1 \\ k_2 \end{pmatrix}$ is applied to $T(s)G$, the steady-state output is $T(0)G \begin{pmatrix} k_1 \\ k_2 \end{pmatrix} = \begin{pmatrix} 2k_1 \\ k_2 \end{pmatrix}$.

27.2 Defining Terms

Decoupling: Separating the system into a number of independent subsystems.

Non-interacting control: The control inputs and the outputs can be partitioned into disjoint subsets; each subset of outputs is controlled by only one subset of inputs, and each subset of inputs affects only one subset of outputs. From an input/output viewpoint, the system is split into independent subsystems; it is called decoupled.

28.1 Introduction

Model predictive control (MPC) refers to a class of control algorithms that compute a sequence of control moves based on an explicit prediction of outputs within some future horizon. The computed control moves are typically implemented in a receding horizon fashion, meaning only the moves for the current time are implemented and the whole calculation is repeated at the next sample time. In essence, MPC is a *feedback* control strategy based on *repeated* calculation of *open-loop* control trajectories.

It is difficult to attribute MPC to any single individual, since the idea of MPC has appeared in many different forms and in the context of a variety of applications. In the process industries, serious applications and research on the subject began in the late 1970s, fueled by seminal papers by several industrialists, who outlined the basic algorithm and pointed out their potential for providing effective solutions to difficult process control problems [1,6]. Owing to its unique ability to handle process interactions and

constraints in a unified manner, MPC progressed rapidly, establishing an impressive track record along the way. The initial applications were mainly in the petrochemical industries, but it has been applied to a variety of industries including chemicals, food, and pulp and paper. Now MPC has become a standard tool for process control and there are several vendors that market general-purpose MPC software and commissioning services.

The objective of this chapter is to introduce the *linear MPC* technique as viewed from the process industries. After introducing a prototypical algorithm in Section 28.2, we discuss some implementation issues in Section 28.3 and introduce several notable idiosyncratic features of various other commercial MPC algorithms. Finally, we point out some future research needs.

28.2 Industrial MPC Algorithm

Dynamic matrix control (DMC) was one of the first commercial implementations of MPC. In this section, we describe the basic ideas of the algorithm.

28.2.1 The Idea of Moving Horizon Control

Consider the diagram in Figure 28.1. At the present time k the behavior of the process over a horizon p is considered. Using the model, the response of the process output to changes in the manipulated variable (MV) is predicted. Current and future moves of the MVs are selected such that the predicted response has certain desirable (or *optimal*) characteristics. For instance, a commonly used objective is to minimize the sum of squares of the future errors, that is, the deviations of the controlled variable (CV) from a desired target (setpoint). This minimization can also take into account constraints, that may be present on the MVs and the outputs.

The idea is appealing but would not work very well in practice if the moves of the MV determined at time k were applied blindly over the future horizon. Disturbances and modeling errors may lead to deviations between the predicted behavior and the actual observed behavior, so that the computed MV moves may not be appropriate any more. Therefore only the first one of the computed moves is actually implemented. At the next time step $k + 1$, a measurement is taken, the horizon is shifted forward by one

FIGURE 28.1 Moving horizon control.

step, and the optimization is done again over this shifted horizon based on the updated prediction of the system behavior. Therefore, this control strategy is also referred to as *moving horizon control*.

A similar strategy is used in many other nontechnical situations. One example is computer chess where the computer moves after evaluating all possible moves over a specified “depth” (the horizon). At the next turn the evaluation is repeated based on the current board situation. Another example would be investment planning. A five-year plan is established to maximize the return. Periodically, a new five-year plan is put together over a shifted horizon to take into account changes that have occurred in the economy.

The DMC algorithm includes as one of its major components a technique to predict the future output of the system as a function of the inputs and disturbances. This prediction capability is necessary to determine the optimal future control inputs and will be discussed next. Afterward we will state the objective function, and formulate the optimization problem.

28.2.2 Multistep Prediction

We consider the setup depicted in Figure 28.2 where we have three different types of external inputs: the MV u , whose effect on the output, usually a CV, is described by P_u ; the measured disturbance variable (DV) d whose effect on the output is described by P_d ; and finally the unmeasured and unmodeled disturbances w_y , which add a bias to the system output. The overall system can be described by

$$y(k) = [P^u \quad P^d] \begin{bmatrix} u(k) \\ d(k) \end{bmatrix} + w_y(k). \tag{28.1}$$

We assume that step response models S^u, S^d are available for the system dynamics P_u and P_d , respectively. We can define the overall multivariable step response model

$$S = [S^u \quad S^d], \tag{28.2}$$

which is driven by the known overall input

$$\Delta v(k) = \begin{bmatrix} \Delta u(k) \\ \Delta d(k) \end{bmatrix}. \tag{28.3}$$

Let us adopt as the system state

$$\tilde{Y}(k) = [\tilde{y}_0^T(k), \tilde{y}_1^T(k), \dots, \tilde{y}_{n-1}^T(k)]^T, \tag{28.4}$$

where n is the number of sample steps it takes for the system to settle down after a step change is made to any of the inputs. The elements of the state represent the future system outputs

$$\tilde{Y}(k) = \begin{bmatrix} y(k) \\ y(k+1) \\ \vdots \\ y(k+n-1) \end{bmatrix} \tag{28.5}$$

FIGURE 28.2 Basic problem setup.

obtained under the assumption that the system inputs do not change from the previous values, that is,

$$\begin{aligned}\Delta u(k) &= \Delta u(k+1) = \dots = 0, \\ \Delta d(k) &= \Delta d(k+1) = \dots = 0.\end{aligned}\quad (28.6)$$

Also, the state does not include any unmeasured disturbance information and hence it is assumed in the definition that

$$w_y(k) = w_y(k+1) = \dots = 0. \quad (28.7)$$

The state is updated according to

$$\tilde{Y}(k) = M \cdot \tilde{Y}(k-1) + S \Delta v(k-1). \quad (28.8)$$

where M is a shift operator expressed as

$$M = \left. \begin{bmatrix} 0 & I & 0 & \dots & \dots & 0 & 0 \\ 0 & 0 & I & 0 & \dots & 0 & 0 \\ \vdots & & & & & & \vdots \\ 0 & 0 & \dots & \dots & \dots & 0 & I \\ 0 & 0 & \dots & \dots & \dots & 0 & I \end{bmatrix} \right\} n \quad (28.9)$$

and

$$S = \begin{bmatrix} S_1 \\ \vdots \\ S_n \end{bmatrix}, \quad (28.10)$$

where S_i is the i th step response coefficient matrix. The equation reflects the effect of the input change $\Delta v(k-1)$ on the future evolution of the system assuming that there are no further input changes. The influence of the input change manifests itself through the step response matrix S . The effect of any future input changes is described as well by the appropriate step response matrix. Let us consider the predicted output over the next p time steps

$$\begin{aligned} \begin{bmatrix} y(k+1|k) \\ y(k+2|k) \\ \vdots \\ \vdots \\ y(k+p|k) \end{bmatrix} &= \begin{bmatrix} \tilde{y}_1(k) \\ \tilde{y}_2(k) \\ \vdots \\ \vdots \\ \tilde{y}_p(k) \end{bmatrix} + \begin{bmatrix} S_1^u \\ S_2^u \\ \vdots \\ \vdots \\ S_p^u \end{bmatrix} \Delta u(k|k) + \begin{bmatrix} 0 \\ S_1^u \\ S_2^u \\ \vdots \\ S_{p-1}^u \end{bmatrix} \Delta u(k+1|k) + \dots \\ &+ \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ S_1^d \end{bmatrix} \Delta u(k+p-1|k) + \begin{bmatrix} S_1^d \\ S_2^d \\ \vdots \\ \vdots \\ S_p^d \end{bmatrix} \Delta d(k) + \begin{bmatrix} 0 \\ S_1^d \\ S_2^d \\ \vdots \\ S_{p-1}^d \end{bmatrix} \Delta d(k+1|k) + \dots \\ &+ \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ S_1^d \end{bmatrix} \Delta d(k+p-1|k) + \begin{bmatrix} w_y(k+1|k) \\ w_y(k+2|k) \\ \vdots \\ \vdots \\ w_y(k+p|k) \end{bmatrix}. \end{aligned} \quad (28.11)$$

Here the first term on the right-hand side, the first p elements of the state, describes the future evolution of the system when all the future input changes are zero. The remaining terms describe the effect of the

present and future changes of the manipulated inputs $\Delta u(k+i|k)$, the measured disturbances $\Delta d(k+i|k)$, and the unmeasured and unmodeled disturbances $w_y(k+i|k)$. The notation $y(k+i|k)$ represents the prediction of $y(k+i)$ made based on the information available at time k . The same notation applies to Δd and w_y .

The values of most of these variables are not available at time k and have to be *predicted* in a rational fashion. From the measurement at time k $d(k)$ is known and therefore $\Delta d(k) = d(k) - d(k-1)$. Unless some additional process information or “upstream” measurements are available to conclude about the future disturbance behavior, the disturbances are assumed not to change in the future for the derivation of the DMC algorithm.

$$\Delta d(k+1|k) = \Delta d(k+2|k) = \dots = \Delta d(k+p-1|k) = 0. \tag{28.12}$$

This assumption is reasonable when the disturbances are varying only infrequently. Similarly, we will assume that the future unmodeled disturbances $w_y(k+i|k)$ do not change.

$$w_y(k|k) = w_y(k+1|k) = w_y(k+2|k) = \dots = w_y(k+p|k). \tag{28.13}$$

We can obtain an estimate of the present unmodeled disturbance from Equation 28.1

$$w_y(k|k) \approx y_m(k) - \tilde{y}_0(k), \tag{28.14}$$

where $y_m(k)$ represents the value of the output as actually measured in the plant. Here $\tilde{y}_0(k)$, the first component of the state $\tilde{Y}(k)$, is the model prediction of the output at time k (assuming $w_y(k) = 0$) based on the information up to this time. The difference between this predicted output and the measurement provides a good estimate of the unmodeled disturbance.

For generality, we want to consider the case where the manipulated inputs are not varied over the whole horizon p but only over the next m steps ($\Delta u(k|k), \Delta u(k+1|k), \dots, \Delta u(k+m-1|k)$) and that the input changes are set to zero after that.

$$\Delta u(k+m|k) = \Delta u(k+m+1|k) = \dots = \Delta u(k+p-1|k) = 0. \tag{28.15}$$

With these assumptions Equation 28.11 becomes

$$\begin{aligned} \mathcal{Y}(k+1|k) = & \underbrace{\begin{bmatrix} \tilde{y}_1(k) \\ \tilde{y}_2(k) \\ \vdots \\ \tilde{y}_p(k) \end{bmatrix}}_{\substack{\mathcal{M}\tilde{Y}(k) \\ \text{from the memory}}} + \underbrace{\begin{bmatrix} S_1^d \\ S_2^d \\ \vdots \\ S_p^d \end{bmatrix}}_{\substack{S^d \Delta d(k) \\ \text{feedforward term}}} \Delta d(k) + \underbrace{\begin{bmatrix} y_m(k) - \tilde{y}_0(k) \\ y_m(k) - \tilde{y}_0(k) \\ \vdots \\ y_m(k) - \tilde{y}_0(k) \end{bmatrix}}_{\substack{\mathcal{I}_p(y_m(k) - \tilde{y}_0(k)) \\ \text{feedback term}}} \\ & + \underbrace{\begin{bmatrix} S_1^u & 0 & \dots & \dots & 0 \\ S_2^u & S_1^u & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ S_m^u & S_{m-1}^u & \dots & \dots & S_1^u \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ S_p^u & S_{p-1}^u & \dots & \dots & S_{p-m+1}^u \end{bmatrix}}_{\substack{S^u \\ \text{dynamic matrix}}} \underbrace{\begin{bmatrix} \Delta u(k|k) \\ \Delta u(k+1|k) \\ \vdots \\ \Delta u(k+m-1|k) \end{bmatrix}}_{\substack{\Delta \mathcal{U}(k) \\ \text{future input moves}}}. \tag{28.16} \end{aligned}$$

Here we have introduced the new symbols

$$\mathcal{Y}(k+1|k) = \begin{bmatrix} y(k+1|k) \\ y(k+2|k) \\ \vdots \\ y(k+p|k) \end{bmatrix}, \quad (28.17)$$

$$S^u = \begin{bmatrix} S_1^u & 0 & \cdots & 0 \\ S_2^u & S_1^u & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ S_m^u & S_{m-1}^u & \cdots & S_1^u \\ \vdots & \vdots & \ddots & \vdots \\ S_p^u & S_{p-1}^u & \cdots & S_{p-m+1}^u \end{bmatrix}, \quad S^d := \begin{bmatrix} S_1^d \\ S_2^d \\ \vdots \\ S_p^d \end{bmatrix}, \quad (28.18)$$

$$\mathcal{I}_p = \left. \begin{bmatrix} I \\ I \\ \vdots \\ I \end{bmatrix} \right\} p, \quad (28.19)$$

$$\Delta\mathcal{U}(k) = \begin{bmatrix} \Delta u(k|k) \\ \Delta u(k+1|k) \\ \vdots \\ \Delta u(k+m-1|k) \end{bmatrix}, \quad (28.20)$$

$$\mathcal{M} = \left. \begin{array}{l} \left[\begin{array}{cccccccc} 0 & I & 0 & \cdots & \cdots & \cdots & \cdots & 0 \\ 0 & 0 & I & 0 & \cdots & \cdots & \cdots & 0 \\ k & \vdots & \vdots & \ddots & \ddots & \ddots & \vdots & \vdots \\ 0 & \cdots & \cdots & 0 & I & 0 & \cdots & 0 \end{array} \right] \\ \left[\begin{array}{cccc} 0 & I & 0 & \cdots & 0 \\ 0 & 0 & I & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & \cdots & 0 & I \\ \vdots & \vdots & & & \vdots \\ 0 & \cdots & \cdots & 0 & I \end{array} \right] \end{array} \right\} p \text{ for } p < n, \quad (28.21)$$

With this new notation the p -step ahead prediction becomes

$$\mathcal{Y}(k+1|k) = \mathcal{M}\tilde{Y}(k) + S^d\Delta d(k) + \mathcal{I}_p(y_m(k) - \tilde{y}_0(k)) + S^u\Delta\mathcal{U}(k), \quad (28.22)$$

where the first three terms are completely defined by past control actions ($\tilde{Y}(k)$, $\tilde{y}_0(k)$) and present measurements ($y_m(k)$, $\Delta d(k)$) and the last term describes the effect of future MV moves $\Delta\mathcal{U}(k)$.

This prediction equation can be easily adjusted if different assumptions are made on the future behavior of the measured and unmeasured disturbances. For instance, if the disturbances are expected to evolve in a ramp-like fashion then we would set

$$\Delta d(k) = \Delta d(k+1|k) = \cdots = \Delta d(k+p-1|k) \quad (28.23)$$

and

$$w_y(k + \ell|k) = w_y(k|k) + \ell(w_y(k|k) - w_y(k - 1|k - 1)). \quad (28.24)$$

28.2.3 State-Space Formulation

Although the first generation of industrial algorithms adopted a finite impulse response or a step response model, given their intuitive appeal to the practitioners, its limitations were quickly pointed out by the academics who went on to propose more general formulations based on state-space models. These formulations were later adopted by the vendor companies to develop a second generation of commercial MPC algorithms. These formulations also incorporated state estimation techniques into MPC for enhanced disturbance estimation and noise filtering.

The state-space model form used was

$$\begin{aligned} x(k + 1) &= Ax(k) + B_u u(k) + B_w w_x(k) + B_d d(k), \\ y(k) &= Cx(k) + w_y(k). \end{aligned} \quad (28.25)$$

Here w_x and w_y are state and output disturbances. Since these disturbances tend to be “persistent,” integrating states are created to reflect their nature:

$$\begin{aligned} w_x(k + 1) &= w_x(k) + \varepsilon_1(k), \\ w_y(k + 1) &= w_y(k) + \varepsilon_2(k), \end{aligned} \quad (28.26)$$

where ε_1 and ε_2 are white-noise sequences. The above can be expressed as

$$\begin{aligned} \begin{bmatrix} x(k + 1) \\ w_x(k + 1) \\ w_y(k + 1) \end{bmatrix} &= \begin{bmatrix} A & B_w & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix} \begin{bmatrix} x(k) \\ w_x(k) \\ w_y(k) \end{bmatrix} + \begin{bmatrix} B_u \\ 0 \\ 0 \end{bmatrix} u(k) + \begin{bmatrix} B_d \\ 0 \\ 0 \end{bmatrix} d_k + \begin{bmatrix} 0 & 0 \\ I & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} \varepsilon_1(k) \\ \varepsilon_2(k) \end{bmatrix}, \\ y(k) &= [C \quad 0 \quad I] \begin{bmatrix} x(k) \\ w_x(k) \\ w_y(k) \end{bmatrix}, \end{aligned} \quad (28.27)$$

which will be denoted using the notation

$$\begin{aligned} z(k + 1) &= \Phi z(k) + \Gamma_u u(k) + \Gamma_d d_k + \Gamma_\varepsilon \varepsilon(k), \\ y(k) &= \Xi z(k). \end{aligned} \quad (28.28)$$

The above is a standard state-space model with white state noise input and Kalman filtering can be used to design a state estimator of the following form:

$$\begin{aligned} \hat{z}(k|k - 1) &= \Phi \hat{z}(k - 1|k - 1) + \Gamma_u u(k) + \Gamma_d d_k, \\ \hat{z}(k|k) &= \hat{z}(k - 1|k - 1) + K (y(k) - \Xi \hat{z}(k|k - 1)), \end{aligned} \quad (28.29)$$

where K is the Kalman filter gain.

One potential problem for using the above model is the lack of detectability: One cannot have more disturbance states (w_x and w_y), which have integrating dynamics, than the number of outputs for detectability to hold. Hence, to use the above model, one would have to choose between input and output disturbances. Alternatively, it may be convenient to adopt the following differenced model form:

$$\begin{aligned} \begin{bmatrix} \Delta x(k + 1) \\ y(k + 1) \end{bmatrix} &= \begin{bmatrix} A & 0 \\ CA & I \end{bmatrix} \begin{bmatrix} x(k) \\ y(k) \end{bmatrix} + \begin{bmatrix} B_u \\ CB_u \end{bmatrix} \Delta u(k) + \begin{bmatrix} B_d \\ CB_d \end{bmatrix} \Delta d_k + \begin{bmatrix} B_w & 0 \\ CB_w & I \end{bmatrix} \begin{bmatrix} \varepsilon_1(k) \\ \varepsilon_2(k) \end{bmatrix}, \\ y(k) &= [0 \quad I] \begin{bmatrix} \Delta x(k) \\ y(k) \end{bmatrix}. \end{aligned} \quad (28.30)$$

The above system is detectable as long as the original (C, A) was a detectable pair. Once again, the above system is in the standard state-space form of Equation 28.28 and the Kalman filter of Equation 28.29 can be designed for state estimation.

The multistep prediction equation can be constructed and has the following structure:

$$\mathcal{Y}(k+1|k) = S^z \hat{z}(k|k) + S^d \Delta d(k) + S^u \Delta U(k). \quad (28.31)$$

The readers are referred to [4] for a detailed derivation of the matrices in the above equation. The above equation has the same linear structure of $\mathcal{Y}(k+1|k) = b(k) + S^u \Delta U(k)$ as before and the subsequent derivations presented hereafter hold for both the step response model-based formulation and the state-space model-based formulation (with some obvious modifications).

28.2.4 Objective Function

Plant operation requirements determine the performance criteria of the control system. These criteria must be expressed in mathematical terms so that a control law can be obtained in algorithmic form. In DMC, a *quadratic* objective function is used, which can be stated in its simplest form as*

$$\min_{\Delta u(k|k) \dots \Delta u(k+m-1|k)} \sum_{\ell=1}^p \|y(k+\ell|k) - r(k+\ell)\|^2 \quad (28.32)$$

This criterion minimizes the sum of squared deviations of the predicted CV values from a time-varying reference trajectory or setpoint $r(k+\ell)$ over p future time steps. The quadratic criterion penalizes large deviations proportionally more than smaller ones so that on the average the output remains close to its reference trajectory and large excursions are avoided.

Note that the MVs are assumed to be constant after m intervals of time into the future, or equivalently,

$$\Delta u(k+m|k) = \Delta u(k+m+1|k) = \dots = \Delta u(k+p-1|k) = 0,$$

where $m \leq p$ always. This means that DMC determines the next m moves, only. The choices of m and p affect the closedly-loop behavior. Moreover, m , the number of degrees of freedom, has a dominant influence on the computational effort. Also, it does not make sense to make the horizon longer than $m+n$ ($p \leq m+n$), because for an FIR system of order n the system reaches a steady state after $m+n$ steps. Increasing the horizon beyond $m+n$ would simply add identical constant terms to the objective function (Equation 28.32).

Due to inherent process interactions, it is generally not possible to keep all outputs close to their corresponding reference trajectories simultaneously. Therefore, in practice only a subset of the outputs is controlled well at the expense of larger excursions in others. This can be influenced transparently by including weights in the objective function as follows:

$$\min_{\Delta u(k|k) \dots \Delta u(k+m-1|k)} \sum_{\ell=1}^p \|\Gamma_{\ell}^y [y(k+\ell|k) - r(k+\ell)]\|^2 \quad (28.33)$$

For example, for a system with two outputs y_1 and y_2 , and constant diagonal weight matrices of the form

$$\Gamma_{\ell}^y = \begin{bmatrix} \gamma_1 & 0 \\ 0 & \gamma_2 \end{bmatrix}; \quad \forall \ell \quad (28.34)$$

the objective becomes

$$\min_{\Delta u(k|k) \dots \Delta u(k+m-1|k)} \left\{ \gamma_1^2 \sum_{\ell=1}^p [y_1(k+\ell|k) - r_1(k+\ell)]^2 + \gamma_2^2 \sum_{\ell=1}^p [y_2(k+\ell|k) - r_2(k+\ell)]^2 \right\}. \quad (28.35)$$

Thus, the larger the weight is for a particular output, the larger is the contribution of its sum of squared deviations to the objective. This will make the controller bring the corresponding output closer to its reference trajectory.

* $\|x\|$ denotes the norm $(x^T x)^{1/2}$ of the vector x .

Finally, the MV moves that make the output follow a given trajectory could be too severe to be acceptable in practice. This can be corrected by adding a penalty term for the MV moves to the objective as follows:

$$\min_{\Delta u(k)} \sum_{\ell=1}^p \|\Gamma_{\ell}^y [y(k+\ell|k) - r(k+\ell)]\|^2 + \sum_{\ell=1}^m \|\Gamma_{\ell}^u [\Delta u(k+\ell-1)]\|^2. \quad (28.36)$$

Note that the larger the elements of the matrix Γ_{ℓ}^u , the smaller the resulting moves, and consequently, the output trajectories will not be followed as closely. Thus, the relative magnitudes of Γ_{ℓ}^y and Γ_{ℓ}^u will determine the trade-off between following the trajectory closely and reducing the action of the MVs.

Of course, not every practical performance criterion is faithfully represented by this quadratic objective. However, many control problems can be formulated as trajectory tracking problems and therefore this formulation is very useful. Most importantly this formulation leads to an optimization problem for which there exist effective solution techniques.

28.2.5 Constraints

In many control applications the desired performance cannot be expressed solely as a trajectory following the problem. Many practical requirements are more naturally expressed as constraints on process variables.

There are three types of process constraints:

MV constraints: these are hard limits on inputs $u(k)$ to take care of, for example, valve saturation constraints.

MV rate constraints: these are hard limits on the size of the MV moves $\Delta u(k)$ to directly influence the rate of change of the MVs.

Output variable constraints: hard or soft limits on the outputs of the system are imposed to, for example, avoid overshoots and undershoots. These can be of two kinds:

- *CV:* limits for these variables are specified even though deviations from their setpoints are minimized in the objective function
- *Associated variables:* no setpoints exist for these output variables but they must be kept within bounds (i.e., corresponding rows of Γ_{ℓ}^y are zero for the projections of these variables in the objective function given in Equation 28.36.

The three types of constraints in DMC are enforced by formulating them as linear inequalities. In the following, we explicitly formulate these inequalities.

28.2.5.1 MV Constraints

The solution vector of DMC contains not only the current moves to be implemented but also the moves for the future m intervals of time. Although violations can be avoided by constraining only the move to be implemented, constraints on future moves can be used to allow the algorithm to anticipate and prevent future violations, thus producing a better overall response. The MV value at a future time $k+\ell$ is constrained to be

$$u_{low}(\ell) \leq \sum_{j=0}^{\ell} \Delta u(k+j|k) + u(k-1) \leq u_{high}(\ell); \quad \ell = 0, 1, \dots, m-1,$$

where $u(k-1)$ is the implemented previous value of the MV. For generality, we allowed the limits $u_{low}(\ell), u_{high}(\ell)$ to vary over the horizon. These constraints are expressed in matrix form for all projections as

$$\begin{bmatrix} -I_L \\ I_L \end{bmatrix} \Delta \mathcal{U}(k) \geq \begin{bmatrix} u(k-1) - u_{high}(0) \\ \vdots \\ u(k-1) - u_{high}(m-1) \\ u_{low}(0) - u(k-1) \\ \vdots \\ u_{low}(m-1) - u(k-1) \end{bmatrix}, \quad (28.37)$$

where

$$I_L = \begin{bmatrix} I & 0 & \cdots & 0 \\ I & I & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ I & I & \cdots & I \end{bmatrix}. \quad (28.38)$$

28.2.5.2 MV Rate Constraints

Often MPC is used in a supervisory mode where there are limitations on the rate at which lower-level controller setpoints are moved. These are enforced by adding constraints on the MV move sizes:

$$\begin{bmatrix} -I \\ I \end{bmatrix} \Delta \mathcal{U}(k) \geq \begin{bmatrix} -\Delta u_{max}(0) \\ \vdots \\ -\Delta u_{max}(m-1) \\ -\Delta u_{max}(0) \\ \vdots \\ -\Delta u_{max}(m-1) \end{bmatrix}, \quad (28.39)$$

where $\Delta u_{max}(\ell) > 0$ is the possibly time-varying bound on the magnitude of the moves.

28.2.5.3 Output Variable Constraints

The algorithm can make use of the output predictions (Equation 28.22 or 28.31) to anticipate future constraint violations:

$$\mathcal{Y}_{low} \leq \mathcal{Y}(k+1|k) \leq \mathcal{Y}_{high}. \quad (28.40)$$

Substituting from Equation 28.22, we obtain constraints on $\Delta \mathcal{U}(k)$:

$$\begin{bmatrix} -S^u \\ S^u \end{bmatrix} \Delta \mathcal{U}(k) \geq \begin{bmatrix} \mathcal{M}\tilde{Y}(k) + S^d \Delta d(k) + \mathcal{I}_p(y_m(k) - \tilde{y}_0(k)) - \mathcal{Y}_{high} \\ -(\mathcal{M}\tilde{Y}(k) + S^d \Delta d(k) + \mathcal{I}_p(y_m(k) - \tilde{y}_0(k))) + \mathcal{Y}_{low} \end{bmatrix}. \quad (28.41)$$

where

$$\mathcal{Y}_{low} = \begin{bmatrix} y_{low}(1) \\ y_{low}(2) \\ \vdots \\ y_{low}(p) \end{bmatrix}; \quad \mathcal{Y}_{high} = \begin{bmatrix} y_{high}(1) \\ y_{high}(2) \\ \vdots \\ y_{high}(p) \end{bmatrix}$$

are vectors of output constraint trajectories $y_{low}(\ell)$, $y_{high}(\ell)$ over the horizon length p .

28.2.5.4 Combined Constraints

The MV constraints (Equation 28.37), MV rate constraints (Equation 28.39) and output variable constraints (Equation 28.41) can be combined into one convenient expression

$$C^u \Delta \mathcal{U}(k) \geq C(k+1|k), \quad (28.42)$$

where C^u combines all the matrices on the left-hand side of the inequalities as follows:

$$C^u = \begin{bmatrix} -I_L \\ I_L \\ -I \\ I \\ -S^u \\ S^u \end{bmatrix}. \quad (28.43)$$

The vector $C(k+1|k)$ on the right-hand side collects all the “error” vectors on the constraint equations as follows:

$$C(k+1|k) = \begin{bmatrix} u(k-1) - u_{high}(0) \\ \vdots \\ u(k-1) - u_{high}(m-1) \\ u_{low}(0) - u(k-1) \\ \vdots \\ u_{low}(m-1) - u(k-1) \\ -\Delta u_{max}(0) \\ \vdots \\ -\Delta u_{max}(m-1) \\ -\Delta u_{max}(0) \\ \vdots \\ -\Delta u_{max}(m-1) \\ \mathcal{M}\tilde{Y}(k) + S^d \Delta d(k) + \mathcal{I}_p(y_m(k) - \tilde{y}_0(k)) - \mathcal{Y}_{high} \\ -(\mathcal{M}\tilde{Y}(k) + S^d \Delta d(k) + \mathcal{I}_p(y_m(k) - \tilde{y}_0(k))) + \mathcal{Y}_{low} \end{bmatrix}. \quad (28.44)$$

28.2.6 Formulation of Control Problem as a Quadratic Program

We make use of the prediction equation 28.22 to rewrite the objective

$$\min_{\Delta \mathcal{U}(k)} \sum_{\ell=1}^p \|\Gamma_\ell^y [y(k+\ell|k) - r(k+\ell)]\|^2 + \sum_{\ell=1}^m \|\Gamma_\ell^u [\Delta u(k+\ell-1)]\|^2 \quad (28.45)$$

and add the constraints (Equation 28.42) to obtain the optimization problem

$$\begin{aligned} \min_{\Delta \mathcal{U}(k)} \quad & \{ \|\Gamma^y [\mathcal{Y}(k+1|k) - \mathcal{R}(k+1)]\|^2 + \|\Gamma^u \Delta \mathcal{U}(k)\|^2 \} \\ \text{s.t.} \quad & \mathcal{Y}(k+1|k) = \mathcal{M}\tilde{Y}(k) + S^d \Delta d(k) + \mathcal{I}_p(y_m(k) - \tilde{y}_0(k)) + S^u \Delta \mathcal{U}(k) \\ & C^u \Delta \mathcal{U}(k) \geq C(k+1|k), \end{aligned} \quad (28.46)$$

where

$$\Gamma^u = \text{diag} \{ \Gamma_1^u, \dots, \Gamma_m^u \} \quad (28.47)$$

and

$$\Gamma^y = \text{diag} \{ \Gamma_1^y, \dots, \Gamma_p^y \} \quad (28.48)$$

are the weight matrices in block diagonal form, and

$$\mathcal{R}(k+1) = \begin{bmatrix} r(k+1) \\ r(k+2) \\ \vdots \\ r(k+p) \end{bmatrix} \quad (28.49)$$

is the vector of reference trajectories.

We can substitute the prediction equation into the objective function to obtain

$$\| \Gamma^y [\mathcal{Y}(k+1|k) - \mathcal{R}(k+1)] \|^2 + \| \Gamma^u \Delta \mathcal{U}(k) \|^2 \quad (28.50)$$

$$= \| \Gamma^y [\mathcal{S}^u \Delta \mathcal{U}(k) - E_p(k+1|k)] \|^2 + \| \Gamma^u \Delta \mathcal{U}(k) \|^2 \quad (28.51)$$

$$\begin{aligned} &= \Delta \mathcal{U}^T(k) (\mathcal{S}^{uT} \Gamma^{yT} \Gamma^y \mathcal{S}^u + \Gamma^{uT} \Gamma^u) \Delta \mathcal{U}(k) \\ &\quad - 2E_p^T(k+1|k) \Gamma^{yT} \Gamma^y \mathcal{S}^u \Delta \mathcal{U}(k) + E_p^T(k+1|k) \Gamma^{yT} \Gamma^y E_p(k+1|k). \end{aligned} \quad (28.52)$$

Here we have defined

$$\begin{aligned} E_p(k+1|k) &= \begin{bmatrix} e(k+1|k) \\ e(k+2|k) \\ \vdots \\ e(k+p|k) \end{bmatrix} \\ &\triangleq \mathcal{R}(k+1) - \left[\mathcal{M} \tilde{Y}(k) + S^d \Delta d(k) + \mathcal{I}_p (y_m(k) - \tilde{y}_0(k)) \right], \end{aligned} \quad (28.53)$$

which is the measurement corrected vector of future output deviations from the reference trajectory (i.e., errors), assuming that all future control moves are zero. Note that this vector includes the effect of the measurable disturbances ($S^d \Delta d(k)$) on the prediction. For the state-space model of Equation 28.31, E_p changes to

$$E_p \triangleq \mathcal{R}(k+1) - \left(S^z \hat{z}(k|k) + S^d \Delta d(k) \right). \quad (28.54)$$

The optimization problem with a quadratic objective and linear inequalities, which we have defined, is a quadratic program (QP). By converting to the standard QP formulation the DMC problem becomes*

$$\begin{aligned} \min_{\Delta \mathcal{U}(k)} \quad & \frac{1}{2} \Delta \mathcal{U}(k)^T \mathcal{H}^u \Delta \mathcal{U}(k) - \mathcal{G}(k+1|k)^T \Delta \mathcal{U}(k) \\ \text{s.t.} \quad & C^u \Delta \mathcal{U}(k) \geq C(k+1|k), \end{aligned} \quad (28.55)$$

where the Hessian of the QP is

$$\mathcal{H}^u = \mathcal{S}^{uT} \Gamma^{yT} \Gamma^y \mathcal{S}^u + \Gamma^{uT} \Gamma^u \quad (28.56)$$

* The term $E_p^T(k+1|k)E_p(k+1|k)$ is independent of $\Delta \mathcal{U}(k)$ and can be removed from the objective function.

and the gradient vector is

$$\mathcal{G}(k+1|k) = S^u T \Gamma^y T \Gamma^y E_p(k+1|k). \quad (28.57)$$

28.3 Implementation Issues

As explained in the introduction of this chapter the implementation of DMC is done in a *moving horizon* fashion. This implies that the QP derived above will be solved at each controller execution time. Because of this feature, the algorithm can be configured online as required to take care of unexpected situations. For example, in case an actuator is lost during the implementation, the high and low constraint limits on that particular MV can be set to be equal. Then the MPC problem with the remaining MVs is solved. Similarly, the weight parameters in the objective function can also be adjusted online, giving the user the ability to tune the control law. In this section we discuss the different implementation issues associated with the DMC.

28.3.1 Moving Horizon Algorithm

The constrained MPC algorithm is implemented online as follows.

1. *Preparation.* Do not vary the MVs for at least n time intervals ($\Delta u(-1) = \Delta u(-2) = \dots = \Delta u(-n) = 0$) and assume the measured disturbances are zero ($\Delta d(-1) = \Delta d(-2) = \dots = \Delta d(-n) = 0$) during that time. Then the system will be at rest at $k = 0$.
2. *Initialization* ($k = 0$). Measure the output $y_m(0)$ and initialize the model prediction vector as*

$$\tilde{Y}(k) = \left[\underbrace{y_m(0)^T, y_m(0)^T, \dots, y_m(0)^T}_n \right]^T. \quad (28.58)$$

3. *State update:* Set $k = k + 1$. Then, update the state according to

$$\tilde{Y}(k) = M \cdot \tilde{Y}(k-1) + S^u \Delta u(k-1) + S^d \Delta d(k-1), \quad (28.59)$$

where the first element of $\tilde{Y}(k)$, $\tilde{y}(k|k)$, is the model prediction of the output $y_m(k)$ at time k .

4. *Obtain measurements:* Obtain measurements ($y_m(k)$, $\Delta d(k)$).
5. Compute the reference trajectory error vector

$$E_p(k+1|k) = \mathcal{R}(k+1) - \mathcal{M}\tilde{Y}(k) + S^d \Delta d(k) + \mathcal{I}_p(y_m(k) - \tilde{y}_0(k)). \quad (28.60)$$

6. Compute the QP gradient vector

$$\mathcal{G}(k+1|k) = S^u T (\Gamma^y)^T \Gamma^y E_p(k+1|k). \quad (28.61)$$

* If Equation 28.58 is used for initialization and changes in the past n inputs did actually occur, then the initial operation of the algorithm will not be smooth. The transfer from *manual* to *automatic* will introduce a disturbance; it will not be "bumpless."

7. Compute the constraint equation's right-hand side vector

$$C(k+1|k) = \begin{bmatrix} u(k-1) - u_{high}(0) \\ \vdots \\ u(k-1) - u_{high}(m-1) \\ u_{low}(0) - u(k-1) \\ \vdots \\ u_{low}(m-1) - u(k-1) \\ -\Delta u_{max}(0) \\ \vdots \\ -\Delta u_{max}(m-1) \\ -\Delta u_{max}(0) \\ \vdots \\ -\Delta u_{max}(m-1) \\ -E_p(k+1|k) + \mathcal{R}(k+1) - \mathcal{Y}_{high} \\ E_p(k+1|k) - \mathcal{R}(k+1) + \mathcal{Y}_{low} \end{bmatrix}. \quad (28.62)$$

8. Solve the QP

$$\begin{aligned} \min_{\Delta \mathcal{U}(k)} \quad & \frac{1}{2} \Delta \mathcal{U}(k)^T \mathcal{H}^u \Delta \mathcal{U}(k) - \mathcal{G}(k+1|k)^T \Delta \mathcal{U}(k) \\ \text{s.t.} \quad & C^u \Delta \mathcal{U}(k) \geq C(k+1|k) \end{aligned} \quad (28.63)$$

and implement $\Delta u(k|k)$ as $\Delta u(k)$ on the plant.

9. Go to 3.

Note that the sequence of moves produced by the moving horizon implementation of the QP will be different from the sequence of moves $\Delta \mathcal{U}(k)$.

28.3.2 Solving the QP

In a moving horizon framework the QP in Equation 28.63 is solved at each controller execution time after a new prediction is obtained. The only time-varying elements in this problem are the vectors $E_p(k+1|k)$ (or equivalently $\mathcal{G}(k+1|k)$) and $C(k+1|k)$. That is, the Hessian \mathcal{H}^u of the QP remains constant for all executions. In that case, as explained above, a parametric QP algorithm which employs the preinverted Hessian in its computations, is preferable in order to reduce online computation effort. Of course, in case either Γ^y or Γ^u (or the step response coefficients) need to be updated, or the model's step response coefficients have changed, the Hessian must be recomputed and inverted in background mode in order not to increase the online computational requirements.

QP is a *convex* program and therefore, is fundamentally tractable, meaning a global optimal solution within a specified tolerance can be assured. Although not as extensively as linear programs (LPs), QPs have been well studied and reliable algorithms have been developed and coded. General-purpose QP solvers like *QPSOL* are readily available but use of tailored algorithms that take advantage of specific problem structures can offer significant computational savings.

The conventional approach for solving QPs is the so-called *active set* method. In this method, one initiates the search by assuming a set of active constraints. For an assumed active set, one can easily solve the resulting least-squares problem (where the active constraints are treated as equality constraints)

through the use of Lagrange multiplier. In general, in the active set one starts out with that it will not be the correct one. Through the use of the Karush–Kuhn–Tucker (KKT) condition,* one can modify the active set iteratively until the correction is found. Most active set algorithms are *feasible path* algorithms, in which the constraints must be met at all times. Hence, the number of constraints can have a significant effect on the computational time.

More recently, a promising new approach called the *interior point (IP)* method has been getting a lot of attention. The idea of the IP method is to “trap” the solution within the feasible region by including a so-called “barrier” function in the objective function. With the modified objective function, the Newton iteration is applied to find the solution. Though originally developed for LPs, the IP method can be readily generalized to QPs and other more general constrained optimization problems. Even though not formally proven, it has been observed empirically that the Newton iteration converges within 5–50 steps. Significant work has been carried out in using this solution approach for solving QPs that arise in MPC, but details are out of the scope of this chapter.

Computational properties of QPs vary with problems. As the number of constraints increases, more iterations are generally required to find the QP solution, and therefore the solution time increases. This may have an impact on the minimum control execution time possible. Also, note that the dimension of the QP (i.e., the number of degrees of freedom $m \cdot n_u$) influences the execution time proportionately.

Storage requirements are also affected directly by the number of degrees of freedom and the number of projections $n \cdot n_y$. For example, the Hessian size increases quadratically with the number of degrees of freedom. Also, because of the prediction algorithm, $\tilde{Y}(k)$ must be stored for use in the next controller execution (both $E_p(k+1|k)$ and $C(k+1|k)$ can be computed from $\tilde{Y}(k)$).

28.3.3 Proper Constraint Formulation

Many engineering control objectives are stated in the form of constraints. Therefore, it is very tempting to translate them into linear inequalities and to include them in the QP control problem formulation. In this section we want to demonstrate that constraints make it very difficult to predict the behavior of the control algorithm under real operating conditions. Therefore, they should be used only when necessary and then only with great caution.

First of all constraints tend to greatly increase the time needed to solve the QP. Thus, we should introduce them sparingly. For example, if we wish an output constraint to be satisfied over the whole future horizon, we may want to state it as a linear inequality only at *selected* future sampling times rather than at *all* future sampling times. Unless we are dealing with a highly oscillatory system, a few output constraints at the beginning and one at the end of the horizon should keep the output more or less inside the constraints throughout the horizon. Note that even when constraint violations occur in the prediction, this does not imply constraint violations in the actual implementation because of the moving horizon policy. The future constraints serve only to prevent the present control move from being short-sighted.

Output constraints can also lead to an “infeasibility.” A QP is *infeasible* if there does not exist any value of the vector of independent variables (the future MV move $\Delta U(k)$), which satisfies all the constraints—regardless of the value of the objective function. Physically, this situation can arise when there are output constraints to be met but the MVs are not sufficiently effective—either because they are constrained or because there is deadtime in the system that delays their effect. Needless to say, provisions must be built into the online algorithm such that an infeasibility never occurs.

Mathematically an infeasibility can only occur when the right-hand side of the output constraint equations is positive. This implies that a nonzero move *must* be made in order to satisfy the constraint equations. Otherwise, infeasibility is not an issue since $\Delta U(k) = 0$ is feasible.

A simple example of infeasibility arises in the case of deadtimes in the response. For illustration, assume a single-input single-output (SISO) system with θ units of deadtime. The output constraint equations for

* The KKT condition is a necessary condition for the solution to a general constrained optimization problem. For QP, it is a necessary and sufficient condition.

this system will look like

$$\begin{bmatrix} 0 & 0 & \dots & 0 \\ \vdots & & & \vdots \\ 0 & 0 & \dots & 0 \\ -S_{\theta+1}^u & 0 & \dots & 0 \\ -S_{\theta+2}^u & -S_{\theta+1}^u & \dots & 0 \\ \vdots & & & \vdots \end{bmatrix} \Delta \mathcal{U}(k) \geq \begin{bmatrix} c(k+1|k) \\ \vdots \\ c(k+\theta|k) \\ c(k+\theta+1|k) \\ c(k+\theta+2|k) \\ \vdots \end{bmatrix}.$$

Positive elements $c(k+1|k), \dots, c(k+\theta|k)$ indicate that a violation is projected unless the MVs are changed ($\Delta \mathcal{U}(k) \neq 0$). Since the corresponding coefficients in the left-hand side matrix are zero, the inequalities cannot be satisfied and the QP is infeasible. Of course, this problem can be removed by simply not including these initial θ inequalities in the QP.

Because inequalities are dealt with *exactly* by the QP, the corrective action against a projected violation is equivalent to that generated by a very tightly tuned controller. As a result, the moves produced by the QP to correct for violations may be undesirably severe (even when feasible). Both infeasibilities and severe moves can be dealt with in various ways.

One way is to include a *constraint window* on the output constraints similar to what we suggested above for computational savings. For each output a time $k + H_c$ in the future is chosen at which constraint violations will start to be checked (Figure 28.3).

For the above illustration, this time should be picked to be at least equal to $\theta + 1$. This allows the algorithm to check for violations after the effects of deadtimes and inverse responses have passed. For each situation there is a minimal value of H_c necessary for feasibility. If this minimal value is chosen large, constraint violations may occur over a significant period of time. In many cases, if a larger value of H_c is chosen, smaller constraint violations may occur over a longer time interval. Thus, there is a trade-off between magnitude and duration of constraint violation.

In general, it is difficult to select a value of H_c for each constrained output such that the proper compromise is achieved. Furthermore, in multivariable cases, constraints may need to be relaxed according to the priorities of the constrained variables. The selection of constraint windows is greatly complicated by the fact that appropriate amount and location for relaxation are usually time dependent due to varying disturbances and occurrences of actuator and sensor failures. Therefore, it is usually preferred to “soften” the constraint by adding a slack variable ϵ and penalizing this violation through an additional term in the objective function.

$$\min_{\epsilon, \Delta \mathcal{U}(k)} [\text{Usual Objective}] + \lambda \epsilon^2$$

$$y_{min} - \epsilon \leq y(k + \ell|k) \leq y_{max} + \epsilon$$

plus other constraints.

FIGURE 28.3 Relaxing the constraints.

The optimization seeks a compromise between minimizing the original performance objective and minimizing the constraint violations expressed by ϵ^2 . The parameter λ determines the relative importance of the two terms. The degree of constraint violation can be fine-tuned arbitrarily by introducing a separate slack variable ϵ for each output and time step, and associating with it a separate penalty parameter λ .

Finally, we must realize that while unconstrained MPC is a form of *linear* feedback control, constrained MPC is a *nonlinear* control algorithm. Thus, its behavior for small deviations can be drastically different from that for large deviations. This may be surprising and undesirable and is usually very difficult to analyze *a priori*.

28.3.4 Choice of Horizon Length

On the one hand, the prediction horizon p and the control horizon m should be kept short to reduce the computational effort; on the other hand, they should be made long to prevent short-sighted control policies. Making m short is generally conservative because we are imposing constraints (forcing the control to be constant after m steps) that do not exist in the actual implementation because of the moving horizon policy. Therefore, a small m will tend to give rise to a cautious control action.

Choosing p small is “short-sighted” and will generally lead to an aggressive control action. If constraint violations are checked only over a small control horizon p , this policy may lead the system into a “dead alley” from which it can escape only with difficulty, that is, only with large constraint violations and/or large MV moves.

When p and m are infinity and when there are no disturbance changes and unknown inputs, the sequence of control moves determined at time k is the same sequence that is realized through the moving horizon policy. In this sense our control actions are truly optimal. When the horizon lengths are shortened, then the sequence of moves determined by the optimizer and the sequence of moves actually implemented on the system will become increasingly different. Thus the short-time objective, which is optimized, will have less and less to do with the actual value of the objective realized when the moving horizon control is implemented. This may be undesirable.

In general, we should try to choose a small m to keep the computational effort manageable, but large enough to give us a sufficient number of degrees of freedom. We should choose p as large as possible, possibly ∞ , to completely capture the consequences of the control actions. This is possible in several ways. Because an FIR system will settle after $m + n$ steps, choosing a horizon $p = m + n$ is a sensible choice used in many commercial systems (Figure 28.4).

Instead or in addition we can impose a large output penalty at the end of the prediction horizon forcing the system effectively to settle to zero at the end of the horizon. Then, with $p = m + n$, the error after $m + n$ is essentially zero and there is little difference between the finite and the infinite horizon objective.

FIGURE 28.4 Choosing the horizon.

28.3.5 Input Blocking

As said, use of a large control horizon is generally preferred from the viewpoint of performance, but available computational resource may limit its size. One way to relax this limit is through a procedure called *blocking*, which allows to the user to “block out” the input moves at selected locations from the calculation by setting them to zero *a priori*. The result is a reduction in the number of input moves that need to be computed through the optimization, hopefully without a significant sacrifice in the solution quality. Obviously, judicious selection of blocking locations is critical for achieving the intended effect. The selection is done mostly on an *ad hoc* basis, although there are some qualitative rules like blocking less of the immediate moves and more of the distant ones.

At a more general level, blocking can be expressed as follows:

$$\Delta\mathcal{U} = \mathbf{B}\Delta\mathcal{U}^b, \quad (28.64)$$

where $\Delta\mathcal{U}^b$ represents the reduced input parameters to be calculated through the optimization. \mathbf{B} is the blocking matrix that needs to be designed for a good performance. Typically, the rows of \mathbf{B} corresponding to the blocked moves would contain all zeros. In general, columns of \mathbf{B} can be designed to represent different basis in the input space. Note that dimension of \mathcal{U}^b , which is less than that of \mathcal{U} , must also be determined in the design.

28.3.6 Filtering of the Feedback Signal

In practice, feedback measurements can contain significant noise and other fast-varying disturbances. Since in DMC the effect of unmeasured disturbances is projected as a constant bias in the prediction, the high-frequency contents of a feedback signal must be filtered out in order to obtain a meaningful long-term prediction. For this, one can pass the feedback signal through a low-pass filter of some sort, perhaps a first- or second-order filter, before putting it into the prediction equation. Use of state estimation, discussed in [3], for example, allows one to model the statistical characteristics of disturbances and noise and perform the filtering in an optimal manner.

28.4 Features Found in Other MPC Algorithms

What we just covered is the basic form of a multivariable control algorithm called DMC, which was one of the first MPC algorithms applied to industrial processes with success. The original DMC algorithm did not use QP to handle constraints; instead, it added an extra output to the prediction to drive the input back to the feasible region whenever a predicted future input came close to a constraint. This was somewhat *ad hoc* and it was not until the 1980s that engineers at Shell Oil proposed the use of QP to handle input and output constraints explicitly and rigorously. They called this modified version QDMC. Currently, this basic form of DMC is still used in a commercial package called *DMC-PLUS*, which is marketed by Aspen Technology.

Besides DMC and QDMC, there are several other MPC algorithms that have seen, and are still seeing, extensive use in practice. These include model predictive heuristic control (MPHC), which led to popular commercial algorithms such as IDCOM and SMC-IDCOM marketed by Setpoint (now Aspen Technology) and Hierarchical Constraint Control (HIECON) and Predictive Functional Control (PFC) marketed by Adersa; Predictive Control Technology (PCT), which was marketed by Profimatics (now Honeywell); and more recent Robust Model Predictive Control Technology (RMPCT), which is currently being marketed by Honeywell. These algorithms share same fundamentals but differ in details of implementation. Rather than elaborating on the details of each algorithm, we will touch upon some popular features not seen in the basic DMC/QDMC method.

28.4.1 Reference Trajectories

In DMC, output deviation from the desired setpoint is penalized in the optimization. Other algorithms such as IDCOM, HIECON, and PFC let the user specify not only *where* the output should go but also *how*. For this, a *reference trajectory* is introduced for each CV, which is typically defined as a first-order path from the current output value to the desired setpoint. The time constant of the path can be adjusted according to the speed of the desired closed-loop response. This is displayed in Figure 28.5.

Reference trajectories provide an intuitive way to control the aggressiveness of control, which is adjusted through the weighting matrix for the input move penalty term in DMC. One could argue that the controller’s aggressiveness is more conveniently tuned by specifying the speed of output response rather than through input weight parameters, whose effects on the speed of response is highly system dependent.

28.4.2 Coincidence Points

Some commercial algorithms such as IDCOM and PFC allowed the option of penalizing the output error only at a few chosen points in the prediction horizon called *coincidence points*. This is motivated primarily by reduction in computation it brings. When the number of input moves has to be kept small (in order to keep the computational burden low), use of a large prediction horizon, which is sometimes necessary due to large inverse responses, and long dynamics, results in a sluggish control behavior. This problem can be obviated by penalizing output deviation only at a few carefully selected points. At the extreme, one could ask the output to match the reference trajectory value at a single time point, which can be achieved with a single control move. Such formulation was used, for example, in IDCOM-M, an offspring of the original IDCOM algorithm, marketed by setpoint.

Clearly, the choice of coincidence points is critical for performance, especially when the number of points used is small. Although some guidelines exist on choosing these points, there is no systematic method for the selection. Because the response time of different outputs can vary significantly, coincidence points are usually defined separately for each output.

28.4.3 The Funnel Approach

The RMPCT algorithm differs from other MPC algorithms in that it attempts to keep each controlled output within a user-specified zone called *funnel*, rather than to keep it on a specific reference trajectory. The typical shape of a funnel is displayed in Figure 28.5. The user sets the maximum and minimum limits and also the slope of the funnel through a parameter called “performance ratio,” which is the desired time to return to the limit zone divided by the open-loop response time. The gap between the maximum and minimum can be closed for exact setpoint control, or left open for range control.

The algorithm solves the following QP at each time:

$$\min_{y^r, u} \sum_{i=1}^p \|y(k+i|k) - y^r(k+i|k)\|_Q^2 + \sum_{j=0}^{m-1} \|\Delta u(k+j|k)\|_R^2 \quad (28.65)$$

or

$$\min_{y^r, u} \sum_{i=1}^p \|y(k+i|k) - y^r(k+i|k)\|_Q^2 + \sum_{j=0}^{m-1} \|u(k+j|k) - u^r\|_R^2 \quad (28.66)$$

subject to usual constraints plus the funnel constraint

$$y_{min}^f(k+i|k) \leq y^r(k+i|k) \leq y_{max}^f(k+i|k), \quad 1 \leq i \leq p, \quad (28.67)$$

where $y_{min}^f(k+i|k)$ and $y_{max}^f(k+i|k)$ represent the upper and lower limit values of the funnel for $k+i$ in the prediction horizon as specified at time k . u^r is the desired settling value for the input. Note that the

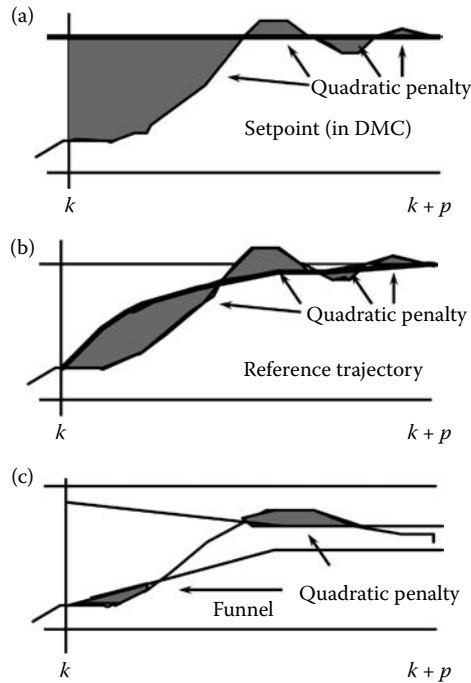

FIGURE 28.5 Output penalties used in various formulations.

reference trajectory y^r is a free parameter, which is optimized to lie within the funnel. Typically, $Q \gg R$ in order to keep the outputs within the funnel as much as possible. Then one can think of the above as a multiobjective optimization, in which the primary objective is to minimize the funnel constraint violation by the output and the secondary objective is to minimize the size of input movement (or input deviation from the desired settling value in the case of Equation 28.66). In this case, as long as there exists an input trajectory that keeps the output within the funnel, the first penalty term will be made exactly zero. Typically, there will be an infinite number of solutions that achieve this, leading to a “degenerate” QP. The algorithm thus finds the minimum norm solution, which corresponds to the least amount of input adjustment—hence the name “Robust” MPCT. However, if there is no input that can keep the output within the funnel, the first term will be the primary factor that determines the input.

The use of funnel is motivated by the fact that, in multivariable systems, the shape of desirable trajectories for outputs is not always clear due to system interaction. Thus, it is argued that an attractive formulation is to let the user specify an acceptable dynamic zone for each output as a funnel and then find the minimum size input moves (or inputs with minimum deviation from their desired values) that keep the outputs within the zone—or, if not possible, minimize the extent of violation.

28.4.4 Use of Other Norms

In defining the objective function, use of norms other than 2-norm is certainly possible. For example, the possibility of using 1-norm (sum of absolute values) has been explored to a great extent. Use of infinity norm has also been investigated with the aim of minimizing worst-case deviation over time. In both cases, one gets an LP, for which a plethora of theories and software exist due to its significance in economics. However, one difficulty with these formulations is in tuning. This is because the solution of an LP lies at the intersection of binding constraints and it can switch abruptly from one vertex to another as one

varies tuning parameters (such as the input weight parameters). The solution behavior of a QP is much smoother and therefore, it is a preferred formulation for control.

28.4.5 Input Parameterization

In some algorithms such as PFC, the input trajectory can be parameterized using continuous basis functions like polynomials. This can be useful if the objective is to follow *smooth* setpoint trajectories precisely, such as in mechanical servo applications, and the sampling time cannot be made sufficiently small to allow this with piecewise constant inputs.

In other commercial algorithms such as HIECON and IDCOM-M, only a single control move is calculated, which would correspond to $m = 1$ in DMC. With this setting, the calculation is greatly simplified. On the other hand, use of $m = 1$ in DMC would limit the closed-loop performance in general. These algorithms get around this problem by using a single coincidence point, at which the output is asked to match the reference value exactly.

28.4.6 Model Conditioning

In multivariable plants, two or more outputs can behave very similarly in response to all the inputs. This phenomenon is referred to as “ill-conditioning” and is reflected by a gain matrix that is nearly singular. An implication is that it can be very difficult to control these outputs independently with the inputs, as it will require an excessive amount of input movement in order to move the outputs in certain directions. Using an ill-conditioned process model for control calculation is not recommended as it can lead to numerical problems (e.g., inversion of a nearly singular matrix) and also excessive input movements and/or even an instability.

Even though one would check the conditioning of the model at the design stage, because control structure can change due to constraints and failures of sensors and actuators, one must make sure at each execution time that an ill-conditioned process model is not directly inverted in the input calculation.

In DMC, direct inversion of an ill-conditioned process model can be circumvented by including a substantive input move penalty term, which effectively increases the magnitudes of the diagonal elements of the dynamic matrix that is inverted during the least-squares calculation.

In other algorithms that do not include an input move penalty in the objective function, ill-conditioning must be checked at each execution time. In RMPCT, this is done through a method called *Singular Value Thresholding*, where a procedure called “singular value decomposition” is performed on the gain matrix to determine those CV directions for which the gain is too low for any effective control at all. Those directions with singular values lower than a threshold value are given up for control and only the remaining “high-gain” directions are controlled. SMC-IDCOM addresses this based on the user-defined ranking of CVs. Here, whenever an ill-conditioning is detected, CVs are dropped from the control calculation in the order of their ranks, starting from the one with the least assigned priority, until the condition number improves to an acceptable level. When two CVs are seen to behave very similarly, the user can rank the less important CV with a very low priority. Even though the control on the dropped CV is given up, it is hoped that it would be controlled indirectly since it behaves similarly to the other high-ranked CV.

28.4.7 Prioritization of CVs and MVs

In most practical control problems, it is not possible to satisfy all constraints and also drive all outputs and inputs to their desired resting values. Hence, priorities need to be assigned to express their relative importance. In DMC, these priorities are determined through weight parameters, which enter into the various quadratic penalty terms in the objective function. For large, complex problems, determining proper weights that lead to an intended behavior can be a daunting task. Even if a set of weights consistent

with the control specification is found, the weights can differ vastly in magnitude from one to another, causing a numerical conditioning problem.

Algorithms such as HIECON and SMC-IDCOM attempt to address this difficulty by letting the user *rank* various objectives in the order of their importance. For example, constraint satisfaction may be the most critical aspect, which must be taken care of before satisfying other objectives. Also driving the CVs to their desired setpoints may be more important than driving the MVs to their most economic values. In these algorithms, an optimization would be solved with the most important objective first and then remaining degrees of freedom would be used to address the other objectives in the order of priority. These algorithms also allow the user to rank each CV and MV according to its priority. Hence, for constraint softening, one may specify the order in which constraints for various CVs must be relaxed. Also, in setpoint tracking, one can prioritize the CVs so that CVs with higher ranks are driven to their setpoints before those with lower ranks are considered.

28.4.8 Bi-Level Optimization

The MPC calculation can be split into two parts for an added flexibility. First, a local *steady-state* optimization can be performed to obtain target values for each input and output. This can be followed by a *dynamic* optimization to determine the most desirable dynamic trajectory to these target values. Even though the local steady-state optimization can be based on an economic index, it does not replace the more comprehensive nonlinear optimization that often runs above the MPC layer—at a much slower rate—in order to provide an optimal range of inputs and outputs for the plant condition experienced during a particular optimization cycle. The local optimization performed in MPC is based on a linear steady-state model, which may be obtained by linearizing a nonlinear model or simply the steady-state version of the step response model used in the dynamic optimization.

The reasons for running the local optimization may vary. For example, one may want to perform an economic optimization at a higher frequency to account for local disturbances. Even if there is no economic objective in the given control problem, the steady-state optimization can be helpful to determine best feasible target values for CVs and the corresponding MV settling values.

The two-stage optimization can be formulated as below:

- **Step 1: Steady-State Optimization** The general form of a steady-state prediction equation is

$$y(\infty|k) = K_s \underbrace{(u(\infty|k) - u(k-1))}_{\Delta u_s(k)} + b(k), \quad (28.68)$$

where $y(\infty|k)$ and $u(\infty|k)$ are the steady-state values of the output and input projected at time k . With only m input moves considered,

$$\Delta u_s(k) = \Delta u(k) + \Delta u(k+1) + \dots + \Delta u(k+m-1). \quad (28.69)$$

Note that, for the step response model,

$$y(\infty|k) = y(k+m+n-1|k) \quad (28.70)$$

and $K_s = S_n$. Also,

$$b(k) = \tilde{y}_{n-1}(k) + S_n^d \Delta d(k) + (y_m(k) - \tilde{y}_0(k)). \quad (28.71)$$

This steady-state prediction model can be used to optimize a given economic objective function subject to various input and output constraints:

$$\min_{\Delta u_s(k)} \ell(u(\infty|k), y(\infty|k)). \quad (28.72)$$

Since an economic objective function is typically linear and the prediction equation is also linear, an LP results. Alternatively, one can also solve

$$\min_{\Delta u_s(k)} \|\Delta u_s(k)\|, \tag{28.73}$$

$$\min_{\Delta u_s(k)} \|r - y(\infty|k)\|_Q. \tag{28.74}$$

In the first case, we would be looking for a minimum input change such that all the constraints are satisfied. In the second case, we would be seek a minimum deviation from the setpoint values that are achievable within the given constraints. The solution sets the target settling values for the inputs and outputs.

- **Step 2: Dynamic Optimization** The dynamic prediction equation is the same as before. A quadratic regulation objective of the following is minimized subject to the given constraints through QP:

$$\left[\sum_{i=1}^{m+n-2} (y(k+i|k) - y^*(\infty|k))^T Q (y(k+i|k) - y^*(\infty|k)) + \sum_{j=0}^{m-1} \Delta u^T(k+j|k) R \Delta u(k+j|k) \right], \tag{28.75}$$

where $y^*(\infty|k)$ is the solution from the steady-state optimization. An additional constraint may be added to match the settling values of the optimized input trajectories to those computed from the steady-state optimization:

$$\Delta u(k|k) + \Delta u(k+1|k) + \dots + \Delta u(k+m-1|k) = \Delta u_s^*(k). \tag{28.76}$$

This also forces $y(k+m+n-1|k)$ to be at the optimal steady-state value $y^*(k+\infty|k)$.

Note that, this steady-state optimization may be performed as often as at every sample time, that is at the same execution rate as the dynamic optimization. However, it is critical to filter the noise and other high-frequency variations from the feedback signal. Otherwise, the solution from the steady-state solution can fluctuate wildly from sample time to sample time, especially in the case of an LP.

28.5 Future Needs

28.5.1 Better Identification

Conventionally, step response models used in DMC (or other industrial MPC algorithms) are identified through a series of step tests. In some cases, pseudorandom binary sequence (PRBS) tests instead of step tests are used and the step response coefficients are fitted through least squares. In almost all cases, input channels are perturbed *one at a time*, leading to SISO identification. While this practice is simple and easy to implement, it does not always yield a multivariable model of required accuracy. This is usually dealt with in practice by detuning or dropping a part of control space, not a desirable remedy from a performance standpoint.

Independent testing of input channels emphasizes the accuracy of individual transfer function elements, and can result in a poor fit of control-relevant multivariable system characteristics (e.g., the gain directionality) [5]. For highly interactive processes, test signals for different input channels need to be correlated in order to yield an accurate model for multivariable control. In general, this points to the need for a systematic method to design identification experiments with control requirements directly considered. In addition, a nonconservative way to quantify the model quality (e.g., uncertainty bounds) would greatly aid the much needed integration between identification and control.

In terms of identification algorithms, development and use of multi-input multi-output (MIMO) algorithms that are capable of capturing output correlations can be helpful. They will not only improve

prediction in conventional control problems, but will also enable construction of a model useful for inferential control. Traditional polynomial-model-based identification algorithms are poorly suited to MIMO identification. Recently proposed subspace identification algorithms [8] may fill this need, but they need to be tested further and perhaps tailored to suit the process control problems.

28.5.2 Robust MPC

Model uncertainty is an important aspect of every process control problem, as most processes are very difficult and time consuming to model accurately. Hence, it is desirable to incorporate the model quality information (e.g., uncertainty bounds, parameter probability distribution) directly into the control computation, instead of achieving robustness margins indirectly through various tuning parameters. In terms of the robust MPC controller synthesis, the most popular approach has been the so-called *min-max predictive control* that aims at minimizing the worst-case error with respect to the model set. Other methods include a stochastic approach where the expectation of the error is minimized, given a certain probability distribution of model parameters [7]. None of these methods have been tested in real problems. See [2] for a review and references. In order for these methods to find practical applications, what is most needed is a method that reliably computes the uncertainty bounds or probability distribution from identification data.

28.5.3 Performance Monitoring, Diagnosis, and Adaptation

It has been reported that many MPCs perform well when commissioned, but their performances deteriorate over time and they eventually have to be taken offline. There are a wide variety of causes for this, including instrumentation problems, process nonlinearity, and parameter variations. In order to sustain the benefits of these controllers over a long period of time, a mechanism to detect and diagnose the cause of significant performance deterioration is needed. The results can be communicated to engineers and can also be used to adapt control parameters. Vigorous research has already begun in this area and some vendors (such as Honeywell) have expressed interests in including such features in the next generation of commercial software.

28.6 Conclusion

This chapter presented a brief review and outlook of MPC in the process industries. The original industrial algorithms, albeit simple and restrictive, are continuing to be used quite successfully in process control applications. Some generalizations and extensions introduced mostly by academics to enhance the original industrial technology have found their way into the next generation of commercial algorithms being marketed currently. This indicates a healthy synergism between academia and industry in this particular area. This chapter also provided some needs (in both research and practice) to make MPC a more appealing and broadly applicable technique in the future.

29.1 Introduction

Traditional control theory is concerned with the design of linear feedback control with desirable asymptotic behavior, such as stability and small steady-state and tracking errors, while properties of transient behavior are expressed in terms of overshoot and speed of response. External disturbances can be handled by modeling these as random processes, leading to the Linear Quadratic Gaussian (LQG) problem formulation. This theory has some limitations.

Because the feedback law is specified to be linear, it is not possible for design methods to explicitly incorporate hard bounds on the control values, for example, the requirement that the applied force should not exceed a specified limit. Second, it is not possible to express finite time requirements, for example, the requirement that the system state reach a prespecified value at a prespecified time. Third, it is not possible to demand guaranteed performance in the face of disturbances, for example, the requirement that a certain target state be reached, no matter what the disturbance. Thus control problems with hard bounds on the control values, restrictions on the state trajectory over a finite time horizon, and guaranteed behavior despite the disturbances, are difficult to solve using frequency-based design methods.

In order to address these problems one needs to study system evolution in the time domain. The central concept that emerges in such studies is that of the *reach* set, which is the set of states that can be reached

by using all possible controls. This chapter is devoted to the formulation and computation of the reach set of a linear system with disturbances. The concept of reachability was introduced in [28]; [29] shows the reach set can be computed by solving the forward Hamilton–Jacobi–Bellman–Isaacs (HJBI) partial differential equation; and the notion of backward reachability with its application to aiming at a specified target set is described in [20]. Reachability of hybrid systems is addressed in [30,35]. Over the last decade, significant advances were made in the characterization of reach sets and their computation for linear systems. These advances are described in this chapter.

Section 29.2 introduces the forward and backward reach sets, the classes of open- and closed-loop controls, and different kinds of reach sets that are appropriate in dealing with disturbances. Although some of the discussion applies to nonlinear systems, explicit formulas for reach sets are available only for linear systems. These formulas lead to explicit algorithms for computing reach sets (of linear systems) and Section 29.3 critically reviews the most promising algorithms. Section 29.4 is devoted to a set of algorithms based on the ellipsoidal calculus. These algorithms have a lower computational complexity, greater accuracy, and can work with systems of a larger size, compared with those reviewed in Section 29.3. Finally, Section 29.5 presents three examples to illustrate the ellipsoidal-based approach.

29.2 Basics of Reachability Analysis

29.2.1 Systems without Disturbances

Consider a general continuous-time

$$\dot{x}(t) = f(t, x, u), \quad (29.1)$$

or discrete-time dynamical system

$$x(t+1) = f(t, x, u), \quad (29.1d)$$

wherein t is time*, $x \in \mathbf{R}^n$ is the state, $u \in \mathbf{R}^m$ is the control, and f is a measurable vector function taking values in \mathbf{R}^n .† The control values $u(t, x(t))$ are restricted to a closed compact control set $\mathcal{U}(t) \subset \mathbf{R}^m$. An *open-loop* control does not depend on the state, $u = u(t)$; for a *closed-loop* control, $u = u(t, x(t))$.

Definition 29.1: Reach Set

The (forward) reach set $\mathcal{X}(t, t_0, x_0)$ at time $t > t_0$ from the initial position (t_0, x_0) is the set of all states $x(t)$ reachable at time t by system (Equation 29.1, or 29.1d), with $x(t_0) = x_0$ through all possible controls $u(\tau, x(\tau)) \in \mathcal{U}(\tau)$, $t_0 \leq \tau < t$. For a given set of initial states \mathcal{X}_0 , the reach set $\mathcal{X}(t, t_0, \mathcal{X}_0)$ is

$$\mathcal{X}(t, t_0, \mathcal{X}_0) = \bigcup_{x_0 \in \mathcal{X}_0} \mathcal{X}(t, t_0, x_0).$$

Here are two facts about forward reach sets.

1. $\mathcal{X}(t, t_0, \mathcal{X}_0)$ is the same for open-loop and closed-loop control.
2. $\mathcal{X}(t, t_0, \mathcal{X}_0)$ satisfies the semigroup property,

$$\mathcal{X}(t, t_0, \mathcal{X}_0) = \mathcal{X}(t, \tau, \mathcal{X}(\tau, t_0, \mathcal{X}_0)), \quad t_0 \leq \tau < t. \quad (29.2)$$

* In discrete-time case, t assumes integer values.

† We are being general when giving the basic definitions. However, it is important to understand that for any specific *continuous-time* dynamical system it must be determined whether the solution exists and is unique, and in which class of solutions these conditions are met. we shall assume that function f is such that the solution of the differential equation 29.1 exists and is unique in Fillipov sense. This allows the right-hand side to be discontinuous. For discrete-time systems, this problem does not exist.

For linear systems

$$f(t, x, u) = A(t)x(t) + B(t)u, \tag{29.3}$$

with matrices $A(t)$ in $\mathbf{R}^{n \times n}$ and $B(t)$ in $\mathbf{R}^{m \times n}$. For a continuous-time linear system, the state transition matrix is

$$\dot{\Phi}(t, t_0) = A(t)\Phi(t, t_0), \quad \Phi(t, t) = I,$$

which for constant $A(t) \equiv A$ simplifies as

$$\Phi(t, t_0) = e^{A(t-t_0)}.$$

For a discrete-time linear system, the state transition matrix is

$$\Phi(t+1, t_0) = A(t)\Phi(t, t_0), \quad \Phi(t, t) = I,$$

which for constant $A(t) \equiv A$ simplifies as

$$\Phi(t, t_0) = A^{t-t_0}.$$

If the state transition matrix is invertible, $\Phi^{-1}(t, t_0) = \Phi(t_0, t)$. The transition matrix is always invertible for continuous-time and for sampled discrete-time systems. However, if for some τ , $t_0 \leq \tau < t$, $A(\tau)$ is degenerate (singular), $\Phi(t, t_0) = \prod_{\tau=t_0}^{t-1} A(\tau)$ is also degenerate and cannot be inverted.

Following Cauchy's formula, the reach set $\mathcal{X}(t, t_0, \mathcal{X}_0)$ for a linear system can be expressed as

$$\mathcal{X}(t, t_0, \mathcal{X}_0) = \Phi(t, t_0)\mathcal{X}_0 \oplus \int_{t_0}^t \Phi(t, \tau)B(\tau)\mathcal{U}(\tau) d\tau \tag{29.4}$$

in continuous-time, and as

$$\mathcal{X}(t, t_0, \mathcal{X}_0) = \Phi(t, t_0)\mathcal{X}_0 \oplus \sum_{\tau=t_0}^{t-1} \Phi(t, \tau+1)B(\tau)\mathcal{U}(\tau) \tag{29.4d}$$

in discrete-time case.

The operation " \oplus " is the *geometric sum*, also known as *Minkowski sum*.^{*} The geometric sum and linear (or affine) transformations preserve compactness and convexity. Hence, if the initial set \mathcal{X}_0 and the control sets $\mathcal{U}(\tau)$, $t_0 \leq \tau < t$, are compact and convex, so is the reach set $\mathcal{X}(t, t_0, \mathcal{X}_0)$.

Definition 29.2: Backward Reach Set

The backward reach set $\mathcal{Y}(t_1, t, y_1)$ for the target position (t_1, y_1) is the set of all states $y(t)$ for which there exists some control $u(\tau, x(\tau)) \in \mathcal{U}(\tau)$, $t \leq \tau < t_1$, that steers system (Equation 29.1 or 29.1d) to the state y_1 at time t_1 . For the target set \mathcal{Y}_1 at time t_1 , the backward reach set $\mathcal{Y}(t_1, t, \mathcal{Y}_1)$ is

$$\mathcal{Y}(t_1, t, \mathcal{Y}_1) = \bigcup_{y_1 \in \mathcal{Y}_1} \mathcal{Y}(t_1, t, y_1).$$

The backward reach set $\mathcal{Y}(t_1, t, \mathcal{Y}_1)$ is the largest *weakly invariant* set with respect to the target set \mathcal{Y}_1 and time values t and t_1 .[†]

^{*} Minkowski sum of sets $\mathcal{W}, \mathcal{Z} \subseteq \mathbf{R}^n$ is defined as $\mathcal{W} \oplus \mathcal{Z} = \{w+z \mid w \in \mathcal{W}, z \in \mathcal{Z}\}$. Set $\mathcal{W} \oplus \mathcal{Z}$ is nonempty if and only if both \mathcal{W} and \mathcal{Z} are nonempty. If \mathcal{W} and \mathcal{Z} are convex, set $\mathcal{W} \oplus \mathcal{Z}$ is convex.

[†] \mathcal{M} is weakly invariant with respect to the target set \mathcal{Y}_1 and times t_0 and t , if for every state $x_0 \in \mathcal{M}$ there exists a control $u(\tau, x(\tau)) \in \mathcal{U}(\tau)$, $t_0 \leq \tau < t$, that steers the system from x_0 at time t_0 to some state in \mathcal{Y}_1 at time t . If all controls in $\mathcal{U}(\tau)$, $t_0 \leq \tau < t$ steer the system from every $x_0 \in \mathcal{M}$ at time t_0 to \mathcal{Y}_1 at time t , set \mathcal{M} is said to be *strongly invariant* with respect to \mathcal{Y}_1, t_0 , and t .

Remark 29.1

Backward reach set can be computed for continuous-time system only if the solution of Equation 29.1 exists for $t < t_1$; and for discrete-time system only if the right-hand side of Equation 29.1d is invertible*.

These two facts about the backward reach set \mathcal{Y} are similar to those for forward reach sets.

1. $\mathcal{Y}(t_1, t, \mathcal{Y}_1)$ is the same for open-loop and closed-loop control.
2. $\mathcal{Y}(t_1, t, \mathcal{Y}_1)$ satisfies the semigroup property,

$$\mathcal{Y}(t_1, t, \mathcal{Y}_1) = \mathcal{Y}(\tau, t, \mathcal{Y}(t_1, \tau, \mathcal{Y}_1)), \quad t \leq \tau < t_1. \quad (29.5)$$

For the linear system (Equation 29.3) the backward reach set can be expressed as

$$\mathcal{Y}(t_1, t, \mathcal{Y}_1) = \Phi(t, t_1)\mathcal{Y}_1 \oplus \int_{t_1}^t \Phi(t, \tau)B(\tau)\mathcal{U}(\tau) d\tau \quad (29.6)$$

in the continuous-time case, and as

$$\mathcal{Y}(t_1, t, \mathcal{Y}_1) = \Phi(t, t_1)\mathcal{Y}_1 \oplus \sum_{\tau=t}^{t_1-1} -\Phi(t, \tau)B(\tau)\mathcal{U}(\tau) \quad (29.6d)$$

in the discrete-time case. The last formula makes sense only for discrete-time linear systems with invertible state transition matrix. Degenerate discrete-time linear systems have unbounded backward reach sets and such sets cannot be computed with available software tools.

Just as in the case of forward reach set, the backward reach set of a linear system $\mathcal{Y}(t_1, t, \mathcal{Y}_1)$ is compact and convex if the target set \mathcal{Y}_1 and the control sets $\mathcal{U}(\tau)$, $t \leq \tau < t_1$ are compact and convex.

Remark 29.2

In the computer science literature, the reach set is said to be the result of operator *post*, and the backward reach set is the result of operator *pre*. In the control literature, the backward reach set is also called the *solvability set*.

29.2.2 Systems with Disturbances

Consider the continuous-time dynamical system with disturbance

$$\dot{x}(t) = f(t, x, u, v), \quad (29.7)$$

or the discrete-time dynamical system with disturbance

$$x(t+1) = f(t, x, u, v), \quad (29.7d)$$

in which we also have the disturbance input $v \in \mathbf{R}^d$ with values $v(t)$ restricted to a closed compact set $\mathcal{V}(t) \subset \mathbf{R}^d$.

In the presence of disturbances, the open-loop reach set (OLRS) is different from the closed-loop reach set (CLRS).

Given the initial time t_0 , the set of initial states \mathcal{X}_0 , and terminal time t , there are two types of OLRs.

Definition 29.3: OLRs of Maxmin Type

The maxmin open-loop reach set $\bar{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0)$ is the set of all states x , such that for any disturbance $v(\tau) \in \mathcal{V}(\tau)$, there exists an initial state $x_0 \in \mathcal{X}_0$ and a control $u(\tau) \in \mathcal{U}(\tau)$, $t_0 \leq \tau < t$, that steers system (Equation 29.7 or 29.7d) from $x(t_0) = x_0$ to $x(t) = x$.

* There exists $f^{-1}(t, x, u)$ such that $x(t) = f^{-1}(t, x(t+1), u, v)$.

Definition 29.4: OLRs of Minmax Type

The minmax open-loop reach set $\underline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0)$ is the set of all states x , such that there exists a control $u(\tau) \in \mathcal{U}(\tau)$ that for all disturbances $v(\tau) \in \mathcal{V}(\tau)$, $t_0 \leq \tau < t$, assigns an initial state $x_0 \in \mathcal{X}_0$ and steers system (Equation 29.7 or 29.7d), from $x(t_0) = x_0$ to $x(t) = x$.

In the maxmin case, the control is chosen *after* knowing the disturbance over the entire time interval $[t_0, t]$, whereas in the minmax case, the control is chosen *before* any knowledge of the disturbance. Consequently, the OLRs do not satisfy the semigroup property.

The terms “maxmin” and “minmax” come from the fact that $\overline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0)$ is the subzero level set of the value function

$$\underline{V}(t, x) = \max_v \min_u \{\mathbf{dist}(x(t_0), \mathcal{X}_0) \mid x(t) = x, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), t_0 \leq \tau < t\}, \tag{29.8}$$

that is., $\overline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0) = \{x \mid \underline{V}(t, x) \leq 0\}$, and $\underline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0)$ is the subzero level set of the value function

$$\overline{V}(t, x) = \min_u \max_v \{\mathbf{dist}(x(t_0), \mathcal{X}_0) \mid x(t) = x, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), t_0 \leq \tau < t\}, \tag{29.9}$$

in which $\mathbf{dist}(\cdot, \cdot)$ denotes Hausdorff semidistance.* Since $\underline{V}(t, x) \leq \overline{V}(t, x)$, $\underline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0) \subseteq \overline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0)$.

Note that maxmin and minmax OLRs imply *guarantees*: these are states that can be reached no matter what the disturbance is, whether it is known in advance (maxmin case) or not (minmax case). The OLRs may be empty.

Fixing time instant τ_1 , $t_0 < \tau_1 < t$, define the *piecewise maxmin open-loop reach set with one correction*,

$$\overline{\mathcal{X}}_{OL}^1(t, t_0, \mathcal{X}_0) = \overline{\mathcal{X}}_{OL}(t, \tau_1, \overline{\mathcal{X}}_{OL}(\tau_1, t_0, \mathcal{X}_0)), \tag{29.10}$$

and the *piecewise minmax open-loop reach set with one correction*,

$$\underline{\mathcal{X}}_{OL}^1(t, t_0, \mathcal{X}_0) = \underline{\mathcal{X}}_{OL}(t, \tau_1, \underline{\mathcal{X}}_{OL}(\tau_1, t_0, \mathcal{X}_0)). \tag{29.11}$$

The piecewise maxmin OLRs $\overline{\mathcal{X}}_{OL}^1(t, t_0, \mathcal{X}_0)$ is the subzero level set of the value function

$$\underline{V}^1(t, x) = \max_v \min_u \{\underline{V}(\tau_1, x(\tau_1)) \mid x(t) = x, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), \tau_1 \leq \tau < t\}, \tag{29.12}$$

with $\underline{V}(\tau_1, x(\tau_1))$ given by Equation 29.8, which yields

$$\underline{V}^1(t, x) \geq \underline{V}(t, x),$$

and thus,

$$\overline{\mathcal{X}}_{OL}^1(t, t_0, \mathcal{X}_0) \subseteq \overline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0).$$

On the other hand, the piecewise minmax OLRs $\underline{\mathcal{X}}_{OL}^1(t, t_0, \mathcal{X}_0)$ is the subzero level set of the value function

$$\overline{V}^1(t, x) = \min_u \max_v \{\overline{V}(\tau_1, x(\tau_1)) \mid x(t) = x, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), \tau_1 \leq \tau < t\}, \tag{29.13}$$

* Hausdorff semidistance between compact sets $\mathcal{W}, \mathcal{Z} \subseteq \mathbf{R}^n$ is defined as

$$\mathbf{dist}(\mathcal{W}, \mathcal{Z}) = \min\{\langle w - z, w - z \rangle^{1/2} \mid w \in \mathcal{W}, z \in \mathcal{Z}\},$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product.

with $V(\tau_1, x(\tau_1))$ given by Equation 29.9, which yields

$$\bar{V}(t, x) \geq \bar{V}^1(t, x),$$

and thus,

$$\underline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0) \subseteq \underline{\mathcal{X}}_{OL}^1(t, t_0, \mathcal{X}_0).$$

We can now recursively define piecewise maxmin and minmax OLRS with k corrections for $t_0 < \tau_1 < \dots < \tau_k < t$. The maxmin piecewise OLRS with k corrections is

$$\bar{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0) = \bar{\mathcal{X}}_{OL}(t, \tau_k, \bar{\mathcal{X}}_{OL}^{k-1}(\tau_k, t_0, \mathcal{X}_0)), \quad (29.14)$$

which is the subzero level set of the corresponding value function

$$\underline{V}^k(t, x) = \max_v \min_u \{ \underline{V}^{k-1}(\tau_k, x(\tau_k)) \mid x(t) = x, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), \tau_k \leq \tau < t \}. \quad (29.15)$$

The minmax piecewise OLRS with k corrections is

$$\underline{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0) = \underline{\mathcal{X}}_{OL}(t, \tau_k, \underline{\mathcal{X}}_{OL}^{k-1}(\tau_k, t_0, \mathcal{X}_0)), \quad (29.16)$$

which is the subzero level set of the corresponding value function

$$\bar{V}^k(t, x) = \min_u \max_v \{ \bar{V}^{k-1}(\tau_k, x(\tau_k)) \mid x(t) = x, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), \tau_k \leq \tau < t \}. \quad (29.17)$$

From Equations 29.12, 29.13, 29.15, and 29.17 it follows that,

$$\underline{V}(t, x) \leq \underline{V}^1(t, x) \leq \dots \leq \underline{V}^k(t, x) \leq \bar{V}^k(t, x) \leq \dots \leq \bar{V}^1(t, x) \leq \bar{V}(t, x).$$

Hence,

$$\begin{aligned} \underline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0) &\subseteq \underline{\mathcal{X}}_{OL}^1(t, t_0, \mathcal{X}_0) \subseteq \dots \subseteq \underline{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0) \\ &\subseteq \bar{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0) \subseteq \dots \subseteq \bar{\mathcal{X}}_{OL}^1(t, t_0, \mathcal{X}_0) \subseteq \bar{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0). \end{aligned} \quad (29.18)$$

We call

$$\bar{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0) = \bar{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0), \quad k = \begin{cases} \infty & \text{for continuous-time system,} \\ t - t_0 - 1 & \text{for discrete-time system,} \end{cases} \quad (29.19)$$

the *maxmin closed-loop reach set* of system (Equation 29.7 or 29.7d) at time t , and we call

$$\underline{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0) = \underline{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0), \quad k = \begin{cases} \infty & \text{for continuous-time system,} \\ t - t_0 - 1 & \text{for discrete-time system,} \end{cases} \quad (29.20)$$

the *minmax closed-loop reach set* of system (Equation 29.7 or 29.7d) at time t .

Definition 29.5: CLRS of Maxmin Type

Given initial time t_0 and the set of initial states \mathcal{X}_0 , the maxmin CLRS $\bar{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0)$ of system (Equation 29.7 or 29.7d) at time $t > t_0$, is the set of all states x , for each of which and for every disturbance $v(\tau) \in \mathcal{V}(\tau)$, there exist an initial state $x_0 \in \mathcal{X}_0$ and a control $u(\tau, x(\tau)) \in \mathcal{U}(\tau)$, such that the trajectory $x(\tau|v(\tau), u(\tau, x(\tau)))$ satisfying $x(t_0) = x_0$ and

$$\dot{x}(\tau|v(\tau), u(\tau, x(\tau))) \in f(\tau, x(\tau), u(\tau, x(\tau)), v(\tau))$$

in the continuous-time case, or

$$x(\tau + 1|v(\tau), u(\tau, x(\tau))) \in f(\tau, x(\tau), u(\tau, x(\tau)), v(\tau))$$

in the discrete-time case, with $t_0 \leq \tau < t$, is such that $x(t) = x$.

Definition 29.6: CLRS of Minmax Type

Given initial time t_0 and the set of initial states \mathcal{X}_0 , the maxmin CLRS $\underline{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0)$ of system (Equation 29.7 or 29.7d), at time $t > t_0$ is the set of all states x , for each of which there exists a control $u(\tau, x(\tau)) \in \mathcal{U}(\tau)$, and for every disturbance $v(\tau) \in \mathcal{V}(\tau)$ there exists an initial state $x_0 \in \mathcal{X}_0$, such that the trajectory $x(\tau, v(\tau)|u(\tau, x(\tau)))$ satisfying $x(t_0) = x_0$ and

$$\dot{x}(\tau, v(\tau)|u(\tau, x(\tau))) \in f(\tau, x(\tau), u(\tau, x(\tau)), v(\tau))$$

in the continuous-time case, or

$$x(\tau + 1, v(\tau)|u(\tau, x(\tau))) \in f(\tau, x(\tau), u(\tau, x(\tau)), v(\tau))$$

in the discrete-time case, with $t_0 \leq \tau < t$, is such that $x(t) = x$.

By construction, both maxmin and minmax CLRS satisfy the semigroup property (Equation 29.2).

For some classes of dynamical systems and some types of constraints on initial conditions, controls and disturbances, the maxmin and minmax CLRS may coincide. This is the case for continuous-time linear systems with convex compact bounds on the initial set, controls and disturbances under the condition that the initial set \mathcal{X}_0 is large enough to ensure that $\mathcal{X}(t_0 + \epsilon, t_0, \mathcal{X}_0)$ is nonempty for some small $\epsilon > 0$.

Consider the linear system case,

$$f(t, x, u) = A(t)x(t) + B(t)u + G(t)v, \tag{29.21}$$

where $A(t)$ and $B(t)$ are as in Equation 29.3, and $G(t)$ takes its values in \mathbf{R}^d .

The maxmin OLRs for the continuous-time linear system can be expressed through set valued integrals,

$$\bar{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0) = \left(\Phi(t, t_0)\mathcal{X}_0 \oplus \int_{t_0}^t \Phi(t, \tau)B(\tau)\mathcal{U}(\tau) d\tau \right) \dot{-} \int_{t_0}^t \Phi(t, \tau)(-G(\tau))\mathcal{V}(\tau) d\tau, \tag{29.22}$$

and for discrete-time linear system through set-valued sums,

$$\bar{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0) = \left(\Phi(t, t_0)\mathcal{X}_0 \oplus \sum_{\tau=t_0}^{t-1} \Phi(t, \tau+1)B(\tau)\mathcal{U}(\tau) \right) \dot{-} \sum_{\tau=t_0}^{t-1} \Phi(t, \tau+1)(-G(\tau))\mathcal{V}(\tau). \tag{29.22d}$$

Similarly, the minmax OLRs for the continuous-time linear system is

$$\underline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0) = \left(\Phi(t, t_0)\mathcal{X}_0 \dot{-} \int_{t_0}^t \Phi(t, \tau)(-G(\tau))\mathcal{V}(\tau) d\tau \right) \oplus \int_{t_0}^t \Phi(t, \tau)B(\tau)\mathcal{U}(\tau) d\tau, \tag{29.23}$$

and for the discrete-time linear system, it is

$$\underline{\mathcal{X}}_{OL}(t, t_0, \mathcal{X}_0) = \left(\Phi(t, t_0)\mathcal{X}_0 \dot{-} \sum_{\tau=t_0}^{t-1} \Phi(t, \tau+1)(-G(\tau))\mathcal{V}(\tau) \right) \oplus \sum_{\tau=t_0}^{t-1} \Phi(t, \tau+1)B(\tau)\mathcal{U}(\tau). \tag{29.23d}$$

The operation ‘ $\dot{-}$ ’ is *geometric difference*, also known as *Minkowski difference*.*

* The Minkowski difference of sets $\mathcal{W}, \mathcal{Z} \in \mathbf{R}^n$ is defined as $\mathcal{W} \dot{-} \mathcal{Z} = \{\xi \in \mathbf{R}^n \mid \xi \oplus \mathcal{Z} \subseteq \mathcal{W}\}$. If \mathcal{W} and \mathcal{Z} are convex, $\mathcal{W} \dot{-} \mathcal{Z}$ is convex if it is nonempty.

Now consider the piecewise OLRs with k corrections. Expression 29.14 translates into

$$\bar{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0) = \left(\Phi(t, \tau_k) \bar{\mathcal{X}}_{OL}^{k-1}(\tau_k, t_0, \mathcal{X}_0) \oplus \int_{\tau_k}^t \Phi(t, \tau) B(\tau) \mathcal{U}(\tau) d\tau \right) \dot{-} \int_{\tau_k}^t \Phi(t, \tau) (-G(\tau)) \mathcal{V}(\tau) d\tau, \quad (29.24)$$

in the continuous-time case, and for the discrete-time case into

$$\bar{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0) = \left(\Phi(t, \tau_k) \bar{\mathcal{X}}_{OL}^{k-1}(\tau_k, t_0, \mathcal{X}_0) \oplus \sum_{\tau=\tau_k}^{t-1} \Phi(t, \tau+1) B(\tau) \mathcal{U}(\tau) \right) \dot{-} \sum_{\tau=\tau_k}^{t-1} \Phi(t, \tau+1) (-G(\tau)) \mathcal{V}(\tau). \quad (29.24d)$$

Expression 29.16 translates into

$$\underline{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0) = \left(\Phi(t, \tau_k) \underline{\mathcal{X}}_{OL}^{k-1}(t, t_0, \mathcal{X}_0) \dot{-} \int_{\tau_k}^t \Phi(t, \tau) (-G(\tau)) \mathcal{V}(\tau) d\tau \right) \oplus \int_{\tau_k}^t \Phi(t, \tau) B(\tau) \mathcal{U}(\tau) d\tau, \quad (29.25)$$

in the continuous-time case, and for the discrete-time case into

$$\underline{\mathcal{X}}_{OL}^k(t, t_0, \mathcal{X}_0) = \left(\Phi(t, \tau_k) \underline{\mathcal{X}}_{OL}^{k-1}(\tau_k, t_0, \mathcal{X}_0) \dot{-} \sum_{\tau=\tau_k}^{t-1} \Phi(t, \tau+1) (-G(\tau)) \mathcal{V}(\tau) \right) \oplus \sum_{\tau=\tau_k}^{t-1} \Phi(t, \tau+1) B(\tau) \mathcal{U}(\tau). \quad (29.25d)$$

Since for any $\mathcal{W}_1, \mathcal{W}_2, \mathcal{W}_3 \subseteq \mathbf{R}^n$ it is true that

$$(\mathcal{W}_1 \dot{-} \mathcal{W}_2) \oplus \mathcal{W}_3 = (\mathcal{W}_1 \oplus \mathcal{W}_3) \dot{-} (\mathcal{W}_2 \oplus \mathcal{W}_3) \subseteq (\mathcal{W}_1 \oplus \mathcal{W}_3) \dot{-} \mathcal{W}_2,$$

from Equations 29.24 and 29.25 and from Equations 29.24d and 29.25d, it is clear that Equation 29.18 is true.

For linear systems, if the initial set \mathcal{X}_0 , control bounds $\mathcal{U}(\tau)$ and disturbance bounds $\mathcal{V}(\tau)$, $t_0 \leq \tau < t$, are compact and convex, the CLRS $\bar{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0)$ and $\underline{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0)$ are compact and convex, provided they are nonempty. For continuous-time linear systems, $\bar{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0) = \underline{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0) = \mathcal{X}_{CL}(t, t_0, \mathcal{X}_0)$.

Just as for forward reachability case, the backward reach sets can be open-loop (OLBRS) or closed-loop (CLBRS).

Definition 29.7: OLBRS of Maxmin Type

Given the terminal time t_1 and target set \mathcal{Y}_1 , the maxmin open-loop backward reach set $\bar{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1)$ of system (Equation 29.7 or 29.7d) at time $t < t_1$ is the set of all y , such that for any disturbance $v(\tau) \in \mathcal{V}(\tau)$ there exists a terminal state $y_1 \in \mathcal{Y}_1$ and control $u(\tau) \in \mathcal{U}(\tau)$, $t \leq \tau < t_1$, which steers the system from $y(t) = y$ to $y(t_1) = y_1$.

$\bar{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1)$ is the subzero level set of the value function

$$\underline{V}_b(t, y) = \max_v \min_u \{\mathbf{dist}(y(t_1), \mathcal{Y}_1) \mid y(t) = y, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), t \leq \tau < t_1\}, \quad (29.26)$$

Definition 29.8: OLBRS of Minmax Type

Given the terminal time t_1 and target set \mathcal{Y}_1 , the minmax open-loop backward reach set $\underline{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1)$ of system (Equation 29.7 or 29.7d) at time $t < t_1$ is the set of all y , such that there exists a control $u(\tau) \in \mathcal{U}(\tau)$ that for all disturbances $v(\tau) \in \mathcal{V}(\tau)$, $t \leq \tau < t_1$, assigns a terminal state $y_1 \in \mathcal{Y}_1$ and steers the system from $y(t) = y$ to $y(t_1) = y_1$.

$\underline{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1)$ is the subzero level set of the value function

$$\bar{V}_b(t, y) = \min_u \max_v \{\mathbf{dist}(y(t_1), \mathcal{Y}_1) \mid y(t) = y, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), t \leq \tau < t_1\}, \quad (29.27)$$

Remark 29.3

The backward reach set can be computed for a continuous-time system only if the solution of Equation 29.7 exists for $t < t_1$, and for a discrete-time system, only if the right-hand side of Equation 29.7d is invertible.

Similar to the forward reachability case, we construct piecewise OLBRS with one correction at time τ_1 , $t < \tau_1 < t_1$. The piecewise maxmin OLBRS with one correction is

$$\bar{\mathcal{Y}}_{OL}^1(t_1, t, \mathcal{Y}_1) = \bar{\mathcal{Y}}_{OL}(\tau_1, t, \bar{\mathcal{Y}}_{OL}(t_1, \tau_1, \mathcal{Y}_1)), \quad (29.28)$$

and it is the subzero level set of the function

$$\underline{V}_b^1(t, y) = \max_v \min_u \{\underline{V}_b(\tau_1, y(\tau_1)) \mid y(t) = y, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), t \leq \tau < \tau_1\}. \quad (29.29)$$

The piecewise minmax OLBRS with one correction is

$$\underline{\mathcal{Y}}_{OL}^1(t_1, t, \mathcal{Y}_1) = \underline{\mathcal{Y}}_{OL}(\tau_1, t, \underline{\mathcal{Y}}_{OL}(t_1, \tau_1, \mathcal{Y}_1)), \quad (29.30)$$

and it is the subzero level set of the function

$$\bar{V}_b^1(t, y) = \min_u \max_v \{\bar{V}_b(\tau_1, y(\tau_1)) \mid y(t) = y, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), t \leq \tau < \tau_1\}, \quad (29.31)$$

Recursively define maxmin and minmax OLBRS with k corrections for $t < \tau_k < \dots < \tau_1 < t_1$. The maxmin OLBRS with k corrections is

$$\bar{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1) = \bar{\mathcal{Y}}_{OL}(\tau_k, t, \bar{\mathcal{Y}}_{OL}^{k-1}(t_1, \tau_k, \mathcal{Y}_1)), \quad (29.32)$$

which is the subzero level set of function

$$\underline{V}_b^k(t, y) = \max_v \min_u \{\underline{V}_b^{k-1}(\tau_k, y(\tau_k)) \mid y(t) = y, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), t \leq \tau < \tau_k\}. \quad (29.33)$$

The minmax OLBRS with k corrections is

$$\underline{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1) = \underline{\mathcal{Y}}_{OL}(\tau_k, t, \underline{\mathcal{Y}}_{OL}^{k-1}(t_1, \tau_k, \mathcal{Y}_1)), \quad (29.34)$$

which is the subzero level set of the function

$$\bar{V}_b^k(t, y) = \min_u \max_v \{\bar{V}_b^{k-1}(\tau_k, y(\tau_k)) \mid y(t) = y, u(\tau) \in \mathcal{U}(\tau), v(\tau) \in \mathcal{V}(\tau), t \leq \tau < \tau_k\}, \quad (29.35)$$

From Equations 29.29, 29.31, 29.33, and 29.35 it follows that

$$\underline{V}_b(t, y) \leq \underline{V}_b^1(t, y) \leq \dots \leq \underline{V}_b^k(t, y) \leq \bar{V}_b^k(t, y) \leq \dots \leq \bar{V}_b^1(t, y) \leq \bar{V}_b(t, y).$$

Hence,

$$\begin{aligned} \underline{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1) &\subseteq \underline{\mathcal{Y}}_{OL}^1(t_1, t, \mathcal{Y}_1) \subseteq \dots \subseteq \underline{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1) \\ &\subseteq \bar{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1) \subseteq \dots \subseteq \bar{\mathcal{Y}}_{OL}^1(t_1, t, \mathcal{Y}_1) \subseteq \bar{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1). \end{aligned} \quad (29.36)$$

We say that

$$\bar{\mathcal{Y}}_{CL}(t_1, t, \mathcal{Y}_1) = \bar{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1), \quad k = \begin{cases} \infty & \text{for continuous-time system} \\ t_1 - t - 1 & \text{for discrete-time system} \end{cases} \quad (29.37)$$

is the *maxmin closed-loop backward reach set* of system (Equation 29.7 or 29.7d) at time t . We say that

$$\underline{\mathcal{Y}}_{CL}(t_1, t, \mathcal{Y}_1) = \underline{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1), \quad k = \begin{cases} \infty & \text{for continuous-time system} \\ t_1 - t - 1 & \text{for discrete-time system} \end{cases} \quad (29.38)$$

is the *minmax closed-loop backward reach set* of system (Equation 29.7 or 29.7d) at time t .

Definition 29.9: CLBRS of Maxmin Type

Given the terminal time t_1 and target set \mathcal{Y}_1 , the maxmin CLBRS $\overline{\mathcal{Y}}_{CL}(t_1, t, \mathcal{Y}_1)$ of system (Equation 29.7 or 29.7d) at time $t < t_1$ is the set of all states y , for each of which for every disturbance $v(\tau) \in \mathcal{V}(\tau)$ there exists terminal state $y_1 \in \mathcal{Y}_1$ and control $u(\tau, y(\tau)) \in \mathcal{U}(\tau)$ that assigns trajectory $y(\tau, |v(\tau), u(\tau, y(\tau)))$ satisfying

$$\dot{y}(\tau|v(\tau), u(\tau, y(\tau))) \in f(\tau, y(\tau), u(\tau, y(\tau)), v(\tau))$$

in continuous-time case, or

$$y(\tau + 1|v(\tau), u(\tau, y(\tau))) \in f(\tau, y(\tau), u(\tau, y(\tau)), v(\tau))$$

in discrete-time case, with $t \leq \tau < t_1$, such that $y(t) = y$ and $y(t_1) = y_1$.

Definition 29.10: CLBRS of Minmax Type

Given the terminal time t_1 and target set \mathcal{Y}_1 , the minmax CLBRS $\underline{\mathcal{Y}}_{CL}(t_1, t, \mathcal{Y}_1)$ of system (Equation 29.7 or 29.7d) at time $t < t_1$ is the set of all states y , for each of which there exists control $u(\tau, y(\tau)) \in \mathcal{U}(\tau)$ that for every disturbance $v(\tau) \in \mathcal{V}(\tau)$ assigns terminal state $y_1 \in \mathcal{Y}_1$ and trajectory $y(\tau, v(\tau)|u(\tau, y(\tau)))$ satisfying

$$\dot{y}(\tau, v(\tau)|u(\tau, y(\tau))) \in f(\tau, y(\tau), u(\tau, y(\tau)), v(\tau))$$

in the continuous-time case, or

$$y(\tau + 1, v(\tau)|u(\tau, y(\tau))) \in f(\tau, y(\tau), u(\tau, y(\tau)), v(\tau))$$

in the discrete-time case, with $t \leq \tau < t_1$, such that $y(t) = y$ and $y(t_1) = y_1$.

Both maxmin and minmax CLBRS satisfy the semigroup property (Equation 29.5).

The maxmin OLBRS for the continuous-time linear system can be expressed through set valued integrals,

$$\overline{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1) = \left(\Phi(t, t_1)\mathcal{Y}_1 \oplus \int_t^{t_1} \Phi(t, \tau)B(\tau)\mathcal{U}(\tau) d\tau \right) \dot{-} \int_t^{t_1} \Phi(t, \tau)G(\tau)\mathcal{V}(\tau) d\tau, \quad (29.39)$$

and for the discrete-time linear system through set-valued sums,

$$\overline{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1) = \left(\Phi(t, t_1)\mathcal{Y}_1 \oplus \sum_{\tau=t}^{t_1-1} -\Phi(t, \tau+1)B(\tau)\mathcal{U}(\tau) \right) \dot{-} \sum_{\tau=t}^{t_1-1} \Phi(t, \tau+1)G(\tau)\mathcal{V}(\tau). \quad (29.39d)$$

Similarly, the minmax OLBRS for the continuous-time linear system is

$$\underline{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1) = \left(\Phi(t, t_1)\mathcal{Y}_1 \dot{-} \int_t^{t_1} \Phi(t, \tau)G(\tau)\mathcal{V}(\tau) d\tau \right) \oplus \int_t^{t_1} \Phi(t, \tau)B(\tau)\mathcal{U}(\tau) d\tau, \quad (29.40)$$

and for the discrete-time linear system it is

$$\underline{\mathcal{Y}}_{OL}(t_1, t, \mathcal{Y}_1) = \left(\Phi(t, t_1)\mathcal{Y}_1 \dot{-} \sum_{\tau=t}^{t_1-1} \Phi(t, \tau+1)G(\tau)\mathcal{V}(\tau) \right) \oplus \sum_{\tau=t}^{t_1-1} -\Phi(t, \tau+1)B(\tau)\mathcal{U}(\tau). \quad (29.40d)$$

Now consider piecewise OLBRS with k corrections. Expression 29.32 translates into

$$\bar{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1) = \left(\Phi(t, \tau_k) \bar{\mathcal{Y}}_{OL}^{k-1}(t_1, \tau_k, \mathcal{Y}_1) \oplus \int_{\tau_k}^t \Phi(t, \tau) B(\tau) \mathcal{U}(\tau) d\tau \right) \dot{-} \int_t^{\tau_k} \Phi(t, \tau) G(\tau) \mathcal{V}(\tau) d\tau, \quad (29.41)$$

in the continuous-time case, and for the discrete-time case into

$$\bar{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1) = \left(\Phi(t, \tau_k) \bar{\mathcal{Y}}_{OL}^{k-1}(t_1, \tau_k, \mathcal{Y}_1) \oplus \sum_{\tau=t}^{\tau_k-1} -\Phi(t, \tau+1) B(\tau) \mathcal{U}(\tau) \right) \dot{-} \sum_{\tau=t}^{\tau_k-1} \Phi(t, \tau+1) G(\tau) \mathcal{V}(\tau). \quad (29.41d)$$

Expression 29.34 translates into

$$\underline{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1) = \left(\Phi(t, \tau_k) \bar{\mathcal{Y}}_{OL}^{k-1}(t_1, \tau_k, \mathcal{Y}_1) \dot{-} \int_t^{\tau_k} \Phi(t, \tau) G(\tau) \mathcal{V}(\tau) d\tau \right) \oplus \int_{\tau_k}^t \Phi(t, \tau) B(\tau) \mathcal{U}(\tau) d\tau, \quad (29.42)$$

in the continuous-time case, and for the discrete-time case into

$$\underline{\mathcal{Y}}_{OL}^k(t_1, t, \mathcal{Y}_1) = \left(\Phi(t, \tau_k) \bar{\mathcal{Y}}_{OL}^{k-1}(t_1, \tau_k, \mathcal{Y}_1) \dot{-} \sum_{\tau=t}^{\tau_k-1} \Phi(t, \tau+1) G(\tau) \mathcal{V}(\tau) \right) \oplus \sum_{\tau=t}^{\tau_k-1} -\Phi(t, \tau+1) B(\tau) \mathcal{U}(\tau). \quad (25.42d)$$

For continuous-time linear systems $\bar{\mathcal{Y}}_{CL}(t_1, t, \mathcal{Y}_1) = \underline{\mathcal{Y}}_{CL}(t_1, t, \mathcal{Y}_1) = \mathcal{Y}_{CL}(t_1, t, \mathcal{Y}_1)$ under the condition that the target set \mathcal{Y}_1 is large enough to ensure that $\underline{\mathcal{Y}}_{CL}(t_1, t_1 - \epsilon, \mathcal{Y}_1)$ is nonempty for some small $\epsilon > 0$.

Computation of backward reach sets for discrete-time linear systems makes sense only if the state transition matrix $\Phi(t_1, t)$ is invertible.

If the target set \mathcal{Y}_1 , control sets $\mathcal{U}(\tau)$, and disturbance sets $\mathcal{V}(\tau)$, $t \leq \tau < t_1$, are compact and convex, then CLBRS $\bar{\mathcal{Y}}_{CL}(t_1, t, \mathcal{Y}_1)$ and $\underline{\mathcal{Y}}_{CL}(t_1, t, \mathcal{Y}_1)$ are compact and convex, if they are nonempty.

29.2.3 Reachability Problem

Reachability analysis is concerned with the computation of the forward $\mathcal{X}(t, t_0, \mathcal{X}_0)$ and backward $\mathcal{Y}(t_1, t, \mathcal{Y}_1)$ reach sets (the reach sets may be maxmin or minmax) in a way that can effectively meet requests like the following:

1. For the given time interval $[t_0, t]$, determine whether the system can be steered into the given target set \mathcal{Y}_1 . In other words, is the set $\mathcal{Y}_1 \cap \bigcup_{t_0 \leq \tau \leq t} \mathcal{X}(\tau, t_0, \mathcal{X}_0)$ nonempty? And if the answer is “yes,” find a control that steers the system to the target set (or avoids the target set).*
2. If the target set \mathcal{Y}_1 is reachable from the given initial condition $\{t_0, \mathcal{X}_0\}$ in the time interval $[t_0, t]$, find the shortest time to reach \mathcal{Y}_1 ,

$$\arg \min_{\tau} \{ \mathcal{X}(\tau, t_0, \mathcal{X}_0) \cap \mathcal{Y}_1 \neq \emptyset \mid t_0 \leq \tau \leq t \}.$$

3. Given the terminal time t_1 , target set \mathcal{Y}_1 , and time $t < t_1$, find the set of states starting at time t from which the system can reach \mathcal{Y}_1 within time interval $[t, t_1]$. In other words, find $\bigcup_{t \leq \tau < t_1} \mathcal{Y}(t_1, \tau, \mathcal{Y}_1)$.
4. Find a closed-loop control that steers a system with disturbances to the given target set in given time.
5. Graphically display the projection of the reach set along any specified two- or three-dimensional subspace.

* So-called verification problems often consist in ensuring that the system is unable to reach an “unsafe” target set within a given time interval.

For linear systems, if the initial set \mathcal{X}_0 , target set \mathcal{Y}_1 , control bounds $\mathcal{U}(\cdot)$, and disturbance bounds $\mathcal{V}(\cdot)$ are compact and convex, so are the forward $\mathcal{X}(t, t_0, \mathcal{X}_0)$ and backward $\mathcal{Y}(t_1, t, \mathcal{Y}_1)$ reach sets. Hence reachability analysis requires the computationally effective manipulation of convex sets, and performing the set-valued operations of unions, intersections, geometric sums, and differences.

Existing reach set computation tools can deal reliably only with linear systems with convex constraints. A claim that a certain tool or method can be used *effectively* for nonlinear systems must be treated with caution, and the first question to ask is for what class of nonlinear systems and with what limit on the state space dimension does this tool work? Some “reachability methods for nonlinear systems” reduce to the local linearization of a system followed by the use of well-tested techniques for linear system reach set computation. Thus these approaches in fact use reachability methods for linear systems.

29.3 Overview of Computational Methods and Tools

Before choosing a method and a tool for reachability analysis, one should answer the following questions to specify the requirements.

1. Do you really need to compute reach sets, or it is enough to perform a safety check, for example, to ensure that trajectories of a system never enter a given target set, or never leave a given initial set? Barrier functions or invariant sets, described in the end of this section, may be sufficient for safety checking.
2. Do you need to compute reach sets exactly, or will approximations, external and internal, be enough? Except for very specific classes of systems, exact reach set computation is not possible, and approximation techniques are required. Unless a reach set has simple structure, its exact representation is possible only for low state-space dimension. Hence, the next question.
3. What is the dimension of your system? The higher the system dimension, the rougher the reach set approximation.

Another important quality of a computational method for reach sets is the preservation of the semigroup property. It is highly desirable that the semigroup property is maintained by the algorithm as well as by its software implementation.

29.3.1 Level Set Method

We start the overview of computational techniques for reach sets with the *level set* method as it points out the essence of the reachability problem, and has been used in practice for specific nonlinear systems. The idea is to solve the HJBI partial differential equation

$$\frac{\partial V}{\partial t} + \max_u \left\langle \frac{\partial V}{\partial x}, f(t, x, u) \right\rangle = 0,$$

with initial condition

$$V(t_0, x) = \mathbf{dist}(x, \mathcal{X}_0),$$

for $t > t_0$, and then to find the reach set $\mathcal{X}(t, t_0, \mathcal{X}_0)$ as the subzero level set of the solution $V(t, x)$,

$$\mathcal{X}(t, t_0, \mathcal{X}_0) = \{x \in \mathbf{R}^n \mid V(t, x) \leq 0\}.$$

This *forward* HJBI equation was introduced in [29]. For systems with disturbances, the HJBI equation is

$$\frac{\partial V}{\partial t} + \min_v \max_u \left\langle \frac{\partial V}{\partial x}, f(t, x, u, v) \right\rangle = 0$$

in the maxmin case, and

$$\frac{\partial \bar{V}}{\partial t} + \max_u \min_v \left\langle \frac{\partial \bar{V}}{\partial x}, f(t, x, u, v) \right\rangle = 0$$

in the minmax case.

For backward reach sets, the HJBI equation is solved in backward time,

$$\frac{\partial V_b}{\partial t} + \min_u \left\langle \frac{\partial V_b}{\partial x}, f(t, x, u) \right\rangle,$$

with boundary condition

$$V_b(t_1, x) = \mathbf{dist}(x, \mathcal{Y}_1),$$

for $t < t_1$. For systems with disturbances, the backward HJBI is

$$\frac{\partial V_b}{\partial t} + \max_v \min_u \left\langle \frac{\partial V_b}{\partial x}, f(t, x, u, v) \right\rangle = 0$$

in the maxmin case, and

$$\frac{\partial \bar{V}_b}{\partial t} + \min_u \max_v \left\langle \frac{\partial \bar{V}_b}{\partial x}, f(t, x, u, v) \right\rangle = 0$$

in the minmax case.

Computation of reach sets as level sets of HJBI solutions was introduced in [21,22,24] with special emphasis on linear systems. In [31], the authors applied the level set method to reachability analysis of hybrid systems. The level set method is implemented in the *Level Set Toolbox* [5], which uses numerical algorithms for time-dependent HJBI equations and structured grids. Work is under way to implement fast marching methods. These are effective numerical schemes that work for time-independent HJBI, but whose major restriction is the need for the control to have the same dimension as the state. Level Set Toolbox tries to compute the surface of the reach set exactly with accuracy dependent on the choice of the grid. This plus the exponential growth of computational complexity with the system dimension makes the level set method impractical for systems with dimension larger than three.

Level Set Toolbox deals with continuous-time systems. To use the level set method in discrete-time case, one has to solve the Bellman equation under the condition that the right-hand side of system (Equation 29.1d) is invertible,

$$V(t+1, x) = \min_u (V(t, f^{-1}(t, x, u)))$$

with initial condition

$$V(t_0, x) = \mathbf{dist}(x, \mathcal{X}_0)$$

for $t > t_0$, and then find the forward reach set

$$\mathcal{X}(t, t_0, \mathcal{X}_0) = \{x \in \mathbf{R}^n \mid V(t, x) \leq 0\}.$$

The backward reach set is the subzero level set of the value function $V_b(t, x)$ obtained from the backward Bellman equation,

$$V_b(t-1, x) = \min_u (V_b(t, f(t-1, x, u))),$$

with boundary condition

$$V_b(t_1, x) = \mathbf{dist}(x, \mathcal{Y}_1),$$

for $t < t_1$. For systems with disturbances \min_u is substituted with $\max_v \min_u$ or with $\min_u \max_v$ in both forward and backward Bellman equations, and the functions f and f^{-1} , whose existence is required, depend on an additional parameter v .

Even though in the discrete-time case the computation of the value function does not involve solving a partial differential equation (PDE), it is still very burdensome, especially for nonlinear systems whose reach sets are nonconvex. Computing the distance function for such sets and minimizing it over u may be difficult. Even more difficult it is to search for maxmin or minmax.

The conclusion is that although the level set method handles nonlinear systems, it is computationally costly, and the need to maintain a grid with the value function values, which must be rather dense to ensure proper accuracy, makes it practical only for low-dimensional dynamical systems.

29.3.2 Quantifier Elimination

For some classes of systems the reach sets can be computed symbolically using *quantifier elimination*. Quantifier elimination is the removal of all quantifiers (the universal quantifier \forall and the existential quantifier \exists) from a quantified system. Each quantified formula is substituted with quantifier-free expression with operations $+$, \times , $=$ and $<$. For example, consider the discrete-time linear system (Equations 29.1d, 29.3), with $A(t) = A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$ and $B(t) = B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$. For initial conditions $x_0 \in \{x \in \mathbf{R}^2 \mid \|x\|_\infty \leq 1\}$ and controls $u(t) \in \{u \in \mathbf{R} \mid -1 \leq u \leq 1\}$, the reach set for $t \geq 0$ is given by the quantified formula

$$\left\{ x \in \mathbf{R}^2 \mid \exists x_0, \exists t \geq 0, \exists u(\tau), 0 \leq \tau < t : x = A^t x_0 + \sum_{\tau=0}^{t-1} A^{t-\tau-1} B u(\tau) \right\},$$

which is equivalent to the quantifier-free expression

$$-1 \leq [1 \ 0]x \leq 1 \wedge -1 \leq [0 \ 1]x \leq 1.$$

It is proved in [27] that if A is constant and nilpotent or is diagonalizable with rational real or purely imaginary eigenvalues, the quantifier elimination package returns a quantifier free formula describing the reach set. This class of systems is evidently rather limited.

Requiem [10] is a Mathematica notebook which, given a linear system, the set of initial conditions and control bounds, symbolically computes the exact reach set, using the experimental quantifier elimination package.

29.3.3 Polytope Method

Definition 29.11: Hyperplane

The hyperplane $H(c, \gamma)$ in \mathbf{R}^n is the set

$$H = \{x \in \mathbf{R}^n \mid \langle c, x \rangle = \gamma\}$$

with fixed $c \in \mathbf{R}^n$ and $\gamma \in \mathbf{R}$.

A hyperplane defines two (closed) *halfspaces*,

$$S_1 = \{x \in \mathbf{R}^n \mid \langle c, x \rangle \leq \gamma\}, \quad \text{and} \quad S_2 = \{x \in \mathbf{R}^n \mid \langle c, x \rangle \geq \gamma\}.$$

Definition 29.12: Polytope

The polytope $P(C, g)$ is the intersection of a finite number of closed halfspaces:

$$P = \{x \in \mathbf{R}^n \mid Cx \leq g\},$$

with fixed $C = [c_1 \ \dots \ c_m]^T \in \mathbf{R}^{m \times n}$ and $g = [\gamma_1 \ \dots \ \gamma_m]^T \in \mathbf{R}^m$.

For linear discrete-time systems (Equations 29.7d and 29.21), with $\mathcal{X}_0, \mathcal{U}(t)$ and $\mathcal{V}(t), t \geq t_0$, being polytopes in $\mathbf{R}^n, \mathbf{R}^m$, and \mathbf{R}^d respectively, the reach sets $\overline{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0)$ and $\underline{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0)$ are also polytopes, because the polytope structure is closed under the operations of affine transformation, geometric sum, and geometric difference. (For continuous-time systems the reach sets need not be polytopes.) Starting with initial condition

$$\overline{\mathcal{X}}_{CL}(t_0, t_0, \mathcal{X}_0) = \underline{\mathcal{X}}_{CL}(t_0, t_0, \mathcal{X}_0) = \mathcal{X}_0,$$

for time step $t > t_0$ these reach sets are computed *exactly* as

$$\overline{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0) = A(t-1)\mathcal{X}(t-1, t_0, \mathcal{X}_0) \oplus B(t-1)\mathcal{U}(t-1) \dot{-} G(t-1)\mathcal{V}(t-1),$$

and

$$\underline{\mathcal{X}}_{CL}(t, t_0, \mathcal{X}_0) = A(t-1)\mathcal{X}(t-1, t_0, \mathcal{X}_0) \dot{-} G(t-1)\mathcal{V}(t-1) \oplus B(t-1)\mathcal{U}(t-1).$$

A similar procedure works for backward reach sets if the matrices $A(t), t < t_1$ are nondegenerate.

As we see, the polytope method consists in sequential computation of affine transformations of polytopes, geometric sum of two polytopes, and geometric difference of two polytopes (or, geometric difference first, then geometric sum for minmax CLRS). In the absence of disturbances the term $G(t-1)\mathcal{V}(t-1)$ vanishes and no geometric difference operation is performed. Each operation of geometric sum or geometric difference for two polytopes consists in finding the vertices of the resulting polytope and calculating its convex hull.

This method is implemented in the *MultiParametric Toolbox* (MPT) for MATLAB[®] [7,26]. Among its advantages are its simplicity, the fact that the reach sets are computed exactly, and that it is easy to compute the distance between two polytopes and to check whether two or more polytopes intersect, or whether a polytope intersects a hyperplane or a halfspace.

However, the polytope method has its limitations. The convex hull algorithm employed by MPT is based on the Double description method [32] and implemented in the *CDD/CDD+* package [1]. Its complexity is K^n , where K is the number of vertices and n is the state-space dimension. Hence, the use of MPT in general is practical only for low-dimensional systems, or for systems with very special structure of matrices A, B , and G that ensure that the number of polytope vertices does not grow too much with each time step. But even in low-dimensional systems the number of vertices in the reach set polytope can grow very large with the number of time steps. For example, consider the discrete-time linear time-invariant system with $A(t) = A = \begin{bmatrix} \cos 1 & -\sin 1 \\ \sin 1 & \cos 1 \end{bmatrix}$, $B(t) = I$, $G(t) = 0$ $u_k \in \{u \in \mathbf{R}^2 \mid \|u\|_\infty \leq 1\}$, and $x_0 \in \{x \in \mathbf{R}^2 \mid \|x\|_\infty \leq 1\}$. Starting with a rectangular initial set, the number of vertices of the reach set polytope is $4t + 4$ at the t th step.

29.3.4 d/dt

In d/dt [3], the reach set of a discrete-time linear system is approximated by unions of rectangular polytopes [13]. The algorithm works as follows. First, given the set of initial conditions \mathcal{X}_0 defined as a polytope at time t_0 , the evolution in time of the polytope's extreme points is computed $\mathcal{X}(\tau_1, t_0, \mathcal{X}_0)$. Second, the algorithm computes the convex hull of vertices of both, the initial polytope \mathcal{X}_0 and $\mathcal{X}(\tau_1, t_0, \mathcal{X}_0)$. The resulting polytope is then bloated (magnified) to include $\bigcup_{t_0 \leq \tau \leq \tau_1} \mathcal{X}(\tau, t_0, \mathcal{X}_0)$. Finally, this overapproximating polytope is in its turn overapproximated by the union of rectangles. The same procedure is repeated for the next time interval $[\tau_1, \tau_2]$, and the union of both rectangular approximations is taken, and so on.

Rectangular polytopes are easy to represent and the number of facets grows linearly with dimension, but a large number of rectangles must be used to assure that the approximation is not overly conservative. Besides, the important part of this method is again the convex hull calculation whose implementation relies on the same *CDD/CDD+* library. This limits the dimension of the system and time interval for which it is feasible to calculate the reach set.

d/dt is implemented in C.

29.3.5 Zonotope Method

Polytopes can give arbitrarily close approximations to any convex set, but the number of vertices can grow prohibitively large and, as shown in [14], the computation of a polytope by its convex hull becomes intractable for large number of vertices in high dimensions. Symmetric polytopes, called zonotopes [11], could be a solution.

Definition 29.13: Zonotope

A zonotope is a special class of polytopes of the form

$$Z = \left\{ x \in \mathbf{R}^n \mid x = c + \sum_{i=1}^k \alpha_i g_i, \quad -1 \leq \alpha_i \leq 1 \right\},$$

wherein c and g_1, \dots, g_k are vectors in \mathbf{R}^n .

Thus, a zonotope Z is compactly represented by its center c and generator vectors g_1, \dots, g_k . The value k/n is called the order of the zonotope.

The zonotope method for external approximation of reach sets of discrete-time linear systems was introduced in [17], implemented in the *MATISSE* package for MATLAB [6], and further discussed in [18]. In [18], the authors introduce computational tricks that work only for *time-invariant* linear systems. The advantage of zonotopes is that they are closed under the operations of affine transformation and geometric sum, hence, the reach set of a discrete-time linear system (Equations 29.1d and 29.3), with \mathcal{X}_0 and $\mathcal{U}(t)$, $t \geq t_0$, being zonotopes, is also a zonotope. Similar properties hold for the backward reach set.

The problem with using zonotopes is that with every time step the order of the approximating zonotope increases by k/n . This difficulty can be averted by limiting the number of generator vectors, and overapproximating zonotopes whose number of generator vectors exceeds this limit by lower-order zonotopes. This may affect the accuracy of the reach set approximation and potentially destroy the semigroup property that is inherently present in the zonotope method.

Further limitations of zonotopes are that geometric difference of two zonotopes, intersections of zonotopes or zonotopes with hyperplanes or halfspaces, are not zonotopes. That presents a difficulty for the computation of reach sets for systems with disturbances and hybrid systems. Effective zonotope approximation algorithms for the geometric difference and intersections are needed. Currently, *MATISSE* does not provide a zonotope library in which these operations are implemented.

29.3.6 CheckMate

CheckMate [2] is a MATLAB toolbox that can evaluate specifications for trajectories starting from the set of initial (continuous) states corresponding to the parameter values at the vertices of the parameter set. This provides preliminary insight into whether the specifications will be true for all parameter values. The method of oriented rectangular polytopes for external approximation of reach sets is introduced in [36]. The basic idea is to construct an oriented rectangular hull of the reach set for every time step, whose orientation is determined by the singular value decomposition of the sample covariance matrix for the states reachable from the vertices of the initial polytope. The limitation of CheckMate and the method of oriented rectangles is that only autonomous (i.e., there is no control) systems are allowed, and only an external approximation of the reach set is provided.

Currently, the development of CheckMate is discontinued. Therefore, we refer the reader to *PHAVer* [8], the newly developed verification tool that uses *Parma Polyhedra Library* (PPL) [9] for its polyhedral computations.

29.3.7 Ellipsoidal Method

All the geometric methods for reach set computation described above, namely polytopes, zonotopes, rectangular hulls, and oriented rectangles employ the notion of time step. At every time step a certain algorithm runs producing a new reach set for that time step. This can work only for discrete-time systems. The ellipsoidal method offers a different approach that works for continuous- and discrete-time linear systems with disturbances, with ellipsoidal constraints on the initial or target set, controls, and disturbances.

Definition 29.14: Ellipsoid

The ellipsoid $\mathcal{E}(q, Q)$ in \mathbf{R}^n with center q and shape matrix Q is the set

$$\mathcal{E}(q, Q) = \{x \in \mathbf{R}^n \mid \langle (x - q), Q^{-1}(x - q) \rangle \leq 1\},$$

wherein Q is positive definite ($Q = Q^T$ and $\langle x, Qx \rangle > 0$ for all nonzero $x \in \mathbf{R}^n$).

Definition 29.15: Support Function

The support function of a set $\mathcal{X} \subseteq \mathbf{R}^n$ is

$$\rho(l \mid \mathcal{X}) = \sup_{x \in \mathcal{X}} \langle l, x \rangle.$$

In particular, the support function of an ellipsoid is

$$\rho(l \mid \mathcal{E}(q, Q)) = \langle l, q \rangle + \langle l, Ql \rangle^{1/2}. \quad (29.43)$$

We say that the ellipsoid \mathcal{E} *tightly overapproximates* a given convex set \mathcal{X} if there exist $l \in \mathbf{R}^n$ such that

$$\rho(\pm l \mid \mathcal{E}) = \rho(\pm l \mid \mathcal{X}) \quad \text{and} \quad \mathcal{X} \subseteq \mathcal{E}.$$

We say that ellipsoid \mathcal{E} *tightly underapproximates* given convex set \mathcal{X} if there exist $l \in \mathbf{R}^n$ such that

$$\rho(\pm l \mid \mathcal{E}) = \rho(\pm l \mid \mathcal{X}) \quad \text{and} \quad \mathcal{E} \subseteq \mathcal{X}.$$

The equality $\rho(\pm l \mid \mathcal{E}) = \rho(\pm l \mid \mathcal{X})$ means that the boundaries of \mathcal{E} and \mathcal{X} touch in directions l and $-l$.

In [23], the authors introduce parametrized families of external and internal ellipsoids that tightly overapproximate and underapproximate the reach set and derive the differential equations that govern the evolution in time of the center and the shape matrices of these ellipsoids. The reach set is represented as the intersection of tight external and as the union of tight internal ellipsoids. In [25], this result is extended to the discrete-time case with special emphasis on systems with degenerate matrices $A(t)$. In the next section we present the equations that describe ellipsoidal overapproximation and underapproximation of reach sets.

The ellipsoidal method provides the following benefits:

- Approximating the reach set of an n -dimensional discrete-time linear system by L ellipsoids over t time steps requires $t[L(8n^3 + 4n^2 + 2n) + 2n^2]$ scalar multiplications. The computational complexity grows polynomially with the system dimension, in contrast with the exponential growth of the polytope method complexity.

- It is possible to refine the reach set approximation as much as needed by adding more ellipsoids to the parameterized family. Theoretically, it is possible to exactly represent the reach set of linear system through both external and internal ellipsoids.
- It is possible to single out individual external and internal approximating ellipsoids that are optimal for a given criterion (e.g., trace, volume, diameter), or a combination of such criteria.
- For systems with no disturbance, there are simple analytical expressions for control sequences that steer the state to a desired target.

Ellipsoidal Toolbox (ET) for MATLAB [4] implements the reach set computations described here.

29.3.8 Parallelotope Method

The parallelotope* method [19] employs the idea of the ellipsoidal method to compute the reach sets of linear systems. The reach set is represented as the intersection of a parametrized family of tight external, and the union of a parametrized family of tight internal parallelotopes. The evolution equations for the centers and orientation matrices of both external and internal parallelotopes are provided. This method also finds controls that can drive the system to the boundary points of the reach set, similar to [23,37]. The computation to solve the evolution equations for tight approximating parallelotopes, however, is more involved than the one for ellipsoids, and in the case of discrete-time systems, this method does not deal with singular state transition matrices.

29.3.9 Other Methods

As was mentioned above, for certain verification problems, computation of reach sets can be avoided. For example, it may be enough to ensure that for given set of initial conditions \mathcal{X}_0 , the trajectories of system (Equation 29.1) never enter a given target set \mathcal{Y}_1 . In this case, the method of *barrier certificates* [34] may help. The idea as well as the main difficulty is to find a Lyapunov-like function $C(x)$ such that

1. $C(x) > 0$ in \mathcal{Y}_1
2. $C(x) \leq 0$ in \mathcal{X}_0
3. $\langle D_x C(x), f(t, x, u) \rangle \leq 0$ where $C(x) = 0$

If such a function exists, system (Equation 29.1) is “safe” with respect to the initial set \mathcal{X}_0 and the target set \mathcal{Y}_1 , that is, system trajectories emanating from \mathcal{X}_0 never reach \mathcal{Y}_1 .

Another example for which reach sets need not be computed exactly occurs when it is possible to ensure that for given initial set \mathcal{X}_0 there exist system trajectories that never leave \mathcal{X}_0 . The set \mathcal{X}_0 is said to be *invariant* with respect to those trajectories.

In [12], the authors show that for certain classes of discrete-time dynamical systems with disturbances (Equation 29.7d) and certain initial sets \mathcal{X}_0 , convex constraints on controls, and disturbances, for every disturbance there exist closed-loop control strategies that keep the state of the system inside \mathcal{X}_0 .

For more information about invariant sets, we refer the reader to the survey paper [15] and references therein.

29.4 Ellipsoidal Method

Consider a continuous-time linear system

$$\dot{x}(t) = A(t)x(t) + B(t)u + G(t)v, \quad (29.44)$$

in which $x \in \mathbf{R}^n$ is the state, $u \in \mathbf{R}^m$ is the control, and $v \in \mathbf{R}^d$ is the disturbance. $A(t)$, $B(t)$, and $G(t)$ are continuous and take their values in $\mathbf{R}^{n \times n}$, $\mathbf{R}^{n \times m}$, and $\mathbf{R}^{n \times d}$, respectively. Control $u(t, x(t))$ and

* Parallelotope is a zonotope with n generator vectors in \mathbf{R}^n .

disturbance $v(t)$ are measurable functions restricted by ellipsoidal constraints: $u(t, x(t)) \in \mathcal{E}(p(t), P(t))$ and $v(t) \in \mathcal{E}(q(t), Q(t))$. The set of initial states at initial time t_0 is assumed to be the ellipsoid $\mathcal{E}(x_0, X_0)$.

The reach sets for systems with disturbances computed by the ET are CLRS. Henceforth, when describing backward reachability, reach sets refer to CLRS or CLBRS. Recall that for continuous-time linear systems maxmin and minmax CLRS coincide, and the same is true for maxmin and minmax CLBRS.

If the matrix $Q(\cdot) = 0$, the system (Equation 29.44) becomes an ordinary affine system with known $v(\cdot) = q(\cdot)$. If $G(\cdot) = 0$, the system becomes linear. For these two cases, ($Q(\cdot) = 0$ or $G(\cdot) = 0$), the reach set is as given in Definition 29.1, and so the reach set will be denoted as $\mathcal{X}_{CL}(t, t_0, \mathcal{E}(x_0, X_0)) = \mathcal{X}(t, t_0, \mathcal{E}(x_0, X_0))$.

The reach set $\mathcal{X}(t, t_0, \mathcal{E}(x_0, X_0))$ is a symmetric compact convex set, whose center evolves in time according to

$$\dot{x}_c(t) = A(t)x_c(t) + B(t)p(t) + G(t)q(t), \quad x_c(t_0) = x_0. \quad (29.45)$$

Fix a vector $l_0 \in \mathbf{R}^n$, and consider the solution $l(t)$ of the adjoint equation

$$\dot{l}(t) = -A^T(t)l(t), \quad l(t_0) = l_0, \quad (29.46)$$

which is equivalent to

$$l(t) = \Phi^T(t_0, t)l_0.$$

If the reach set $\mathcal{X}(t, t_0, \mathcal{E}(x_0, X_0))$ is nonempty, there exist tight external and tight internal approximating ellipsoids $\mathcal{E}(x_c(t), X_l^+(t))$ and $\mathcal{E}(x_c(t), X_l^-(t))$, respectively, such that

$$\mathcal{E}(x_c(t), X_l^-(t)) \subseteq \mathcal{X}(t, t_0, \mathcal{E}(x_0, X_0)) \subseteq \mathcal{E}(x_c(t), X_l^+(t)), \quad (29.47)$$

and

$$\rho(l(t) \mid \mathcal{E}(x_c(t), X_l^-(t))) = \rho(l(t) \mid \mathcal{X}(t, t_0, \mathcal{E}(x_0, X_0))) = \rho(l(t) \mid \mathcal{E}(x_c(t), X_l^+(t))). \quad (29.48)$$

The equation for the shape matrix of the external ellipsoid is

$$\begin{aligned} \dot{X}_l^+(t) &= A(t)X_l^+(t) + X_l^+(t)A^T(t) + \pi_l(t)X_l^+(t) + \frac{1}{\pi_l(t)}B(t)P(t)B^T(t) \\ &\quad - (X_l^+(t))^{1/2}S_l(t)(G(t)Q(t)G^T(t))^{1/2} - (G(t)Q(t)G^T(t))^{1/2}S_l^T(t)(X_l^+(t))^{1/2}, \end{aligned} \quad (29.49)$$

$$X_l^+(t_0) = X_0, \quad (29.50)$$

in which

$$\pi_l(t) = \frac{\langle l(t), B(t)P(t)B^T(t)l(t) \rangle^{1/2}}{\langle l(t), X_l^+(t)l(t) \rangle^{1/2}},$$

and the orthogonal matrix $S_l(t)$ ($S_l(t)S_l^T(t) = I$) is determined by the equation

$$S_l(t)(G(t)Q(t)G^T(t))^{1/2}l(t) = \frac{\langle l(t), G(t)Q(t)G^T(t)l(t) \rangle^{1/2}}{\langle l(t), X_l^+(t)l(t) \rangle^{1/2}}(X_l^+(t))^{1/2}l(t).$$

In the presence of disturbance, if the reach set is empty, the matrix $X_l^+(t)$ becomes sign indefinite. For a system without disturbance, the terms containing $G(t)$ and $Q(t)$ vanish from Equation 29.49.

The equation for the shape matrix of the internal ellipsoid is

$$\begin{aligned} \dot{X}_I^-(t) = & A(t)X_I^-(t) + X_I^-(t)A^T(t) + (X_I^-(t))^{1/2}T_I(t)(B(t)P(t)B^T(t))^{1/2} \\ & + (B(t)P(t)B^T(t))^{1/2}T_I^T(t)(X_I^-(t))^{1/2} - \eta_I(t)X_I^-(t) - \frac{1}{\eta_I(t)}G(t)Q(t)G^T(t), \end{aligned} \quad (29.51)$$

$$X_I^-(t_0) = X_0, \quad (29.52)$$

in which

$$\eta_I(t) = \frac{\langle l(t), G(t)Q(t)G^T(t)l(t) \rangle^{1/2}}{\langle l(t), X_I^+(t)l(t) \rangle^{1/2}},$$

and the orthogonal matrix $T_I(t)$ is determined by the equation

$$T_I(t)(B(t)P(t)B^T(t))^{1/2}l(t) = \frac{\langle l(t), B(t)P(t)B^T(t)l(t) \rangle^{1/2}}{\langle l(t), X_I^-(t)l(t) \rangle^{1/2}}(X_I^-(t))^{1/2}l(t).$$

Similar to the external case, the terms containing $G(t)$ and $Q(t)$ vanish from Equation 29.51 for a system without disturbance.

The point where the external and internal ellipsoids touch the boundary of the reach set is given by

$$x_I^*(t) = x_c(t) + \frac{X_I^+(t)l(t)}{\langle l(t), X_I^+(t)l(t) \rangle^{1/2}}.$$

The boundary points $x_I^*(t)$ form trajectories, which we call *extremal trajectories*. Due to the nonsingular nature of the state transition matrix $\Phi(t, t_0)$, every boundary point of the reach set belongs to an extremal trajectory. To follow an extremal trajectory specified by parameter l_0 , the system has to start at time t_0 at initial state

$$x_I^0 = x_0 + \frac{X_0 l_0}{\langle l_0, X_0 l_0 \rangle^{1/2}}. \quad (29.53)$$

In the absence of disturbances, the open-loop control

$$u_I(t) = p(t) + \frac{P(t)B^T(t)l(t)}{\langle l(t), B(t)P(t)B^T(t)l(t) \rangle^{1/2}}. \quad (29.54)$$

steers the system along the extremal trajectory defined by the vector l_0 . When a disturbance is present, this control keeps the system on an extremal trajectory if and only if the disturbance plays against the control always taking its extreme values.

Expressions 29.47 and 29.48 lead to the following fact:

$$\bigcup_{\langle l_0, l_0 \rangle=1} \mathcal{E}(x_c(t), X_I^-(t)) = \mathcal{X}(t, t_0, \mathcal{E}(x_0, X_0)) = \bigcap_{\langle l_0, l_0 \rangle=1} \mathcal{E}(x_c(t), X_I^+(t)).$$

In practice, this means that the more values of l_0 we use to compute $X_I^+(t)$ and $X_I^-(t)$, the better will be our approximation.

Remark about Discrete-Time Systems

For discrete-time linear system

$$x(t+1) = A(t)x(t) + B(t)u(t, x(t)) + G(t)v(t), \quad (29.44d)$$

the equivalent of Equation 29.46 is

$$l(t+1) = \left(A^T\right)^{-1}(t)l(t), \quad l(t_0) = l_0, \quad (29.46d)$$

which implies nonsingular $A(t)$.*

For discrete-time systems, maxmin and minmax CLRS do not coincide and are computed separately. For maxmin CLRS, the ellipsoidal approximation (external or internal) $\mathcal{E}(x_c(t+1), \bar{X}_l(t+1))$ defined by parameter $l_0 \in \mathbf{R}^n$ is computed as tight external or internal approximating ellipsoid of

$$\mathcal{E}(A(t)x_c(t), A(t)\bar{X}_l(t)A^T(t)) \oplus \mathcal{E}(B(t)p(t), B(t)P(t)B^T(t)) \dot{-} \mathcal{E}(G(t)q(t), G(t)Q(t)G^T(t)),$$

and for minmax CLRS, the ellipsoidal approximation $\mathcal{E}(x_c(t+1), \underline{X}_l(t+1))$ is computed as tight external or internal approximating ellipsoid of

$$\mathcal{E}(A(t)x_c(t), A(t)\underline{X}_l(t)A^T(t)) \dot{-} \mathcal{E}(G(t)q(t), G(t)Q(t)G^T(t)) \oplus \mathcal{E}(B(t)p(t), B(t)P(t)B^T(t))$$

specified by direction $l(t)$ that satisfies Equation 29.46d.

For details and equations related to the discrete-time case, we refer the reader to the manual of the ET [4].

Analogous results hold for the backward reach set.

Given the terminal time t_1 and ellipsoidal target set $\mathcal{E}(y_1, Y_1)$, the CLBRS $\mathcal{Y}_{CL}(t_1, t, \mathcal{Y}_1) = \mathcal{Y}(t_1, t, \mathcal{Y}_1)$, $t < t_1$, if it is nonempty, is a symmetric compact convex set whose center is governed by

$$y_c(t) = Ay_c(t) + B(t)p(t) + G(t)q(t), \quad y_c(t_1) = y_1. \quad (29.55)$$

Fix a vector $l_1 \in \mathbf{R}^n$, and consider

$$l(t) = \Phi(t_1, t)^T l_1. \quad (29.56)$$

If the backward reach set $\mathcal{Y}(t_1, t, \mathcal{E}(y_1, Y_1))$ is nonempty, there exist tight external and tight internal approximating ellipsoids $\mathcal{E}(y_c(t), Y_l^+(t))$ and $\mathcal{E}(y_c(t), Y_l^-(t))$ respectively, such that

$$\mathcal{E}(y_c(t), Y_l^-(t)) \subseteq \mathcal{Y}(t_1, t, \mathcal{E}(y_1, Y_1)) \subseteq \mathcal{E}(y_c(t), Y_l^+(t)), \quad (29.57)$$

and

$$\rho(l(t) \mid \mathcal{E}(y_c(t), Y_l^-(t))) = \rho(l(t) \mid \mathcal{Y}(t_1, t, \mathcal{E}(y_0, Y_0))) = \rho(l(t) \mid \mathcal{E}(y_c(t), Y_l^+(t))). \quad (29.58)$$

The equation for the shape matrix of the external ellipsoid is

$$\begin{aligned} \dot{Y}_l^+(t) &= A(t)Y_l^+(t) + Y_l^+(t)A^T(t) - \pi_l(t)Y_l^+(t) - \frac{1}{\pi_l(t)}B(t)P(t)B^T(t) \\ &\quad + (Y_l^+(t))^{1/2}S_l(t)(G(t)Q(t)G^T(t))^{1/2} + (G(t)Q(t)G^T(t))^{1/2}S_l^T(t)(Y_l^+(t))^{1/2}, \end{aligned} \quad (29.59)$$

$$Y_l^+(t_1) = Y_1, \quad (29.60)$$

* The case when $A(t)$ is singular is described in [25]. The idea is to substitute $A(t)$ with the nonsingular $A_\delta(t) = A(t) + \delta U(t)W(t)$, in which $U(t)$ and $W(t)$ are obtained from the singular-value decomposition

$$A(t) = U(t)\Sigma(t)W(t).$$

The parameter δ can be chosen based on the number of time steps for which the reach set must be computed and the required accuracy. The issue of inverting ill-conditioned matrices is also addressed in [25].

in which

$$\pi_l(t) = \frac{\langle l(t), B(t)P(t)B^T(t)l(t) \rangle^{1/2}}{\langle l(t), Y_l^+(t)l(t) \rangle^{1/2}},$$

and the orthogonal matrix $S_l(t)$ satisfies the equation

$$S_l(t)(G(t)Q(t)G^T(t))^{1/2}l(t) = \frac{\langle l(t), G(t)Q(t)G^T(t)l(t) \rangle^{1/2}}{\langle l(t), Y_l^+(t)l(t) \rangle^{1/2}}(Y_l^+(t))^{1/2}l(t).$$

The equation for the shape matrix of the internal ellipsoid is

$$\begin{aligned} \dot{Y}_l^-(t) &= A(t)Y_l^-(t) + Y_l^-(t)A^T(t) - (Y_l^-(t))^{1/2}T_l(t)(B(t)P(t)B^T(t))^{1/2} \\ &\quad - (B(t)P(t)B^T(t))^{1/2}T_l^T(t)(Y_l^-(t))^{1/2} + \eta_l(t)Y_l^-(t) + \frac{1}{\eta_l(t)}G(t)Q(t)G^T(t), \end{aligned} \quad (29.61)$$

$$Y_l^-(t_1) = Y_1, \quad (29.62)$$

in which

$$\eta_l(t) = \frac{\langle l(t), G(t)Q(t)G^T(t)l(t) \rangle^{1/2}}{\langle l(t), Y_l^+(t)l(t) \rangle^{1/2}},$$

and the orthogonal matrix $T_l(t)$ is determined by the equation

$$T_l(t)(B(t)P(t)B^T(t))^{1/2}l(t) = \frac{\langle l(t), B(t)P(t)B^T(t)l(t) \rangle^{1/2}}{\langle l(t), Y_l^-(t)l(t) \rangle^{1/2}}(Y_l^-(t))^{1/2}l(t).$$

Just as in the forward reachability case, the terms containing $G(t)$ and $Q(t)$ vanish from Equations 29.59 and 29.61 in the absence of disturbances. The boundary value problems (Equations 29.55, 29.59 and 29.61) are converted to the initial value problems by the change of variables $s = -t$.

Owing to Equations 29.57 and 29.58,

$$\bigcup_{\langle l_1, l_1 \rangle=1} \mathcal{E}(y_c(t), Y_l^-(t)) = \mathcal{Y}(t_1, t, \mathcal{E}(y_1, Y_1)) = \bigcap_{\langle l_1, l_1 \rangle=1} \mathcal{E}(y_c(t), Y_l^+(t)).$$

Remark 29.3

In expressions 29.49, 29.51, 29.59, and 29.61, the terms $1/\pi_l(t)$ and $1/\eta_l(t)$ may not be well defined for some vectors l , because matrices $B(t)P(t)B^T(t)$ and $G(t)Q(t)G^T(t)$ may be singular. In such cases, we set these entire expressions to zero.

29.5 Applications

We illustrate the ellipsoidal approach with three applications.

29.5.1 Steering the System to a Target

Given system Equation 29.44, target set defined by ellipsoid $\mathcal{E}(y_1, Y_1)$, and terminal time t_1 , we want to find a closed-loop control that steers the system from some state y_0 at time $t_0 < t_1$ to $\mathcal{E}(y_1, Y_1)$ at t_1 .

First we compute external and internal ellipsoidal approximations $\mathcal{E}(y_c(t), Y_l^+(t))$ using Equations 29.59 and 29.60, and $\mathcal{E}(y_c(t), Y_l^-(t))$ using Equations 29.61 and 29.62, $t_0 \leq t < t_1$, for different values of the parameter $l_1 \in \mathbf{R}^n$. If there exists an external ellipsoid $\mathcal{E}(y_c(t_0), Y_l^+(t_0))$ such that $y_0 \notin \mathcal{E}(y_c(t_0), Y_l^+(t_0))$, there is no closed-loop control that can guarantee taking the system from y_0 at t_0 to a state within $\mathcal{E}(y_1, Y_1)$ at t_1 . On the other hand, if there exists an internal ellipsoid $\mathcal{E}(y_c(t_0), Y_l^-(t_0))$ defined by the choice of l_1 , such that $y_0 \in \mathcal{E}(y_c(t_0), Y_l^-(t_0))$, such a control does exist.

We build the closed-loop control $u(t, y(t))$ so as to keep the system state $y(t)$ inside, if possible, or as close as we can, if not, to the internal approximating ellipsoid $\mathcal{E}(y_c(t), Y_l^-(t))$ for $t_0 \leq t < t_1$. The steps below describe control synthesis at time t .

1. Compute

$$\gamma(t) = \langle y(t) - y_c(t), (Y_l^-(t))^{-1}(y(t) - y_c(t)) \rangle.$$

If $\gamma(t) \leq 1$, then $y(t) \in \mathcal{E}(y_c(t), Y_l^-(t))$, and the control $u(t, y(t))$ can be chosen arbitrarily in $\mathcal{E}(p(t), P(t))$. For example, set $u(t, y(t)) = p(t)$.

2. Otherwise, if $\gamma(t) > 1$, $y(t)$ is a boundary point of ellipsoid $\mathcal{E}(y_c(t), \gamma(t)Y_l^-(t))$ corresponding to the direction $m(t) \in \mathbf{R}^n$,

$$m(t) = (Y_l^-(t))^{-1}(y(t) - y_c(t)).$$

In order to steer the system closer to the internal approximating ellipsoid, control $u(t, y(t))$ must act in the direction $-m(t)$.

3. Choose $u(t, y(t))$ so that the vector $B(t)u(t, y(t))$ is a boundary point of the ellipsoid $\mathcal{E}(B(t)p(t), B(t)P(t)B^T(t)) \subset \mathbf{R}^n$ in the direction $-m(t)$,

$$u(t, y(t)) = p(t) - \frac{P(t)B^T(t)m(t)}{\langle m(t), B(t)P(t)B^T(t)m(t) \rangle^{1/2}}.$$

To summarize,

$$u(t, y(t)) = \begin{cases} p(t), & \text{if } \langle y(t) - y_c(t), (Y_l^-(t))^{-1}(y(t) - y_c(t)) \rangle \leq 1, \\ p(t) - \frac{P(t)B^T(t)(Y_l^-(t))^{-1}(y(t) - y_c(t))}{\langle (Y_l^-(t))^{-1}(y(t) - y_c(t)), B(t)P(t)B^T(t)(Y_l^-(t))^{-1}(y(t) - y_c(t)) \rangle^{1/2}}, & \text{otherwise.} \end{cases} \tag{29.63}$$

The rigorous proof that this closed-loop control works can be found in [22]. In [16], the authors apply this technique to stop a high-dimensional oscillating system using the ET for backward reach set computation.

Formula (Equation 29.63) holds for discrete-time linear systems, except that instead of $Y_l^-(t)$, shape matrices of internal approximating ellipsoids for maxmin or minmax CLBRS must be used.

29.5.2 Switching System

A *switching system* is a system whose dynamics changes at known times. Consider the RLC circuit shown in Figure 29.1. It has two inputs, the voltage v and current i . Define

- x_1 , the voltage across capacitor C_1 , so $C_1\dot{x}_1$ is the corresponding current.
- x_2 , the voltage across capacitor C_2 , so the corresponding current is $C_2\dot{x}_2$.
- x_3 , the current through the inductor L , so the voltage across the inductor is $L\dot{x}_3$.

FIGURE 29.1 RLC circuit with two inputs.

Applying Kirchoff's laws we arrive at the linear system,

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \end{bmatrix} = \begin{bmatrix} -\frac{1}{R_1 C_1} & 0 & -\frac{1}{C_1} \\ 0 & 0 & \frac{1}{C_2} \\ \frac{1}{L} & -\frac{1}{L} & -\frac{R_2}{L} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1 C_1} & \frac{1}{C_1} \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} v \\ i \end{bmatrix}. \quad (29.64)$$

The parameters R_1 , R_2 , C_1 , C_2 , and L , as well as the inputs, may depend on time. Suppose, for time $0 \leq t < 2$, $R_1 = 2\Omega$, $R_2 = 1\Omega$, $C_1 = 3$ F, $C_2 = 7$ F, $L = 2$ H, and both inputs, v and i , are present and bounded by ellipsoid $\mathcal{E}(0, I)$; and for time $t \geq 2$, $R_1 = R_2 = 2\Omega$, $C_1 = C_2 = 3$ F, $L = 6$ H, the current source is turned off, and $|v| \leq 1$. Then, system (Equation 29.64) can be rewritten as

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \end{bmatrix} = \begin{cases} \begin{bmatrix} -\frac{1}{6} & 0 & -\frac{1}{3} \\ 0 & 0 & \frac{1}{7} \\ \frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} + \begin{bmatrix} \frac{1}{6} & \frac{1}{3} \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} v \\ i \end{bmatrix}, & 0 \leq t < 2, \\ \begin{bmatrix} -\frac{1}{6} & 0 & -\frac{1}{3} \\ 0 & 0 & \frac{1}{3} \\ \frac{1}{6} & -\frac{1}{6} & -\frac{1}{3} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} + \begin{bmatrix} \frac{1}{6} \\ 0 \\ 0 \end{bmatrix} v, & 2 \leq t. \end{cases} \quad (29.65)$$

We can use the ET to compute the reach set of Equation 29.65 for some time $t > 2$, say, $t = 3$.

```
>> % define system 1:
>> A1 = [-1/6 0 -1/3; 0 0 1/7; 1/2 -1/2 -1/2];
>> B1 = [1/6 1/3; 0 0; 0 0];
>> U1 = ellipsoid(eye(2));
>> s1 = linsys(A1, B1, U1);
>>
>> % define system 2:
>> A2 = [-1/6 0 -1/3; 0 0 1/3; 1/6 -1/6 -1/3];
>> B2 = [1/6; 0; 0];
>> U2 = ellipsoid(1);
>> s2 = linsys(A2, B2, U2);
>>
>> X0 = ellipsoid(0.01*eye(3)); % set of initial states
>> L0 = eye(3); % 3 initial directions
>> TS = 2; % time of switch
>> T = 3; % terminal time
>>
>> % compute the reach set:
>> rs1 = reach(s1, X0, L0, TS); % reach set of the first system
>> % computation of the second reach set starts
>> % where the first left off
>> rs2 = evolve(rs1, T, s2);
>>
>> % obtain projections onto (x1, x2) subspace:
```

```

>> BB = [1 0 0; 0 1 0]'; % (x1, x2) subspace basis
>> ps1 = projection(rs1, BB);
>> ps2 = projection(rs2, BB);
>>
>> % plot the results:
>> subplot(2, 2, 1);
>> plot_ea(ps1, 'r'); % external appr. of reach set 1 (red)
>> hold on;
>> plot_ia(ps1, 'g'); % internal appr. of reach set 1 (green)
>> plot_ea(ps2, 'y'); % external appr. of reach set 2 (yellow)
>> plot_ia(ps2, 'b'); % internal appr. of reach set 2 (blue)
>>
>> % plot the 3-dimensional reach set at time t = 3:
>> subplot(2, 2, 2);
>> plot_ea(cut(rs2, 3), 'y');
>> hold on;
>> plot_ia(cut(rs2, 3), 'b');

```

Figure 29.2a shows how the reach set of system (Equation 29.65) projected onto the (x_1, x_2) plane evolves in time from $t = 0$ to $t = 3$. The external reach set approximation for the first dynamics is in light gray, the internal approximation is in dark gray. The dynamics switches at $t = 2$. The external reach set approximation for the second dynamics is in very light gray, its internal approximation is in dark gray. The full three-dimensional external (very light gray) and internal (dark gray) approximations of the reach set at $t = 3$ are shown in Figure 29.2b.

To find out where the system should start at time $t = 0$ in order to reach a neighborhood M of the origin at time $t = 3$, we compute the backward reach set from $t = 3$ to $t = 0$.

```

>> M = ellipsoid(0.01*eye(3)); % terminal set
>> TT = 3; % terminal time
>>
>> % compute backward reach set:
>> % compute the reach set:
>> brs2 = reach(s2, M, L0, [TT TS]); % second system comes first
>> brs1 = evolve(brs2, 0, s1); % then the first system
>>
>> % obtain projections onto (x1, x2) subspace:
>> bps1 = projection(brs1, BB);
>> bps2 = projection(brs2, BB);
>>
>> % plot the results:
>> subplot(2, 2, 3);
>> plot_ea(bps1, 'r'); % external appr. of backward reach set 1
    (red)
>> hold on;
>> plot_ia(bps1, 'g'); % internal appr. of backward reach set 1
    (green)
>> plot_ea(bps2, 'y'); % external appr. of backward reach set 2
    (yellow)
>> plot_ia(bps2, 'b'); % internal appr. of backward reach set 2
    (blue)
>>

```

FIGURE 29.2 Forward and backward reach sets of the switched system (external and internal approximations). The dynamics switches at $t = 2$. (a) Forward reach set for the time interval $0 \leq t \leq 3$ projected onto (x_1, x_2) subspace. (b) Forward reach set at $t = 3$ in \mathbb{R}^3 . (c) Backward reach set evolving from $t = 3$ to $t = 0$ projected onto (x_1, x_2) subspace. (d) Backward reach set at $t = 0$ in \mathbb{R}^3 .

```
>> % plot the 3-dimensional backward reach set at time t = 0:
>> subplot(2, 2, 4);
>> plot_ea(cut(brs1, 0), 'r');
>> hold on;
>> plot_ia(cut(brs1, 0), 'g');
```

Figure 29.2c presents the evolution of the reach set projected onto the (x_1, x_2) plane in backward time. Again, external and internal approximations corresponding to the first dynamics are shown in dark and light gray, and these corresponding to the second dynamics in very light and dark gray. The full dimensional backward reach set external and internal approximations of system (Equation 29.65) at time $t = 0$ is shown in Figure 29.2d.

29.5.3 Hybrid System

There is no explicit implementation of the reachability analysis for hybrid systems in the ET. Nonetheless, the operations of intersection available in the toolbox allow us to work with certain class of hybrid systems, namely, hybrid systems with affine continuous dynamics whose guards are ellipsoids, hyperplanes, halfspaces, or polytopes.

We consider the *switching-mode model* of highway traffic presented in [33]. The highway segment is divided into N cells as shown in Figure 29.3. In this particular case, $N = 4$. The traffic density in cell i is x_i vehicles per mile, $i = 1, 2, 3, 4$.

Define

- v_i , the average speed in mph, in the i th cell, $i = 1, 2, 3, 4$.
- w_i , the backward congestion wave propagation speed in mph, in the i th highway cell, $i = 1, 2, 3, 4$.

FIGURE 29.3 Highway model. (Adapted from L. Muñoz, et al. In *American Control Conference*, pp. 3750–3755, 2003.)

- x_{Mi} , the maximum allowed density in the i th cell; when this value is reached, there is a traffic jam, $i = 1, 2, 3, 4$.
- d_i , the length of i th cell in miles, $i = 1, 2, 3, 4$.
- T_s , the sampling time in hours.
- b , the split ratio for the off-ramp.
- u_1 , the traffic flow coming into the highway segment, in vehicles per hour (vph).
- u_2 , the traffic flow coming out of the highway segment (vph).
- u_3 , the on-ramp traffic flow (vph).

Highway traffic operates in two modes: *free-flow* in normal operation; and *congested* mode, when there is a jam. Traffic flow in free-flow mode is described by

$$\begin{bmatrix} x_1[t+1] \\ x_2[t+1] \\ x_3[t+1] \\ x_4[t+1] \end{bmatrix} = \begin{bmatrix} 1 - \frac{v_1 T_s}{d_1} & 0 & 0 & 0 \\ \frac{v_1 T_s}{d_2} & 1 - \frac{v_2 T_s}{d_2} & 0 & 0 \\ 0 & \frac{v_2 T_s}{d_3} & 1 - \frac{v_3 T_s}{d_3} & 0 \\ 0 & 0 & (1-b)\frac{v_3 T_s}{d_4} & 1 - \frac{v_4 T_s}{d_4} \end{bmatrix} \begin{bmatrix} x_1[t] \\ x_2[t] \\ x_3[t] \\ x_4[t] \end{bmatrix} + \begin{bmatrix} \frac{v_1 T_s}{d_1} & 0 & 0 \\ 0 & 0 & \frac{v_2 T_s}{d_2} \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix}. \quad (29.66)$$

The equation for the congested mode is

$$\begin{bmatrix} x_1[t+1] \\ x_2[t+1] \\ x_3[t+1] \\ x_4[t+1] \end{bmatrix} = \begin{bmatrix} 1 - \frac{w_1 T_s}{d_1} & \frac{w_2 T_s}{d_1} & 0 & 0 \\ 0 & 1 - \frac{w_2 T_s}{d_2} & \frac{w_3 T_s}{d_2} & 0 \\ 0 & 0 & 1 - \frac{w_3 T_s}{d_3} & \frac{1-b}{d_3} \frac{w_4 T_s}{d_3} \\ 0 & 0 & 0 & 1 - \frac{w_4 T_s}{d_4} \end{bmatrix} \begin{bmatrix} x_1[t] \\ x_2[t] \\ x_3[t] \\ x_4[t] \end{bmatrix} + \begin{bmatrix} 0 & 0 & \frac{w_1 T_s}{d_1} \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & -\frac{w_4 T_s}{d_4} & 0 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} \\ + \begin{bmatrix} \frac{w_1 T_s}{d_1} & -\frac{w_2 T_s}{d_1} & 0 & 0 \\ 0 & \frac{w_2 T_s}{d_2} & -\frac{w_3 T_s}{d_2} & 0 \\ 0 & 0 & \frac{w_3 T_s}{d_3} & -\frac{1-b}{d_3} \frac{w_4 T_s}{d_3} \\ 0 & 0 & 0 & \frac{w_4 T_s}{d_4} \end{bmatrix} \begin{bmatrix} x_{M1} \\ x_{M2} \\ x_{M3} \\ x_{M4} \end{bmatrix}. \quad (29.67)$$

The switch from the free-flow to the congested mode occurs when the density x_2 reaches x_{M2} . In other words, the hyperplane $H([0 \ 1 \ 0 \ 0]^T, x_{M2})$ is the guard. (When the state enters the guard, the system equation switches.)

We indicate how to implement the reach set computation of this hybrid system using the ET. We first define the two linear systems and the guard.

```
>> % assign parameter values:
>> v1 = 65; v2 = 60; v3 = 63; v4 = 65; % mph
>> w1 = 10; w2 = 10; w3 = 10; w4 = 10; % mph
>> d1 = 2; d2 = 3; d3 = 4; d4 = 2; % miles
>> Ts = 2/3600; % sampling time in hours
>> xM1 = 200; xM2 = 200; xM3 = 200; xM4 = 200; % vehicles per lane
>> b = 0.4;
>>
>> A1 = [(1-(v1*Ts/d1)) 0 0 0
         (v1*Ts/d2) (1-(v2*Ts/d2)) 0 0
         0 (v2*Ts/d3) (1-(v3*Ts/d3)) 0
         0 0 ((1-b)*(v3*Ts/d4)) (1-(v4*Ts/d4))];
>> B1 = [v1*Ts/d1 0 0; 0 0 v2*Ts/d2; 0 0 0; 0 0 0];
>> U1 = ellipsoid([180; 150; 50], [100 0 0; 0 100 0; 0 0 25]);
>>
>> A2 = [(1-(w1*Ts/d1)) (w2*Ts/d1) 0 0
         0 (1-(w2*Ts/d2)) (w3*Ts/d2) 0
         0 0 (1-(w3*Ts/d3)) ((1/(1-b))*(w4*Ts/d3))
         0 0 0 (1-(w4*Ts/d4))];
>> B2 = [0 0 w1*Ts/d1; 0 0 0; 0 0 0; 0 -w4*Ts/d4 0];
>> U2 = U1;
>> G2 = [(w1*Ts/d1) (-w2*Ts/d1) 0 0
         0 (w2*Ts/d2) (-w3*Ts/d2) 0
         0 0 (w3*Ts/d3) ((-1/(1-b))*(w4*Ts/d3))
         0 0 0 (w4*Ts/d4)];
>> V2 = [xM1; xM2; xM3; xM4];
>>
>> % define linear systems:
>> s1 = linsys(A1, B1, U1, [], [], [], [], 'd'); % free-flow mode
>> s2 = linsys(A2, B2, U2, G2, V2, [], [], 'd'); % congestion mode
>>
>> % define guard:
>> GRD = hyperplane([0; 1; 0; 0], xM2);
```

We assume that initially the system is in free-flow mode. Given a set of initial conditions, we compute the reach set according to dynamics (Equation 29.66) for certain number of time steps. We consider an external approximation of the reach set by a single ellipsoid.

```
>> initial conditions:
>> X0 = [170; 180; 175; 170] + 10*ell_unitball(4);
>
>> L0 = [1; 0; 0; 0]; % single initial direction
>> N = 100; % number of time steps
>>
>> ffrs = reach(s1, X0, L0, N); % free-flow reach set
>> EA = get_ea(ffrs); % 101x1 array of external ellipsoids
```

Having obtained the ellipsoidal array EA representing the reach set evolving in time, we determine the ellipsoids in the array that intersect the guard.

```
>> I = hpintersection(EA, GRD); % some of the intersections are empty
>> D = find(~isempty(I)); % determine nonempty intersections
>> min(D)

ans =

    19

>> max(D)

ans =

    69
```

Analyzing the values in array D, we conclude that the free-flow reach set has nonempty intersection with hyperplane GRD at $t = 18$ for the first time, and at $t = 68$ for the last time. Between $t = 18$ and $t = 68$ the reach set crosses the guard. Figure 29.4a shows the free-flow reach set projected onto the (x_1, x_2, x_3) subspace for $t = 10$, before the guard crossing; Figure 29.4b for $t = 50$, during the guard crossing; and Figure 29.4c for $t = 80$, after the guard was crossed.

For each time step that the intersection of the free-flow reach set and the guard is nonempty, we establish a new initial time and a set of initial conditions for the reach set computation according to dynamics (Equation 29.67). The initial time is the array index minus one, and the set of initial conditions is the intersection of the free-flow reach set with the guard.

```
>> crs = [];
>> for i = 1:size(D, 2)
    rs = reach(s2, I(D(i)), L0, [(D(i)-1) N]);
    crs = [crs rs];
end
```

The union of reach sets in array crs forms the reach set for the congested dynamics.

A summary of the reach set computation of the linear hybrid system (Equations 29.66 and 29.67) for $N = 100$ time steps with one guard crossing is given in Figure 29.4d, which shows the projection of the reach set trace onto the (x_1, x_2) subspace. The system starts evolving in time in free-flow mode from a set of initial conditions at $t = 0$, whose boundary is shown in magenta. The free-flow reach set evolving from $t = 0$ to $t = 100$ is shown in blue. Between $t = 18$ and $t = 68$, the free-flow reach set crosses the guard. The guard is shown in red. For each nonempty intersection of the free-flow reach set and the guard, the congested mode reach set starts evolving in time until $t = 100$. All the congested mode reach sets are shown in green. Observe that in the congested mode the density x_2 in the congested part decreases slightly, while the density x_1 upstream of the congested part increases. The blue set above the guard is not actually reached, because the state evolves according to the green region.

29.6 Conclusion

Control problems with hard bounds on the control set and for which finite time behavior has to meet guarantees (reaching or avoiding a target set) despite disturbances cannot be addressed by traditional methods of design. Central to recent approaches to solving these design problems are the concept and calculation of the OLRs or CLRS. Effective reach set computational tools have been developed over the

FIGURE 29.4 Reach set of the free-flow system is dark gray, reach set of the congested system is very light gray, the guard is gray straight line. (a) Reach set of the free-flow system at $t = 10$, before reaching the guard (projection onto (x_1, x_2, x_3)). (b) Reach set of the free-flow system at $t = 50$, crossing the guard (projection onto (x_1, x_2, x_3)). (c) Reach set of the free-flow system at $t = 80$, after the guard is crossed (projection onto (x_1, x_2, x_3)). 30.1 Introduction

Hybrid systems are heterogeneous dynamical systems, the behaviors of which are determined by interacting continuous variables and discrete switching logics [1,2]. By heterogeneity, we mean hybrid systems containing two different kinds of dynamics. One is time-driven continuous variable dynamics, usually described by differential or difference equations; the other is event-driven discrete logic dynamics, whose evolutions depend on “if-then-else” type of rules and may be described by automata or Petri nets. In addition, these two kinds of dynamics interact with each other and generate complex dynamical behaviors, such as switching once certain continuous variable passes through a threshold, or state jumping when certain discrete event occurs. As a simple example, the temperature regulation in an air-conditioned room can be considered as a hybrid system; the room temperature evolution forms the continuous variable dynamics following thermophysical laws, whereas the on–off evolution of the air conditioner can be modeled as a discrete event process.

Hybrid systems have been identified in a wide variety of applications; in the control of mechanical systems, in process control, in automotive industry, power systems, aircraft, and traffic control, among many other fields. Specifically, hybrid systems have a central role in embedded control systems, where program codes interact with the physical world. In particular, the logic rules programmed in the embedded devices,

which can be modeled as discrete event systems, are affected and influenced by the continuous variable physical processes, such as spatial location, temperature, and pressure evolutions. Studies in hybrid systems could provide a unified modeling framework for embedded systems, and systematic methods for performance analysis, verification, and embedded microcontroller design. Therefore, hybrid systems have attracted the attention of researchers not only from control engineering, but also from computer science and mathematics. Topics, such as modeling, verification, stability, controllability, optimal control, and supervisory control, have been extensively studied in the hybrid system literature, and the interested readers may refer to [1,2,4,5,13] and the references therein. In this chapter, we focus on the stability issues of hybrid systems.

It is known that the stability of hybrid systems includes several interesting phenomena due to the interaction of continuous variable dynamics and discrete switching logics [3,6,8]. For example, even when all the continuous variable subsystems are exponentially stable, the hybrid system may have divergent trajectories under certain discrete switching logic. On the other hand, one may carefully switch between unstable continuous variable subsystems to make the overall hybrid system exponentially stable. As these examples suggest, the stability of hybrid systems depends not only on the continuous variable dynamics of each subsystem, but also on the properties of discrete switching logics. Therefore, the stability study of hybrid systems can be roughly divided into two kinds of problems. One is the stability analysis of hybrid systems under given discrete switching logics; the other is the synthesis of stabilizing switching logics for a given collection of continuous variable dynamical systems.

We mainly focus on a subclass of hybrid systems that consists of a finite number of continuous-variable subsystems and a discrete logical rule, which orchestrates switching between these subsystems. The systems are usually called switched systems in the literature [6,8]. In this chapter, we use the terms “hybrid systems” and “switched systems” interchangeably. One convenient way to classify hybrid/switched systems is based on the dynamics of their subsystems, for example, continuous-time or discrete-time, linear or nonlinear and so on. In this chapter, we focus our attention to hybrid/switched systems where all subsystems are linear time-invariant (LTI) systems. The generalization of these results to nonlinear switched systems or more general cases are well documented in the literature; see, for example, survey papers [3,6,8] for further references.

The rest of this chapter is organized as follows. First, we focus on the stability analysis of hybrid systems under given discrete switching logics. In particular, some results on the stability analysis for hybrid systems under arbitrary switching are introduced in Section 30.2, while the stability under slow switching (like dwell time and average dwell time) is studied in Section 30.3.1. The general case of hybrid system stability under restricted switching is investigated in Section 30.3 through multiple Lyapunov functions. Then, we turn to the synthesis of stabilizing switching logic for a given collection of continuous variable dynamical systems in Section 30.4, where several stabilization conditions and design methods are described. Finally, the chapter concludes with remarks and a list of references.

30.2 Arbitrary Switching

In this section, we first consider the stability analysis problem where there are no restrictions on the discrete event dynamics of the hybrid system. This may be due to our lack of knowledge of the discrete event logic, or of the partitions of the state space, or of the constraints in the hybrid system of concern. Under these circumstances, one usually tends to be more conservative and assumes that all discrete switchings are possible; this is called *arbitrary switching* in the literature. On the other hand, when the stability under arbitrary switching is guaranteed, this could provide us with flexibility in the discrete logic design, where one may focus on improving the performances, since the closed-loop system stability is not a problem any longer.

30.2.1 Common Lyapunov Function

We know that a hybrid system may become unstable even when all subsystems are exponentially stable. Therefore, to identify conditions under which a hybrid system is stable under arbitrary switching is nontrivial and interesting. For this, it is necessary that all the subsystems are asymptotically stable, since if one subsystem were unstable, one switching strategy would have been to always select that subsystem all the time, which is a valid “switching logic” as well, and that would make the system unstable. In general, the above subsystems’ stability assumption is not sufficient to ensure stability for the hybrid systems under arbitrary switching. However, if there exists a *common Lyapunov function* for all the subsystems, that is, a continuously differentiable, radially unbounded, positive definite function $V : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}$, for which the derivative $\dot{V}(x, t)$ is negative definite along all subsystems’ trajectories, then the stability of the hybrid systems is guaranteed under arbitrary switchings. This provides us with a possible way to solve this problem, and a lot of research efforts have been focused on finding common quadratic Lyapunov functions (CQLFs).

30.2.1.1 Common Quadratic Lyapunov Functions

First, we consider a collection of continuous-time LTI systems

$$\dot{x}(t) = A_i x(t), \quad t \in \mathbb{R}^+, \quad i \in \mathcal{I}, \quad (30.1)$$

where \mathcal{I} stands for a finite index set. For all $i \in \mathcal{I}$, the state matrices $A_i \in \mathbb{R}^{n \times n}$. Note that the origin $x_e = 0$ is a common equilibrium for the systems described in Equation 30.1. The hybrid system of interest is built by allowing arbitrary switching among these LTI systems (Equation 30.1).

A CQLF for Equation 30.1 is a special class of Lyapunov functions of the form

$$V(x) = x^T P x, \quad (30.2)$$

where $P = P^T$ (symmetric) and $P > 0$ (positive definite). In addition, its time derivative along any trajectory of systems (Equation 30.1) is negative definite, or alternatively

$$A_i^T P + P A_i = -Q_i, \quad i \in \mathcal{I}, \quad (30.3)$$

where Q_i are symmetric and positive definite for all $i \in \mathcal{I}$. The existence of a CQLF for all its subsystems assures the quadratic stability of the hybrid system. Quadratic stability is a special class of exponential stability, which implies asymptotic stability, and has attracted a lot of research efforts due to its importance in practice.

A CQLF for Equation 30.1 can be obtained by solving a set of linear matrix inequalities (LMIs). for example, there exists a positive definite symmetric matrix P , $P \in \mathbb{R}^{n \times n}$, such that

$$P A_i + A_i^T P < 0, \quad \forall i \in \mathcal{I}, \quad (30.4)$$

hold simultaneously. However, the standard interior point methods for LMIs may become ineffective as the number of subsystems increases. This motivates researchers to identify easily verifiable conditions that guarantee the existence of a CQLF for Equation 30.1. Here, we take a look at a well-studied special case in the literature; interested readers may refer to [6,8] for further references.

30.2.1.2 Commutative Systems

Let us first look at a special case, where the subsystems’ state matrices are pairwise commutative, that is, $A_i A_j = A_j A_i$ for all $i, j \in \mathcal{I}$. Because of the commutativity, it is easy to show that

$$A_i^{k_1} A_j^{k_2} = A_j^{k_2} A_i^{k_1}$$

for any nonnegative integer k_1 and k_2 , and

$$e^{A_i t_1} e^{A_j t_2} = e^{A_j t_2} e^{A_i t_1}$$

for any nonnegative real number t_1 and t_2 . By direct computation, it is straightforward to verify that in this case the arbitrary switching system is stable if and only if all its subsystems are stable.

Theorem 30.1:

For a collection of LTI systems (Equation 30.1) with the index set $\mathcal{J} = \{1, \dots, N\}$, if all subsystem matrices are stable (i.e., all eigenvalues of A_i have negative real part) and commute pairwise ($A_i A_j = A_j A_i, \forall i, j \in \mathcal{J}$), then the hybrid system with subsystems given by Equation 30.1 is asymptotically stable under arbitrary switching.

A CQLF exists in this case, and can be determined by solving a collection of chained Lyapunov equations as shown in the following:

Theorem 30.2:

Assume that the index set $\mathcal{J} = \{1, \dots, N\}$. Let P_1, \dots, P_N be the unique symmetric positive definite matrices that satisfy the Lyapunov equations

$$A_1^T P_1 + P_1 A_1 = -I, \quad (30.5)$$

$$A_i^T P_i + P_i A_i = -P_{i-1}, \quad i = 2, \dots, N. \quad (30.6)$$

Then the function $V(x) = x^T P_N x$ is a CQLF for systems $\dot{x}(t) = A_i x(t), i = 1, \dots, N$.

In addition, the matrix P_N can be expressed in integral form as

$$P_N = \int_0^\infty e^{A_N^T t_N} \dots \left(\int_0^\infty e^{A_1^T t_1} e^{A_1 t_1} dt_1 \right) \dots e^{A_N t_N} dt_N.$$

It is not difficult to extend this result to the discrete-time case.

Theorem 30.3:

Let P_1, \dots, P_N be the unique symmetric positive definite matrices that satisfy the Lyapunov equations

$$A_1^T P_1 A_1 + P_1 = -I, \quad (30.7)$$

$$A_i^T P_i A_i + P_i = -P_{i-1}, \quad i = 2, \dots, N. \quad (30.8)$$

Then the function $V(x) = x^T P_N x$ is a common Lyapunov function for the systems $x[k+1] = A_i x[k], i = 1, \dots, N$.

In the literature, there exist several interesting necessary and also sufficient algebraic conditions for the existence of a CQLF for more general cases but usually for low-dimensional systems, and interested readers may consult [6,8] for further references. Note that Lie algebraic conditions were proposed in the

literature; see, for example, [6], for arbitrary switching systems, which are based on the solvability of the Lie algebra generated by the subsystems' state matrices. It was shown that if the Lie algebra generated by the set of state matrices A_i is solvable, then there exists a CQLF, and the hybrid system is stable under arbitrary switching.

30.2.2 Switched Quadratic Lyapunov Functions

It should be pointed out that the existence of a CQLF is only sufficient for the stability of arbitrary switching systems. Therefore, in general, the existence of a CQLF is only sufficient for the asymptotic or exponential stability of hybrid systems under arbitrary switching, and could be rather conservative. Hence, some attention has been paid to a less conservative class of Lyapunov functions, called *switched quadratic Lyapunov functions*.

In this subsection, we investigate the stability of the following discrete-time arbitrary switching LTI systems:

$$x[k+1] = A_i x[k], \quad t \in \mathbb{Z}^+, \quad (30.9)$$

where $x \in \mathbb{R}^n$, and $i \in \mathcal{I}$. Basically, since every subsystem is stable, there exists a positive definite symmetric matrix P_i that solves the Lyapunov equation for each i th subsystem:

$$A_i^T P_i A_i - P_i < 0,$$

for all $i \in \mathcal{I}$. Next, these matrices, P_i , are patched together based on the switching signals to construct a global Lyapunov function as

$$V(k, x[k]) = x^T[k] P_{\sigma(k)} x[k], \quad (30.10)$$

where $\sigma(k) : k \rightarrow \mathcal{I}$ stands for the switching signal at step k . Since all P_i are positive definite, it is clear that the function $V(k, x[k]) = x^T[k] P_{\sigma(k)} x[k]$ is also positive definite. If it further holds that $\Delta V(k, x[k]) = V(k+1, x[k+1]) - V(k, x[k])$ is negative definite along the solution of Equation 30.9, then the origin of the system (Equation 30.9) is globally asymptotically stable. In particular, a sufficient condition for the stability of the arbitrary switching system (Equation 30.9) is given as follows.

Theorem 30.4:

If there exist positive definite symmetric matrices $P_i \in \mathbb{R}^{n \times n}$ ($P_i = P_i^T$) for $i \in \mathcal{I}$, satisfying

$$\begin{bmatrix} P_i & A_i^T P_j \\ P_j A_i & P_j \end{bmatrix} > 0 \quad (30.11)$$

for all $i, j \in \mathcal{I}$, then the linear system (Equation 30.9) with arbitrary switching is asymptotically stable.

The stability checking for arbitrary switching linear systems can be performed by solving LMIs.

It is clear that when $P_i = P_j$ for all $i, j \in \mathcal{I}$, the switched quadratic Lyapunov function becomes the CQLF. Therefore, the stability criteria based on the switched quadratic Lyapunov function generalize the CQLF approach and usually give us less conservative results. However, it is worth pointing out that the switched quadratic Lyapunov function method is still only a sufficient condition.

30.2.3 Necessary and Sufficient Conditions

In the sequel, we will provide some necessary and sufficient conditions for the asymptotic stability of arbitrary switching linear systems. It is shown that the asymptotic stability problem for hybrid linear systems with arbitrary switching is equivalent to the robust asymptotic stability problem for polytopic uncertain linear time-variant systems, for which several strong stability conditions exist.

Theorem 30.5: [8,10]

The following statements are equivalent:

1. The arbitrary switching system

$$\dot{x}(t) = A_{\sigma(t)}x(t),$$

where $A_{\sigma(t)} \in \{A_1, A_2, \dots, A_N\}$, is asymptotically stable;

2. The linear time-variant system

$$\dot{x}(t) = A(t)x(t),$$

where $A(t) \in \mathcal{A} \hat{=} \text{Conv}\{A_1, A_2, \dots, A_N\}$, where $\text{Conv}\{\cdot\}$ stands for the convex combination, is asymptotically stable;

3. There exists a full column rank matrix $L \in \mathbb{R}^{m \times n}$, $m \geq n$, and a family of matrices $\{\bar{A}_i \in \mathbb{R}^{m \times n} : i \in \mathcal{I}\}$ with strictly negative row dominating diagonal, that is, for each \bar{A}_i , $i \in \mathcal{I}$ its elements satisfying

$$\bar{a}_{kk} + \sum_{k \neq l} |\bar{a}_{kl}| < 0, \quad k = 1, \dots, m,$$

such that the matrix relations

$$LA_i = \bar{A}_i L$$

are satisfied.

It is interesting to note that the nice property of \bar{A}_i ($i \in \mathcal{I}$) implies the existence of a CQLF for the higher-dimensional arbitrary switching system. Unfortunately, applying the above Theorem is still difficult, because, in general, the numerical search for the matrix L is not simple. However, this equivalence bridges two research fields, namely the fields of hybrid system and robust stability. Therefore, existing results in the robust stability area, which has been extensively studied for over two decades, can be directly introduced to study the arbitrarily switching systems and vice versa. For example, it is known in the robust stability literature that the global attractiveness, (global) asymptotic stability, and (global) exponential stability are all equivalent for the polytopic uncertain linear time-variant systems [10]. Hence, these stability concepts are also equivalent for arbitrary switching systems. Similar results can be developed for the discrete-time case as shown below.

Theorem 30.6: [8,10]

The following statements are equivalent:

1. The arbitrary switching system $x[k+1] = A_{\sigma(k)}x[k]$, where $A_{\sigma(k)} \in \{A_1, A_2, \dots, A_N\}$, is asymptotically stable.
2. The linear time-variant system $x[k+1] = A(k)x[k]$, where $A(k) \in \mathcal{A} \hat{=} \text{Conv}\{A_1, A_2, \dots, A_N\}$, is robustly asymptotically stable.
3. There exists an integer $m \geq n$ and $L \in \mathbb{R}^{n \times m}$, $\text{rank}(L) = n$ such that for all A_i , $i \in \mathcal{I}$, there exists $\bar{A}_i \in \mathbb{R}^{m \times m}$ with the following properties:
 - a. $A_i^T L = L \bar{A}_i^T$.
 - b. Each column of \bar{A}_i has no more than n nonzero elements and

$$\|\bar{A}_i\|_{\infty} = \max_{1 \leq k \leq m} \sum_{l=1}^m |\bar{a}_{kl}| < 1.$$

Based on the equivalence between the asymptotic stability of arbitrary switching linear systems and the robust stability of polytopic uncertain linear time-variant systems, some well-established converse Lyapunov theorems can be introduced for arbitrary switching linear systems. For example, the following results were taken from [10].

Theorem 30.7:

If the arbitrary switching system is exponentially stable, then it has a strictly convex, homogenous (of second order) common Lyapunov function of a quasi-quadratic form $V(x) = x^T L(x)x$, where $L(x) = L^T(x) = L(\tau x)$ for all nonzero $x \in \mathbb{R}^n$ and $\tau \in \mathbb{R}$.

Furthermore, we may restrict our search to include only polyhedral Lyapunov functions (also known as piecewise linear Lyapunov functions) as the following result pointed out.

Theorem 30.8:

If an arbitrary switching linear system is asymptotically stable, then there exists a polyhedral Lyapunov function, which is monotonically decreasing along the switched system's trajectories.

This converse Lyapunov theorem holds for both discrete-time and continuous-time cases, which suggests that the existence of a common Lyapunov function (not necessarily quadratic) is not only sufficient, but also necessary for the stability of a hybrid system under arbitrary switching.

Before we move on to another topic, let us take a look at the following example, which is taken from the robust stability literature.

Example 30.1:

Consider an arbitrary switching system, $\dot{x} = A_i x, i \in \{1, 2\}$, where

$$A_1 = \begin{bmatrix} 0 & 1 \\ -0.06 & -1 \end{bmatrix}; \quad A_2 = \begin{bmatrix} 0 & 1 \\ -1.94 & -1 \end{bmatrix}.$$

It is known that no CQLF exists. However, the arbitrary switching system is asymptotically stable, which is assured by the existence of a piecewise quadratic Lyapunov function; a particular piecewise linear Lyapunov function is also suggested in the robust literature.

30.3 Restricted Switching

Hybrid systems may fail to preserve stability under arbitrary switching. On the other hand, one may have some knowledge about the occurrence of possible discrete event dynamics in the hybrid systems and this knowledge can be translated into restrictions on the switching signals. For example, there must exist certain bounds on the time interval between two successive switchings, which may be due to the fact that the state trajectories have to spend some finite period of time in traveling from the initial set to certain boundary sets before switching, if these two sets are separated. With such kind of prior knowledge about the switching signals, we may derive stronger results on the stability for a given hybrid system instead of just using the worst-case arguments of the previous section.

30.3.1 Slow Switching

By studying the cases where divergent trajectories are generated through switching between two stable systems, one may note that the unboundedness is caused by the failure to absorb the energy increase caused by frequent switchings. In addition, when there is an unstable subsystem present (e.g., controller failure or sensor fault), if one either stays too long on it or switches too frequently to it, this may cause instability. Therefore, a natural question is what if we restrict the switching signals to some constrained subclasses. Intuitively, if one stays at stable subsystems long enough and switches less frequently, that is, slow switching, one may trade off the energy increase caused by switching or unstable modes, and it should perhaps become possible to attain stability. These ideas are proved to be reasonable and are captured by concepts such as *dwell time* and *average dwell time* [4] between switchings that are introduced below.

The simplest way to characterize the concept of slow switching is perhaps to request a lower bound on two consecutive switching times.

Definition 30.1:

A positive scalar τ_d is called the *dwell time* if the time interval between any two consecutive switchings is no smaller than τ_d .

Assume that all subsystems of the hybrid system are exponentially stable. Then, it can be shown that there exists a scalar $\tau_d > 0$ such that the hybrid system remains exponentially stable if the dwell time is larger than τ_d . In addition, one may give an estimate on the bound of the dwell time and decay rate.

In fact, it really does not matter if one occasionally has a smaller dwell time between switching, provided this does not occur too frequently. This concept is captured by the concept of “average dwell-time.”

Definition 30.2:

A positive constant τ_a is called the *average dwell time* if $N_\sigma(t) \leq N_0 + t/\tau_a$ holds for all $t > 0$ and some scalar $N_0 \geq 0$, where $N_\sigma(t)$ denotes the number of discontinuities of a given switching signal σ over $[0, t)$.

Here the constant τ_a is called the *average dwell time* and N_0 the *chatter bound*. The reason for calling a class of switching signals that satisfy

$$N_\sigma(t) \leq N_0 + \frac{t}{\tau_a}$$

having an average dwell no less than τ_a is because

$$N_\sigma(t) \leq N_0 + \frac{t}{\tau_a} \iff \frac{t}{N_\sigma(t) - N_0} \geq \tau_a.$$

This means that on an average the “dwell time” between any two consecutive switchings is no smaller than τ_a . The idea is that there may exist consecutive switching separated by less than τ_a , but the average time interval between consecutive switching is not less than τ_a .

Theorem 30.9:

Assume that all subsystems, $\dot{x} = A_i x$ for $i \in \mathcal{J}$, in the hybrid system are exponentially stable. Then, there exists a scalar $\tau_a > 0$ such that the hybrid system is exponentially stable if the average dwell time is larger than τ_a .

Moreover, we can also obtain a bound on the decay rate.

Theorem 30.10:

Given a positive scalar λ_0 such that $A_i + \lambda_0 I$ is stable for all $i \in \mathcal{I}$. Then, for any given $\lambda \in (0, \lambda_0)$, there exists a finite constant τ_a such that the hybrid system is exponentially stable with decay rate λ provided that the average dwell time is no less than τ_a .

The stability results for slow switching can be extended to discrete-time case, where the dwell time τ_d or average dwell time τ_a are counted as the number of sampling periods. In particular,

Definition 30.3:

A positive constant τ_a is called the average dwell time if $N_\sigma(k) \leq N_0 + k/\tau_a$ holds for all $k > 0$ and some scalar $N_0 \geq 0$, where $N_\sigma(k)$ denotes the number of switchings of a given switching signal σ over $[0, k)$.

Theorem 30.11:

Given a positive scalar λ_0 such that A_i/λ_0 is stable for all $i \in \mathcal{I}$. Then, for any given $\lambda \in (\lambda_0, 1)$, there exists a finite constant τ_a such that the hybrid system, consisting of $x[k+1] = A_i x[k]$ as its subsystems, is exponentially stable with decay rate λ provided that the average dwell time is no less than τ_a .

Interested readers may refer to the survey papers [4,6,8] for further references on the stability of hybrid systems under slow switchings.

We continue our study of the stability of hybrid systems under restricted switchings in this section. It should be pointed out that not all restrictions on switching signals can be captured by the dwell time or average dwell time. For example, it is difficult to transform the invariant set constraints, guard set constraints, and so on, which determine the switching signals, into only dwell-time or average dwell time restrictions on switching signals. The main difficulty comes from the fact that most constraints in hybrid systems are state dependent and in the form of partitions of the state space, and so it is hard to transform them into pure time-dependent constraints such as dwell time, and so on. This calls for a more general tool to study hybrid system stability, and we introduce a powerful tool, *multiple Lyapunov functions* (MLFs).

30.3.2 Multiple Lyapunov Functions

The stability analysis under constrained switching has usually been pursued in the framework of MLFs. The basic idea is to use multiple Lyapunov or Lyapunov-like functions, each of which may correspond to a single subsystem or certain regions in the state space, concatenated together to produce a nontraditional Lyapunov function. The nontraditionality is in the sense that the MLF may not be monotonically decreasing along the state trajectories, may have discontinuities, and be piecewise differentiable. The reason for considering nontraditional Lyapunov functions is that the traditional Lyapunov function may not exist for hybrid systems with restricted switching signals. For such cases, one may still construct a collection of Lyapunov-like functions, which only requires nonpositive Lie-derivative for certain subsystems in a certain region of the state space instead of globally negativity conditions.

Lyapunov-like functions are defined as a family of real-valued functions $\{V_i, i = 1, \dots, N\}$ with certain properties, each associated with the vector field $\dot{x} = f_i(x)$ that represents the continuous dynamics for the hybrid system under the i th discrete mode.

Definition 30.4: Lyapunov-Like Function

By saying that a subsystem has an associated Lyapunov-like function V_i in region $\Omega_i \subseteq \mathbb{R}^n$, we mean that

1. There exist constant scalars $\beta_i \geq \alpha_i > 0$, such that

$$\alpha_i \|x\|^2 \leq V_i(x) \leq \beta_i \|x\|^2$$

holds for any $x \in \Omega_i$.

2. For all $x \in \Omega_i$ and $x \neq 0$, $\dot{V}_i(x) < 0$.

Here $\dot{V}_i(x) = (\partial V_i(x)/\partial x)f_i(x)$. The first condition implies positiveness and radius unboundedness for $V_i(x)$ when $x \in \Omega_i$, while the second condition guarantees the decrease of the abstracted energy, value of function $V_i(x)$, along the trajectories of subsystem i inside Ω_i .

Suppose that these regions Ω_i cover the whole state space, and so a cluster of Lyapunov-like functions is obtained. By concatenating these Lyapunov-like functions together, we obtain a nontraditional Lyapunov function, called MLF, which can be used to study the global stability of hybrid systems. MLFs are proved to be a powerful tool for studying the stability of switched systems and hybrid systems; see, for example, [3,6,8,9]. There are several versions of MLF results in the literature. A very intuitive MLF result [3] is illustrated in Figure 30.1, where the Lyapunov-like function decreases when the corresponding mode is active and does not increase its value at each switching instant. Formally, this result can be stated by the following theorem [3].

Theorem 30.12:

Suppose that each subsystem has an associated Lyapunov-like function V_i in its active region Ω_i , each with equilibrium point $x = 0$. Also, suppose that $\bigcup_i \Omega_i = \mathbb{R}^n$. Let $\sigma(t)$ be a class of piecewise-constant switching

FIGURE 30.1 The hybrid system is asymptotically stable if the Lyapunov-like functions' values at the switching instants form a decreasing sequence.

sequences such that $\sigma(t)$ can take value i only if $x(t) \in \Omega_i$, and in addition

$$V_j(x(t_{i,j})) \leq V_i(x(t_{i,j})),$$

where $t_{i,j}$ denotes the time when switched system switches from subsystem i to subsystems j , that is, $x(t_{i,j}^-) \in \Omega_i$ while $x(t_{i,j}) \in \Omega_j$. Then, the switched linear system (Equation 30.1) is exponentially stable under the switching signals $\sigma(t)$.

The above MLF theorem requires that at each switching instant the Lyapunov-like function does not increase its value, which is quite conservative. Actually, one may obtain less conservative results. For example, the switching signals may be restricted in such a way that at every time when we exit (switch from) a certain subsystem its corresponding Lyapunov-like function value is smaller than its value at the previous exiting time. Then the switched system is asymptotically stable. In other words, for each subsystem, the corresponding Lyapunov-like function values at every exiting instant form a monotonically decreasing sequence. Alternatively, the decreasing tendency is captured by the Lyapunov-like function's value at the entering instant instead. This case is illustrated in Figure 30.2. This result can be presented as follows.

Theorem 30.13: [3]

Assume that there exists a family of Lyapunov functions $\{V_i : i \in \mathcal{J}\}$ for each stable subsystem. If for any two switching instants t_i and t_j such that $i < j$ and $\sigma(t_i) = \sigma(t_j)$ we have

$$V_{\sigma(t_j)}(x(t_{j+1})) - V_{\sigma(t_i)}(x(t_{i+1})) \leq -\rho \|x(t_{i+1})\|^2,$$

for some constant $\rho > 0$, then the switched system is asymptotically stable.

Furthermore, as shown in [9], the Lyapunov-like function may increase its value during a time interval, only if the increment is bounded by certain kind of continuous functions as illustrated in Figure 30.3.

FIGURE 30.2 For every subsystem, its Lyapunov-like function's value V_i at the start point of each interval exceeds the value at the start point of the next interval on which the i th subsystem is activated, then the hybrid system is asymptotically stable.

FIGURE 30.3 The hybrid system can remain stable even when the Lyapunov-like function increases its value during a certain period.

Interested readers may refer to the survey papers [3,6,9] and references therein. Note that all the arguments for continuous-time hybrid/switched systems can be extended to the discrete-time case without essential differences.

30.3.3 Piecewise Quadratic Lyapunov Functions

The critical challenge of applying the MLF theorems to practical switched/hybrid systems is how to construct a proper family of Lyapunov-like functions. Usually this is a hard problem. However, if one focuses on the linear case, piecewise quadratic Lyapunov-like functions could be attractive candidates, since the stability conditions in the MLF theorems can be formulated as LMIs [3,5], for which efficient software solution packages exist.

Considering the hybrid system with an LTI subsystem, $\dot{x}(t) = A_i x(t)$, since we do not assume that the subsystem is stable, there may not exist a quadratic Lyapunov function in a classical sense. However, it is still possible to restrict our search to certain regions of the state space, say $\Omega_i \subset \mathbb{R}^n$, and the energy of the i th subsystem could be decreasing along the trajectories inside this region (there is no decreasing requirements outside Ω_i). Suppose that the union of all these regions Ω_i covers the whole state space; then we obtain a cluster of Lyapunov-like functions. Broadly speaking, the problem entails searching for Lyapunov-like functions whose associated Ω -region covers the state space.

Assume that the state space \mathbb{R}^n has a partition given by $\{\Omega_1, \dots, \Omega_N\}$, and these regions Ω_i are defined *a priori* as a restriction of the possible switching signals (state-dependent). In this subsection, we present LMI conditions for the existence of quadratic Lyapunov-like functions of the form $V_i(x) = x^T P_i x$, assigned to each region Ω_i . A Lyapunov-like function $V_i(x) = x^T P_i x$ needs to satisfy the following two conditions:

Condition 30.1:

There exist constant scalars $\beta_i \geq \alpha_i > 0$ such that

$$\alpha_i \|x\|^2 \leq V_i(x) \leq \beta_i \|x\|^2$$

hold for all $x \in \Omega_i$.

Consider a quadratic Lyapunov-like function candidate, $V_i(x) = x^T P_i x$, and require that

$$\alpha_i x^T I x \leq x^T P_i x \leq \beta_i x^T I x$$

holds for any $x \in \Omega_i$. That is

$$\begin{cases} x^T (\alpha_i I - P_i) x \leq 0 \\ x^T (P_i - \beta_i I) x \leq 0 \end{cases}$$

holds for all $x \in \Omega_i$.

Condition 30.2:

For all $x \in \Omega_i$ and $x \neq 0$, $\dot{V}_i(x) < 0$.

This negativeness of the Lyapunov-like function's derivative along the trajectories of a subsystem can be represented as $\exists P_i, (P_i = P_i^T)$ such that

$$x^T [A_i^T P_i + P_i A_i] x < 0 \quad (30.12)$$

for $x \in \Omega_i$.

30.3.3.1 Switching Condition

In addition, based on the MLF theorem of [3], for stability it is also required that the Lyapunov-like functions' values at switching instant are nonincreasing, which can be expressed by

$$x^T P_j x \leq x^T P_i x$$

for $x \in \Omega_{i,j} \subseteq \Omega_i \cap \Omega_j$. The region $\Omega_{i,j}$ stands for the states where the trajectory passes from region Ω_i to Ω_j .

Note that all the above matrix inequalities are constrained in a local region, such as $x \in \Omega_i$ or $\Omega_{i,j}$. A technique called \mathcal{S} -procedure can be applied to replace a constrained matrix inequality condition by a condition without constraints. To employ the \mathcal{S} -procedure, the regions Ω_i and $\Omega_{i,j}$ need to be expressed by or be contained in regions characterized by quadratic forms. For simplicity, we assume here that each region Ω_i has a quadratic representation or approximation, that is

$$\Omega_i = \{x \mid x^T Q_i x \geq 0\},$$

and regions $\Omega_{i,j}$ can be expressed or approximated by

$$\Omega_{i,j} = \{x \mid x^T Q_{i,j} x \geq 0\}.$$

Then the above matrix inequalities can be transformed into unconstrained ones based also on the \mathcal{S} -procedure, namely

Theorem 30.14:

The system (Equation 30.1) is (exponentially) stable if there exist matrices $P_i (P_i = P_i^T)$ and scalars $\alpha > 0, \beta > 0, \mu_i \geq 0, \nu_i \geq 0, \vartheta_i \geq 0$, and $\eta_{i,j} \geq 0$, such that

$$\begin{cases} \alpha I + \mu_i Q_i \leq P_i \leq \beta I - \nu_i Q_i \\ A_i^T P_i + P_i A_i + \vartheta_i Q_i \leq -I \\ P_j + \eta_{i,j} Q_{i,j} \leq P_i \end{cases} \quad (30.13)$$

are satisfied.

The above theorem is an adaptation of a result in [3]. If there is a solution to the above LMI problem, the exponential stability is verified. In addition, a bound on the convergence rate can be estimated:

$$\|x(t)\| \leq \sqrt{\frac{\beta}{\alpha}} e^{-\frac{1}{2\beta}t} \|x_0\|,$$

where $x(t)$ is the continuous trajectory with an initial state x_0 , and the constants α, β are solutions of the LMI (Equation 30.13). Based on similar arguments, LMI-based sufficient conditions for the discrete-time case can be derived; see, for example, [8].

An example is now presented to illustrate Theorem 30.14.

Example 30.2:

Consider a hybrid system

$$\begin{cases} \dot{x}(t) = \begin{bmatrix} 0 & 10 \\ 0 & 0 \end{bmatrix} x(t), & \text{if } x(t) \in \Omega_1 = \{x | x^T Q_1 x \geq 0\}, \\ \dot{x}(t) = \begin{bmatrix} 1.5 & 2 \\ -2 & -0.5 \end{bmatrix} x(t), & \text{if } x(t) \in \Omega_2 = \{x | x^T Q_2 x \geq 0\}, \end{cases} \quad (30.14)$$

where $Q_1 = \begin{bmatrix} -0.25 & -0.25 \\ -0.25 & 2 \end{bmatrix}$ and $Q_2 = \begin{bmatrix} 0.25 & 0.25 \\ 0.25 & -2 \end{bmatrix}$. Since $Q_1 = -Q_2$, it is straightforward to verify that $\Omega_1 \cup \Omega_2 = \mathbb{R}^2$.

Solving the LMI problem in Theorem 30.14 results in a solution

$$P_1 = \begin{bmatrix} 0.1000 & -0.4500 \\ -0.4500 & 41.1167 \end{bmatrix}, \quad P_2 = \begin{bmatrix} 4.3792 & 3.8292 \\ 3.8292 & 6.8833 \end{bmatrix}$$

with a value of $\beta = 41.12$. Hence, the hybrid system is exponentially stable. Interested readers may refer to [3] for details and illustration of trajectories and Lyapunov-level curves.

Note that the above conditions are all based on MLF theorems; hence the results developed in this subsection are only sufficient. To reduce the possible conservativeness, a new kind of polynomial Lyapunov functions has been introduced and investigated for the stability analysis of hybrid systems. The computation of such polynomial Lyapunov functions can be efficiently performed using convex optimization, based on the sum of squares (SOS) decomposition of multivariate polynomials. It is also possible to use SOS techniques together with the \mathcal{S} -procedure to construct piecewise polynomial Lyapunov functions, with each polynomial as a SOS while incorporating the state constraints, and hence to generalize piecewise quadratic Lyapunov functions. Interested readers may refer to the survey paper [8] for further references.

30.4 Switching Stabilization

Implicitly, the above MLF results provide methodologies for the design of switching logics between vector fields so as to achieve a stable trajectory, since MLF results characterize the conditions on switching signals, under which the hybrid system is stable. In this section, we explicitly consider the design of stabilizing switching logics for hybrid systems. The formulation of the problem can be stated as follows.

- Given a collection of LTI systems $\dot{x} = A_i x$, design switching logics so that the induced hybrid system is stable.

This is usually called the *switching stabilization problem* in the literature. It is known that even when all subsystems are unstable, there still may exist stabilizing switching signals.

30.4.1 Quadratic Switching Stabilization

In the switching stabilization literature, most of the work has focused on quadratic stabilization for certain classes of systems. A hybrid system is called quadratically stabilizable when there exist switching signals that stabilize the system along a quadratic Lyapunov function, $V(x) = x^T P x$.

It is known that a necessary and sufficient condition for a pair of LTI systems to be quadratically stabilizable is the existence of a stable convex combination of the two subsystems' matrices. Specifically,

Theorem 30.15:

A hybrid system that contains two LTI subsystems, $\dot{x}(t) = A_i x(t)$, $i = 1, 2$, is quadratically stabilizable if and only if the matrix pencil $\gamma_\alpha(A_1, A_2) = \{A_\alpha \mid A_\alpha = \alpha A_1 + (1 - \alpha)A_2, 0 \leq \alpha \leq 1\}$ contains a stable matrix.

A generalization to more than two LTI subsystems was suggested by using a “min-projection strategy,” that is,

$$\sigma(t) = \arg \min_{i \in \mathcal{I}} x(t)^T P A_i x(t). \quad (30.15)$$

Theorem 30.16:

If there exist constants $\alpha_i \in [0, 1]$, and $\sum_{i \in \mathcal{I}} \alpha_i = 1$ such that

$$A_\alpha = \sum_{i \in \mathcal{I}} \alpha_i A_i,$$

is stable, then the min-projection strategy (Equation 30.15) quadratically stabilizes the switched system.

However, the existence of a stable convex combination matrix A_α is only sufficient for switched LTI systems with more than two subsystems. There are example systems for which no stable convex combination state matrix exists, yet the system is quadratically stabilizable using certain switching signals. A necessary and sufficient condition for the quadratic stabilizability of switched controller systems is as follows.

Theorem 30.17: [12]

The switched system is quadratically stabilizable if and only if there exists a positive definite real symmetric matrix $P = P^T > 0$ such that the set of matrices $\{A_i P + P A_i^T\}$ is strictly complete, that is, for any $x \in \mathbb{R}^n / \{0\}$, there exists $i \in \mathcal{I}$ such that $x^T (A_i P + P A_i^T) x < 0$. In addition, a stabilizing switching signal can be selected as $\sigma(t) = \min_i \{x^T(t) (A_i P + P A_i^T) x(t)\}$.

Analogously, for the discrete-time case, it is necessary and sufficient for quadratic stabilizability to check whether there exists a positive symmetric matrix P such that the set of matrices $\{A_i^T P A_i - P\}$ is strictly complete. Obviously, the existence of a convex combination of state matrices A_α automatically satisfies the above strict completeness conditions due to convexity, while the inverse statement is not true in general. Unfortunately, checking the strict completeness of a set of matrices is NP hard [12]. Interested readers may refer to survey papers [3,6,8] for further references.

Quadratic stability means that there exists a positive constant ϵ such that $\dot{V}(x) \leq -\epsilon x^T x$. All of these methods guarantee stability by using a common quadratic Lyapunov function, which is conservative in the

sense that there are switched systems that can be asymptotically (or exponentially) stabilized in case when a CQLF function does not exist. Therefore, we will turn our attention to multiple Lyapunov functions, and describe constructive synthesis methods based on the piecewise quadratic Lyapunov function in the next section, which are mainly based on [11].

30.4.2 Piecewise Quadratic Switching Stabilization

According to Theorem 30.14, if there exist real matrices P_i ($P_i = P_i^T$) and scalars $\alpha > 0$, $\beta > 0$, $\mu_i \geq 0$, $\nu_i \geq 0$, $\vartheta_i \geq 0$, and $\eta_{ij} \geq 0$, satisfying

$$\begin{cases} \alpha I + \mu_i Q_i \leq P_i \leq \beta I - \nu_i Q_i \\ A^T P_i + P_i A + \vartheta_i Q_i \leq -I \\ P_j + \eta_{ij} Q_{ij} \leq P_i \end{cases},$$

then the switched linear system (Equation 30.1) is exponentially stable.

In contrast to the stability analysis problem, here the state-space partitions Ω_i are not given *a priori* any more. Actually, the state partitions Ω_i , which induce the state-dependent switching signals, are to be designed. Moreover, the state space cannot be partitioned in an arbitrary way. The partition of the state space should facilitate the search of proper quadratic Lyapunov-like functions, and satisfy the nonincreasing conditions when switching occurs. This will be discussed in detail in the following.

30.4.2.1 State-Space Partition

Once again, the purpose of dividing the whole state space \mathbb{R}^n into pieces, denoted as Ω_i , is to facilitate the search for Lyapunov-like functions for one of these subsystems. After successfully obtaining these Lyapunov-like functions associated with each region Ω_i , one may patch them together, following the conditions of the above MLF theorem, so as to guarantee global stability.

For this purpose, it is necessary that these regions Ω_i cover the whole state space, that is, the following *covering property* holds:

$$\Omega_1 \cup \Omega_2 \cup \dots \cup \Omega_N = \mathbb{R}^n.$$

This condition merely says that there are no regions in the state space where none of the subsystems are activated.

Since we will restrict our attention to quadratic Lyapunov-like functions for the purpose of computational efficiency, we will consider regions given (or approximated) by quadratic forms

$$\Omega_i = \{x \in \mathbb{R}^n \mid x^T Q_i x \geq 0\},$$

where $Q_i \in \mathbb{R}^{n \times n}$ are symmetric matrices, and $i \in \{1, \dots, N\}$.

The following lemma gives a sufficient condition for the covering property.

Lemma 30.1: [11]

If for every $x \in \mathbb{R}^n$

$$\sum_{i=1}^N \theta_i x^T Q_i x \geq 0, \quad (30.16)$$

where $\theta_i \geq 0$, $i \in \mathcal{I}$, then $\bigcup_{i=1}^N \Omega_i = \mathbb{R}^n$.

30.4.2.2 Switching Condition

In order to guarantee exponential stability we also need to make sure that

1. Subsystem i is active only when $x(t) \in \Omega_i$.
2. When switching occurs, it is required to guarantee that the Lyapunov-like function values do not increase.

To verify the first requirement, we consider the *largest region function strategy*, that is,

$$\sigma(x(t)) = \arg \left(\max_{i \in \mathcal{I}} x(t)^T Q_i x(t) \right). \quad (30.17)$$

This is due to the selection of subsystems (at state $x(t)$) corresponding to the largest value of the region function $x(t)^T Q_i x(t)$.

Suppose that the covering condition (Equation 30.16) holds, that is,

$$\sum_{i=1}^N \theta_i x^T Q_i x \geq 0$$

for some $\theta_i \geq 0, i \in \mathcal{I}$. Then, based on the largest region function strategy, the state x with the current active mode i satisfies $x^T Q_i x \geq 0$. This implies that $x \in \Omega_i$. So the first condition holds for the largest region function strategy (Equation 30.17).

To satisfy the second energy decreasing condition at switching instants, we need to know in which direction the state trajectory $x(t)$ passes through the switching surfaces. However, the switching surface is to be designed, and so such information is lacking in general. Then we make a compromise and require that

$$x^T P_i x = x^T P_j x$$

for states at the switching plane, that is, $x \in \Omega_i \cap \Omega_j$. Assume that the set $\Omega_i \cap \Omega_j$ can be represented by the following quadratic form:

$$\Omega_i \cap \Omega_j = \{x | x^T (Q_i - Q_j)x = 0\}.$$

Again, applying the S -procedure, we obtain

$$P_i - P_j + \eta_{ij}(Q_i - Q_j) = 0,$$

for an unknown scalar η_{ij} , as the switching condition.

30.4.2.3 Synthesis Condition

The above discussion can be summarized by the following sufficient conditions for the collection of continuous-time systems (Equation 30.1) to be exponentially stabilized.

Theorem 30.18: [11]

If there exist real matrices P_i ($P_i = P_i^T$) and scalars $\alpha > 0, \beta > 0, \mu_i \geq 0, \nu_i \geq 0, \theta_i \geq 0, \vartheta_i \geq 0$, and η_{ij} , solving the optimization problem

$$\begin{aligned} & \min \beta \\ & \text{s.t.} \begin{cases} \alpha I + \mu_i Q_i \leq P_i \leq \beta I - \nu_i Q_i \\ A^T P_i + P_i A + \vartheta_i Q_i \leq -I \\ P_j = P_i + \eta_{ij}(Q_i - Q_j) \\ \theta_1 Q_1 + \dots + \theta_N Q_N \geq 0 \end{cases} \end{aligned}$$

for all $i, j \in \{1, \dots, N\}$, then the switched linear system (Equation 30.1) can be exponentially stabilized (with decay rate $\frac{1}{2\beta}$) by the largest region function strategy (Equation 30.17).

The extension of the synthesis method for continuous-time switched linear systems to discrete-time counterpart is not obvious. The main difficulty is that, unlike the continuous-time case, discrete-time switched systems do not have the nice property that the switching occurs exactly on the switching surface. Instead, the switching happens in a region around the switching surface. As a result, we cannot simply capture the switching instants for discrete-time switched systems at the time instants when the state trajectories cross the switching surfaces. Therefore, in order to guarantee the nonincreasing requirement at the switching instants for the discrete-time case, we need to include more constraints involving state transitions for the discrete-time switched systems around the switching surfaces. This makes the switching stabilization problem for discrete-time switched systems more challenging.

Some remarks are in order. First, for both the continuous-time and discrete-time cases, the optimization problem above is a Bilinear Matrix Inequality (BMI) problem, due to the product of unknown scalars and matrices. BMI problems are non-convex, and not computationally efficient. However, practical algorithms for optimization problems over BMIs exist and typically involve approximations, heuristics, branch-and-bound, or local search. One possible way to solve the BMI problem is to grid up the unknown scalars, and then solve a set of LMIs for fixed values of these parameters. It is argued in [11] that the gridding of the unknown scalars can be made quite sparsely.

Example 30.3: [11]

To illustrate the synthesis procedure, consider the case of two unstable subsystems given by

$$A_1 = \begin{bmatrix} 1 & -5 \\ 0 & 1 \end{bmatrix}, \quad A_2 = \begin{bmatrix} 1 & 0 \\ 5 & 1 \end{bmatrix}.$$

It can be shown that there is no stable convex combination of these two matrices, which means that the system cannot be quadratically stabilized. However, solving the BMI in Theorem 30.18 through gridding up the unknown parameters results in a solution

$$\beta = 3.7941, \quad \alpha = 0.2101$$

and

$$Q_1 = -Q_2 = \begin{bmatrix} -0.08242 & 0.8648 \\ 0.8648 & 0.8053 \end{bmatrix}, \quad (30.18)$$

$$P_1 = \begin{bmatrix} 1.1896 & 1.1440 \\ 1.1440 & 3.2447 \end{bmatrix}, \quad P_2 = \begin{bmatrix} 3.3325 & -1.1044 \\ -1.1044 & 1.1509 \end{bmatrix}. \quad (30.19)$$

Hence, the switched linear system can be exponentially stabilized by the largest region function strategy (Equation 30.17), and the estimate of the exponential convergence becomes $\|x(t)\| \leq 4.2495e^{-0.1318t} \|x_0\|$.

So far, we have only derived sufficient conditions for the existence of stabilizing switching signals for a given collection of linear systems. A more difficult problem has been the necessity part of the switching stabilizability problem, and a particularly challenging part has been the problem of finding necessary and sufficient conditions for switching stabilizability. In [7], a necessary and sufficient condition was proposed for the existence of a switching control law (in static state-feedback form) for asymptotic stabilization of continuous-time switched linear systems.

30.5 Conclusion

In this chapter, we discussed, by necessity, a brief introduction to the basic concepts and results of the field of stability and stabilizability of hybrid systems. For further references, we would suggest several survey papers on the stability of hybrid and switched systems, for example [3,6,8,9].
