Abstract

We present a new Generalized Markov Equilibrium (GME) approach to studying sudden stops and financial crises in emerging countries in small open economies with price dependent equilibrium collateral constraints. These models are known to have multiple equilibria. Our approach to characterizing and computing stochastic equilibrium dynamics is global, encompasses recursive equilibrium as a special case, yet allows for a much more flexible approach to modeling memory and multiple equilibrium in models with equilibrium price-dependent collateral constraints. We construct ergodic GME selections from the sequential competitive equilibrium that at the same time can replicate all the observed phases of the macro crises associated with a sudden stop (boom, collapse, spiraled recession, recovery) while still being able to capture the long-run stylized behavior of the data. We also compute stochastic equilibrium dynamics associated with stationary and a non-stationary GME selections, and we find that a) the ergodic GME selectors generate stochastic dynamics which are less financially constrained, b) non-stationary GME selections exhibit a great range of fluctuations in macroeconomic aggregates compared to the stationary selections. Finally, from a theoretical perspective, we prove the existence of both sequential competitive equilibrium and (minimal state space) recursive equilibrium, and provide a complete constructive qualitative theory of recursive equilibrium comparative statics in deep parameters of these economies. Consistent with recent results in the literature, relative to the set of recursive equilibrium, we find 2 stationary equilibrium: one with high/over borrowing, the other with low/under borrowing. These equilibrium are extremal and “self-fulfilling” under rational expectations.

1 Introduction

This paper proposes a new Generalized Markov Equilibrium (GME) approach to characterizing the stochastic dynamic equilibrium dynamics in the canonical Sudden-Stops model of financial crises in small open economies. As such models involve binding equilibrium price-dependent collateral constraints, the models are known to be highly nonlinear, often possessing multiple sequential competitive equilibrium. Therefore, characterizing the global structure of stochastic equilibrium dynamics, the stationary equilibria as well as the associated stochastic steady-state (if they exist), can be a very challenging endeavor. We argue in this paper that GME methods provide a systematic and flexible approach to overcoming many of these conceptual difficulties, and are able to characterize the *set* of sequential competitive equilibria (including minimal state space recursive equilibrium) in this class of models, as well as examining the role of "memory" in models of financial crises in the presence of multiple stochastic equilibrium paths.

More specifically, in the paper we show how to use GME methods to construct an *ergodic representation* of stationary equilibrium of the stochastic equilibrium dynamics for particular GME selectors in these models in the presence of *multiple* sequential competitive equilibria. Ergodic GME selections are capable of replicating the dynamics of a sudden stop without relying on a large unanticipated shocks that impose the loss of access to capital markets *by assumption* (as it is often appealed to in the literature), and they are able to keep track of both *short and long-run dynamics*. As regards to the former, the ergodic GME replicates the anatomy of different aspects of financial crises. With respect to the latter, it characterizes the effects of recurrent crises, as well as its frequency, on the *long-run* behavior of more general macroeconomic aggregates. In this sense, ergodicity provides a natural type of equilibrium selection device/criterion for characterizing stochastic equilibrium dynamics among multiple possible SCE paths.

When computing the set of GME for these models we are also able compare both stationary ergodic and non-stationary GME equilibria. When doing this, we find that in these models of sudden stops, ergodic selections have a different equilibrium stochastic structure: they are less financially constrained, have smoother consumption paths when compared to the other type of Markov equilibria, and the "size" of the recession associated with a financial crises is shown in simulations to depend on the structure of the *pre-phase* (which in turn connects the role of memory associated with equilibrium stochastic process with its short-run predictions). Non-stationary GME can also generate large fluctuations in macroeconomic fundamentals using standard preferences and with the same shock structure. This last fact indicates that by changing the definition of equilibrium, the same theoretical structure is capable of generating a great range of balance of payments crises.

We then able to sharpen the characterization of SCE by providing a systematic study of "short-memory" minimal state space recursive equilibrium (RE, for short), a class of sequential equilibrium often studied in the literature both theoretically and numerically.¹ Relative to the set of RE, we build a new monotone approach that is literally built upon the two distinct equilibrium "regimes", one where equilibrium collateral constraints are not binding, the other where they are not. Importantly, these two different regimes are shown to have distinct qualitative properties in any RE, as well as also having different structural properties over the minimal state space. Further, we find at least 2 different stationary equilibria associated with RE, one with high/over borrowing and the other with low/under borrowing.

To characterize the RE behavior over these different "collateral constrained" regimes, we propose a novel two-step monotone operator approach that systematically addresses both the existence and computation of the *set* of RE, which delivers "ordered" multiple equilibrium RE, where the least RE (resp., greatest RE) has low consumption/under-borrowing (resp., high consumption/over-borrowing). The monotonicity of our RE operator is based upon providing a new *equilibrium single-crossing* characterization built upon the well-known "pecuniary externality" that exists in these models in equilibrium states where price-dependent collateral constraints bind. We refer to this new form of equilibrium complementarity as a *pecuniary complementarity*, and we show this is the global source of multiple dynamic equilibrium in these models. Our monotone approach to RE is also able deliver a simple successive approximation algorithm that "computes" extremal elements of the RE correspondence, the low/under (resp, high/over) borrowing RE in the model. Moreover, we are able to compute RE comparative statics

¹e.g., see the seminal paper of Bianchi ([12]), among others, for example.

in important deep parameters.

Therefore our new theoretical approach to constructing RE is of independent interest, as it provides a *global* formalization of the "self-fulfilling" nature of multiple equilibrium for stochastic small open economies model when collateral constraints bind in RE that has been recently discussed in the literature (i.e. Schmitt-Grohe and Uribe ([67], [68]), Bianchi and Mendoza ([16]).

1.1 Preview of our Results

The paper considers the canonical workhorse small open economy two sector model that has been studied extensively in literature over the last decade (e.g., Bianchi ([12]) and Schmitt-Grohe and Uribe ([67], [68]), among many others). We first provide the first set of general existence results for both SCE and RE for this class of models in the literature. For the methods in this paper, these existence constructions are not purely of theoretical concerns; rather, they are necessary to prove in order to guarantee the GME methods we develop in the paper are well-defined globally from all admissible initial conditions of the stochastic model.

Next, we prove the existence of GME representations for the *set* of SCE, where the GME are defined over an enlarged state space. This allows us in a very precise manner to keep track of the structure of *memory* when representing the stochastic dynamic equilibrium paths as GME, and hence provides a sharp and flexible tool for characterizing of the structure of stationary equilibrium of these models. Most importantly, this allows us build GME equilibrium selections for SCE that have different stochastic equilibrium properties for stationary equilibrium (e.g., as ergodic vs. invariant measures).

For GME paths, we prove stochastic equilibrium dynamics hit the collateral constraint in finite time with probability one starting from any initial condition. We then propose a new systematic way of forming *ergodic* GME selections for the set of SCE. These selections exploit the "long memory" structure of the SCE which is used to guarantee the existence of positive "hit" rates of the collateral constraint in finite time, a critical component of the characterization of different possible stochastic equilibrium paths. Such ergodicity results can have profound implications also for empirical work which seeks to estimate Sudden Stops models from a structural perspective (e.g., see the recent work on Benigno, Chen, Otrok, and Rebucci ([11])), and should be of independent interest for the econometric study of these models.

The key ingredient to identifying an ergodic GME selections in this paper is the occasionally binding price-dependent collateral constraint, the critical feature of sudden stops models that allows the model to generate financial crises. In particular, the equilibrium collateral constraint allows us to characterize the regeneration properties of stochastic equilibrium dynamics, a critical ingredient in proving the existence of ergodic GME selectors. We show ergodic GME selectors have important quantitative properties when representing stochastically the anatomy of important properties of financial crises. In particular, ergodic GME are able numerically to replicate observed frequencies and structural characteristics of the crises within the context of modeling multiple *long run stylized facts* associated with macroeconomic aggregates, whole also characterizing *short-run* stochastic features of these models related to the coexistence of Fisherian deflation/recessions dynamics in the data alongside with long run empirical regularities.

Mathematically, ergodic GME selectors are identified by constructing a so-called "atom" of the equilibrium Markov process (which, in particular, regenerates at the atom), a property that turns out to be deeply connected with ergodicity of stochastic equilibrium dynamics. We show how such an identification of an atom in these models relies upon the equilibrium collateral constraint itself. In the end, we argue that ergodicity is a type of sequential equilibrium selection criterion which selects subsets for SCE from among multiple possible (non-ergodic) GME equilibria paths. If we say that every time the process hits the collateral constraints the model predicts a crises, our GME approach can integrate the *frequency* of them with the long-run characteristics of macroeconomic aggregates to discipline the parameters in the model, while at the same time keep track of the short run anatomy of different types of crises.

The intuition behind our GME approach is direct, and based in the existence of 2 stochastic equilibrium regimes, one defined when the collateral constraint does not bind, the other when this constraint is active, making the equilibrium collateral constraint the key building block to obtain any tractable approach to characterize the nature of stochastic equilibrium dynamics. Importantly, our methods are robust to the presence of multiple equilibria and the existence of discontinuous GME selections, and are

able to characterize the ergodic / long-run stochastic properties of SCE by constructing a GME path that "jumps" to the atom every time the collateral constraint is "hit" and generates a crisis. Thus, the presence of multiple equilibria allows us to better match long run empirical regularities.

Next, we are able connect the existence of an invariant measure (or ergodic measure) with the frequency of financial crises. Let τ_α be the time when the process hits the collateral constraint, α is the atom and $\mu(A)$ the cumulative probability of hitting A avoiding a crises. Therefore, *the frequency of a Sudden Stops affects the stationary distribution μ* . Moreover, frequent crises imply more volatility even in the steady state of the model. To understand the intuition behind this last relationship, note that every time the process hits the collateral constraint it reverts to α . The definition of an atom implies that $P_\varphi(\alpha, A) = \nu(A)$, where P is a Markovian transition kernel and φ a selection from the GME correspondence. This result implies that the realization of the process after hitting the collateral constraint, $z_{\tau_\alpha+1}$, is independent of the past, which implies that it loses all the inertia inherited from the Markovian structure of the process. This fact in turn implies that the equilibrium stochastic dynamics behaves unconditionally with respect to the past, increasing its variability.

To relate these facts with the empirical performance of the model, we need a Law of Large numbers. If the measure is ergodic, it is well known that $\sum z_t \rightarrow E_\mu(z)$ almost everywhere.² Thus, the historical time periods without a Sudden Stops are allowed to shape the long run distribution of the model, affecting its ability to replicate stylized facts. Then, use ergodic GME selections, we solve the model for a parameter set borrowed from the empirical literature, and we show that the ergodic GME selections are capable of simulating a "Fisherian deflation" (i.e. a path of real exchange rate depreciation coupled with falling consumption) and a sudden stop without relying on a large, unanticipated shock that impose the loss of access to capital markets by assumption.³ This shock is typically represented by a sudden change in a (non-stochastic) parameter or a change in the support of the distribution of exogenous shocks.

A central theme of the paper is actually that modeling memory is critical to address the coexistence of the anatomy of the financial crisis with the long-run structure of macroeconomic data. That is, neither of the mentioned assumptions are required once we change the type of equilibrium from the short-memory structure of RE to the potential longer memory structure of SCE via its GME. To our knowledge, this is the first attempt to show that a general equilibrium model with occasionally binding price dependent collateral constraints can generate a collapse in borrowing followed by a "financial accelerator effect", caused by de-leveraging, and at the same time preserve the ergodicity of the dynamical system. We show that the order of magnitude of the "recession" associated with a Sudden Stop depends on the level of consumption reached in the pre-phase which, given the unconstrained nature of this phase and the smoothness of consumption in that regime, will depend on a sequence of positive shocks to income. The longer the sequence, the bigger the difference between the observed consumption level and those at the bottom of the ergodic distribution. We show that the process can revert to the latter once we observe a financial crises. Thus, memory matters in order to capture the quantitative properties of the sudden stop and the GME is capable of capturing it.

We also compute the effects of a change in the interest rate in the long run of the model, and show that it is possible to remove the ergodic component of any selection in a GME, this selection is still time invariant and thus, stationary. We then compute the difference between simulations generated by an ergodic and a stationary GME equilibrium. We find that ergodic simulations generate *smoother* consumption paths or, equivalently, agents are *less financially constrained*. Additionally, we compute for reference the non-stationary GME, and compare the stochastic properties of these GME with ergodic GME selectors. As it is expected, this equilibrium can generate large fluctuations in macroeconomic fundamentals (i.e. current account) using standard preferences and with the same shock structure. That is, simply by changing the definition of equilibrium, if we are willing to give up the long run performance of the model, the same theoretical structure is capable of generating a great range of balance of payments crises. There are at least 2 important differences between the ergodic and the stationary selections. In the latter simulations overestimate i) the elasticity of average consumption and debt with respect to the interest rate, ii) the volatility of consumption for a given interest rate, which implies that debt is less volatile.

²See Stokey, Lucas and Prescott, ([71], chapters 11 and 12), for example.

³See Mendoza and Smith ([46]) for a discussion of the importance of this point.

In the end, given our existence results on both SCE and/or RE, we are also to compare rigorously minimal state space equilibrium paths with GME's realizations within the context of GME's "long memory" representation of SCE. Per this comparison, if one uses minimal state space RE, the stochastic dynamics are obtained for consecutive periods, hence create dynamic sequential equilibrium representations that are "short memory". The GME representations, as they are computed directly from the SCE, bring into the picture the relevance of "modeling memory" to understanding the model's relation to observed data. A critical issue with modeling memory is how to build useful criterion for GME selections. If it is possible to construct a finite time path from the sequential equilibria such that GME selections hit the collateral constraint, we can construct a natural GME selection criterion based upon ergodicity, which allows us to match observed stylized facts and at the same time choose the appropriate selection from the equilibrium correspondence. Short memory paths can be embedded into the GME, allowing us to get short term match with data. At the same time, due to the existence of "longer memory" equilibrium, we can tie the deep parameters of the model to the long run behavior of the same observed time series. In other words: we show that there exist a selection which insures ergodicity and it is also compatible with the presence of multiple different "phases" of crises, which may have variable time spells.

Finally, and of independent interest, in addition to providing existence results for SCE and RE, the paper provides a *complete and constructive qualitative theory* of equilibrium comparative statics relative to the *set* of RE for this class of models in important deep parameters of the economy.⁴ Establishing the existence and equilibrium comparative statics results for the set of RE is important for these class of models. First, RE form an important subclass of sequential equilibria in our economies for many reasons, and there are no known results on sufficient conditions for such RE to exist. Second, much of the existing literature which apply these models actually presumes RE exists, and focuses on its computation (e.g., Bianchi ([12]). Third, by focusing on RE if they exist, one can sharpen the characterization of the structural properties of equilibrium dynamics as its nature is greatly simplified. This allows use to identify *sharply* the *global* sources of multiple equilibria in this class of models. We prove the existence of least and greatest minimal state space RE, and our methods also able to provide the first set of equilibrium comparative statics results in the deep parameters of the model in the literature. The two-step approach developed in this paper is in the spirit of recent work of Datta, Reffett, and Wozny ([23]) on characterizing models with multiple equilibrium and dynamic equilibrium complementarities, but adapted to a much more general setting of equilibrium price-dependent collateral constraints.

The existence of a monotone operator in the present class of models is based upon identifying a *equilibrium single-crossing* condition that arises in the equilibrium structure of the household's Euler inequality in a candidate set of RE. This single crossing condition critically only appears in *subclasses* of dynamic equilibrium, and is shown to arises between household tradeables consumption decisions in a RE and their per-capita aggregate counterparts (when per-capita aggregate tradeables consumption is used to parameterize the relative price of non-tradeables). The equilibrium single crossing condition holds in any state where the model with the price dependent collateral constraints "hits". In a very precise sense, the paper therefore provides an *global* formalization of the "self-fulfilling" nature of multiple equilibrium as discussed in the recent papers of Schmitt-Grohe and Uribe ([67], [68]) and Bianchi and Mendoza ([16]) relative to the set of RE.

The intuition of the self-fulfilling nature of multiple equilibrium in a RE is simple. For a typical household in a candidate RE parameterized by a function for per-capita aggregate tradeables consumption (say, denoted by $C^T(S)$ where S denotes the aggregate state variables in the economy, and where C^T implies the aggregate law of motion for aggregate borrowing/debt), then *in equilibrium*, if a typical household takes are given a "low" (resp., "high") C^T for aggregate tradeables consumption (and associated aggregate borrowing), the associated equilibrium price-dependent collateral constraint is relatively tight (resp., relatively relaxed), and this implies the household has relative low (resp., high) levels of tradeables consumption/borrowing. Then, we show this "belief" in low (resp., high) borrowing can be made "self-fulfilling" when the nature of equilibrium complementarities is sufficiently large implying the existence of least (resp., greatest) fixed points of our monotone RE operator.

⁴This paper considers the case discrete iid endowment shocks. Introducing Markov shocks on continuous shock spaces is a significant complication. and requires typically order continuous approaches to the existence of RE question. See Pierri and Reffett ([57]).

Previous work on multiple equilibrium in these models stems from the important work of Schmitt-Grohe and Uribe ([67], [68]). A limitation of their approach is that it was based entirely on the *deterministic* version of the model, and in particular sequential equilibrium behavior "local" near a (deterministic) steady-state. Our results show the construction that Schmitt-Grohe and Uribe identify in their work relative to the source of multiple equilibrium in these models is *global* and arises from the existence of an equilibrium complementarity in prices of the *stochastic* version of the model, implying the existence of *multiple* stochastic stationary equilibria. As these are *stochastic* dynamic equilibrium models, where the object of interest from a quantitative point of view is the stochastic steady state of the model (i.e., the stationary equilibrium), we are interested in establishing the existence of multiplicities from a global perspective and then using these results to match observed data relative to predicted stochastic equilibrium dynamics. So questions of ergodicity, existence of invariant measures for stationary Markov equilibrium and multiplicities introduce key complications into the analysis.

1.2 This Paper and the Existing Literature

The literature on Sudden Stops and financial crises in emerging economies has been voluminous over the last two decades. The empirical regularities of Sudden Stops that characterize Sudden Stop in emerging markets are well-documented in many papers including Mendoza ([45]) and Bianchi and Mendoza ([16]), and include the following: Sudden Stops are (a) infrequent, (b) involve reversals of international capital flows and current accounts, as well as the abrupt loss of access to international capital markets, (c) create severe economic downturns in output, consumption, and investment, where collapses in business cycle variables are preceded by economic expansions, and then followed by long and protracted economic slumps, (d) typically involve contemporaneous collapses of equity prices and real exchange rates during the crisis, which are also preceded by run ups of equity and exchange rate values, and then their collapse, (e) tend to occur during big global financial events.⁵

A large theoretical literature has emerged seeking to explain these empirical regularities. What is common to all these theoretical papers in the literature is the importance of equilibrium price-dependent collateral constraint in understanding the structure and genesis of the emerging market financial crises. The theoretical literature begins with the important papers by Mendoza ([44], [45]), Mendoza and Smith ([46]), Bianchi and Mendoza ([13]), and Bianchi ([12]), but has continued with many recent papers exploring the different dimensions of Sudden Stops and emerging market financial crises.⁶ These equilibrium collateral constraints, in particular, are critical in explaining not only the mechanism by which financial crises occur (e.g., the presence of binding borrowing constraints that forces emerging economies to pay down past debts, creating a possible collapse in tradeables consumption, prices, and current accounts), but the observed co-movement in between measurements of the financial crises and important macro aggregates such as consumption, output, debt, and prices over the business cycle (e.g., in providing a Fisherian deflation narrative to understanding the emergence and structure of financial crises in emerging markets).

The class of models we study in this paper (i.e., the endowment two-sector version of the small open economy model of Sudden Stops) was proposed in Bianchi ([12]), and studied also extensively in a series of recent papers by Schmitt-Grohe and Uribe ([66], [67], [68]). Relative to the work of Bianchi ([12]), we extend his result in number directions. First, for this class of models, we prove we prove the existence of RE, characterize the structural properties of such RE on a minimal state space, provide a complete qualitative theory of how the *set* of RE vary in the deep parameters of the model, and provide a simple successive approximation algorithm for computing RE comparative statics. These existence results are novel to this literature. Additionally, as in Bianchi ([12]), we study global stochastic equilibrium properties that are induced by the *set* of RE within the context of a GME representation. The GME setting allows us to address many new and interesting questions. For example, we can compare the stochastic properties of stationary equilibrium and its relationship with the long-memory structure into

⁵See also the recent paper of Pierri, Montes, Rojas, and Mira ([56]) for further discussion of the nature of Sudden Stops, and and discussion of the related empirical literature.

⁶For a discussion of this extensive recent theoretical literature, see Bianchi and Mendoza ([16]) and Schmitt-Grohe and Uribe ([67]).

the GME representation of SCE,⁷ and then compare the stationary equilibrium properties of such GME representations to the properties of stationary Markov equilibria induced by the set of RE of the model. We find that incorporating long-memory is important in fitting the anatomy of the observed financial crises.

Relative to the work of Schmitt-Grohe and Uribe (eg., [67], [68]), the approach taken in this paper is very different, but related. First, as mentioned earlier, our approach to the study of dynamic equilibria is very different, built on global stochastic equilibrium constructions. Second, exploiting the same sources of multiplicities they discuss in the context of SCE, we take a very different quantitative approach via GME methods. In Schmitt-Grohe and Uribe's work, they characterize stochastic SCE dynamics using technique building "stationary sunspot" approaches (e.g., see related work in Woodford ([75]) and Schmitt-Grohe ([63]), for example). Our GME approach makes no mention of local steady state structure, local sunspot equilibria, or even the determinist steady state. Rather, GME is *global* approach to stationary equilibrium, studies stochastic dynamics from *arbitrary initial conditions*, and builds the theory of modeling multiple equilibrium, memory, and the associated stationary equilibrium from vantage point of selectors from the set of GME representations of SCE. What is critical in our approach to study stochastic properties of GME selections using the "hit" times for equilibrium collateral constraint relative to stochastic equilibria, and use the borrowing constraint itself to regenerate the equilibrium Markov process associated with the set of GME.⁸ In particular, we can distinguish *ergodic GME selectors* versus invariant GME selectors, and we show in Section 5 of the paper, this flexibility appears very important in matching the structure of observed financial crises within the context of the long-run run stochastic behavior of other macroeconomic aggregates.

Our GME approach is general and can be potentially be applied in other important models of Sudden Stops found in the existing literature. In particular, we the GME approach in this paper can be extended to some Sudden Stop models with production. Versions of the models with production include the early papers of Mendoza ([44]) and Mendoza and Smith ([46]), as well as the series of interesting papers by Benigno, Chen, Otrok, Rebucci, and Young (e.g., see [8], [9], [10]). and Deveraux and Yu ([24]).⁹

Our paper also relates to an emerging literature that seeks to characterize dynamic model with equilibrium borrowing constraints (or occasionally-binding constraints). Relative to this literature, we provide a new set of methodological tools for characterizing RE and SCE stochastic dynamic equilibrium dynamics in model equilibrium price-dependent collateral constraints. This means the tools could be useful on other related dynamic equilibrium models, including models of credit cycles in the spirit of Kiyotaki and Moore ([34]),¹⁰ models of financial frictions and productive with collateral constraints such as Moll ([51]), or models of self-fulfilling credit cycles such as Azariadis, Kaas, and Wen ([7]).

This paper also contributes to the growing literature on GME methods in the study of self-generation via strategic dynamic programming approaches to dynamic stochastic general equilibrium models (DS-GEs) in the literature. These self-generation techniques were first introduced in the repeated games in the Abreu, Pearce, and Stacchetti ([1], [2]) and as well as stochastic games by Mertens and Parthasarathy ([48]), and are related to implementations of the methods for studying the existence of Markovian equilibrium in dynamic stochastic models/games found in Blume ([17]) and Duffie, Geanakoplos, Mas-Colell, and McLennan ([25]). Approaches to making operational these methods in the context of GME representations and enlarge state spaces stems from the work of Kydland and Prescott ([38]), Phelan and Stacchetti ([54]), Kubler and Schmedders ([37]), Feng, Miao, Peralta-Alva, and Santos ([27]), and Cao ([19]). A novel aspect of this paper is that by exploiting the structure of equilibrium price-dependent collateral constraints, we are able to propose a systematic approach to SCE selections, based upon ergodic GME selectors.

Relative to this literature, at least Blume ([17]), when studying stochastic stability, it has along been

⁷In this paper, we reserve the term "stationary equilibria" to be invariant measures and/or ergodic measure induced by the GME representations of the models stochastic equilibrium dynamics. So Stationary equilibria are a type of stochastic steady state of the model.

⁸In this sense, our approach to characterizing stochastic dynamic equilibrium and stationary equilibria using "hit" times is somewhat reminiscent to work in using deterministic versions of these models as in Schmitt-Grohe and Uribe ([68]).

⁹See Pierri and Reffett ([57]) for a discussion.

¹⁰See the survey of Gertler and Kiyotaki [31] for a nice discussion of this large literature on price dependent collateral constraints, credit cycles, and economic fluctuations, as well as Kiyotaki and Moore ([35]) for recent work along these lines.

recognized the trade off between the multiplicity of sequential equilibria and the smoothness properties of the associated recursive representation. In other words, the presence of multiple equilibrium can generate discontinuities in minimal state space transition functions. In some cases, by enlarging the state space, it is possible to obtain a continuous Markov equilibrium (see Martinez and Pierri, [29]); but unfortunately, there is no general theory about how to do this (see Kubler and Schmedders, ([36]), for a counter-example). Interestingly, in the context of models with price dependent collateral constraints, we show that the GME methods we develop in section 4 are critical in the presence of this type of discontinuities, which may affect the existence of an ergodic equilibrium. Both RE and SCE via GME representations are robust to the presence of "non-smooth" and "discontinuous" selections. Using the set of GME, we can add memory to the analysis, which in turn is deeply connected with the presence of multiple equilibrium, and at the same time find a well behaved stochastic steady state. Thus, it is critical to investigate if the multiplicity of equilibrium is a serious issue. Section 5.1 takes the model in section 2 and shows that it is possible to obtain multiple equilibrium when the collateral constraint binds for a *wide range of parameter values*. We show that the number of possible exogenous shocks is critical to generate multiplicity. Our approach to this issue is novel in a *stochastic* setting (for instance, Schmitt-Grohe and Uribe ([67]) discussed these issues in the setting of a non-stochastic steady state of the economy).

Finally, our work also directly related to the literature on the equilibrium comparative statics in dynamic economies, as well as monotone-map methods and equilibrium policy iteration. The latter literature includes the papers of Coleman ([20]), Reffett ([58]), Datta, Mirman, and Reffett ([22]), Morand and Reffett ([52]), and Mirman, Morand, and Reffett ([50]), among others. In a recent paper, Datta, Reffett, and Wozny ([23]) propose a multistep monotone map methods that is especially suited for dynamic models with multiple RE. Our paper relates this latter paper by extending the class of multi-step monotone map method to dynamic models with equilibrium price-dependent collateral constraints. In addition, our paper is related to Mirman, Morand, and Reffett ([50]), Acemoglu and Jensen ([3]), and Datta, Reffett, and Wozny ([23]) as it provides sufficient conditions for monotone dynamic equilibrium comparative statics in the deep parameters of the economy. In particular, this paper extending these results into the dynamic models with equilibrium price-dependent borrowing constraints.

The paper is organized as follows: section 2 discusses the model, section 3 presents the results for the RE, section 4 contains the results for the GME and section 5 contains applications to a) different anatomies of short run crises, b) multiple equilibrium in a stochastic setting, c) solve the model, compute and simulate ergodic, stationary and non-stationary equilibrium. Section 6 concludes.

2 The Model and Sequential Competitive Equilibrium

We consider the endowment version of the two-sector small open economy model studied in Bianchi ([12]) and Schmitt-Grohe and Uribe ([67], [68]).¹¹ This is a workhorse model in the international finance and macroeconomics literature for the study of emerging market debt crisis and sudden stops and abstracts from production.¹² We choose the endowment version this model as it allows us to focus on the issues at hand in this paper, the importance of modeling of memory in the presence of multiple equilibrium, both from a qualitative and quantitative perspective.

As is well know, what is critical in these models is presence of occasionally binding *price dependent* equilibrium collateral constraints, and how those constraints introduce pecuniary externalities in equilibrium tradeables consumption via prices, we do not feel this abstraction from production is important. We is novel in this paper is we show how pecuniary externalities actually introduce an class of "pecuniary complementarities" in equilibrium tradeables consumption, and we show how such complementarities are one key source multiple equilibrium, and give rise to a rich potential set of stochastic equilibrium dynam-

¹¹For related studies of sudden stops using the endowment version of the two-sector model of Bianchi ([12]), see Bianchi, Liu, and Mendoza ([14]) and Arce, Bengui, and Bianchi ([6]), Lutz and Zessner-Spitzenberg ([41]),

¹²Although this paper studies the endowment version of the two-sector small open economy model, our methodological approach can be extended to setting with production. The model (and our approach) can be extended to models with production such as Mendoza ([44]), Mendoza and Smith [46]), Biachi and Mendoza ([13]), the series of papers by Benigno, Chen, Otrok, Rebucci, and Young (e.g., [8], [10]), and Devereux and Yu ([24]), among many others.

ics, critical to explaining the observed regularities in the data when the generalized Markov equilibrium of the model is calibrated to actual data.

The model is a small open economy with a fixed global interest rate that takes place in discrete time over an infinite horizon with time denoted by $t \in \{0, 1, 2, \dots\}$. There is a representative agent and 2 sectors of finished consumption goods in the economy, a tradable consumption good y_t^T and a non-tradable y_t^N consumption good. Each household is endowed a strictly positive amount of each good in each period. Upon receiving their current period endowments, households sell off their endowments at current market prices and choose consumption of both goods where the consumption of tradeables and non-tradeables is denoted, respectively, by c_t^T and c_t^N . It turns out to be useful to take as the numeraire the tradable good, so the relative price of non-tradeables relative to the numeraire tradeables in period t is denoted by p_t .

Household preferences are defined over infinite sequences of dated consumption vectors of tradeables and non-tradeable goods $c_t = (c_t^T, c_t^N) \in X \subset \mathbf{R}_+^2$ where X is the commodity space for consumption of tradeables and non-tradeables in each period, and are assumed to be time separable. These preferences are represented by a nested utility function which is a composition of two functions: a utility over composite consumption $U : \mathbf{R} \rightarrow \mathbf{R}$, and an aggregator $A : X \rightarrow \mathbf{R}$ over tradeables and non-tradeables consumption $c_t = (c_t^T, c_t^N)$, where the preferences $U(A(c))$ gives the instantaneous utility of the vector of consumptions $c \in X$ in any period. We also assume discounting with $\beta \in (0, 1)$ the subjective discount factor. Then, the lifetime discounted expected utility preferences of a typical household has the form:

$$E_0 \sum_{t=0}^{\infty} \beta^t U(A(c_t)) \quad (1)$$

where the mathematical expectation operator here is taken over the stochastic structure of uncertainty with respect to the date 0 information.¹³

Uncertainty in the economy is modeled as an iid stochastic process governing tradeables endowments $y = \{y_t^T\}_t$ where each element of sequence y as distribution given by the measure $\chi(\cdot)$. Here, for convenience, we assume the sequence of non-tradeables endowments $\{y_t^N\}_t$ is non-stochastic, as it plays no role in the characterization of stochastic equilibrium dynamics in this paper. We assume further that the realizations for tradeables endowments in any period denoted by $y_t^T \in Y$ has a shock space Y that finite set.¹⁴ These assumptions on shocks implies by an application of standard results that it is possible to define a stochastic process $(Y_\infty, \Omega, \mu_{y_0^T})$ which takes realizations in each period in Y .¹⁵ Then, denote by Y_∞ the space of infinite sequences in Y , and assume $y_0^T \in Y$ is the initial condition for this stochastic process for tradeables.

Household face a sequence of budgets constraints when they make their sequential choices for consumption and debt over their lifetimes. In particular, given a candidate price sequence $p = \{p_t\}_{t=0}^\infty$, and denoting the net debt position for a typical household with debt borrowed at date t but maturing at date $t + 1$ by d_{t+1} , the budget constraint for a household in any period t is given by:

$$c_t^T + p_t c_t^N + d_t = y_t^T + p_t y_t^N + \frac{d_{t+1}}{R} \quad (2)$$

where agents are allowed to borrow or lend at a fixed interest rate $R = 1 + r$ and, as this is a small open

¹³A typical functional form for $A(c)$ in the literature is the Armington/CES aggregator

$$c_t = A(c_t^T, c_t^N) = [a c_t^T \frac{1}{1-\xi} + (1-a) c_t^N \frac{1}{1-\xi}]^{\frac{1-\xi}{1-\xi}}$$

with $\xi > 0$, $a \in (0, 1)$, which is increasing, concave, and supermodular on X when $X = \mathbf{R}_+^2$.

¹⁴All the results of sections 2 and 3 of the paper concerning the existence of sequential competitive equilibrium and recursive equilibrium hold for more general shocks (i.e., endowment processes for tradeables consumption that follow a first order Markov process with stationary transition $\chi(y^T, y^{T'})$), but with substantive difference in proof. See Pierri and Reffett ([57]) for a discussion. For this paper, for quantitative purposes, such generality is not essential, we abstract from the complications of a continuous shock space and Markovian structure of shocks.

¹⁵e.g., see Stokey, Lucas and Prescott ([71], chapter 7)).

economy, R is taken as given.¹⁶ We also in the paper when developing sequential budget constraints follow the timing convention used in Schmitt-Grohe and Uribe ([67], [68]), and assume consumption and income decisions are taken at the beginning of the period, and interest is then paid/earned over that same period. We adopt this timing only because it proves to be convenient in characterizing the structure of dynamic equilibrium.¹⁷

In addition to the budget constraint in (2), a typical household agent also faces a period by period flow collateral constraint on debt given by:

$$d_{t+1} \leq \kappa(y_t^T + p_t y_t^N) \quad (3)$$

where $\kappa > 0$. This is the critical friction in the model.¹⁸ We should note, this paper does not focus on steady state equilibrium analysis, rather on the global stochastic structure of sequential or recursive equilibrium.

A few remarks on this model are in order at this stage. First, the collateral constraint in (3) is an occasionally binding equilibrium price-dependent collateral constraint. That is, in what states the collateral constraint binds is *endogenous*. This fact, in conjunction with its implicit equilibrium complementarities it can induce is the key friction in this class of economies. As has been shown in Bianchi ([12]) and Schmitt-Grohe and Uribe ([66], [67],[68]), among many related papers, the presence of this price-dependent collateral constraint introduces a pecuniary externality into this dynamic equilibrium structure of economy. What is new in this paper is that we shall characterize this pecuniary externality as a global equilibrium pecuniary complementarity (i.e., it induces an equilibrium single-crossing condition between individual tradeables consumption and their per-capita aggregate counterparts when equilibrium collateral constraints bind). This equilibrium single-crossing condition appears via the following simple mechanism: as the relative price of tradeables to non-tradeables p_t is increasing in the per-capita level of tradeables consumption in equilibrium, when agents believe in equilibrium paths for per-capita tradeables consumption will be "higher", the equilibrium collateral constraint is relaxed, allowing household tradeables consumption to expand via access to additional debt. This dynamic equilibrium complementarity generates an implicit (equilibrium) monotone relationship between per-capita tradeables and household tradeables consumption, and becomes the single *global* source of multiple dynamic equilibria in this economy in both sequential competitive equilibria, as well as (minimal state space) recursive equilibrium.

Second, in many alternative versions of these models, agents have access to at least two assets, with only one of them subject to price-dependent equilibrium collateral constraint (e.g., see Mendoza and Smith ([46])). This choice of multiple assets is relevant often to understand the quantitative implications of borrowing constraints when such borrowing constraints bind in equilibrium, allowing one to further capture the "spiraling" process of "fisherian deflation" associated with a sequence of descending equilibrium prices. In this case, the deflation is caused by a real exchange rate depreciation occurring after a balance of payment crises. In models with two assets, this "deflation" simply occurs as a consequence of an equilibrium sell-off in the pledgeable assets in order to obtain resources needed to allow agents to smooth consumption. Further, the theoretical approaches to constructing and characterizing dynamic equilibrium in such multi-asset models does not change substantially, so in this paper we focus on the single asset case which facilitates comparisons with the existing literature.

Finally, another distinctive characteristic in constraints (2) and (3) is the absence of default. In the general equilibrium literature, agents are allowed to default by paying with the value of the collateral

¹⁶In some cases in the literature, this interest rate is interpreted as the steady-state real interest rate, and therefore influences the parameterization of price-dependent collateral constraints (e.g., as in Schmitt-Grohe and Uribe ([66], [67], [68])). As our approach to studying dynamic equilibrium is global, such considerations are not necessary to impose. But often in quantitative work later in the paper, for sake of comparison with related work in the literature, we follow this practice. When interpreting the interest rate R as the steady-state interest rate, we follow Schmitt-Grohe and Uribe ([67], [68]), and assume $\kappa \in (0, \frac{1+r}{r})$ as this makes the collateral constraint economically meaningful in this context (i.e, the collateral constraint is not necessarily slack at the a natural limit on debt).

¹⁷Bianchi ([12]) uses a slightly different timing convention, but it turns out this timing convention is without loss of generality in our case (see, for example, Adda and Cooper ([4]) for a detailed discussion of this matter).

¹⁸As is well-known in this literature, one can write down more fundamental versions of this model where this debt constraint emerges as an equilibrium object from the primitives of the underlying economy. For our purposes, we just follow the literature and impose this form of a collateral constraint.

instead of facing the nominal value of debt (see , for instance, Kubler and Schmedders ([37])). To our knowledge, the literature has not addressed the effects of over-borrowing in sovereign default decisions.

2.1 Existence of Sequential Competitive Equilibrium

We first consider sufficient conditions for the existence of a sequential competitive equilibrium (SCE). In a SCE for this economy, the representative household takes as given an interest rate R , a level of initial debt $d_0 \in D$ (where $D \subset \mathbf{R}$ is a compact set of debt states which will be constructed in a moment), a stochastic process governing $y^T = \{y_t^T\}_{t=0}^\infty$ conditional on an initial level of tradeables endowment $y_0^T \in Y$ with $y_0^T > 0$, a constant level of non-tradeables endowment $y_t^N = y^N$, a history-dependent sequence of measurable prices $p = \{p_t(y^t)\}_{t=0}^\infty$, where we use the notation $y^t = \{y_0^T, y_1^T, \dots, y_t^T\}$ to denote the history of tradeables endowment realizations up to period t , and maximizes lifetime utility in (1) subject to constraints (2) and (3) for each time period. That is, given $R \geq 0$, d_0 , the stochastic processes p and y , the household solves the following:

$$V^*(s_0, p, R) = \max E_0 \sum_{t=0}^{\infty} \beta^t U(A(c_t)) \quad (4)$$

$$c_t^T + p_t c_t^N + d_t = y_t^T + p_t y_t^N + \frac{d_{t+1}}{R}; \quad d_{t+1} \leq \kappa(y_t^T + p_t y_t^N), t \in \{0, 1, 2, \dots\} \quad (5)$$

where the initial states are $s_0 = (d_0, y_0^T)$, and $y_0^T \in Y$. We denote the optimal policy sequences for consumption and debt achieving the maximum on (4) by

$$c^*(s_0, p, R) = \{c_t^*(s_0, p, R)\}_{t=0}^\infty; \quad d^*(s_0, p, R) = \{d_t^*(s_0, p, R)\}_{t=0}^\infty \quad (6)$$

where in a moment we shall impose sufficient convexity and continuity conditions on the primitive data of the model such that (a) the value function $V^*(s_0, p, R)$ is finite, and (b) optimal sequences $c^*(s_0, p, R)$ and $d^*(s_0, p, R)$ are well-defined and unique.

Under standard convexity, continuity conditions, and continuous differentiability assumptions on preferences, by well-known arguments (e.g., Rincon-Zapatero and Santos ([59]), theorem 3.1), there exists a well-defined standard Lagrangian formulation for the sequential primal problem in (4) with (summable) dual variables $\beta^t \lambda_t$ and $\beta^t \lambda_t \mu_t$ associated with the sequence of constraints (2) and (4), respectively. Noting our constrained system satisfies sequential linear independence constraint qualifications, strong duality holds between the resulting Lagrangian formulation and the primal program in (4) and the infinite dimensional system of KKT multipliers are well-defined and unique. We can then formulate the system of first order conditions for this problem in a sequential competitive equilibrium using the Lagrangian dual as follows: the optimal stochastic processes $c^*(s_0, p, R)$ and $d^*(s_0, p, R)$ satisfy

$$\lambda_t^* = U'(A(c_t^*)) A_1(c_t^*) \quad (7)$$

$$p_t = \frac{A_2(c_t^*)}{A_1(c_t^*)} \quad (8)$$

$$\left[\frac{1}{R} - \mu_t^*\right] \lambda_t^* = \beta E_t \lambda_{t+1}^* \quad (9)$$

$$\mu_t^* [d_{t+1}^* - \kappa(y_t^T + p_t y_t^N)] = 0, \mu_t^* \geq 0 \quad (10)$$

A sequential competitive equilibrium for this economy is then defined as follows:¹⁹

Definition 1 *Sequential Competitive equilibrium (SCE) is a collection of progressively Ω -measurable random variables for consumption $c^*(s_0, p^*(s_0, R), R)$, debt $d^*(s_0, p^*(s_0, R), R)$, and relative prices of nontradeables to tradeables consumption $p^*(s_0, R)$ such that: 1) the representative agent chooses $c^*(s_0, p^*(s_0, R), R)$, $d^*(s_0, p^*(s_0, R), R)$ to solve (4) given s_0 at $p^*(s_0, R)$ such that $V^*(s_0, p, R)$ is finite and equations (7-10) hold, and 2) markets clear $c_t^{N*}(s^t) = y^N$ where y^t holds $\mu_{y_0^T}$ -a.e*

¹⁹In the appendix, where we prove existence of sequential competitive equilibrium, we had the formalities of measurability of SCE processes more rigorous. See the details there.

We first consider the question of existence of SCE. Before mentioning the sufficient conditions we propose, we need to mention a few key technical issues that arise when studying the structure of SCE in stochastic infinite horizon debt models that motivate the sufficient conditions for existence we propose. A first critical object to place enough structure on the model we can characterize the set of *stochastic steady state* distributions (i.e., the set of *stationary equilibrium*). This stationary equilibrium can be associated with either the SCE and/or the recursive equilibrium of the model. As a stationary equilibrium is *global stochastic equilibrium* object, we need to impose sufficient structure on the model such that we can obtain sufficient boundedness (actually, compactness) for the models stochastic equilibrium dynamics.²⁰ In the existing literature, the question of how to provide lower and upper bounds for stochastic equilibrium paths for endogenous variables in small open economy frameworks such as ours has not been addressed. Yet, it is well known that in stochastic models of debt, issues related to lower and upper bounds can be delicate.

To impose such sufficient structure on the economic primitives to obtain such lower and upper bounds on stochastic sequential equilibrium dynamics, in the extensive existing literature on stochastic debt models, typically sufficient conditions involve bounds on the marginal utility of c^T in addition an otherwise standard conditions on these model in applications. These bounds are guaranteed to hold by slightly modifying standard preferences in the literature in a manner we will define in a moment when we state our sufficient conditions for existence of SCE. What is critical to note here is that these type of restrictions *do not affect the stochastic dynamic behavior* of the model when compared to the more "traditional" CES preferences (as we shall discuss in the quantitative section of the paper in section 5). They are simply critical to insure the necessary compactness of the sequential equilibrium set, as well as provide the basis for the existence of a stationary and compact state space in both the SCE and recursive formulations of the dynamic equilibrium of the model. That is, when studying the quantitative stochastic properties of these models in calibrated settings, compactness of the state space is often present without these types of "boundary" conditions on preferences.

The rest of the section is devoted to show that any sequential competitive equilibrium in this economy is compact in the sense that realizations of equilibrium random variables are all contained in a compact subset of a finite dimensional space. This property is essential to define a proper Markovian representation. We state our assumptions on the primitive data of the model as follows:

Assumption 1: The functions $U(x)$ and $x = A(c)$ satisfy the following: a.i) $\lim_{x \rightarrow \infty} U'(x) = 0$ or a.ii) $\exists x \in X$ such that $\forall y \in B_\epsilon(x) \quad U(y) \leq U(x) \quad \epsilon > 0$, a.iii) $A(0) \neq 0$, b) $\mathbf{R}_+^2 \subset X, X$ open, c) $A_1(c) = A_1(c_1)^{21}$, d) $A_2(c) = A_2(c_2)$, e) $\lim_{c_1 \rightarrow \infty} A_1(c_1) = cl_1 > 0$, f) $\lim_{c_1 \rightarrow 0} A_1(c_1) = cu_1 < \infty$, g) $U(A(c)) : X \rightarrow \mathfrak{R}$ is continuous, strictly increasing, concave.

When the existence of recursive competitive equilibria in the next section of the paper, as the equilibrium dynamical system are greatly simplified in such a representation, we can also allow for the following case of preferences:

Assumption 2. $U(x)$ satisfies the Inada condition $\lim_{x \rightarrow 0} U'(x) \rightarrow \infty$.

We make a few remarks on these assumptions. Assumption 1.a.ii can be used to prove the existence of any SCE only in the case where $\beta R \geq 1$, which is typically missing in the literature. It simply says that lifetime preferences must have an asymptotic "satiation point" $x \in X$. As these preference structure affects the underlying stochastic process significantly, attracting equilibrium paths to the satiation point, we defer the treatment of this case to a companion paper. Thus, we focus in the traditional case (i.e. $\beta R < 1$). Assumption 1.a.iii gives us some flexibility in the choice of U , as it automatically implies that $U'(c)$ will be well behaved when $c \rightarrow 0$. Assumption 1.b, 1.e, and 1.f insures sequential equilibrium prices

²⁰Questions concerning the existence and characterization of the stochastic steady state (e.g, stationary equilibrium) the results in Schmitt-Grohe and Uribe ([64]) involve the *non-stochastic steady state*, which is not relevant for the purpose of this paper, or the formulation of Assumption 1. We would like to thank Javier Garcia Cicco mentioning this fact to us.

²¹The notation A_j denotes the partial derivative with respect to the $j = 1, 2$ argument of A .

are bounded above and bounded below away from zero. This, in turn, will imply that in a SCE, debt is bounded above due to the collateral constraint in (3) and bounded below as wealth will be finite at every possible node. It is possible to relax Assumption 1.e and 1.f by restricting the superdifferential, the set which includes all possible supergradients, of the concave mapping c on X to be compact. However, in applications, preferences are assumed to be stronger than Assumption 1.g and continuously differentiable. In this case, the strengthening of Assumption 1.e and 1.f can be done without loss of generality.

We also remark, that in the case of the study of RE (and its existence), we can replace Assumption 1.f with Assumption 2 (the standard Inada condition case). This is because in a RE, the characterization of stochastic equilibrium dynamics can be greatly sharpened, allowing us to characterize the (strong) interiority properties of equilibrium dynamics paths. Finally, Assumption 1.g is standard in the general equilibrium literature (see for instance Braido ([18])). In applications, Assumption 1.g will be insured by assuming that the set X is uniformly bounded below, $U : \mathbf{R} \rightarrow \mathbf{R}$ and $A : X \rightarrow \mathbf{R}$ are both increasing, concave and twice-continuously differentiable.

We now state our first critical result in building SCE: ²²

Lemma 2 *Suppose $\beta R < 1$. Under assumptions 1-a.i, 1-a.iii, 1-b to 1-g, if a SCE exists, it must satisfy (54),(55) and $\lim_{t \rightarrow \infty} \beta^t E_t(U'(A(c_t^*))A_1(c_t^*)) = 0$. Moreover, if (c, d, p) in is a SCE, then $[c(y^t), d(y^t), p(y^t)] \in K_1 \times K_2 \times K_3 \subset \mathbb{R}^4$ y^t -a.e. and uniformly in $[y_0, d_0] \in Y \times K_2$, where $K_1 \times K_2 \times K_3$ is compact.*

We mention that following the results in [59], Lemma 2 gives an equivalent characterization of the SCE in terms of the equations (7)-(10) with well defined sequential KKT multipliers that we use in the appendix. Also, notice that this lemma does not guarantee the existence of the SCE, which will be considered in Theorem 3 below.

As we are allowing the cardinality of Y to be arbitrarily large, proving the existence of this type of equilibria can be rather challenging (See, for instance, Mas-Colell and Zame, [42]). Once the almost every where compactness of any "suitable candidate for equilibria" (c, d, p) is proved using lemma 2, the existence of the SCE will be proved assuming that Y is a finite set. MasColell and Zame ([?]) needed to state by assumption the uniform compactness of the SCE for the case of uncountable shocks. As it is natural, to show the existence of a recursive representation in this last case, we must impose the same assumption. The sequence of remarks which follows the Theorem 3 go deeper into this topic.

Finally, Lemma 2 shows necessity of Assumption 1 for the existence of a sequential equilibrium. The following theorem shows sufficiency.

Theorem 3 *Suppose $\beta R < 1$ and the Y is a finite set. Under Assumptions 1-a.i,1-a.iii, 1-b -1-g, there exist a SCE*

The following set of remarks are connected with the results shown above.

Remark 4 *The existence of the SCE for an uncountable set of shocks could be shown using the arguments in Mas-Colell and Zame ([42]). The authors showed existence assuming the uniform compactness of the equilibrium variables for an economy with an uncountable number of i.i.d shocks and finite time. It remains to be verified if the uniform compactness assumption, needed because of the almost everywhere nature of the characterization of the SCE even in finite time, is sufficient to extend the proof to an infinite horizon. However, this paper shows that, in order to study the long run properties of the model, it suffices to assume a finite set of shocks.*

²²All the proofs of the Lemmas and Theorems in the paper are in the Appendix.

Remark 5 *Once the dual minimal state space recursive representation of equilibria is shown to exist in section 3, it is possible to apply standard envelope arguments. Equipped with these results and assuming the absolute continuity of the Markov operator χ , it is immediate to show the existence of a subset of all possible SCE in Definition 1 with Y uncountable and compact and Markov exogenous shocks. Because of lemma 2, the equilibrium will be compact almost everywhere. This result constitutes an extension to Mas-Collel and Zame (1996) and to our knowledge, it has not been shown before.*

2.2 Discussion

The previous subsection characterize the sequential competitive equilibrium for $\beta R < 1$ with Y finite. Thus we are providing sufficient conditions, in the sense that all random variables (c, d, p) have finite realizations, to obtain a stationary distribution for this type of models even if we allow for a stochastic steady state. These findings constitute an extension with respect to previous results in the literature (see for instance Schmitt-Grohe and Uribe ([64])), which provide conditions to insure a stationary long run behavior in a non-stochastic steady state. Taking into account that most applied papers evaluate the effects of alternative economic policies using simulations generated from a computed model, the existence of a well behaved (i.e. stochastic) steady state is critical as it allows for the possibility of convergent simulations.

We will discuss the $\beta R \geq 1$ case in the end of the paper. We found sufficient conditions for compactness which affect the predictions for the long run behavior of the model markedly. In particular, if we endow the model with a satiation point, the equilibrium has a degenerate steady state as consumption converges to a Dirac measure a.e.. It is possible, as in Hansen and Sargent ([33]), to allow for a generalization of this last type of equilibrium by assuming that the satiation point (called "bliss point") is a random variable. Although it can be useful in some applications (i.e. asset pricing with no trading, etc.), this type of equilibrium has really restrictive dynamics. Taking into account the question at hand, we only present conditions for the existence of the SCE at the end of the paper.

An example of the restriction on preferences implied by Assumption 1 can be seen in the table below.

Pref.	Does SCE Exist?	$c > 0$?	MU bounded?	Are Homothetic?
CD	Unknown	YES	NO	YES
LOG	Unknown	YES	NO	YES
CES	Unknown	YES	NO	YES
Mod. CD	Theorem 1	YES	YES, above	NO
Mod. LOG	Theorem 1	YES	YES, above	NO
Mod. CES	Theorem 1	YES	YES, above	NO
Mod. CES 2	Theorem 1	YES	YES, AF zero	NO

Table 1: Restriction on preferences

Where "MU" stands for "marginal utility", "SCE" for "sequential competitive equilibrium" and AF for "away from". Below we provide a concrete parametrization of preferences for each of the cases presented in table 1. Note that Theorem 3 requires MU to be bounded above and away from zero

$$u : X \rightarrow \mathfrak{R}, \quad X \supseteq \mathfrak{R}_+^2, \quad \gamma > 0, \quad c \in X \Rightarrow c + \vec{1}\gamma > 0$$

Mod. CD $(c_1 + \gamma)^\alpha (c_2 + \gamma)^\beta$

The "Mod. CD" preferences are defined over a consumption set which includes the "zero"-vector and γ insures that marginal utility remains bounded above over the entire consumption set, X . The "Mod. LOG" and "Mod. CES" are similar. Just replace $(c_1 + \gamma)^\alpha (c_2 + \gamma)^\beta$ by $\ln(c_1 + \gamma) + \ln(c_2 + \gamma)$ and by $(a(c_1 + \gamma)^\alpha + a(c_2 + \gamma)^\alpha)^{(1/a)}$ respectively with $a > 0$. The "Mod. CES 2" are rather different as they are intended to keep MU bounded away from zero. In particular,

$$\begin{aligned} \text{Mod. CES 2} \quad & (a_1(c_1)^{1-\alpha} + (1-\alpha)a_2c_1 + b_1(c_2)^{1-\alpha} + (1-\alpha)b_2c_2)^{1/(1-\alpha)} \\ u : X \rightarrow \mathfrak{R}, \quad & X \supseteq \mathfrak{R}_+^2, \quad \alpha > 1, \quad a_1, a_2, b_1, b_2 > 0 \end{aligned}$$

If we combine "Mod. CES" with "Mod. CES 2" we insure that MU remains bounded above and away from zero, which in turn guarantees that p is positive and finite. These are sufficient conditions for the existence of an a.e. compact equilibrium.

The non-homotheticity of preferences is a side effect of the boundness requirement. In the literature preferences are typically homothetic. However, Assumption 1 gives an additional source of nonlinearity to the equilibrium dynamics as income effects are not restricted by homotheticity. Recently, Straub ([?]) found that under homothetic preferences consumption is linear in (permanent) income, a fact which is at odds with data. He extends the canonical precautionary savings model (with heterogeneous agents) to include non-homothetic preferences. To our knowledge, the literature on macroeconomic crises has not explored the implications of non-homothetic preferences on the empirical performance of standard models.

More to the point, the proposed utility functions can be made arbitrarily close to their homothetic counterpart (for instance by changing the value of γ accordingly) and the numerical section in this paper suggests that assuming boundedness (instead of imposing restrictions on marginal utility) and using standard CES preferences works in practice. We need bounds on marginal utility to insure the compactness of the equilibrium set in order to complete the existence proof of the SCE (and of any meaningful recursive representation of course). However, we will later show that the minimal state space recursive equilibrium exists even without bound above marginal utility. As the numerical results in this paper use extensively the quantitative implications of this last type of equilibrium, simulations are well behaved under the standard CES preferences.

3 Existence and Characterization of Recursive Equilibrium

Next we construct (minimal state space) recursive equilibrium for our models, as well as provide a complete *constructive* qualitative theory of monotone RE comparative statics. To construct RE, we begin by representing the aggregate economy recursively on a minimal state space. The minimal state space for the (set) of RE will consist of current state variables summarizing the individual state of a representative household and the aggregate state of the aggregate economy. In this economy, in any period of a RE, a household enters the period with an individual level of debt $d \in \mathbf{D} \subset \mathbf{R}$, where \mathbf{D} is compact²³, as well as an endowment of tradeables and non-tradeables denoted by the vector $y = (y^T, y^N)$, where $y \in \mathbf{Y} \times \{\mathbf{y}^{NT}\} \subset \mathbf{R}_{++}^2$. So the *individual state* of the household is characterized by the vector $(d, y) \in \mathbf{D} \times \mathbf{Y}$. The household then faces an aggregate economy that enters the period in an *aggregate state* consisting of per-capita aggregate measures of each of these individual state variables; namely, the vector $S = (D, Y) \in \mathbf{D} \times \mathbf{Y} = \mathbf{S}$, where $D \in \mathbf{D}$ is the per-capita level of aggregate debt, Y^T (resp, Y^N) are the per-capita endowment draws for tradeable (resp., non-tradeables) endowments with vector $Y = (y^T, y^{NT}) \in \mathbf{Y} \times \{\mathbf{y}^{NT}\} \subset \mathbf{R}_{++}^2$. Therefore, the state of a household entering any given period in a RE will be denoted by $s = (d, y, S) \in \mathbf{D} \times \mathbf{Y} \times \mathbf{S}$.

Next, we construct a recursive representation of the aggregate economy on the aggregate state space $S = (D, Y) \in \mathbf{S}$. To do so, and anticipating the structure of RE, first notice the relative price for non-tradeables to tradeables (denoted by $p(C^T)$) in any RE will be equal to equilibrium marginal rate of substitution between non-tradeables and tradeables: i.e,

$$\frac{U_2(C^T, y^N)}{U_1(C^T, y^N)} = \frac{A_2(C^T)}{A_1(y^N)} = p(C^T) \tag{11}$$

where C^T is some per-capita aggregate level of tradeables consumption, and we impose in any RE the fact that $c^N = y^N = Y^N$, where Y^T is constant (and we suppress the dependence of p on the assumed

²³Under Assumption 1(a)-(e) and 1(g), we can take \mathbf{D} compact given results on existence of SCE in Lemma 1 and Theorem 1.

constant level of non-tradeables Y^N). Under the supermodularity and concavity conditions in Assumption 1 relative to the composition $U(A(c))$, we have $p(C^T)$ is increasing in C^T .²⁴

Using equation (11), we can generate a recursive representation sequential prices $p = \{p\{S_t\}\}$ by constructing candidate laws of motion for the per-capita aggregate debt D , which used in conjunction with realizations of endowment $\{Y_t\}$ generate realizations of sequential paths for prices $p = \{p(S_t)\}_{t=0}^{\infty}$. To do this, define a collection of candidate socially feasible per-capita tradeables consumption $C^T : \mathbf{S} \rightarrow [0, c^{\max}] \subset \mathbf{R}_+$ denoted by $\mathbf{C}^f(\mathbf{S})$:

$$C^T \in \mathbf{C}^f(\mathbf{S}) = \{C^T(S) | 0 \leq C^T(S) \leq c^{\max}, C^T \text{ is increasing in } Y, \text{ decreasing in } D \text{ and jointly continuous}\} \quad (12)$$

where from the previous section, under Assumption 1, c^{\max} is finite.²⁵ Endow the space \mathbf{C}^f with the standard pointwise partial order \geq . Then space (\mathbf{C}^f, \geq) is a nonempty lattice in this partial ordering.²⁶ For any element $C^T \in \mathbf{C}^f$, when $C^T(S) > 0$, we can identify an implied law of motion for per-capita debt D by using equilibrium versions of the household's budget constraints and collateral constraints, so the per-capital debt evolves according to:

$$D' = \Phi(S; C^T) = \inf[R\{C^T(S) - Y + D\}, \kappa\{y^T + p(C^T(S))y^N\}], \quad C^T \in \mathbf{C}^f \quad (13)$$

where R is the current interest rate. As D is the only endogenous aggregate state in this economy, in conjunction with the primitives of the stochastic process on the endowment shocks Y , we now have a full characterization of the stochastic transition structure of the aggregate economy in any candidate RE $C^T(S) \in \mathbf{C}^f(\mathbf{S})$. We use this representation of the aggregate economy to parameterize a recursive representation of household dynamic program in a moment.

Before continuing, we make two important remarks concerning the function space \mathbf{C}^f that is used at this stage to parameterize the aggregate economy. First, we must prove the existence of RE within a *strict subset* of functions $\mathbf{C}^*(S) \subset \mathbf{C}^f(\mathbf{S})$, (where the construction of this subspace $\mathbf{C}^*(S)$ will be discussed in great detail later in this section). There are many reasons for this fact. First, there exist elements $C^T \in \mathbf{C}^f$ which do not admit admissible RE representations of SCE prices $\{p(C^T(S_t))\}$. In particular, for $C^T(S) \in \mathbf{C}^f$, we only impose $0 \leq C^T(S) \leq c^{\max} < \infty$, and as $p(0)=0$ for many parameterizations of preferences, $p(C^T) = 0$ whenever $C^T(S) = 0$ in any state. This obviously not consistent with households facing a compact sequential budget constraint (or a compact budget correspondence for any RE formalization). Therefore, it must be for an RE price system p satisfy the basic conditions needed for any SCE, any RE must have $C^{T*}(S) > 0$ for any state S , so $p^u \geq p^* \geq p^l > 0$ in all states $S \in \mathbf{S}$. This is not trivial, as Schmitt-Grohe and Uribe ([67]) discuss in some detail, so we handle this issue systematically in the existence proofs related to this section in the appendix.

Second, the space \mathbf{C}^f does also not capture all of the *necessary* structural restrictions of *any* RE policy functions for tradeables goods. For example, if we have *multiple* RE, RE will in general be *discontinuous*; but, as will be clear in a moment, in any RE, the RE *cannot* be discontinuous over *individual states*.²⁷ So, in any RE policy for tradeables consumption $C^{T*} \in \mathbf{C}^* \subset \mathbf{C}^f$ given as a fixed

²⁴For example, much of the applied literature uses Armington aggregators for the mapping $A(c)$, so the relative price p is just:

$$p(C) = \frac{1-a}{a} \left(\frac{C^T}{Y^N} \right)^{1/\xi}$$

Under Assumption 1.g, for constants $\alpha^T > 0$ and $\alpha^N > 0$, we could have utility such that the price function is:

$$p(C) = \frac{1-a}{a} \left(\frac{C^T + \alpha^T}{Y^N + \alpha^N} \right)^{1/\xi}$$

such that marginal utility (and hence, prices) are bounded for all $C^T \geq 0$. Note, this special case is important to keep in mind when relating our multiplicity of RE results in the sequel to Schmitt-Grohe and Uribe ([67]). Our results do not require Armington aggregators for any of our theoretical results, rather simply preferences which satisfy Assumption 1.

²⁵A useful fact concerning elements $C^T(S) \in \mathbf{C}^f$ is for any element $C^T \in \mathbf{C}^f$, $D'(S) = \kappa(Y^T + p(C^T(S)))Y^{NT}$ is increasing in S . That will be a useful fact in our construction of RE.

²⁶For latter reference, we note that $\mathbf{C}^f(\mathbf{S})$ is not a complete lattice.

²⁷This fact basically follows from the fact that in any RE, the household policy function for tradeable consumption must be continuous over individual states (by Berge's maximum theorem).

point of the mapping $C^{T*}(S) = c^{T*}(d, y, S; C^{T*}(S))$ where when $d = D$, and $y = Y$ and $c^{T*}(d, y, S; C^T)$ is the typical household's policy function, *all* the discontinuities over the RE state space must be isolated to *only aggregate states* S . This is a somewhat subtle issue, and often not handled explicitly in the literature when constructing RE. It should also be clear, this requirement can be *very demanding* in settings with multiple equilibria.

To handle this latter issue, we propose a two step fixed-point approach, where the fixed points of the "first step" guarantee all the needed continuity conditions for any RE policy function c^{T*} in its first two arguments, while the "second step" computes aggregate laws of motions (which parameterize the first step fixed point, as well as the household's collateral constraint) such the *equilibrium* collateral constraint at $C^{T*}(S)$ is consistent with equilibrium policy functions $c^{T*}(d, y, d, y, C^{T*}(d, y)) = C^{T*}(d, y)$. We discuss these issues in a moment in this section, and in detail in the appendix of the paper where our main existence theorem for RE is proven.

3.1 The Household's Dynamic Programming Problem

A household entering any period faces a fixed interest rate $R > 0$ such that $\beta R < 1$,²⁸ with a current level of individual household debt $d \in \mathbf{D}$, current realizations of endowments $y = (y^T, y^N) \in \mathbf{Y}$, and facing an aggregate economy in state $S \in \mathbf{S}$ whose continuation aggregate dynamics are parameterized by a single function $C^T \in \mathbf{C}^f(\mathbf{S})$. When entering the period in state $s = (d, y, S)$, the household then faces a feasible correspondence given by:

$$G(s; C^T) = \{c \in \mathbf{R}_+^2, d' \in \mathbf{D} \mid (14a) \text{ and } (15) \text{ hold}\}$$

where

$$c^T + p(C^T(S))c^N \leq y - d + p(C^T(S))y^N + \frac{d'}{R} \quad (14a)$$

$$d' \leq \kappa(y^T + p(C^T(S))y^N) \quad (15)$$

which is a continuous correspondence in (d, y) for each $S \in \mathbf{S}$. In state $s = (d, y, S) \in \mathbf{D} \times \mathbf{Y} \times \mathbf{S}$, facing an aggregate economy characterized by a law of motion on per-capita debt D' using (13), a recursive representation of the household's sequential decision problem can be then be constructed as unique value function $V^*(s; C^T)$ solving a Bellman equation for each $C^T(S) \in \mathbf{C}^f$, $C^T(S) > 0$ for all $S \in \mathbf{S}$:²⁹

$$V^*(s; C^T) = \max_{x=(c^T, c^N, d') \in G(s; C^T)} U(c^T, c^N) + \beta \int V^*(d', y', Y', \Phi(S; C^T); C^T) \chi(dy') \quad (16)$$

Under Assumption 1(a-e), 1(g), and Assumption 2, for each $C^T \in \mathbf{C}^f$, $C^T(S) > 0$, standard arguments in the literature yield the following facts about solutions to equation (16).³⁰ First, noting the strict concavity of the primitive data under Assumption 1(g), the unique optimal policy function associated with the solution to (16) is given by:

$$c^*(s; C^T(S)) = \arg \max_{x=(c^T, c^N, d') \in G(s; C^T)} U(c^T, c^N) + \beta \int V^*(d', y', Y', \Phi(S; C^T); C^T) \chi(dy') \quad (17)$$

²⁸We shall only in this section consider the case of RE for the more common case that $\beta R < 1$. The case of $\beta R = 1$ has been studied in the literature (e.g., Schmitt-Grohe and Uribe ([67]), but this case is delicate per the question of existence of SCE and/or RE. The problem is compactness. Similar issues arise when studying the case where $\beta R \geq 1$. In Pierri and Reffett ([57]), we consider these cases, and impose sufficient structure of SCE and RE to exist.

We should note, when studying the stochastic properties of the DSGE model under consider here in Section 5, setting $\beta R < 1$ is not a problem when fitting the model to the observations of Sudden Stops in the empirical literature.

²⁹Note, when $C^T(D, Y) = 0$ in any state, just set the value function $V^* = 0$ and the policy functions also all equal zero in all states (D, Y) . This trivial case will be carefully handled in our construction of a RE below.

³⁰Notice, for this section, we do not need Assumption 1(f). That is, we can allow Inada conditions at $c_1 \rightarrow 0$. This means, for our arguments per characterizing RE, we allow for all standard utility functions (noting, that to meet assumption 1(e), we can always take period utility to be $U(c) = u(c) + \eta c$ for $\eta > 0$ and sufficiently small.

where by a standard application of Berge's maximum theorem to the right side of (16), the vector of consumption policies $c^*(s; C^T) = (c^{T*}(s; C^T), c^{N*}(s; C^T))$ are jointly continuous in its first two arguments at $V^*(s; C^T)$, where $V^*(s; S; C^T)$ is continuous in (d, y) , strictly concave and decreasing in d for each (y, S) , and increasing in y , each (d, S) .

Second, relative to the primal dynamic programming problem in ((16)), and appealing to the results in Rincon-Zapatero and Santos ([59]), Proposition 3.1 and Theorem 3.1), one can prove there exists a well-defined recursive Lagrangian dual formulation of (16) that can be characterized as follows: for $C^T(S) > 0$, $C^T \in \mathbf{C}^f$, $c \in \mathbf{C} = \{c \in \mathbf{R}_+^2 | c^T \in [0, c^{\max}], c^N \in Y^N\}$, $d' \in \mathbf{D}$, we have:

$$v^*(s; C^T) = \inf_{\lambda, \mu \geq 0} \max_{c, d' \in \mathbf{C} \times \mathbf{D}} L(c, d', \lambda, \mu; s, v^*; C^T) \quad (18)$$

where, the recursive dual Lagrangian is given by:

$$\begin{aligned} L(c, d', \lambda, \mu; d, y, S, v^*; C^T) &= U(c^T, c^N) + \beta \int v^*(d', y', \Phi(S; C^T), y; C^T) \chi(dy') \\ &+ \lambda \{y^T - p(C^T(S))y^N - \frac{d'}{R} - c^T + p(C^T(S))c^N\} \\ &+ \lambda \mu \{\kappa(y^T + p(C^T(S))y^N) - d'\} \end{aligned} \quad (19)$$

where under Assumption 1(a-e), 1(g), and 2, $v^*(s; C^T) = V^*(s, C^T)$, the recursive dual problem in (18) is well-defined, finite, strong duality holds with the Lagrangian dual value equal to the Lagrangian primal value, the Lagrangian dual solutions and values equal to those of the (16). Finally, this Lagrangian dual formulation in (19) admits a system of unique system of *stationary* KKT multipliers, $\lambda^*(s; C^T)$ and $\mu^*(s; C^T)$ associated with the infinite horizon sequential dual program that dualizes the household's sequential primal optimization problem in (4) from all initial conditions. Importantly, the associated KKT solutions $\{(\lambda^*(s; C^T), \mu^*(s; C^T)); (c^{T*}(s; C^T), c^{N*}(s; C^T), g^*(s; C^T))\}$ in (19) are the unique saddlepoints of (18) dual with value function $V^*(s; C^T) = v^*(s, C^T)$, with the envelope theorem for (16) in d given by:

$$\begin{aligned} \partial_d v^*(s; C^T) &= \lambda^*(s; C^T) \\ &= \partial_d V^*(s; C^T) \\ &= U'(A(c^{T*}(s; C^T), c^{N*}(s; C^T))) A_1(c^{T*}(s; C^T)) \end{aligned}$$

where $(c^{T*}(s; C^T), c^{N*}(s; C^T))$ is the vector optimal solutions for consumption goods for the primal dynamic program in (16).

Using these facts, the system of first order conditions (necessary and sufficient) for our problem in (19) can be stated as follows: for stationary KKT multipliers $(\lambda^*(s; C^T), \mu^*(s; C^T))$, the optimal policy functions $((c^{T*}(s; C^T), c^{N*}(s; C^T)), \text{ and } d'^*(s; C^T) = g^*(s; C^T))$ satisfy the following:

$$\lambda^*(s; C^T) = U'(A(c^{T*}(s; C^T), c^{N*}(s; C^T))) A_1(c^{T*}(s; C^T)) \quad (20)$$

$$p(C^T(S)) = \frac{A_1(c^{T*}(s; C^T))}{A_2(c^{N*}(s; C^T))} \quad (21)$$

$$\left\{ \frac{1}{R} - \mu^*(s; C^T) \right\} \lambda^*(s; C^T) = \beta \int \lambda^*(d', y', \Phi(S; C^T), y'; C^T) \quad (22)$$

$$\{d' - \kappa\{p(C^T(S))y^N + y^T\}\mu^*(s; C^T) = 0, \mu^*(s; C^T) \geq 0 \quad (23)$$

where the law of motion on individual debt in (22) is given by:

$$d'^*(s; C^T) = \inf \{R\{c^{T*}(s, C^T) - y^T - p(C^T(S))y^N + d\}, \kappa\{y^T + p(C^T(S))y^N\} \quad (24)$$

and the law of motion on per-capita debt D' in (22) is given by $\Phi(S; C^T)$ in equation (13).

3.2 The Structure of RE Tradeables Consumption

When developing our RE operator in a moment, it proves critical to first characterize how the structure of the optimal tradeables consumption policy varies over the two "regimes" (i.e., equilibrium states where the household is collateral constrained versus equilibrium states where household is not collateral constrained). To provide an answer to this question, first note that for any household who enters any period in state $s = (d, y, S) \in \mathbf{S}$, after we impose in a RE $c^{*N}(s^e) = y^N = Y^N$, the household's budget constraint in (??) is:

$$c^{*T} = y^T - d + \frac{d'^*}{R} \quad (25a)$$

If the per-capita tradeables consumption is given by $C^T \in C^f$, then the law of motion on optimal level of debt in equilibrium for the representative household is:

$$d'^*(s; C^T) = \inf\{R\{c^{T*}(s, C^T) - y^T + d\}, \kappa\{y^T + p(C^T(S))y^N\}\} \quad (26)$$

where $c^{T*}(s; C^T(S))$ is the household's optimal tradeables consumption. Using (20) into (22), we can then define the mapping :

$$Z_p^*(x, s; C^T) = \frac{U_1(x, y^N)}{R} - \beta \int U_1(c^{T*}(d', y', D', Y'; C^T))\chi(dy') \quad (27)$$

where the evolution of per-capita (or aggregate) debt D' in (27) is given by equation (13), and the evolution of individual optimal debt for d' is given by (24). If we let $x^*(s; C^T)$ be the implicit solution of the following:

$$Z_p^*(x^*(s; C^T(S)), s; C^T(S)) = 0$$

which under Assumption 1(a)-(e), 1(g) and Assumption 2 is well-defined as a function continuous in (d, y) , the implied optimal debt level associated with a tradeables consumption plan $x^*(s; C^{T*})$ would be:

$$d_{x^*}(s; C^T) = R\{x^*(s; C^T) - y^T + d\} \quad (28)$$

If the debt level $d_{x^*}(s, C^T)$ in (28) satisfies $d_{x^*}(s; C^T) \leq \kappa\{y^T + p(C^T(S))y^N\}$, the household is not debt-constrained in state $s = (d, y, S) \in \mathbf{S} \times \mathbf{S}$ for the aggregate tradeables policy $C^T(S)$, and the optimal policy for tradeables is given by:³¹

$$c_{uc}^{T*}(s; C^T) = x^*(s; C^T) \quad (29)$$

Alternatively, $d_{x^*}(s, C^T) > \kappa\{y^T + p(C^T(S))y^N\}$, the debt constraint binds in this state s , and the optimal tradeables consumption is

$$c_c^{T*}(s; C^T(S)) = (1 + \frac{\kappa}{R})y^T - d + \frac{\kappa}{R}p(C^T(S))y^N. \quad (30)$$

In the latter case, the Euler equation in (20) binds, with $\mu^*(s; C^T) > 0$.

So the RE optimal policy for tradeables consumption has the following form for each state $s = (d, y, S)$:

$$c^{T*}(s; C^T) = \inf\{c_{uc}^{T*}(s; C^T), c_c^{T*}(s; C^T)\} \quad (31)$$

where the infimum is computed at each (s, C^T) , preserves joint continuity over individual states (d, y) for each S to $c^{T*}(s; C^T)$ by a standard application of the maximum theorem (noting the compactness of the state space), and one can show $c^{T*}(s; C^T)$ decreasing in d , increasing in y , each $S \in \mathbf{S}$.³² We can use this structure of the optimal tradeables policy over the "two collateral constraint" regimes to develop our two step monotone approach to constructing RE in the next section.

³¹If if $d_{x^*}(s; C^T) \leq \kappa\{y^T + p(C^T(S))y^N\}$, this implies the collateral constraint is either slack or saturated (but not binding) at this state s . This, in turn, implies in equation (22) that the KKT multiplier on the debt constraint is $\mu^*(s; C^T) = 0$, and $Z_p^*(x, s; C^T)$ is the actual FOC for the household after imposing $c^{NT*} = y^{NT}$ in a RE.

³²In the appendix, in the proof of Lemma 6, the proof of this lemma actual proves these comparative statics of $c_c^{T*}(s; C^T(S))$ in (d, y) each $S \in \mathbf{S}$ are the case.

One last final note about the policy $c^{T*}(s; C^T)$. It can easily be shown that $c^{T*}(s; C^T)$ in (31) is *not* monotone increasing in $C^T(S)$ for each s . That is, the pecuniary complementarities induced by the equilibrium price-dependent collateral constraint *do not induce a monotone operator* directly via the household's policy function. Indeed, as we shall show in a moment, the requisite *single-crossing property* induced by pecuniary externalities that generates a global source of multiple RE in this model is an *equilibrium object*, and cannot be disentangle from the fixed point construction we shall use to construct the set RE itself.

3.3 A Multistep-Monotone Operator for Constructing RE

Motivated by the structure of the optimal tradeables consumption policy in equation (31), we now define our approach to constructing RE. The challenge of construction a RE operator models of Sudden Stops is because of collateral constraints are *price dependent*, they are *equilibrium objects*. To address this complication of structural change over different equilibrium "regimes" (e.g., collateral constrained states vs uncollateral constrained states), we construct an RE equilibrium consumption operator that models RE tradeables consumption as a "coupled" fixed point of a *two-step* operator that in its definition explicitly keeps track of the two equilibrium regimes that characterize the stochastic equilibrium dynamics of Sudden Stop models. Roughly, in the first step, we compute the RE tradeables decision rule *conditional* on holding the "pecuniary externality" *fixed* at the relative price of non-tradeables parameterized by tradeables consumption level $C^T(S)$. This first step mapping will turn out to be monotone, a contraction, and have a unique positive fixed point for each fixed $C^T(S)$. Then, in the second step, using a order-theoretic fixed point comparative statics argument, we define a second step operator (also monotone) which verifies (and can compute) the "least" and "greatest" RE collateral constraint consistent with this first step fixed point, which in turn induces the set of actual RE via its coupling with first stage fixed point(s).

Along these lines, image the structure of the (unknown) RE tradeables consumption "tomorrow" is given by the following mapping when $d = D$, and $y = Y$:

$$C(c, C^T)(d, y, S) = \inf\{c(d, y), C_c^T(D, Y, C^T(S))\} \quad (32)$$

where $C_c^T = (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C^T(D, Y)Y^N$, depends on only $C^T(S)$ the per-capital level of tradeables consumption. Observe, the mapping $C(c, C^T)(d, y, S)$ is constructed as the pointwise infimum of *two unknown functions*: (i) $c(d, y) \in \mathbf{C}^p(S)$, where \mathbf{C}^p is the space of candidate functions that will represent tradeables consumption in states where the household in a RE is not collateral constrained to be specified in a moment, and (ii) $C^T \in \mathbf{C}^*$ which RE tradeables consumption tomorrow when households are collateral constrained (where \mathbf{C}^* will be defined below). Per the latter function, notice $C^T(S)$ parameterizes a "guess" at the *equilibrium* collateral constraint (and, hence the per-capital *equilibrium* collateral-constrained consumption $C_c^T(D, Y, C^T(S))$).³³ Given this guess at "tomorrow's" tradeables consumption, we use the household's Euler inequality in equilibrium to compute the implied level of tradeables consumption "today", which will be given by a "couple" mapping, denoted by $A(c, C^T)(d, y, S)$ when $d = D$ and $y = Y$. It will true out then a strictly positive solution to the implied "coupled" fixed point problem will be shown to induce a RE for the economy. It will turn out our operator $A(c, C^T)(d, y, S)$ when $d = D$ and $y = Y$.³⁴ Previewing our arguments, it will turn out our mapping $A(c, C^T)(d, y, S)$ is be *jointly monotone* transformation of its domain, and it's domains will be complete lattices under pointwise partial orders, so powerful order theoretic fixed point methods can be brought to bear on this problem to characterize the existence and order structure of the set of RE (as well as RE comparative statics).

To formalize our RE construction, we begin by defining the domain of our RE operator for the fixed point step. For the first step of our construction, we shall fix $C^T \in \mathbf{C}^f$, and we take the domain of our the operator $A(c; C^T)(d, y, S)$ the set of functions $c = c(d, y) \in \mathbf{C}^p(\mathbf{D}^e \times \mathbf{Y}^e)$, where:

³³What will be critical in a moment, when defining our RE operator, is by imposing $d = D$, $y = Y$ in the definition of the operator, and computing tomorrow's consumption as $C(c, C^T)(d', y', d', y')$, the two equilibrium "branches" will be coupled by imposing equilibrium between transition structures for individual and aggregate state variables.

³⁴By the terminology "coupled mapping", we mean that the two branches of this infimum operation that defines $C(c, C^T)$ are interrelated by individual and aggregate states (hence, the pointwise infimum operation is allowed vary along the two different equilibrium branches). Namely, the collateral constrained consumption depends on the *entire* individual state space.

$$\begin{aligned} \mathbf{C}^p(\mathbf{D}^e \times \mathbf{Y}^e) &= \{c(d, y) | c \in \mathbf{C}^f, 0 \leq c(d, y) \leq y^T - d + (d^{Max}/R), \\ c(d, y) &= \bar{c}(d, y, d, y), \bar{c}(d, y; d, y) \text{ decreasing in } d, \\ &\text{increasing in } y, \end{aligned} \quad (33)$$

s.t. (*) for a fixed y , $-d' = R(y^T - d - c(d, y, d, y))$ decreasing in d , increasing in y

where d^{Max} is the maximal level of debt as shown in section 2, and we use the notation $s^e = (d, y, d, y) \in \mathbf{D}^e \times \mathbf{Y}^e$ to make clear the domain of any RE function is defined over a *diagonal* of individual state variable $s = (d, y, S)$:

$$\mathbf{D}^e \times \mathbf{Y}^e = \{(d, y) | (d, y) = (d, y, D, Y), d = D, y = Y\} = \mathbf{S}$$

where by construction $s^e \in \mathbf{D}^e \times \mathbf{Y}^e = \mathbf{S}^e$ is an *equilibrium* state of the household. We endow $\mathbf{C}^p(\mathbf{S}^e)$ with its relative pointwise partial order.

Notice a few facts about $\mathbf{C}^p(\mathbf{S}^e)$: (a) it is an equicontinuous collection of functions in the uniform topology (hence, compact), so each $c \in \mathbf{C}^p$ is continuous; (b) it is a nonempty subcomplete lattice of $\mathbf{C}^f(\mathbf{S})$ in its relative pointwise partial order; (c) for any function $c(d, y) \in \mathbf{C}^p$, the implied policy function for $d'(d, y)$ is *decreasing* in y , and *increasing* in d , so the elements of the space $\mathbf{C}^p(\mathbf{D}^e \times \mathbf{Y}^e)$ are consistent with the fact that when the household is *not* debt constrained, debt works as a consumption smoothing device for household relative to tradeables endowment shocks.

To define our RE operator, we first rewrite Z_p^* in (27) in a RE as follows: for any $c(d, y) \in \mathbf{C}^p$, when $c(d, y) > 0$, using $C(d, y; c, C^T(d, y))$ is defined in (32), imposing equilibrium between individual and aggregate states $d' = D'$ and $y' = Y'$, we can define the mapping Z_{uc}^* is defined as follows:

$$\begin{aligned} Z_{uc}^*(x, s^e; c, C^T), &= \frac{U_1(x, y^N)}{R} - \\ &\beta \int U_1(C(R(x - y^T + d), y', R(x - y^T + d), y')) \chi(dy') \end{aligned} \quad (34)$$

where we denote equilibrium state space by $s^e = (d, y, d, y) \in \mathbf{S}^e$. Relative to Z_p^* in (27), we have done the following: (a) assumed the state s^e is *not* collateral constrained, and (b) set $x = C^T(S)$ pointwise in equilibrium for the updating of the aggregate debt state in the it's aggregate law of motion. Of course, per (a), in a moment when defining the our RE operator, we will verify if this "assumption" is correct. Relative to (b), this is critical as this substitution is precisely what we need to model *equilibrium* single crossing between the household's tradeables consumption and the per-capita aggregate level of tradeables consumption.

To define then our RE operator, for any $c(d, y) \in \mathbf{C}^p$, $c > 0$, and $C^T \in \mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e)$, $Z_{uc}^*(x, s^e; c, C^T)$ is strictly decreasing in x , increasing in (c, C^T, y) , and decreasing in d , and we can compute function $x_{uc}^*(s^e; c, C^T)$ implicitly in this expression:

$$Z_{uc}^*(x_{uc}^*(s^e; c, C^T), s^e; c, C^T) = 0 \quad (35)$$

which is well-defined as a function as Z_{uc}^* is strictly decreasing under Assumption 1, is continuous in its first two arguments, all the parameters, and pointwise continuous (topology of pointwise convergence) in (c, C^T) for each s^e ,³⁵ and under Assumption 1 plus Assumption 2, the root $x_{uc}^*(s^e; c, C^T) > 0$. By a standard comparative statics argument, under Assumptions 1 and 2, $x_{uc}^*(s^e; c, C^T)$ is increasing in (c, C^T, y) and decreasing in d .

Then following the construction in the previous section for the optimal tradeables consumption policy, the implied debt level associated with the tradeables consumption $x_{uc}^*(s^e; c, C^{T*})$ will be:

$$d_{x_{uc}^*}(s^e; c, C^T) = R\{x_{uc}^*(s^e; c, C^T) - y^T + d\} \quad (36)$$

³⁵For the situation that $c(d, y) = 0$ in any state, take $x_{uc}^*(s^e; c, C^T) = 0$. This will imply our first stage fixed point problem below in Lemma 2 will have a trivial fixed point at 0. So we can only work with strictly positive fixed points in Lemma 2 below.

If the debt level $d_{x_{uc}^*}(s^e, c, C^T)$ in (36) satisfies $d_{x_{uc}^*}(s^e; c, C^T) \leq \kappa\{Y^T + p(C^T(S))Y^N\}$, the household is in a not debt-constrained state $s^e = (d, y, d, y) \in \mathbf{S} \times \mathbf{S}$ for (c, C^T) ,³⁶ and:

$$A_{uc}(c; C^T)(s^e) = x_{uc}^*(s^e; c, C^T) \quad (37)$$

Alternatively, if $d_{x_{uc}^*}(s, C^T) > \kappa\{y^T + p(C^T(S))y^N\}$, the debt constraint binds in state s , and the optimal tradeables consumption is

$$A_c(C^T)(S) = (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C^T(S))y^N. \quad (38)$$

Then our operator for $(c, C^T) \in \mathbf{C}^p \times \mathbf{C}^f$ will be defined as:

$$\begin{aligned} A(c, C^T)(s^e) &= \inf\{A_{uc}(c, C^T)(s^e), A_c(C^T)(S)\} \text{ when } (c, C^T) > 0 \\ &= 0 \text{ else} \end{aligned} \quad (39)$$

We now construct the RE in two steps. In Lemma 6, we show for each fixed $C^T \in \mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e)$, there is a unique positive fixed point of partial mapping $A(c; C^T, \beta, \kappa, R)(s^e) \in \mathbf{C}^p$ (where in the Lemma, we now make explicit how the operator varies in the deep parameters (β, κ, R) eventually RE comparative statics will be of interest in our main theorem).

Lemma 6 *Under Assumption 1(a-e), 1(g), and 2, for each $C^T(S) \in \mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e)$, and $S \in \mathbf{S}$, for the operator $A(c; C^T, \beta, \kappa, R)(s^e)$, (a) there exists a unique positive fixed point $c^*(d, y, C^T(S), \beta, \kappa, R)$ in $\mathbf{C}^p(S)$; (b) this fixed point can be computed by the successive approximations $\inf A^n(c_{\max}; C^T(S), \beta, \kappa, R)(d, y) \rightarrow c^*(C^T(S), \beta, \kappa, R)(d, y)$; (c) $c^*(C^T, \beta, \kappa, R)(d, y)$ is a monotone operator on $\mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e)$, (d) $c^*(C^T, \beta, \kappa, R)(s^e)$ is decreasing in (β, R) , and increasing in κ .*

We now prove our main existence result in this section using the results in Lemma 6. To do this, we now construct our second step operator using the first step unique strictly positive fixed point $c^*(C^T, \beta, \kappa, R)(d, y)$. The domain for second step mapping will be denoted by $\mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e)$, and defined as follows:

$$C^T \in \mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e) = \{C^T(d, y) | C^T \in \mathbf{C}^f, 0 \leq C^T(d, y) \leq y^T - d + (d^{Max}/R), \quad (40)$$

$$\begin{aligned} C^T(d, y, d, y) &= \inf\{c^*(d, y, C(d, y)), C(D, Y)\}, d = D, y = Y \\ c(d, y; C(d, y)) &\in \mathbf{C}^{p*}(d, y), C(D, Y) \in \mathbf{C}^f \text{ st } D'(d, y) = \kappa(y^T + p(C(d, y))y^{NT}) \end{aligned} \quad (41)$$

The elements of the space $\mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e)$ have the exact same structure as those in \mathbf{C}^p over *individual states*, but drop the condition (*) in (33) governing RE debt dynamics when collateral constrained binds. This reflects the fact that when the collateral constraint binds in equilibrium, the properties of the implied RE debt dynamics *reverse in order* to those implied when $c^*(d, y, C(d, y)) \in \mathbf{C}^{p*}$ (the unconstrained regime), hence, the sudden stop occurs. We should note that $\mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e)$ is a nonempty complete lattice under pointwise partial orders.³⁷

To define the second step operator we use the unique positive fixed point of the first step operator, and define the following nonlinear operator on the space \mathbf{C}^* : when $(d, y) = (D, Y) = S$:

$$\begin{aligned} A^*(C^T; \beta, \kappa, R)(s^e) &= C(c^*(C^T), C^T; \beta, \kappa, R)(s^e) \\ &= \inf\{c^*(C^T; \beta, \kappa, R)(s^e), A_c(C^T; \kappa, R)(s^e)\} \end{aligned} \quad (42)$$

where we now make the dependence of the operator A^* and $C(c^*(C^T), C^T; \beta, \kappa, R)$ on the deep parameters (β, κ, R) explicit. We now have the following result.

³⁶Notice, when the debt $d_{x_{uc}^*}(s^e; c, C^T) = \kappa\{Y^T + p(C^T(S))Y^N\}$, the collateral constraint is saturated, but not binding. In this case, the implied KKT multiplier on the collateral constraint would be 0.

³⁷If you fix (d, y) , the collection $c^*(d, y; C(d, y)) \in \mathbf{C}^{p*}$ for $C \in \mathbf{C}^f$ forms an equicontinuous collection. Also, when $C \in \mathbf{C}^f$ such that the associated debt $D'(D, Y) = \kappa(Y^T + p(C^T(D, Y))Y^{NT})$, $D'(D, Y)$ is also decreasing (resp., increasing) in D (resp., Y). That implies $C(D, Y) - D'(D, Y) = Y - D$ is decreasing (resp, increasing) in D (resp, Y) in decreasing, the resulting set is equicontinuous. That is sufficient for $\mathbf{C}^*(\mathbf{D}^e \times \mathbf{Y}^e)$ to be a complete lattice, pointwise partial orders.

Theorem 7 Under Assumption 1(a-e), 1(g), and 2, there exist (i) a nonempty complete lattice $\Psi^*(R, \kappa, \beta)$ of RE in C^* , and (ii) the least and greatest elements of $\Psi^*(R, \kappa, \beta)$ are increasing in κ , and decreasing in (R, β) , (iii) the least and greatest RE can be computed by successive approximations: i.e.

$$\inf_n A^{*n}(0; R, \kappa, \beta) \nearrow \wedge \Psi^*(R, \kappa, \beta)$$

$$\sup_n A^{*n}(c_{\max}; R, \kappa, \beta) \searrow \vee \Psi^*(R, \kappa, \beta)$$

We conclude this section by relating our approach to RE to the results in Schmitt-Grohe and Uribe ([66], [67]) relative to multiplicities of SCE near (deterministic) steady-states. What is clear from our approach is that relative to the set of RE, the issues raised in Schmitt-Grohe and Uribe ([66], [67]) are *global*. That is, multiple equilibria can exist relative to the set of RE in these models *across all states* where collateral constraints hit. In the appendix, an implication of the proof of lemma 6 is that multiple equilibria cannot exist in this model in the absence of states where collateral-constraints *hit* (as we prove in all such states, RE are *unique*). But in *any state* where collateral constraints bind (not just near steady state), in the stochastic RE (not just the deterministic version of the model), multiplicities of RE are possible (and in particular, "low" and "high" borrowing equilibria are possible).

More specifically, in Schmitt-Grohe and Uribe ([66], [67]), they show near a *deterministic* steady-state of this model, multiple equilibria can exist, as for the SCE dynamical system for debt $(D_{t+1}) = \Psi^*(D_t)$, Ψ^* can have multiple fixed points near the steady-state. For example, one positive fixed point, which we denote by D^{ss} , corresponding with a deterministic steady-state with binding collateral constraints and "high borrowing". Via budget constraints, this implies the existence of a steady-state tradeables consumption level $c^{T,ss} = C^{T,ss} > 0$. They also give sufficient conditions on primitives such that there exists a second equilibria of Ψ^* that is a type of "self-fulfilling" low borrowing equilibria, which can occur when there exists a state $D^* < D^{ss}$, where people are "pessimistic" about the level of borrowing and aggregate tradeables consumption at debt-level D^* . In this case, if the collateral constraint binds at D^* , and if $c^{T*} = C^{T*} < C^{T,ss}$ is the level of tradeables consumption at $d^* = D^*$ for the household in a SCE, one can obtain an implicit equilibrium relation (written here in terms of C^{T*}) that has at D^* .³⁸

$$Z_c^*(C^{T*}, y; \kappa/R, D^*) = C^{T*} - (y^T + y^{NT} p(C^{T*}))(1 + \frac{\kappa}{R}) - D^* = 0$$

Which is also a (self-fulfilling) equilibrium with low debt and low tradeables consumption. An important feature of this argument is it is "local" and based upon *deterministic* perfect foresight equilibrium constructions. For example, one should note this argument need not imply multiple *stochastic* dynamic equilibrium in our main theorem.

But by a simple argument, we can see the results in Schmitt-Grohe and Uribe ([67]) is actually *robust and global* for set of (stochastic) RE using the results in Theorem 7. To see this, in any state equilibrium state s^e where the collateral constraint binds, we have $A^*(C^T)(s^e)$ given by

$$A^*(C^T)(s^e) = A_c(C^T)(s) = (y^T + y^{NT} p(C^T(S)))(1 + \frac{\kappa}{R}) - d$$

Consider the following mapping when $d = D$, $y = Y$:

$$Z_{cc}(x^*(d, y, S, C^T), C^T(S); d, y, S) = x^*(d, y, d, y, C^T) - (y^T + y^{NT} p(C^T(S)))(1 + \frac{\kappa}{R}) - d = 0$$

where the subscript indicates this an equilibrium state that is collateral constrained, and where in this expression, we have $A_c(C^T)(s^e) = x^*(d, y, d, y; C^T)$ (which corresponds with our fixed point operator $A^*(C^T)(s^e)$ in a state s^e where the collateral constraint binds). Evaluating Z_{cc} at a fixed point of $A_c(C^T)(s^e) = x^*(d, y, d, y) = C^{T*}(d, y)$ when $d = D$ and $y = Y$, we see unless the mapping $p(\cdot)$ and parameters κ , R , and y^{NT} are such that

$$Z_{cc}(x, C^T(D); y, \kappa/R, D) = x - (y^T + y^{NT} p(x))(1 + \frac{\kappa}{R}) - D = 0$$

³⁸Schmitt-Grohe and Uribe ([67]) give explicit necessary and sufficient conditions for such multiplicities near steady states to exist at D^* for the case of Armington Aggregators for consumption $c = A(c^T, c^{NT})$.

is *strictly increasing* in x , there will be *multiple fixed points* at this state s^e for the mapping

$$Z_c^*(x^*(d, y, d, y), C^{T^*}(d, y); d, y, d, y) = 0.$$

This means we have *global* sources of multiple RE possible.³⁹ As when in states where the equilibrium collateral constraint binds, the mapping $A_c(C^T)(s^e)$ is also monotone, the fixed points for each such state s^e will be *ordered*, and as Schmitt-Grohe and Uribe ([67]) suggest, we will have "low borrowing" (or "least" equilibria) and "high borrowing" (or "greatest" equilibria) RE.

4 Generalized Markov Equilibrium

The previous section proves the existence of a time invariant recursive representation with a minimal state space (a RE). The difference of this equilibrium type with respect to other recursive equilibrium notions can be seen from a theoretical and from a numerical perspective. The former was discussed in section 3. Basically, it can be said that all RE are a subset of more general representations like Duffie, et. al. ([25]) or Feng, et. al. ([27]). This characteristic is at the heart of the numerical implications of the results in section 3. As minimal state space recursive equilibria is a "smaller" set, it is possible to compute it "efficiently".

While the results in section 3 can be used to numerically approximate the SCE and to perform accurate numerical comparative statics exercises, we have been silent about simulations in these class of models. As discussed in Santos and Peralta-Alva ([60]), the starting point of any simulation experiment is an appropriate steady state notion. The most frequent one is an *invariant measure* (IM) for *some* recursive representation of the sequential equilibrium. Heuristically, an IM gives a sense of *probabilistic time invariance*. That is, if $\{x_t\}$ is a sequence of random variables generated from some Markov process and x_t is distributed according to an IM μ , then x_τ will be distributed according to μ for $\tau > t$.

This section introduces the notion of Generalized Markov Equilibrium (GME), which has an expanded state space when compare to the results in section 3. This equilibrium is a slightly modified version of the one in Feng, et. al. ([27]), which is known to have multiple equilibria. Moreover, a GME is defined using the set of equations characterizing the SCE. Thus, the additional state variable and the direct connection with the SCE brings more memory into the model at the cost of multiplicity. This paper proves that it is possible to refine the equilibrium set in a GME by picking a selection which insures the existence of an IM. In this sense, we are imposing long run restrictions in order to refine the equilibrium set.

Provided a stationary recursive representation, the existence of an IM implies that simulations obtained from the SCE can be approximated by a time invariant and finite set of functions, abstracting from numerical errors.⁴⁰ This is possible by means of a *law of large numbers* which in turn requires the IM to be *ergodic*. From a practical perspective, ergodicity insures that "averages converges". That is, the existence of a stationary recursive representation, as the one derived in section 3 for instance, is not enough to insure the desired convergence, which is typically obtained using a law of large numbers. The ergodicity of the IM guarantees that the Cesaro average of any simulation starting from a "nice" initial condition will converge to an expected value computed using the steady state distribution. This last fact allows to connect the model with observed (time independent) stylized facts.

As discussed in Pierri ([55]), existence of an IM and its ergodicity in this type of models are related to the cardinality of the set of exogenous shocks. We prove the existence of an ergodic IM for economies with a *finite set of shocks* under milder assumptions than in Pierri ([55]). This is possible because of the monotonicity properties of the minimal state space recursive equilibrium combined with an occasionally binding (collateral) constraint. Under this setting it is possible to show that the model described in section 2 has an "irreducible atom", which is used in the stochastic process literature to prove the existence of an IM (see for instance Meyn and Tweedie, section 10). The ergodicity of this measure follows from its uniqueness. While these results are enough to insure convergence in the sense implied by a law of large

³⁹Schmitt-Grohe and Uribe ([67]) give a *local* sufficient condition for this to be case for the case that the utility aggregator $A(c^T, c^{NT})$ is an Armington aggregator.

⁴⁰As pointed out in Santos and Peralta Alva ([60]), truncation and interpolation errors could accumulate over time if they are not "controlled" over time.

numbers, finding the appropriate set of initial conditions maybe problematic as the process may have divergent paths. Fortunately, we can characterize the set of appropriate initial conditions and at the same time prove the existence of an ergodic IM.

4.1 A convenient recursive representation

In this subsection we derive the Generalized Markov Equilibrium (GME). As this equilibrium have a bigger state space when compared with the recursive representation presented in section 3, it is more flexible (see for instance in Kubler and Schmedders ([36] for a detailed discussion). However, we are interested in preserving some of the structural properties (i.e. differentiability of the value function, etc.) proved before as they will be useful to derive some of the results in this section. Thus, one of the purposes of writing the minimal state space equilibrium is to refine all possible GME in order to build a selection which replicates the observed behavior. It turns out that, if we restrict attention to a finite set of exogenous shocks, it is easy to describe and characterize a "regeneration point" for the global stochastic dynamics in the model using the GME. This is a first step in order to find a recurrent structure that is robust to the presence of multiple equilibria, which typically generate discontinuous selections. Taking into account this last property, it will only be possible to prove the existence of an invariant measure using some of the results derived for the minimal state space equilibrium (RE) but applied to Feng, et. al.'s representation. In particular, the properties of the endogenous variables derived for the optimization problem in the RE for the unconstrained case (i.e. when the collateral restriction does not hold with equality) will be useful to construct trajectories with positive probability which can be used, in turn, to prove ergodicity. This is possible as any sequential equilibrium must be optimal given prices for the household.

As can be seen in the appendix for section 2, given assumption 1 and the results in theorem 1, any SCE can be characterized using a set of primal first order conditions, which don't depend on Lagrangian multipliers. The usefulness of this representation will be clear in this subsection. Moreover, the existence of well behaved envelopes for the value function in the RE implied that a SCE can be characterized recursively by the following equations:

$$[-A1(c_1)p + A_2(c_2)] = 0 \tag{43}$$

$$[\kappa\{y^T + py^N\} - d_+][U'\{A_1(y^T + d_+R^{-1} - d)\} - E(m_+)] = 0 \tag{44}$$

where $m = \frac{\partial V}{\partial d}$ is the envelope of the value function of the minimal state space representation and $U' \equiv U'(A(y^T + R^{-1}d_+ - d; y^N))$. Given the compactness of the equilibrium set, the results in Feng, et. al. imply that equations (43) and (44) can be used to derive a correspondence, Φ , called *equilibrium correspondence*, which contains all the GME, maps $Z \times Y \mapsto Z$ where $z = [d \ y^T \ y^N \ c_1 \ c_2 \ p \ m]$ with $z \in Z$, $y^T \in Y$ and Z is compact.

Note that we are restricting m to be an envelope of the value function from the RE. This restriction is required to show ergodicity as the proof involves a path for d_+ with some qualitative properties which follow directly from the optimization problem in the RE. Moreover, the results in section 3 insure that equation (44) under this restriction can be used to characterized any SCE. Thus, when the (collateral) constraint hits, we know that $U'\{A_1(y^T + R^{-1}\kappa\{y^T + py^N\} - d)\} \geq E(m_+)$ and the equilibrium for any given period can be computed using the following set of equations:

$$p = \frac{A_2(y^N)}{A_1(y^T + R^{-1}\kappa\{y^T + py^N\} - d)} \tag{45}$$

$$c_1 = y^T + R^{-1}\kappa\{y^T + py^N\} - d \tag{46}$$

$$c_2 = y^N \tag{47}$$

$$m = U' A_1(c_1) \quad (48)$$

$$U'\{A_1(y^T + R^{-1}\kappa\{y^T + py^N\} - d)\} \geq E(m_+) \quad (49)$$

Given (y^T, d) , all the remaining variables in z can be computed using (45) to (48) as long as $U'\{A_1(c_1)\} \geq E(m_+)$. That is, any $d \geq \bar{d}$ can be used to compute z with $U'\{A_1(y^T + R^{-1}\kappa\{y^T + py^N\} - \bar{d})\} = E(m_+)$. As the recursive equilibrium notion in Feng, et. al. is computed "backwards" (i.e. given "z₊" you obtain z), the Euler equation imposes a looser restriction to the system when compared to the non-binding case. This fact turns out to be very useful to prove the ergodicity of the process in the finite state space case. We are now in position to formally define a GME.

Definition 8 *Generalized Markov Equilibrium (GME):* Given a compact set Z which contains any state z_s that solves (45) to (49) backwards with $s = 0, \dots, t + 2$, the correspondence Φ mapping $Z \times Y \rightarrow Z$ can be defined as follows: take the sequence of backwards solutions $\{z_0, z_1, \dots, z_{t+2}\}$. Let $L = 0$ be the system formed by equations (45) to (49). Note that for a given vector $d_{t+3}(y_{t+2})$ with $y_{t+2} \in Y$, any pair (z_s, z_{s+1}) satisfies: $L(z_s, z_{s+1}; d_{t+3}) = 0$. Then, $z_{s+1} \in \varphi_{t+3}(z_s)$ where $\varphi_{t+3} \in \Phi$ is the selection associated with $d_{t+3}(y_{t+2})$. We will say that φ_{t+3} is a GME. If the vector $d_{t+3}(y_{t+2})$ can be chosen independently of t , we will say the the GME is stationary, in which case we denote it simply by $\varphi \in \Phi$. Let (Z, P_φ) defines a stationary Markov process with kernel given by P_φ . If (Z, P_φ) has an ergodic invariant measure, we say that φ is ergodic.

Given the compactness of Z , as there are a finite number of shocks, the measurability requirements for P_φ follows from Feng, et. al. ([27]). In section 5, we compute the 3 classes of selections and simulate the model for a standard set of parameters.

4.2 Stationarity and Ergodicity under a finite set of shocks

In this subsection we derive stochastic steady state/stationary equilibria for the model. Formally, we show that Φ has an ergodic selection. It turns out that if we restrict the number of possible distinct values that y^T can take to be finite, we can prove the existence of an ergodic probability measure. In this framework, equation (49) can be used to construct a *point* d_* that generates a set which the process hits with positive probability starting from any initial condition. This point will be called *atom* and solves the system of equations given by (45) to (49) for wealth d_* , with the Euler equation holding with equality and for the lowest possible level of y^T . Moreover, the process will hit the atom in finite time. Thus, it creates an orbit which endows the dynamical system with a recurrent structure, which in turn implies that there will be a unique (and thus ergodic) invariant measure for each atom.

Once we find d_* , we will construct a stable state space. That is, any meaningful (i.e. with positive measure) subset of this state space will be hit by the process in finite time. This property, called irreducibility, will insure the uniqueness and ergodicity of the process. The existence of 2 regimes, one defined for equations (43) and (44) when the collateral constraint does not bind and the other given by equations (45) to (49), together with the possible multiple solutions to equation (45) suggests the presence of multiple possibly discontinuous Markov equilibria. If we allow for discontinuous selections of the equilibrium correspondence in the GME, we can construct a transition function that "jumps" to the atom every time the collateral constraint is hit, generating a "crises". Thus, the presence of multiple equilibria, which is in part a consequence of the long-term memory inherited from the SCE, and its implications for the smoothness of the selections $\varphi \in \Phi$ increases the predictive power of the model in the sense that it allows a better match of long run empirical regularities. Thus, it is critical to understand the "anatomy" of the equilibrium set, something that is done in section 5.1.

As suggested by Stokey, Lucas and Prescott ([71])⁴¹, the existence of such a point is enough to derive a stationary Markov process. The results in Meyn and Tweedie ([49])⁴² give us the tools to prove all the intermediate steps required to go from the existence of an stationary selection of the equilibrium correspondence to its ergodicity. To our knowledge, this is the first time that the notion of an "atom" is related to the presence of occasionally binding constraints in non-optimal general equilibrium economies. Thus, we will prove the results step by step as it is immediate to extend the methodology used in this paper to another related framework.

In any RE the model is characterized using the Markov kernel and, thus, in 1 "step". This is a consequence of the "short memory" approach in this type of equilibrium. The GME, as it is computed directly from the sequential equilibria, allows us to bring "memory" into the picture. That is, it is possible to construct a *finite time path from the sequential equilibria*, which insures that the model will match the observed stylized facts, and to choose the appropriate selection from the equilibrium correspondence, that guarantees the existence of an ergodic Markov process. Using the former we obtain a short term match with data and because of the latter we can tie the deep parameters of the model to the long run behavior of the same observed time series. In other words: we show that there exist a selection which insures ergodicity and it is also compatible with the presence of multiple different "phases" of crises, which may have variable time spells. Section 5.2 illustrates how to use an ergodic GME to match the anatomy of a "typical" sudden stop.

Let us start by formally defining an "accessible atom", which can be thought as a point that is non-negligible from a probabilistic perspective and it is hit frequently. Let $\varphi \sim \Phi$ be a selection of the equilibrium correspondence defined in the previous section. The compactness of $Y \times Z$ and Z guarantees the measurability of φ .⁴³ Further, $P_\varphi(z, A) \equiv \{p(y^T \in Y : \varphi(z, y^T) \in A)\}$ defines a Markov operator (i.e. $P_\varphi(\cdot, A)$ is measurable and $P_\varphi(z, \cdot)$ is a probability measure) and (Z, P_φ) a Markov process where y^T is assumed to be iid with probability $p(y^T)$.⁴⁴ Let $P_\varphi^n(z, A)$ be the probability that the chain goes from z to any point in A in n steps with A being measurable. Let ψ be some measure and $B(Z)$ the Borel sigma algebra generated by Z , then $A \in B(Z)$ is *non-negligible* if $\psi(A) > 0$. A chain is called *irreducible* if, starting from any initial condition, then chain hits all non-negligible sets with positive probability in finite time (i.e. $\psi(A) > 0 \rightarrow P_\varphi^n(z, A) > 0$ (e.g., see Meyn and Tweedie ([49], proposition 1)). Intuitively, irreducibility is a notion of connectedness for the Markov process as it implies that non-negligible sets are visited with positive probability in finite time and, similarly, the state space does not break into different islands. Now we are in position to define an atom and state an important intermediate result.

Definition 9 *Accessible Atom.* A set $\alpha \in B(Z)$ is an atom for (Z, P_φ) if there exists a probability measure ν such that $P_\varphi(z, A) = \nu(A)$ with $z \in \alpha$ for all $A \in B(Z)$. The atom is called *accessible* if $\psi(\alpha) > 0$.

Intuitively an atom is a set containing points in which the chain behave like an iid process. Any singleton $\{\alpha\}$ is an atom. Note that there is a trade off: if the atom is a singleton, the iid requirement is trivial but, taking into account that the state space is uncountable, the accessibility clause becomes an issue as it is not clear how to choose ψ . For instance, the typical measure, the Lebesgue measure, it is not useful as any singleton has zero measure in it. The same happens with irreducibility: when the state space is finite, it suffices to ask for a transition matrix with positive values in all its positions. In the general case, we need to define carefully what is a meaningful set as it is not possible to list all of them. Fortunately, when the state space Z is a product space between a finite set (Y) and an uncountable subset of \mathfrak{R}^m there is a well know results that help us find an accessible atom in an irreducible chain (for proof, see See Proposition 5.1.1 in Meyn and Tweedie.)

⁴¹See for instance exercise 11.4, Ch. 11.

⁴²See Ch. 5, 8 and 10 for a detailed discussion on the implications of an atom for the existence of an invariant probability measure.

⁴³for example, Stokey, Lucas and Prescott, ([71]), Th. 7.6, p. 184).

⁴⁴For example, see Grandmont and Hildenbrand ([32]).

Proposition 10 *Suppose that $P_\varphi^n(z, \alpha) > 0$ for all $z \in Z$. Then α is an accessible atom and (Z, P_φ) is a $P_\varphi(\alpha, \cdot)$ -irreducible.*

Note that in proposition 10, which follows directly from standard results borrowed from Meyn and Tweedie, ([49], the atom is implicitly assumed to be a singleton and the reference measure may be different from ψ , which is called "maximal". Fortunately, if the chain is irreducible with respect to some measure, say $P_\varphi(\alpha, \cdot)$, then it can be "expanded" to ψ (e.g, Meyn and Tweedie, ([49], Proposition 4.2.2).

In order to apply Proposition 10 in the SS model the finiteness of Y and the definition of the Markov kernel P will be critical. As we are considering a point, in order to show that $P_\varphi^n(z, \alpha) > 0$, it suffices to find a finite sequence $\{y_0, \dots, y_n\}$ such that $\{\alpha\}$ is a solution to equations (45) to (49), the system associated with a binding collateral constraint. We want to associate the atom with an economic crises as this fact that will allow us to connect the invariant measure with a SS or, equivalently, to relate the steady state of the model with the frequency of crises.

The power of an atom for characterizing the behavior of the Markov chain.⁴⁵ However, it is possible to illustrate the effect of an atom in the recurrence structure of the chain, which is critical to define an invariant measure (i.e. a measure μ which satisfy $\mu = \int P_\varphi(z, A)\mu(dz)$). Suppose that the atom is hit for the first time with positive probability in period $\tau_\alpha < \infty$ starting from z_0 . Then, it is possible to define a (not necessarily probability) measure μ which gives the expected number of visits to a particular set in $B(Z)$, called it A , before τ_α . Stated differently, $\mu(A)$ gives the sum of the probabilities of hitting A avoiding α . Imagine that you are in period $\tau_\alpha - 1$ starting from z_0 . Remarkably, when you "forward" μ 1 period (i.e. by applying the Markov operator to it, $\int P_\varphi(z, A)\mu(dz)$) the expected number of visits to A avoiding α is the same as the chain will hit α in period $n = \tau_\alpha$. Thus, μ must not change or equivalently $\mu = \int P_\varphi(z, A)\mu(dz)$. That is, μ is an IM. Provided that $\tau_\alpha < \infty$, it is possible to normalize μ to be a probability measure, which we will call π (this property is called "positivity"). Further, as the accessibility of the atom comes together with the irreducibility of the chain (see proposition 1), it is not surprising that the IM is unique as the chain does not break into different "unconnected islands". Finally, the Krein-Milman theorem insures the ergodicity of the chain provided its uniqueness (see Futia, ([28])).

Now, in order to connect the existence of an invariant measure with the frequency of crises let τ_α be the time when the process hits the collateral constraint. Then, $\mu(A)$ gives the cumulative probability of hitting A avoiding a crises. Thus, the frequency of a SS affects the stationary distribution μ . Frequent crises implies more volatility. To understand this relationship for equilibrium paths in the steady state, note that every time the process hits the collateral constraint it reverts to α . Because $P_\varphi(\alpha, A) = \nu(A)$, the value of $z_{\tau_\alpha+1}$ is *independent* of the past, which implies that it loses all the inertia inherited from the Markovian structure of the process. Thus, the equilibrium stochastic dynamics behave unconditionally with respect to the past, increasing its variability.

To relate these facts with the empirical performance of the model, we need a Law of Large numbers. As the measure is ergodic, it is well known⁴⁶ that $\sum_{t=0}^T (z_t/T) \rightarrow E_\mu(z)$ almost everywhere, where \rightarrow means T tends to infinite. In other words, the existence of an invariant measure insures that a sample mean computed by an increasing large time series of simulated data will hit the steady state of the model, represented by the mean $E_\mu(z)$, for a large fraction of possible paths $\{z_t\}_{t=0}^\infty$. Thus, the time spells without a SS shape the long run distribution of the model, affecting its ability to replicate stylized facts. The following theorem proves the existence of an ergodic invariant measure μ for the model described in section 2.

Theorem 11 *There exists an $\varepsilon > 0$ such that $y_{lb} \in (0, \varepsilon)$, a compact set $J_1 \subseteq Z$ with $\Phi : J_1 \times Y \rightarrow J_1$ and a selection $\varphi \sim \Phi$ such that the process defined by (J_1, P_φ) has an unique ergodic invariant probability measure.*

⁴⁵As Meyn and Tweedie discuss the importance of an atom for general state space Markov chains relative to countable state space Markov chains extensively. (see [49], p96). A discussion of the important of the existence of an atom in the context of the Markov chain theory is outside the scope of this paper, but a systematic discussion of this fact is presented in Meyn and Tweedie (Chapters 8, 10 and 17).

⁴⁶e.g., see Stokey, Lucas and Prescott, ([71]), chapters 11 and 12)

5 Applications

In this section we apply the results obtained in sections 3 and 4 to characterize the model described in section 2. It is organized in 3 subsections: a characterization of the equilibrium set which focus on multiplicity, a qualitative description of short term equilibrium dynamics together with its connection with the anatomy of observed crises and a quantitative exploration of short and long run simulations. In this last subsection, we describe the algorithms generated by the Generalized Markov Equilibria (GME) and then use them to compute and simulate an ergodic, a stationary and a non-stationary equilibrium.

Since Blume ([17]) the literature recognizes a trade off between the multiplicity of sequential equilibria and the smoothness properties of the associated recursive representation. In other words, the presence of multiple equilibrium can generate discontinuities in minimal state space transition functions. The usefulness of the methods developed in sections 3 and 4 comes into play in the presence of this type of discontinuities, which may affect the existence of an ergodic equilibrium. Both RE and GME are robust to the presence of non-smooth selections. Using the GME, we can add memory to the analysis, which is deeply connected with the presence of multiple equilibrium, and at the same time find a well behaved steady state. Thus, it is critical to investigate if the multiplicity of equilibrium is a serious issue. Section 5.1 takes the model in section 2 and shows that it is possible to obtain multiple equilibrium when the collateral constraint binds for a *wide range of parameter values*. We show that the number of possible exogenous shocks is critical to generate multiplicity. To our knowledge, this is the first attempt to address this issue in a *stochastic* setting (for instance, Schmitt-Grohe and Uribe ([67]) for a discussion of the non-stochastic steady state of the economy).

The type of models described in section 2 are typically used to designed macro-prudential policies that prevents the occurrence of sudden stops (SS, see Bianchi, ([12])). This is desirable because, following for instance Mendoza and Smith ([46]), it is possible to define this event as a sharp reduction in consumption caused by a reversion in the capital account surplus. By its own nature, a SS suggests the presence of a discrete jump in the endogenous variables of the model; a fact that is at odds with a continuous Markov equilibrium. The literature has solved this issue by imposing a discrete jump in the maximum debt-to-GDP ratio κ when the collateral constraint binds (see Seoane and Yurdagul ([62]), for a detailed discussion). This type of strategy suggests that the theory is insufficient to explain the occurrence of a SS as the model requires an unexpected change in the parameters to match the observed behavior. By allowing the presence of multiple equilibrium and using a GME representation, section 5.2 shows that a canonical SS model is capable of generating a collapse in foreign borrowing without imposing a change in the parameters or a "big negative shock" and at the same time preserves the desired ergodic properties of the recursive equilibrium. Further, section 5.2 shows that the model generates a "Fisherian deflation" (see Bianchi, ([12]) for a discussion of Fisherian deflations and sudden stops), a term which is often used to describe a monotonically decreasing path of debt, consumption and real exchange rate associated with a downturn in credit conditions, caused by a tightening in the collateral constraint. Thus, a GME is capable of replicating the anatomy of a balance of payment crises and at the same time match the long run behavior of the economy using an ergodic selection.

As regards the existence of an appropriate solution algorithm, sometimes the literature only computes the dynamics associated with a Ramsey optimal taxation problem, which can be implemented as a solution to the model described in section 2, distorted with taxes (see Mendoza and Smith ([46])). Using this solution methods, it is not possible to keep track of the decentralized equilibrium. In other cases, a minimal state space recursive representation is imposed for the decentralized equilibrium and then compute using a "Taylor made" procedure (see for instance Bianchi, ([12])). Unfortunately, it is not clear if the algorithm will converge to an equilibrium transition function. Section 5.3 presents the outline of an algorithm to compute several selections of a GME which does not suffer from the mentioned problems. In this sense, we present a global algorithmic solution to the presence of multiple equilibrium and memory. We compute an ergodic, a stationary and a non-stationary selection. We find that, for a standard parameter set in the literature, the ergodic selection generates smoother consumption paths when compared with a stationary equilibrium. Equivalently, market incompleteness is less severe in the first type of equilibrium. The intuition is connected with the presence of an atom, which acts as an orbit for the dynamical system. Consequently, divergent paths are rule out in this equilibrium due to its

recurrent structure; implying smoother paths for the same frequency of crises.

5.1 Multiplicity of equilibrium

From the discussion above, it is clear that the GME (and therefore, the SCE) generate multiple selections, each of them associated with a different envelope, m_+ . In order to study this type of multiplicity, we must restrict attention to the subset of compact SCE as otherwise the set of GME could be empty. Thus, the bounds on marginal utility in assumption 1 are critical. However, there is another source of multiplicity, frequently studied in the literature (see Schmitt-Grohe and Uribe ([67])), which is concerned with the possibility of having more than 1 solution to equation (45) when the collateral constraint is binding. In order to handle this sort of multiplicity, the bounds on marginal utility are not required. Thus, as this section is concerned with this type of multiple equilibrium, we will use standard CES preferences as, for instance, in Bianchi ([12]).

We restrict attention to the source of multiplicity (and discontinuity) associated with the price dependent collateral constraint. Thus, we will focus only in the system generated by equations (45) to (49). Let $U(A(x)) = (A^{1-\sigma} - 1)/(1 - \sigma)$, $A(c) = (ac_1^{1-1/\xi} + (1-a)c_2^{1-1/\xi})^{1/(1-1/\xi)}$ with $\sigma = 1/\xi = 2$ and $a = 1/2$. We will assume that Z is compact. Then, equation (45) becomes:

$$f(P) \equiv P^{1/2} - \kappa P y^N = y_{lb}/y^N + \kappa y_{lb} - d/y^N \equiv K(d) \quad (50)$$

Where we have set $y^T = y_{lb}$ and $(1-a)/a = Ry^N = 1$. The left hand side of (50) is a function of P and the right hand side of d . Let $f(P)$ and $K(d)$ be the former and the latter respectively. As we have assumed $Ry^N = 1$, f is increasing for $0 < P < R^2/(4\kappa^2)$ and decreasing otherwise (for $P > 0$, of course). Further, $f(R^2/(4\kappa^2)) = R/2\kappa = K(y_{lb}(1 + \kappa R) - (1/2\kappa))$ and $K(0) = y_{lb}(R + \kappa)$. Figure 1 illustrates equation (50) for the described parametrization with $R^2/(4\kappa^2) \equiv P^*$.

The K locus depends on d , which is not depicted in the figure below. The f locus depends on P , that is depicted in the "x-axis". The $K(0)$ line represents the smallest possible value for d in the constrained regime (i.e. $d = 0$). Between $K(0)$ and $R/4\kappa$ the regime is not collateral constrained. Below $K(0)$ and over the locus formed by f lie all the candidate pairs (d, P) for the constrained regime.

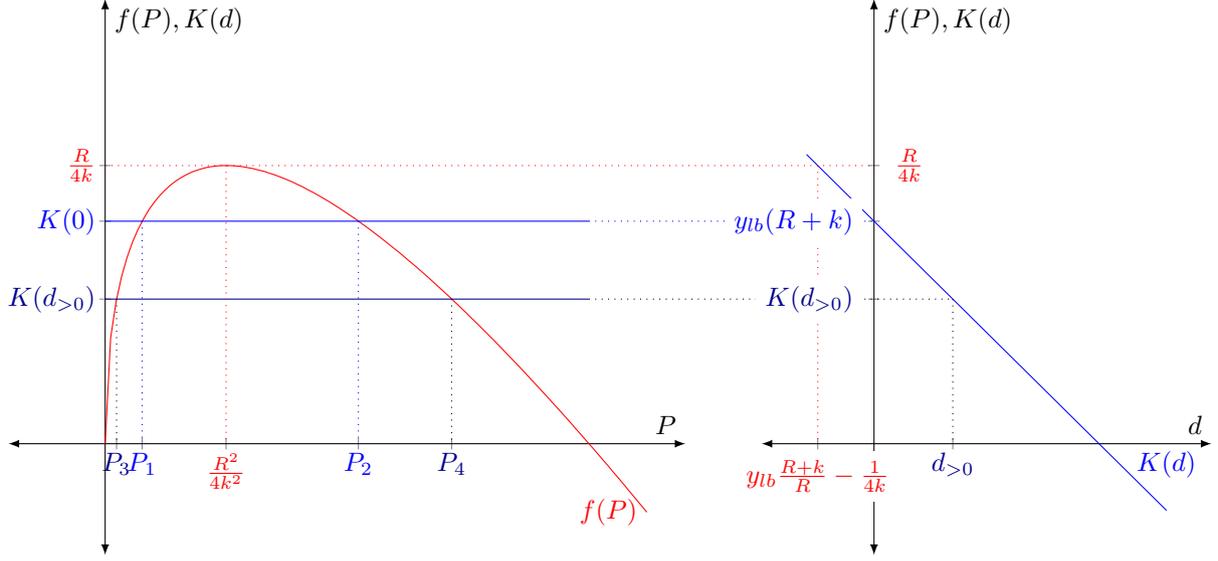

Note that for $d = 0$ there 2 possible exchange rate levels, $P1$ and $P2$, and a change in d with $d > 0$ can either increase or decrease P . This is depicted in points $P3$ and $P4$ in the same figure. Moreover, an increase in y^T implies that the $K(0)$ locus must jump upwards while the $f(P)$ locus remains constant as it is independent of tradable output by construction. Figure 2 illustrates this situation. Note that the collateral constraint doesn't bind when the agent saves (i.e. $d < 0$) as endowments and prices are positive. Thus, after the depicted increase in y^T , the region of possible multiple prices for a positive level of debt now includes the whole f locus.

The figures above illustrate the implications of the stochastic structure in the multiplicity of equilibrium: *as we increase the shock level from y_{lb} to y^T there is an increase in the admissible (positive) debt levels which can generate multiple equilibria*. This fact follows immediately from the definition of K .

In order to continue with the description of possible multiple equilibria we must incorporate 2 restrictions. The first comes from $P > 0$ as figures 1 and 2 don't guarantee that $P1 > 0$, even tough $P^* > 0$. From equation (50) it is clear that if $P = 0$, then $d = y_{lb}(1 + \kappa/R) \equiv d_{P=0}(y_{lb})$ and $d < d_{P=0}(y_{lb})$ implies $P > 0$. Thus, $d_{P=0}(y_{lb})$ is the upper bound on debt, d_{ub} . Further, we must insure that consumption remains positive. Using equation (50) again we can see that the locus, on the plane (d, P) , for which consumption equals 0 is given by:

$$d = y^T + (\kappa/R)[y^T + Py^N] \quad (51)$$

Figure 1: Equation (50), $y^T = y_{lb}$

The K locus depends on d , which is not depicted in the figure above. The f locus depends on P in the "x-axis". The $K(0)$ line represents the smallest possible value for d in the constrained regime (i.e. $d = 0$). Between $K(0)$ and $R/2\kappa$ the regime is not collateral constrained. Below $K(0)$ and over the locus formed by f lie all the candidate pairs (d, P) for the constrained regime.

Assume $\kappa/R = 1$. Clearly, in the (d, P) plane, equation (51) is a linear function $P = dR - 2y^T R$. Moreover, $P(y^T) \equiv -2y^T/y^N = -2y^T R$, where the second equality follows from $y^T R = 1$ which was imposed above, defines the intersection of this locus with the P -axis (i.e. the value for P that generates $c^T = 0$ with $d = 0$) and $d_2(y^T) \equiv 2y^T$ with the d -axis (i.e. the value for d that generates $c^T = 0$ with $P = 0$)⁴⁷. Above this locus lie all the pairs (d, P) for which $c^T > 0$. Applying the implicit function theorem to (50) for $P > 0$, we get:

$$\frac{DP}{Dd} = -1 (y^N [1/2P^{-1/2} - \kappa y^N])^{-1} < 0 \text{ if } P < [2\kappa y^N]^{-2} \text{ and } \frac{DP}{Dd} > 0 \text{ if } P > [2\kappa y^N]^{-2}.$$

Remarkably, note at point the $P^* = [2\kappa y^N]^{-2}$, we get $DP/Dd = -\infty$. This point can be used in (50) to obtain $f(P^*) = y^{T*}(R + \kappa) = K(0)$, the value for y^T which generates P^* in (50) when $d = 0$. Any $y^T < y^{T*}$ will generate a discontinuity in equation (50) in the (d, P) plane for $d > 0$. We call this point E . Figure 3 combine figures 1 and 2 with the 2 restrictions mentioned above.

For expositional purposes we have replaced y_{lb} with $Ymin$, $y_{ub} > y^T > y_{lb}$ and $y_{ub} = Ymax$. Above the line joining the points $d_2(Y)$ and $P(Y)$, to the right of vertical axis and over the locus formed by $f(p) = K(d)$ we can find the admissible real exchange rate. If $y^T = Ymin$ and y^T is close to 0, the set of debt levels that admit multiple equilibrium is negligible. However, when $y^T = y^{T*}$, this set is formed by all debt levels between 0 and $d_2(y^{T*})$.

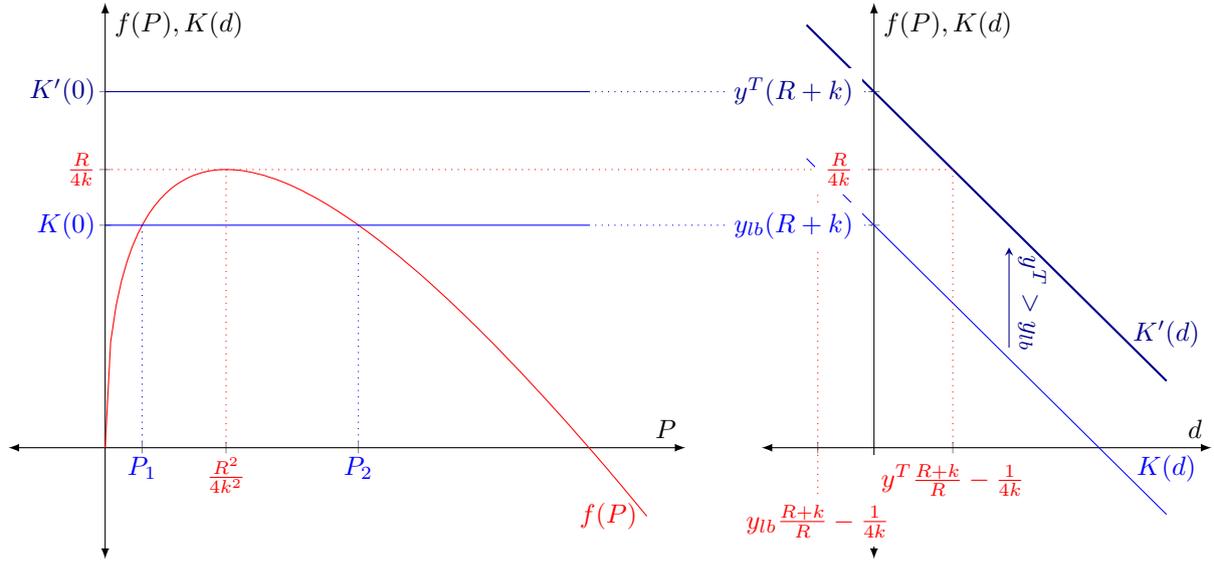

Summing up, equations (50) and (51) gives the admissible pairs (d, P) in figure 3. Note that $P(y^T) / d_2(y^T)$ are all functions of y^T . Thus, an increase in this variable will shift both locus to the right, as

⁴⁷In this section we are assuming the SG-U preferences. That is, the relative price P from optimality is just:

$$p(C) = \frac{1-a}{a} \left(\frac{C^T}{Y^N} \right)^{1/\xi}$$

This implies that $P = 0$ if and only if $c^T = 0$, which why the value for d that generates both restrictions is the same, d_2 .

Figure 2: Equation (50), $y^T > y_{lb}$

An increase in y^T shifts the K line. Thus, the whole locus f contains all the candidate pairs (d, P) for the constrained regime.

depicted in figure 3. Thus, the set of admissible equilibria increases along with y^T as can be seen by looking at the region formed by points $A - B$ on the P -axis. That is, between 0 and d_2 there are 2 admissible exchange rates for each debt level d .

The following claim states, by showing the optimality of the feasible pairs in figure 3, the existence of multiple equilibrium for a sufficiently rich set of shocks. The results are depicted in figure 4. See the supplementary material in the appendix for section 5 for a detailed discussion

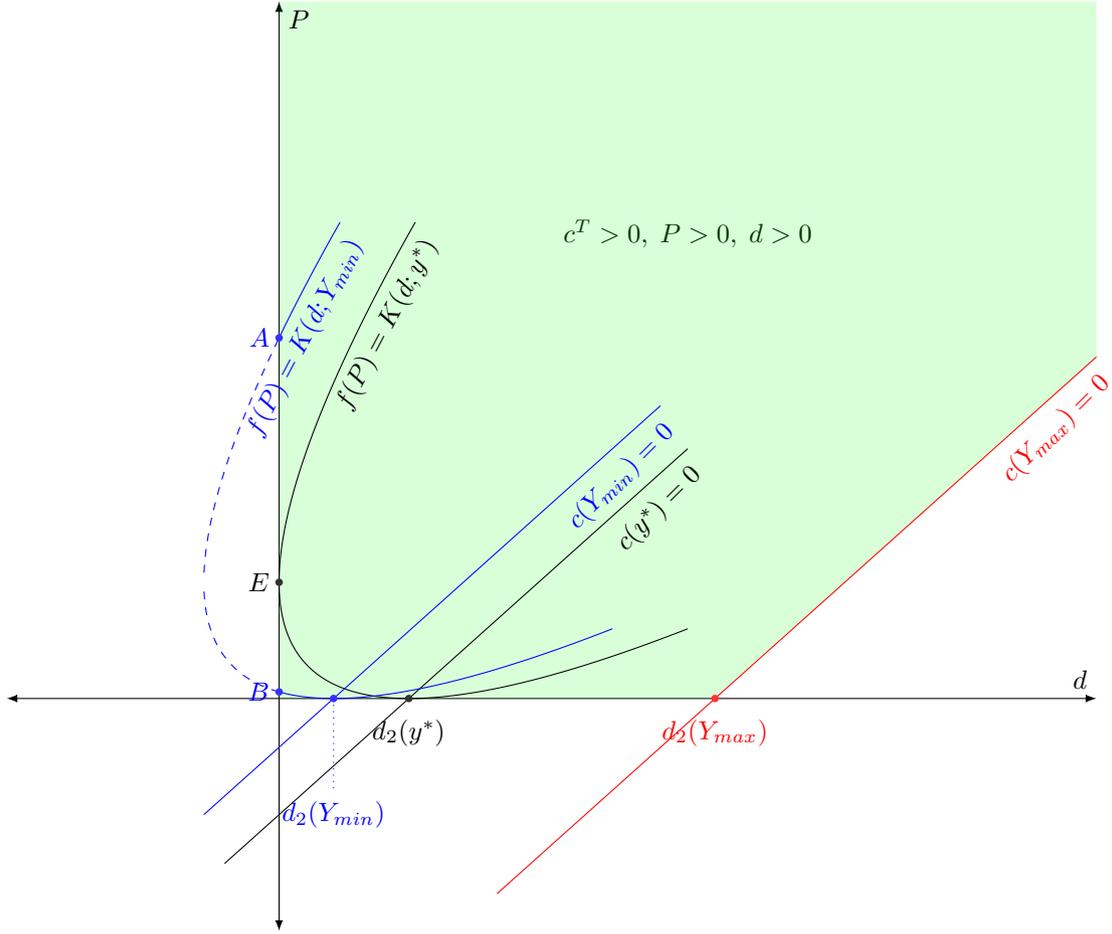

Assume that the equilibrium set is compact. Then, if the set containing exogenous shocks Y has at least 3 elements, then the system of equations formed by (45) to (49) has 2 solutions for at least 2 different elements in Y (i.e. the model has multiple equilibrium).

The figure above completely describes the presence of multiple equilibrium. Note that, with respect to figure 3, we added the locus h . The claim above shows that: i) below h we can find the optimal pairs (d, p) , ii) there are at least 2 optimal contours which insure the existence of multiple equilibrium for at least 2 shocks.

5.2 Dynamic Behavior

In this subsection we show that an ergodic GME, summarized by equations (45) to (49), is capable of generating 2 different types of sudden stops. At the same time, each of these events can be divided in 3 phases. i) The pre-sudden stop, characterized by an increase in the current account deficit. ii) The sudden stop itself, which consists of a sharp drop in consumption and a current account reversal. iii) The post-sudden stop. The events are mainly differentiated by phase iii). In the first type, exemplified by Portugal in 2008, there is a moderate recovery in consumption. In the second type, represented by Spain in 2008, consumption keeps falling after the sudden stop. Figures 5 and 6, borrowed from Pierri, et. al. ([56]) illustrate this situation.

Figure 3: Genericity of Multiple Equilibria: Feasibility and Intra-temporal optimality

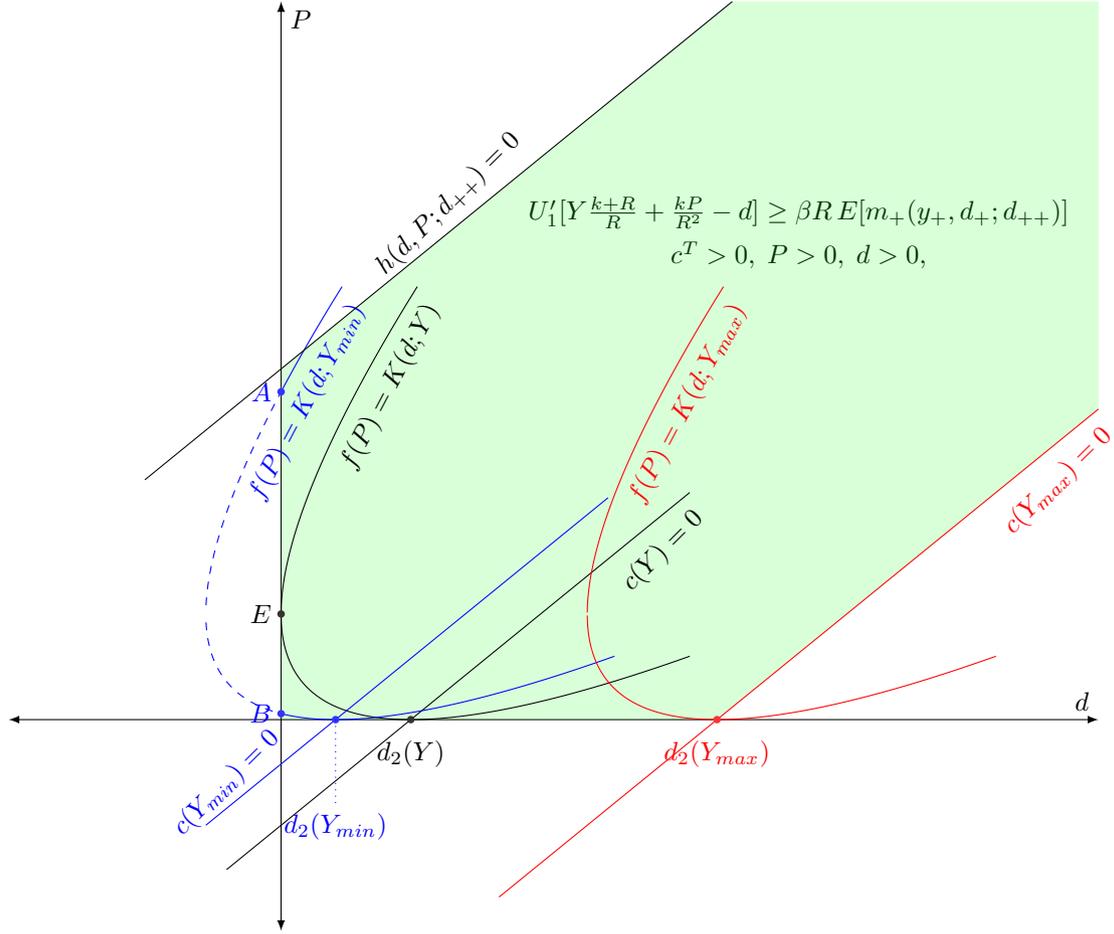

The feasible set of any GME is depicted in this figure. The $P - d_2$ locus defines the "non-negative consumption region". The "x-axis" defines the debt region. The "y-axis" the positive prices region. Optimality according to the intra-temporal optimization condition in the constrained regime is represented by the oval contours. Note that for low tradable income levels, this last locus is "truncated" as can be seen in figure 1. There is a level of tradable income, y^T , for which the whole f locus contains prices in the constrained regime as $K(0) = R/2\kappa$. For bigger income levels, prices are not determined in the constrained regime and, thus, they do not belong to the $f = K$ locus.

Moreover, the GME is capable of simulating a "Fisherian deflation" (i.e. a path of real exchange rate depreciation coupled with falling consumption) and a sudden stop without relying on a large, unanticipated shock that impose the loss of access to capital markets by assumption.⁴⁸ This shock is typically represented by a sudden change in a (non-stochastic) parameter or a change in the support of the distribution of exogenous shocks. Neither of these assumptions are required once we change the type of equilibrium from RE to GME. To our knowledge, this is the first attempt to show that a general equilibrium model with occasionally binding price dependent collateral constraints is capable of generating a collapse in borrowing followed by a "financial accelerator effect", caused by de-leveraging, and at the same time preserve the ergodicity of the dynamical system which, as will be shown in section 5.3, is essential for simulating and calibrating the model.

To model a sudden stop we must show the existence of an abrupt reversal in foreign borrowing. By "abrupt" we mean that it must be an intra-period event. This is the *same* effect caused by a sharp reduction in κ but without imposing an exogenous event (i.e. an event that can not be explained within

⁴⁸See Mendoza and Smith ([46]) for a discussion.

Figure 4: Genericity of Multiple Equilibria: Feasibility and Optimality

The h locus contains the (d, P) pairs which satisfy intertemporal optimality with equality in the constrained regime. Below it we can find the optimal (d, P) . As h is increasing in $d_{++}(y_+)$, which represents the selection of the equilibrium correspondence Φ , we can choose h to be conveniently located. In the ergodic case, as $d_{++}(y_+)$ is restricted by Remark 3.2, the equilibrium correspondence could be a truncated version of figure 4. theorem 1 insures that the intersection of the region below h , for the ergodic selection defined in Remark 3.2, and the region defined by the oval contours in the non-negative orthant formed by the (d, P) -axis is not empty.

the theoretical framework embodied in the model). In order to show the existence of such an event the multiplicity of equilibria will be essential.

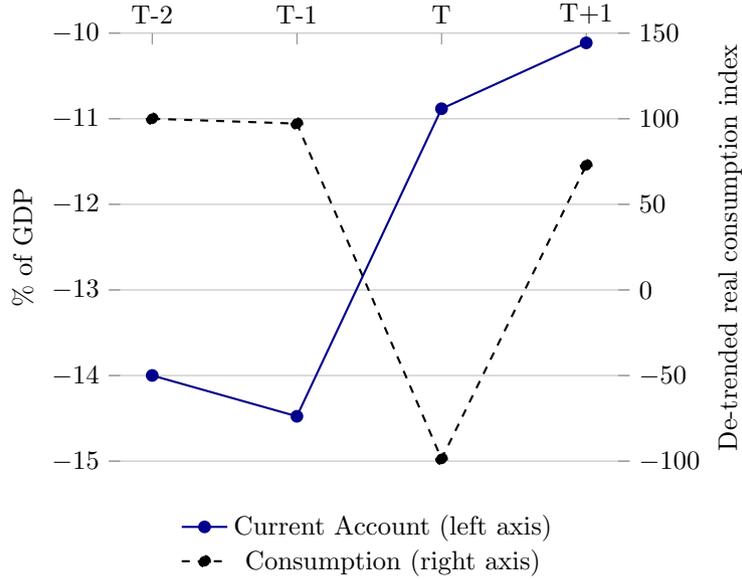

Let "T" in figures 5 and 6 be the time of the sudden stop. Before that, in phase i), we are in the unconstrained regime. In the case of Portugal, we observe a small decrease in consumption (3%) and an increase in the current account deficit. By setting $y_{T-2}^T = y_{T-1}^T = y_{lb}$, as the unconstrained regime can be thought as a standard partial equilibrium concave savings problem, we can match the observed path ⁴⁹. In the case of Spain, we observe both an increase in consumption and a reduction in the current account deficit. The same arguments can be used to show that this path can also be generated in the unconstrained regime for a sequence of shocks which satisfies $y_{T-2}^T > y_{T-1}^T > y_{lb}$ ⁵⁰. Then, suppose that for some debt level d and $y^T = y_{lb}$, the collateral constraint is binding. This happens in period T without loss of generality ⁵¹. Then, equation (49) implies:

⁴⁹The proof follows immediately from Lemma 13 and 16 in the appendix of section 4

⁵⁰See Lemma 16 in the appendix for section 4.

⁵¹Lemma 14 in the appendix containing the proofs of section 4 implies that starting from any initial condition, the collateral constraint binds in finite time with positive probability.

Figure 5: Anatomy of a Sudden Stop: Portugal 2008

The figure is constructed using the data set in Pierri, et. al. (2018). The authors refine the definition of a sudden stop to incorporate the 3 phases mentioned in section 5.2. The dotted line represents the current account divided by GDP, both at current prices. The left index is measured in percentage points. The right index, in full line, contains a consumption index constructed using the de-trended (by Hodrick and Prescott, HP) series at constant prices. The base of the index is 100 at "T-2", where "T" is the date of the sudden stop (2008).

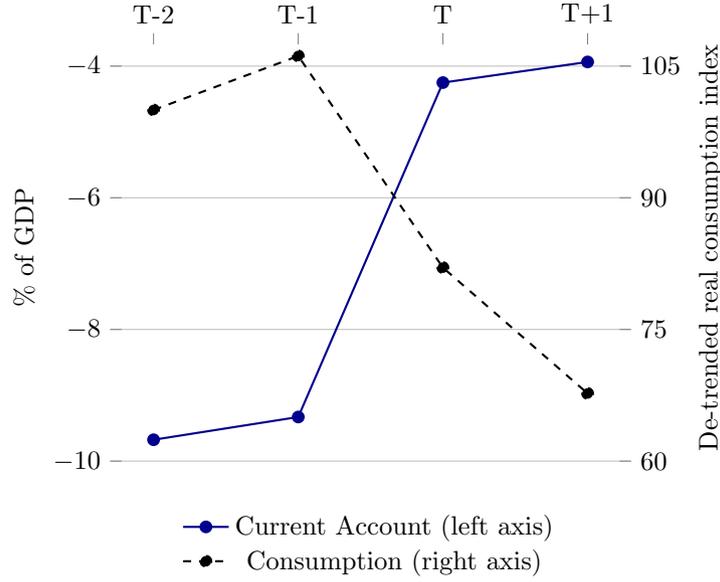

$$U' \{A_1(y_{lb} + R^{-1}\kappa\{y_{lb} + py^N\} - d)\} \geq E(U' \{A_1(y_+^T - \kappa\{y_{lb} + py^N\} + R^{-1}\bar{d})\}) \quad (52)$$

Where \bar{d} defines the ergodic selection $\varphi \sim \Phi$ in theorem 1 and the right hand side of equation (52) follows from the existence of an envelope shown in section 3.

One of the most relevant aspects of a GME is that it is computed "backwards". That is, we are interested in finding d , instead of d_+ as in the RE. It turns out that this fact can be used, combined with the primal version of the Euler equation (52), to obtain a sudden stop without requiring a jump in the exogenous parameters of the model. Let c, d_+ be the consumption and debt level tomorrow in (52). Note that, as we are in the constrained regime and P is increasing in tradable consumption, any $c_* < c$ will also satisfy (52). Take a pair (d_*, P_*) with $y_{lb} + py^N > y_{lb} + p_*y^N$, where $P(c^T) \equiv p > P(c_*^T) \equiv p_*$ with p and p_* defined by the intra-temporal optimality condition in the system defined by equations (45) to (49). Now, the discussion in the preceding section implies that there are 2 possible branches for the equilibrium selection. Taking the lower one, we know that p is decreasing in d as the branch has negative slope (see figure 4), which in turn implies $d < d_*$. Thus, $c = y_{lb} + R^{-1}\kappa\{y_{lb} + py^N\} - d > y_{lb} + R^{-1}\kappa\{y_{lb} + p_*y^N\} - d_* = c_*$ as desired. As equation (52) holds with inequality, this implies that the level of debt tomorrow is binding at p_* , that is $d_{+,*} = \kappa\{y_{lb} + p_*y^N\}$.

The discussion above suggests that it is possible to set the level of next period borrowing such that it is binding for the new level of consumption c_* as equation (52) is allowed to hold with strict inequality. Remarkably note that there exist a $\kappa' < \kappa$ such that $\kappa'\{y_{lb} + py^N\} = d'_+ = \kappa\{y_{lb} + p_*y^N\}$ which implies that $\kappa\{y_{lb} + p_*y^N\}$ is a sudden stop level of debt if the pair (d_*, p_*) implies a sharp contraction in consumption and a reversal in the current account. The first fact was already shown. Note that the order of magnitude of this "recession" depends on the level of consumption reached in phase i) before the sudden stop which, given the unconstrained nature of this phase and the smoothness of consumption in that regime, is similar to c and bigger than c_* . Thus, *memory in the form of a sequence* $y_{T-n}^T, \dots, y_{T-1}^T$,

Figure 6: Anatomy of a Sudden Stop: Spain 2008

matters in order to capture the quantitative properties of the sudden stop and the GME is capable of capturing it. Technically, the compactness of the SCE insures that we can adjust the severity of the crises along with a finite lower bound on consumption, both proved in lemma 2

It remains to show that the jump from (d, p) to (d_*, p_*) generates a current account reversal. Let $d_+, d_{*,+}$ be the level of next period debt associated with c, c_* respectively. In order to generate the mentioned reversal, we must have $d_{*,+} - d_* < d_+ - d$. As $d_{*,+} = y_{lb} + p_* y^N < d_+ = y_{lb} + p y^N$ and $d < d_*$, the desired result follows. In order to connect $d_{*,+} - d_*$ with the current account level before the sudden stop, note that, by the arguments used to show phase i), a sequence of negative shocks to income, $y_{t-n} = y_{lb}$ with $n = 2, 3, \dots, N$, will generate an increasing sequence of debt. Thus, $d_{t-n} > d_{*,+}$ without loss of generality. To sum up, the sudden stop generates a *reduction in consumption and a current account reversal* as desired. Finally, as this event happens for a particular trajectory of exogenous shocks y_0, y_1, \dots, y_T in finite time, the event has positive probability but can be considered a "rare event" as noted by Mendoza and Smith ([46]).

In order to show the existence of Fisherian deflation, we must prove that there exist a *binding* level of debt d_{++} which simultaneously satisfies equations (45) and (52) with $0 < d_{++} < \kappa\{y_{lb} + p_* y^N\} = d_{*,+}, c_+ < c_*$ and $p_+ < p_*$. That is, $d_{++} = \kappa\{y_+^T + p_+ y^N\}$ must satisfy:

$$p = \frac{A_2(y^N)}{A_1(y_+^T + R^{-1}\kappa\{y_+ + p_+ y^N\} - \kappa\{y_{lb} + p_* y^N\})} \quad (53)$$

By setting $y_+^T > y_{lb}$, it is possible to choose $\kappa\{y_+^T + p_+ y^N\} < \kappa\{y_{lb} + p_* y^N\}$ and c_+ will remain positive. Note that the last 2 inequalities together imply $p_+ < p_*$. Moreover, p is increasing and real valued in c , which imply that we must have $c_+ < c_*$. Finally, to show optimality, d_{++} must satisfy:

$$\begin{aligned} U'\{A_1(y_+^T + R^{-1}\kappa\{y_+ + p_+ y^N\} - \kappa\{y_{lb} + p_* y^N\})\} &\geq \\ &\geq E(U'\{A_1(y_+^T - \kappa\{y_+ + p_+ y^N\} + R^{-1}\bar{d})\}) \end{aligned}$$

As $c_+ < c_*$, we know $U'\{A_1(c_+)\} > U'\{A_1(c_*)\}$. As $y_+ + p_+ y^N < y_{lb} + p_* y^N$, it follows that $E(U'\{A_1(y_+^T - \kappa\{y_+ + p_+ y^N\} + R^{-1}\bar{d})\}) < E(U'\{A_1(y_+^T - \kappa\{y_{lb} + p_* y^N\} + R^{-1}\bar{d})\})$, which implies

that the condition above is satisfied. As mentioned before, the path of Spain in the 2008 sudden stop was characterized by a monotonically decreasing consumption sequence; even after the sharp drop in period "T". At the same time, we observed an improvement in the current account. The "Fisherian deflation" described above matches these facts as $d_{++} < d_+$, which implies the observed improvement in the current account, and $c_+ < c_*$, which gives us the decreasing consumption sequence.

It is sometimes observed that after a sharp depreciation, it follows a recovery in consumption coupled with a real appreciation and a current account improvement. This is the case of Portugal 2008 in phase iii). A GME is capable of replicating these facts as a path in the unconstrained regime. In particular, the model associates an increase in the national income with this type of phase iii). That is, we must observe an increase in $y_{T+1}^T - d_+$. This shock implies ⁵² an increase in consumption which generates the real appreciation due to the intra-temporal optimality condition $p(c^T)$. Moreover, the concavity of the utility function implies $d_{++} < d_+$, as it is possible to smooth consumption in an unconstrained economy. Thus, the observed current account improvement follows.

5.3 Empirical Procedure, Algorithms and Simulations

We now turn to the quantitative implications of the results presented in sections 3 and 4. Taking into account the lack of a closed form solution, we must take care of the numerical approximation of the model presented in section 2.

We first show how to compute the ergodic selection in the GME. It can be used to simulate a recurrent, and thus ergodic, behavior as the stochastic paths visit the atom in some type of crisis. In particular, in section 4 we showed that the process hits the atom if consumption and debt are bigger than the atomic level. However, this can happen with very low probability. Numerically, given the characteristics of the model, we can find recurrent sets that are observed more often, affecting significantly the data at low frequencies. Following the theoretical results in section 4, each ergodic selection has a unique invariant measure. Thus, we have to find (numerically) another selection. Each selection is associated with d_{++} in the Euler equation. The one found in section 4 is invariant with respect to (y, d) . This is convenient to prove its existence but it forced us to construct different paths of exogenous shocks for each initial condition, affecting the frequency in which this atom is observed. In order to circumvent this problem, we can connect d_{++} with (y, d) . Thus, we can use "shorter" paths to hit the atom, increasing its frequency.

Using this selection, at the end of this subsection, we solve the model for a parameter set borrowed from the empirical literature and compute the effects of a change in the interest rate in the long run of the model. The discussion in section 5.2 shows that it is possible to remove the ergodic component of any selection in a GME simply by visiting a different point every time the collateral constraint binds. However, this selection is still time invariant and thus, stationary. We compute the difference between simulations generated by an ergodic and a stationary GME equilibrium. We found that ergodic simulations generate smoother consumption paths or, equivalently, agents are less financially constrained. Finally, we compute a non-stationary GME. As it is expected, this equilibrium can generate large fluctuations in macroeconomic fundamentals (i.e. current account) using standard preferences and with the same shock structure. That is, simply by changing the definition of equilibrium, if we are willing to give up the long run performance of the model, the same theoretical structure is capable of generating a great range of balance of payments crises.

5.3.1 Numerical procedure

We describe how to compute an ergodic selection and use it to simulate the long run (a path of length N) and short run (a path of length $T < N$) behavior of the model. The appendix contains additional details.

⁵²See Lemmas 16 and 17 in the appendix for section 4.

GME Ergodic Algorithm

Step 1: Computation

- Fix the vector of parameters from section 2.1, $[\kappa, \beta, \sigma, \xi, a] \equiv \Theta \gg \vec{0}$ with $U(c_1, c_2) = \frac{A(c_1, c_2)^{(1-\sigma)}}{1-\sigma}$ and $A(c_1, c_2) = (a(c_1)^{(1-1/\xi)} + (1-a)(c_2)^{(1-1/\xi)})^{\frac{1}{1-1/\xi}}$.
- Fix $Y \times K_1 \times K_2$
- Compute $d'(d, y)$ from (18) *ignoring* the collateral constraint.
- Compute d_* from equation (58) in the appendix
- Compute $\varphi \in \Phi$ from equation (59) in the appendix

Step 2.1: Stationary simulation

- Take a "draw" of length $T + 1$ from (Y, q) , the exogenous Markov process which generates tradable output.
- Fix $[d_{T-1}, y_{T-1}]$ from $Y \times K_2$, obtain d_T from $d'(d, y)$. Verify if the collateral constraint binds and adjust d_T if necessary. Then compute $d_{T+1}(y_T, d_{T-1}, y_{T-1})$ from $\varphi \in \Phi$ for every $y_T \in Y$. Compute the rest of the endogenous variables from equations (45)-(49).
- Take $[p_T(y_T), d_T(y_{T-1})]$ as given from the previous • and compute $[p_{T-1}(y_{T-1}), d_{T-1}(y_{T-2})]$ from equations (45)-(49). Note that d_{T-1} is in the preimage of $d'(d, y)$ with $d_T = d'(d_{T-1}, y_{T-1})$.
- Repeat the above • until you get $[p_0(y_0), d_0]$, where d_0 is allowed to be independent of y_0 as they are both initial conditions of the system.

Step 2.2: Ergodic simulation

- Take a "draw" of length $N + 1$ from (Y, q) , the exogenous markov process which generates tradable output.
- Compute $[p_j(y_j), d_j(y_{j-1})]$ for $j = N + 1, N, N - 1$ as in the stationary simulation procedure
 - If d_N binds, $y_{N-1} - d_{N-1} + d_N/R > y_{LB} - d_* + d'(d_*, y_{LB})/R$ and $d_N > d'(d_*, y_{LB})$, the process hits the atom and reverts to it.
- Continue until $[p_0(y_0), d_0]$

Let (d, d_+) denote the debt levels observed today and tomorrow. The presence of the collateral constraint implies that $d_+ \neq d'(d, y)$. Thus, the ergodic selection of the GME φ depends on $\varphi(d, y)$ for every $(d, y) \in K_2 \times Y$ if the collateral does not bind and on $\varphi(d_+, d, y)$ for every $(d_+, d, y) \in K_2 \times K_2 \times Y$ if it binds. The discussion on the previous sections, especially the connection between the RE and the GME insured by the existence of well behaved envelopes, implies that there is a stationary structure for the GME given by equations (45)-(49) and $d'(\cdot, \cdot)$, the policy function in the unconstrained regime for the RE. This fact implies that the GME is computationally efficient. That is, once $d'(\cdot, \cdot)$ is available, it can be computed fast.

The above algorithm generates a sequence $\{p_t, d_{t+1}\}_{t=0}^T$ which *depends* on $p_{T+1}(y_{T+1})$ and $d_{T+1}(y_T)$ for a given point in the set Θ . This variables are pinned down by picking an ergodic selection for the GME. The results in section 4 implies that we need to constraint the paths generated by the GME using the policy function of the RE. However, this is not necessarily the case if we only need a stationary equilibrium. That is, in this last case, we may allow $d_+ \neq d'(d, y)$ even if the collateral does not bind. Thus, we are adding memory to the selection as $\varphi(d_+, d, y)$ and d_+ may not depend on (d, y) . Going

backwards we only have 1 additional restriction to satisfy: in order to compute d_- , given d , we know that $E(m)$ includes $\varphi(d, d_-, y')$ for any $y' \in Y$. This fact insures that we can still find d_- to satisfy the restrictions associated with intertemporal optimality for any $d_- \in K_2$. Contrarily, any sequence generated from the minimal state space algorithm depends *only* on the point in Θ and the draw from (Y, q) for a given d_0, y_0 . That is, $\varphi \in \Phi$ *does not necessarily satisfied* $d_{T+2}(y_{T+1}) = d'(d'(d_T, y_T), y_{T+1})$ as it is the case for the minimal state space algorithm. Taking into account the results in section 5.2, this distinction is critical as it allows to choose d_+ to be the collateral constrained level and to vary d_- along with the degrees of freedom in $E(m)$ to generate a "crises".

Finally, the function which maps $[y_t, p_t, d_t] \mapsto [y_{t+1}, p_{t+1}, d_{t+1}]$ for each $y_{t+1} \in Y$, which defines the markov kernel in the GME, *does not necessarily satisfy* the structural properties required to prove the existence of a RE. Thus, the path $\{p_t, d_{t+1}\}_{t=0}^T$ is more flexible to capture the different phases of a macro crises as the transition function in the GME can be computed pointwise as in the SCE. This is the *numerical implication of expanding the memory in the recursive equilibrium notion as the transition function is computed exactly as in the SCE* (i.e. pointwise for each element in the draw from (Y, q)).

The process is shown to be stationary by induction as $N \rightarrow \infty$. However, if we iterate forward, using d_T, d_{T+1} and computing $d_{T+2}(y_{T+1})$ for every $y_{T+1} \in Y$ we are obtaining a path from the SCE which is not necessarily stationary. From a purely practical perspective, it may be interpreted that as a prediction of the model that is not constrained by the structure imposed by ergodicity or stationarity.

Finally, we briefly describe the non-stationary GME Algorithm.

GME Non-Stationary Algorithm

Step 1

- Fix the vector of parameters from section 2.1, $[\kappa, \beta, \sigma, \xi, a] \equiv \Theta \gg \vec{0}$
- Fix $Y \times K_1 \times K_2$ in order to define a compact set for (y, p, d) respectively.
- Fix a $[p_{T+2}(y_{T+2}), d_{T+2}(y_{T+1})]$ for each $(y_{T+1}, y_{T+2}) \in Y \times Y$. This will define a selection $\varphi \in \Phi$ using the Euler equation in time T .

Step 2

- Take a "draw" of length $T + 1$ from (Y, q) , the exogenous markov process which generates tradable output.
- Fix $[p_{T+1}(y_{T+1}), d_{T+1}(y_T)]$ from $K_1 \times K_2$ and compute $[p_T(y_T), d_T(y_{T-1})]$ from equations (45)-(49)
- Take $[p_T(y_T), d_T(y_{T-1})]$ as given from the previous • and compute $[p_{T-1}(y_{T-1}), d_{T-1}(y_{T-2})]$ from equations (45)-(49). Include $[p_{T+1}(y_{T+1}), d_{T+1}(y_T)]$ in the Euler equation. This step implies a change in the selection from Φ and, thus, breaks the stationarity of the process.
- Repeat the above • until you get $[p_0(y_0), d_0]$, where d_0 is allowed to be independent of y_0 as they are both initial conditions of the system.

Note that the sequence $\{p_t, d_{t+1}\}_{t=0}^T$ now *depends* on the histories of the form $p_y(y^t), d_t(y^{t-1})$ with $y^t = y_0, \dots, y_t$. Thus there is a trade off: *we gain flexibility with respect to the stationary / ergodic GME in order to incorporate more "memory" from the SCE but in return we can not claim that these paths are connected with the steady state of the model*. Thus, depending on the relevance that we assign to the long run behavior, we can choose between the GME ergodic/ stationary or non-stationary procedure.

Table 1: Parameters

Parameter	κ	β	σ	ξ	a	z_l	z_h	$p(z_l)$	R	R'
Value	0.3	0.99	2.0	0.5	0.5	0.5	1.5	0.2	1.05	1.025

5.3.2 Results

We now turn to the solution of the model. The following table contains the parameters, borrowed from Pierri, et. al. ([56]).

We now show the results of simulating the ergodic and the stationary process. We present the effects of a reduction in the interest rates in both cases for consumption (Table 2) and debt (Table 3).

Table 2: Summary of Simulations Statistics for Consumption

Statistics	Mean(R)	STD(R)	Mean(R')	STD(R')
Ergodic	1.0497	0.450	1.0501	0.453
Stationary	1.01	0.52	1.04	0.53

Table 3: Summary of Simulations Statistics for Debt

Statistics	Mean(R)	STD(R)	Mean(R')	STD(R')
Ergodic	0.230	0.086	0.235	0.094
Stationary	0.27	0.06	0.29	0.07

The statistics are reported at distinct truncation levels as there are some cases for which 2 decimal positions are not enough to differentiate between simulations. A reduction in the interest rate generates the expected changes in both ergodic and stationary simulations: an increase in consumption and thus a reduction in the savings rate which implies more debt. However, there are at least 2 important differences, which are connected: stationary simulations overestimate i) the elasticity of average consumption and debt with respect to the interest rate, ii) the volatility of consumption for the same interest rate, which implies that debt is less volatile. For the first fact, the intuition goes as follows: as the atom is not directly affected by the change in the interest rate, only through its effect on the unconstrained policy function for the RE, and ergodic simulations are generated as a sequence of recurrent sets which has a regeneration point in the atom, average observed endogenous variables are not severely affected. For the second fact, note that in the ergodic simulation debt is regenerated to a very low level as by construction the atom is defined to hit the collateral constraint with equality. Thus, de-leveraging is more significant in an ergodic crises, which implies that the economy has more time to accumulate debt and, thus, to smooth consumption.

The take away point from the above results is related to the invariance of the atom with respect to parameter changes. The most direct way to change the ergodic distribution is to affect the regeneration point. In this case, numerically, the atom does not change significantly after the interest rate shock even though the unconstrained policy function and the value of the collateral are both affected. In particular, the atom is given, as described in the appendix, by:

$$d'(d_*, y_{lb}; R) = \kappa \left[y_{lb} + y^N \left(\frac{A_2(y^N)}{A_1(y_{lb} + (d'(d_*, y_{lb}; R)/R) - d_*)} \right) \right]$$

After the change in the interest rate both the left and right hand side of the equation above rises as $d'(d_*, y_{lb}; R)$ and $d'(d_*, y_{lb}; R)/R$ goes up. Thus, the change in d_* is not significant. Finally, we present a non-stationary simulation in the table below.

Table 4: Non Stationary Crises

Non Stationary Simulations	$t - 1$	t	$t + 1$
Current Account / GDP	-10%	-8%	+5%

The table below reflects the flexibility contained in the model. By changing selections, the SCE is able to replicate a sharp reversion in the current account, as it is frequently observed in data, without requiring a change in the parameters (i.e. a reduction of κ or y_{lb}).

6 Conclusions and Directions for Future Research

In this paper, we have proposed a new set of tools for characterizing models of financial crises in small open economies in the presence of multiple dynamic equilibria. We have proven the first results in this literature in the existence of both SCE and RE, and provided a complete qualitative theory of the set of RE. In principle per the set of RE, our methods are constructive, and provide a global basis for the existence of robust multiplicities of RE.

We then show that our GME approach to studying the implied stochastic equilibrium dynamics can replicate the short run dynamic of a crises and still be connected with long run stylized facts. These properties depend on the existence of a sequential competitive equilibria and minimal state space markov equilibria. Once these elements are available, we can classical results in stochastic process the existence of ergodic GME selectors, we can compare the stochastic properties of RE to based upon ergodic selectors vs GME selectors associated with invariant measures, we can study nonstationary GME selectors, and we can compare the stochastic properties of Sudden Stops generated by these different GME selectors vs selecting exclusively from the set of RE. Our methods are also easily implemented numerical, as GME can be efficiently computed using a standard laptop.

The results in this paper are derived for a restrictive set of assumptions to illustrate the power of our approach (i.e., the case where the exogenous endowment shocks must be drawn from a finite set, are iid, and we assume $\beta R < 1$. For the set of SCE, we do impose some conditions on asymptotic bounds for marginal utility (to obtain needed compacted for proving the existence of SCE), which in turn in principle could affect the homotheticity of equilibrium paths. We are able to relax the sufficient condition on preferences to the standard case in the literature relative to the set of RE, but many of our results in this paper how for me general environments of preferences, shocks, and cases where $\beta R \geq 0$. (e.g., see [57]).

The results obtain for the minimal state space RE are of independent interest, taking into account the relevance of the high / low borrowing for the design of economic policies. Under rational expectations, this equilibrium can be self-fulfilling. However, it remains to be shown if this type of equilibrium can co-exist under another rationality assumption such as learning, among others.

Appendix

Proofs for section 2

We now turn to the characterization of the SCE. In order to get the paper self-contained, we write the primal version of the first order conditions which will be useful to prove the long run properties of the equilibrium. We keep the notation $c_1 \equiv c^T, c_2 \equiv c^N$ in line with Assumption 1.

For any given sequence of prices $p = \{p_t\}_{t=0}^\infty$, from the first order conditions in (7-10), we can obtain the following two expressions critical in characterizing the stochastic structure of binding collateral constraints:

$$[c_2(y^t)][\{\beta^t U'(A(c(y^t)))\}\{-A_1(c_1(y^t))p(y^t) + A_2(c_2(y^t))\}] = 0, \quad y^t - a.e \quad (54)$$

$$\begin{aligned} & [\kappa\{y^t + p(y^t)y^N\} - d(y^t)][U'(A(c(y^t)))A_1(c_1(y^t))] \\ & - E_t(U'(A(c(y^t)y_{t+1}))A_1(c_1(y^t)y_{t+1})) = 0, \quad y^t - a.e \end{aligned} \quad (55)$$

where E_t can be obtained using the y_t th row of the transition matrix if the cardinality of this shock set Y is finite, or by integrating using the density associated with χ evaluated at y_t if Y is an uncountable set. In the i.i.d case, we have $E_t = E$.

We make a few remarks on (54) and (55). First, the characterization of optimal solutions uses the primal formulation of the problem, and hence is written in terms of the "complementary slackness" version of the Karush-Kuhn-Tucker (KKT) equations. In particular, in either equation (54) or (55), the first bracket contains the inequality constraint, $c_2 \geq 0$ in equation (54) or $\kappa\{y^t + p(y^t)y^N\} - d(y^t) \geq 0$ in equation (55), and the second bracket consists of the derivative of the objective function with respect to the control, $c_2(y^t)$ in equation (54) and $d(y^t)$ in (55). Additionally, note we have eliminated the control, c_1 , and the restriction in equation (2) from the KKT system. Formally, $c_1(y^t)$ must be replaced with $-p(y^t)c_2(y^t) - d(y^{t-1}) + y^t + p(y^t)y^N + \frac{d(y^t)}{R}$. This last issue is relevant for the dual formulation of the problem as it allows us to avoid dealing with the Lagrange multiplier associated with (2). It turns out that the dual representation is more difficult to characterize in terms of its dynamic behavior when compared with the primal version.

Now, in order to close the characterization of the model, we need a terminal condition on the right hand side of the Euler equation $\beta^t E_t(U'(A(c(y^t)y_{t+1}))A_1(c_1(y^t)y_{t+1}))$, which results after iterating equation (55) (see Constantinides and Duffie ([21]) for a discussion). Under assumptions 1-a.i, 1-a.iii, 1-e, and 1-f, this requirement will be satisfied. The relevance of these assumptions, their relationship with the restriction we place on βR and the sufficient conditions for the compactness needed to obtain the existence of SCE will be proved in lemma 1, stated in the body of the paper. Note that the results below are necessary conditions. The associated sufficient conditions for existence will be proved in theorem 1.

Proof of Lemma 2

Proof. 1) Let $Y = [y_{min}, y_{max}]$. From assumption 1-g), lemma 1 in Braidó ([18]) implies that $-d(y^t) < \frac{R}{1-\rho} \equiv k_{2,min}$ uniformly in $y^t \in \Omega$ with ρ sufficiently close to 1. From assumption 1-a3), 1-b), 1-c) and 1-d), equation (54) implies $p(y^t) = \frac{A_2(c_2(y^t))}{A_1(c_1(y^t))}$. Definition 1-2), equation (54), assumption 1-e), 1-f) then imply $p(y^t) \in [\frac{y^N}{c_{u1}}, \frac{y^N}{c_{l1}}] \equiv K_3 \equiv [k_{3,min}, k_{3,max}] \quad y^t - a.e..$ Then, the collateral constraint implies $d(y^t) \leq \kappa(y_{max} + k_{3,max}y^N) \equiv k_{2,max}$. Then, $d(y^t) \in [k_{2,min}, k_{2,max}] \equiv K_2 \quad y^t - a.e..$ Finally, using K_2 and K_3 , K_1 can be derived using equation (2) and Definition 1-2). Using these results, it is straightforward to verify that $\lim_{t \rightarrow \infty} \beta^t E_t(U'(A(c_t^*))A_1(c_t^*)) = 0$. Note that the integral in E_t is taken with respect to either the density associated with $\chi(y_t)$ or the y_t th-row in the transition matrix in case Y has finite cardinality. Thus, this result also holds $y^t - a.e..$ Then, the conditions in Lemma 1 in Kubler and Schmedders ([36]) hold, which implies that equations (54) and (55) together with the terminal condition on $\beta^t E_t(U'(A(c_{t+1}))A_1(c_1(t+1)))$ are equivalent to definition 1, as desired. ■

$Z_{uc}^* \rightarrow -\infty$. Then, by the intermediate value theorem, $x_{uc}^*(d, y, S, c, C^T)$ exists (hence, it is well-defined as a function).

Next, we show $x_{uc}^*(d, y, S; c, C^T) \in \mathbf{C}^{p*} \subset \mathbf{C}^p$. We first show $A_{uc}(c; C^T(S))(d, y) = x_{uc}^*(d, y, S; c, C^T) \in \mathbf{C}^p$. Again, when $c(d, y) \in \mathbf{C}^p$, $c(d, y) = 0$ in any state (d, y) , $\Rightarrow C(c, C^T) = 0$; hence, $x_{uc}^*(d, y, S; c, C^T) = 0 \in \mathbf{C}^p$. Therefore, consider the case when $c \in \mathbf{C}^p$, $c(s^e) > 0$. As $C^T \in \mathbf{C}^f$, for fixed $c \in \mathbf{C}^p$, Z_{uc}^* in (34) is (strictly) decreasing in d , (strictly) increasing in y , and strictly decreasing in x ; hence, at such $s = (d, y, S)$, the root $x_{uc}^*(d, y, S; c, C^T)$ is decreasing in d , and increasing in y . Further, when $d_2 \geq d_1$ and $y_1 \geq y_2$, by the concavity of utility in Assumption 1, we have from the definition of the $x_{uc}^*(d, y, S, c, C^T)$ in Z_{uc}^* the following inequality

$$\frac{U_1(x_{uc}^*(d_1, y_1, S; c, C^T), y^N)}{R} \leq \int \beta U_1(C(R(x_{uc}^*(d_2, y_2, S; c, C^T) - y_2^T + d_2), y'), R(x_{uc}^*(d_2, y_2, S; c, C^T) - y_2^T + d_2), y') \chi(dy')$$

hence, for the root $x_{uc}^*(d, y, S; c, C^T)$ must make the right side of the above expression fall at $x_{uc}^*(d_2, y_2, S; c, C^T)$ in a new solution, which implies:

$$x_{uc}^*(d_1, y_1, S; c, C^{T*}) - y_1^T + d_1 \geq x_{uc}^*(d_2, y_2, S; c, C^{T*}) - y_2^T + d_2$$

or

$$y_1^T - d_1 - x_{uc}^*(d_1, y_1, S; c, C^{T*}) \leq y_2^T - d_2 - x_{uc}^*(d_2, y_2, S; c, C^{T*})$$

Therefore, for each $C^T \in \mathbf{C}^*$, $A_{uc}(c; C^T(S))(d, y) = x_{uc}^*(d, y, S; c, C^T) \in \mathbf{C}^p$.

Finally, as $A_{uc}(c; C^T)(s^e) \in \mathbf{C}^p$, and $A_c(C^T)(S)$ is independent of (d, y) at $C^T(S) \in \mathbf{C}^f$, $A(c; C^T)(s^e) = \inf\{A_{uc}(c; C^T)(s^e), A_c(C^T)(S)\} \in \mathbf{C}^{p*}$. Therefore, we conclude $A(c; C^T(S))(d, y) : \mathbf{C}^p \rightarrow \mathbf{C}^{p*}$.

Step 2: $A(c, C^T(S))(d, y)$ is monotone (increasing) on $\mathbf{C}^p \times \mathbf{C}^f$. Take $x_1 = (c_1, C_1^T)$ and $x_2 = (c_2, C_2^T) \in \mathbf{C}^p \times \mathbf{C}^f$, with $x_1 \leq x_2$ under the pointwise partial order on the product space $\mathbf{C}^p \times \mathbf{C}^f$. First, consider the case $0 \leq x_1 \leq x_2$, where in some state (d, y, S) , either $0 = c_1(d, y)$ or $0 = C_1^T(S)$. Then, by definition of the operator $A(c, C^T(S))(d, y)$, $A(c_1, C_1^T)(d, y, S) = 0 \leq A(c_2, C_2^T)(d, y, S)$. So, now consider the case where $0 < x_1(d, y) \leq x_2(d, y)$, so in all states, $0 < c_1(d, y)$ and $0 < C_1^T(S)$. Then, we have from the definition of x_{uc}^* in Z_{uc}^* the following inequality:

$$\begin{aligned} \frac{U_1(x_{uc}^*(d, y, S; c_1, C_1^T), y^N)}{R} &= \\ &\int \beta U_1(C_1(R(x_{uc}^*(d, y, S; c_1, C_1^T) - y^T + d), y'), R(x_{uc}^*(d, y, S; c_1, C_1^T) - y^T + d_2), y') \chi(dy') \\ &\geq \int \beta U_1(C_2(R(x_{uc}^*(d, y, S; c_1, C_1^T) - y^T + d), y'), R(x_{uc}^*(d, y, S; c_1, C_1^T) - y^T + d_2), y') \chi(dy') \end{aligned}$$

where for $i = 1, 2$, the subscript on continuation consumption is used to denote.

$$C_i(c, C^T)(d, y, S) = \inf\{c_i(d, y), C_c^T(D, Y, C_i^T(S))\}$$

where recall $C_c^T = (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C^T(D, Y)Y^N)$. Therefore, as Z_e^* is strictly falling in x , we have

$$x_{uc}^*(d, y, S; c_1, C_1^T) \leq x_{uc}^*(d, y, S; c_2, C_2^T)$$

Then, if the implied debt at $d_{x_{uc}}(d, y, S; c_1, C_1^T) \leq \kappa(Y^T - D + p(C_1^T)Y^N)$, then

$$\begin{aligned} A(c_1, C_1^T(S))(d, y) &= A_{uc}(c_1, C_1^T(S))(d, y) \\ &= x_{uc}^*(d, y, S; c_1, C_1^T) \\ &\leq x_{uc}^*(d, y, S; c_2, C_2^T) \end{aligned}$$

else,

$$\begin{aligned} A(c_1, C_1^T(S))(d, y) &= (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C_1^T(S))Y^N \\ &\leq (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C_2^T(S))Y^N \end{aligned}$$

In either case, for $A(c_2, C_2^T(S))(d, y)$, we have $A(c_1, C_1^T(S))(d, y) \leq A(c_2, C_2^T(S))(d, y)$. So the operator $A(c, C^T(S))(d, y)$ is monotone.

Next, we prove $A(c; C^T(S))(d, y) : \mathbf{C}^p \rightarrow \mathbf{C}^{p*}$ is order continuous for each fixed $C^T(S) \in \mathbf{C}^f$. First, some definitions. Let X be a countably chain complete partially ordered set,⁵⁴ and $X_c = (x_n)_{n \in \mathbf{N}} \subset X$, $x_n \in X$, be a countable chain. We say a operator $A : X \rightarrow X$ for is *order continuous* if for any countable chain $X_c \subset X$, $A(x)$ (a) sup-preserving: $A(\vee X_c) = \vee A(X_c)$ and (b) inf-preserving: $A(\wedge X_c) = \wedge A(X_c)$. We remark, order continuous operators are necessarily isotone (e.g., Dugundji and Granas ([?], p. 15)). We now show for each $C^T(S) \in \mathbf{C}^f$, $A(c; C^T(S))(d, y)$ preserves sup operations; a similar argument works for preserving inf operations. Fix the state (d, y) , and $C^T(S) \in \mathbf{C}^f$, and denote by $C_c = (c_n(d, y))_{n \in \mathbf{N}}$, $c_n(d, y) \in \mathbf{C}^p$ any countable chain in \mathbf{C}^p . Define $\vee C_c(d, y) \in \mathbf{C}^p$ and $\vee A(C_c; C^T(S))(d, y) \in \mathbf{C}^{p*}$, which both exist in \mathbf{C}^p (resp, \mathbf{C}^{p*}) are both complete lattices (hence, countably chain complete). If in any state (d, y) , $\vee C_c(d, y, S) = 0$, then $\vee A(C_c; C^T(S))(d, y) = A(\vee C_c; C^T(S)) = 0$. Therefore, assume for every state (d, y, S) , $\vee C_c(d, y) > 0$. Then, we have the following inequalities for continuation tradeables consumption $C(c_n; C^T) = \inf\{c_n(d, y), C_c^T(D, Y, C^T(S))\}$

$$\begin{aligned} C(\vee C_c) &= C(\vee c^n; C^T) \\ &= \inf\{\vee c_n(d, y), (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C^T(S))y^N\} \\ &= \vee \inf_n\{c_n(d, y), (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C^T(S))Y^N\} \\ &= \vee C(c^n; C^T) = \vee C(C_c; C^T(S)) \end{aligned}$$

where in the second line $\vee c_n(d, y)$ is computed, and then the infimum over two continuous functions $(\vee c_n(d, y), (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C^T(S))y^N)$ is taken over a compact set $(d, y, S) \in \mathbf{D} \times \mathbf{Y} \times \mathbf{S}$, and hence continuous by Berge's theorem, in the third line, \inf_n is computed pointwise over $(d, y) \in D \times Y$ (a compact set and hence continuous) at each $n \in \mathbf{N}$, and this collection is then increasing pointwise in n as C_c is a countable chain) and the sup is taken over $n \in \mathbf{N}$. Then, the remaining equalities follow from p continuous, and the fact that sup and inf operations over two continuous functions are each continuous over the compact set $(d, y, S) \in \mathbf{D} \times \mathbf{Y} \times \mathbf{S}$ by Berge's maximum theorem.

Using these facts, and substituting into the definition of $Z_{uc}^*(x, d, y, S; c, C^T)$, we have for the root $x_{uc}^*(d, y, S, c, C^T)$ the following equalities:

$$\begin{aligned} Z_{uc}^*(x_{uc}^*(d, y, S; \vee c_n, C^T), d, y, S; \vee c_n, C^T) &= \vee Z_{uc}^*(x_{uc}^*(d, y, S; \vee c_n, C^T), d, y, S; c_n, C^T) \\ &= \vee Z_{uc}^*(x_{uc}^*(d, y, S; c_n, C^T), d, y, S; c_n, C^T) \\ &= Z_{uc}^*(\vee x_{uc}^*(d, y, S; c_n, C^T), d, y, S; c_n, C^T) \end{aligned}$$

where the first equality follows from $U_1(c, y^N)$ continuous and $C(\vee c_n, C^T) = \vee C(c_n, C^T)$, the second line follows from Z_{uc}^* continuous (pointwise) in (x, c_n) for fixed C^T , the third line follows from Z_{uc}^* continuous in x . Then, noting that for any state where collateral constraints do not bind, we have $x_{uc}^*(d, y, S, c_n, C^T) \leq A_c(C^T)(S)$, our operator $A(c, C^T(S))(d, y)$ is for each $n \in \mathbf{N}$ defined as:

$$A(c_n, C^T(S))(d, y) = \inf_n\{x_{uc}^*(d, y, S; c_n, C^T), A_c(C^T)(S)\}$$

⁵⁴Let X be a partially ordered set. We say X is countably chain complete if for all countable subset X_c that are a chain (i.e., for no two elements $x_1, x_2 \in X_c$, x_1 and x_2 are ordered), $\vee X_c \in X$ and $\wedge X_c \in X$.

so we have the following:

$$\begin{aligned}
A(\vee c_n; C^T(S))(d, y) &= \inf\{x_{uc}^*(d, y, S; \vee c_n, C^T), A_c(C^T)(S)\} \\
&= \inf\{\vee x_{uc}^*(d, y, S; c_n, C^T), A_c(C^T)(S)\} \\
&= \vee \inf_n\{x_{uc}^*(d, y, S; c_n, C^T), A_c(C^T)(S)\} \\
&= \vee A(c^n, C^T(S))(d, y) \\
&= \vee A(c_n; C^T(S))(d, y)
\end{aligned}$$

where the second equality follows again from $U_1(c, y^N)$ is continuous and $C(\vee c_n; C^T) = \vee C(c_n; C^T)$ for each C^T , and for the third equality again uses the fact that \inf_n here is an increasing pointwise in n , and the sup is then taken over $n \in \mathbf{N}$. Hence, $A(c; C^T(S))(d, y)$ is order continuous in \mathbf{C}^p for each fixed $C^T \in \mathbf{C}^f$, which completes the proof of Step 2.

Remark: Before proceeding to step 3, we mention that as equilibrium fixed point comparative statics be an important question in Steps 4 and 5, for the remaining steps of the proof of this lemma, we add to the notation for our operator for the parameters of interest, and remark that the operator $A(c; C^T(S), \beta, R, \kappa)(d, y)$ is increasing in κ , and decreasing in (β, R) for fixed (c, C^T, d, y, S) . To see this, noting $c \in \mathbf{C}^p$ is decreasing in d , U_1 is decreasing in c under assumption 1, Z_{uc}^* in (34) is decreasing in (R, β) . So, the root $x_{uc}^*(d, y, S, c, C^T; \beta, R, \kappa)$ is decreasing in (β, R) . Further, $A_c(C^T; R, \kappa)$ is decreasing in R . As our operator is defined as the infimum of two decreasing mappings, $A(c; C^T(S), \beta, R, \kappa)(d, y)$ is decreasing in (β, R) . As Z_{uc}^* is independent of κ , but $A_c(C^T; R, \kappa)$ is increasing in κ , $A(c; C^T(S), \beta, R, \kappa)(d, y)$ is increasing in κ .

Step 3. *Existence and computation he greatest fixed point of $A(c; C^T(S), \beta, R, \kappa)(d, y) \in \mathbf{C}^{p*} \subset \mathbf{C}^p$.* Fix $C^T \in \mathbf{C}^f$, and denote by $\Psi_A(C^T(S), \beta, R, \kappa)(d, y) \subset \mathbf{C}^{p*}$ the set of fixed points of mapping of $A(c; C^T(S), \beta, R, \kappa)(d, y) \in \mathbf{C}^{p*} \subset \mathbf{C}^p$.⁵⁵ By definition, the least fixed point is trivial, and is $c^* = 0$ for all $y \in Y$. By step 2 above, $A(c; C^T(S), \beta, R, \kappa)(d, y)$ is order continuous on \mathbf{C}^p . Further, $A(c^{\max}; C^T(S))(d, y) \leq c_{\max}$ (with strict inequality for some states (d, y)). Hence, by the Tarski-Kantorovich theorem (e.g, Dugundji and Granas ([26], p.15), the greatest fixed point $c^*(C^T(S))(d, y)$ can be computed as:

$$\wedge A^n(c^{\max}; C^T(S), \beta, R, \kappa)(d, y) \rightarrow c^*(C^T(S), \beta, R, \kappa)(d, y) > 0$$

where the strict positivity of $c^*(C^T(S), \beta, R, \kappa)(d, y) > 0$ follows from the Inada condition on $U_1(c; y^N)$ in its first argument, and we note the dependence of $c^*(C^T(S), \beta, R, \kappa)(d, y)$ on deep parameters for later reference. That proves the existence of a strictly positive greatest fixed point.

Step 4. *Fixed point comparative statics.* By standard fixed point statics argument for order continuous operators, the greatest fixed point $c^*(C^T(S), \beta, R, \kappa)(d, y)$ is increasing in $(C^T(S), \kappa)$, and decreasing in (β, R) . Then, the associated stationary policy function for tradeable consumption conditioned on the equilibrium collateral constraint be fixed at $C^T(S) \in \mathbf{C}^f$ is given by

$$C(C^T(S), \beta, R, \kappa)(d, y) = \inf\{c^*(C^T(S), \beta, R, \kappa)(d, y), (1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C^T(S))y^N\}$$

which is continuous in $(d, y) \in \mathbf{D} \times \mathbf{Y}$ by Berge's theorem, increasing in $(C^T(S), \kappa)$ and decreasing in (β, R) . This completes to proof of the fixed point comparative statics claim in the lemma.

Step 5: $c^*(C^T(S), \beta, R, \kappa)(d, y)$ *the unique strictly positive fixed point.* This follows from an application of Corollary 4.1 in Li and Stachurski ([39]) for each $C^T \in \mathbf{C}^f$. To see this, for fixed $C^T \in \mathbf{C}^f$ put

$$\begin{aligned}
\varsigma(d, y) &= u'((1 + \frac{\kappa}{R})Y^T - D + \frac{\kappa}{R}p(C^T(d, y))y^N) \\
&= A_c(C^T)(d, y)
\end{aligned} \tag{57}$$

and restrict the first step operator $A(c; C^T(S), \beta, R, \kappa)(d, y)$ to the set $\mathbf{C}_{++}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma) \subset \mathbf{C}_{++}^p = \{c \in \mathbf{C}^p | c(d, y) > 0\}$, where

$$\mathbf{C}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma) = \{c | c = \inf\{\hat{c}(d, y), \varsigma(d, y)\}, \hat{c} \in \mathbf{C}_{++}^p\}$$

⁵⁵Note, as as \mathbf{C}^{p*} as \mathbf{C}^{p*} is a subcomplete sublattice in \mathbf{C}^p , \mathbf{C}^p is a complete lattice, this implies the fixed point of the mapping $A(c; C^T(S), \beta, R, \kappa)(d, y) \in \mathbf{C}^{p*}$.

where in our notation we make explicit the dependence of the the space $\mathbf{C}_{++}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma)$ on the upper bound in (57). Let c_1 and c_2 be elements of $\mathbf{C}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma)$. Equipped the space the $\mathbf{C}_{++}^p(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma(d, y))$ with the norm

$$\rho(c_1, c_2) = \| u'_\varsigma \circ c_1 - u' \circ c_2 \|$$

where $\| u' \circ c_1 - u' \circ c_2 \| < \infty$, where $u'(c) = U'(A(c))A_1(c^T, y^{NT})$ is strictly decreasing in c^T under Assumption 1, and give $\mathbf{C}_{++}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e) \subset \mathbf{C}_{++}^p(\mathbf{D}^e \times \mathbf{Y}^e)$ its relative distance structure.

Clearly, from the arguments in Step 1 of this proof, $A(c; C^T(S), \beta, R, \kappa)(d, y)$ maps $\mathbf{C}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma)$ into itself. By Li and Stachurski ([39], Proposition 4.1.a), the pair $(\mathbf{C}_{++}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma), \rho)$ is a complete metric space. As $\beta R < 1$, by Li and Stachurski ([39], Proposition 4.1.c), for each $A(c; C^T(S), \beta, R, \kappa)(d, y)$ is a contraction of modulus $0 < \beta R < 1$ in $(\mathbf{C}_{++}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma), \rho)$. Then, by the contraction mapping theorem, $A(c; C^T(S), \beta, R, \kappa)(d, y)$ has exactly one fixed point in $(\mathbf{C}_{++}^{p*}(\mathbf{D}^e \times \mathbf{Y}^e; \varsigma), \rho)$. So, $c^*(C^T(S), \beta, R, \kappa)(d, y)$ is the unique strictly positive fixed point of $A(c; C^T(S), \beta, R, \kappa)(d, y)$ for $C^T \in \mathbf{C}^f$. ■

Corollary 12 (Corollary of Lemma 6). *The mapping $A^*(C^T; \beta, \kappa, R)(s^e)$ in (42) is order continuous on \mathbf{C}^f .*

Proof. As the operator in step 5 $A(c; C^T(S), \beta, R, \kappa)(d, y)$ is easily shown to be continuous in $C^T(S) \in \mathbf{C}^f$ in the topology of pointwise convergence, by the Bonsall-Nadler theorem on parameterized contractions, $c^*(C^T(S), \beta, R, \kappa)(d, y)$. (e.g., see Nadler ([53], Theorem 2 and Lemma, p. 581)). As $c^*(C^T(S), \beta, R, \kappa)(d, y)$ is also monotone increasing (in pointwise partial orders) by Step 4, $c^*(C^T(S), \beta, R, \kappa)(d, y)$ is order continuous on \mathbf{C}^f .

■

Proof of Theorem 7.

Proof. (i) Let $\Psi^*(R, \kappa, \beta) \subset \mathbf{C}^*$ be the set of fixed points of the mapping $A^*(C^T; \beta, R, \kappa)(s^e) = \inf\{c^*(C^T(S); \beta, R, \kappa)(d, y), A_c(C^T)(s^e)\}$ defined in (42). That $A^*(C^T, \beta, R, \kappa)(s^e) \in \mathbf{C}^*$ is immediate, as (a) by construction for fixed S , when $d = D$, $y = Y$, $c^*(C^T(S); \beta, R, \kappa)(d, y) \in \mathbf{C}^p$, and (b) when (d, y) is fixed, as $c^*(C^T(S); \beta, R, \kappa)(d, y)$ is increasing in $C^T \in \mathbf{C}^*$, and C^T is increasing in Y , and decreasing in D , $\inf\{c^*(C^T(S); \beta, R, \kappa)(d, y), A_c(C^T)(S)\}$ is increasing in Y , and decreasing in D . Further, if s^e is a collateral constrained state, then $d_{A^*(C^T)}(s^e) = \kappa\{y^T + p(C^T(d, y))y^N\}$ is increasing in y , and decreasing in d . By lemma 6. step 4, the operator $A^*(C^T)(s^e)$ is monotone increasing on \mathbf{C}^* . As \mathbf{C}^* is a nonempty complete lattice, by Tarski's theorem (Tarski ([72], theorem 1), $\Psi^*(R, \kappa, \beta)$ is a nonempty complete lattice.

(ii) Noting its dependence on deep parameters now, as $A^*(C^T, \beta, R, \kappa)(s^e)$ is decreasing in (β, R) , and increasing in κ , by Veinott's comparative statics version of Tarski's theorem (see Veinott ([74]), also see Topkis ([73], Theorem 2.5.2), the least and greatest selections of $\Psi^*(R, \kappa, \beta)$ exist as fixed points, and are decreasing in (β, R) , and increasing in κ .

(iii) $A^*(C^T, \beta, R, \kappa)(s^e) = \inf\{c^*(C^T(S); \beta, R, \kappa)(d, y), A_c(C^T)(s^e)\}$ is order continuous under pointwise partial orders on \mathbf{C}^f as (a) $A_c(C^T)(s^e) = 1 + \frac{\kappa}{R}Y^T - D + \frac{\kappa}{R}p(C^T(d, y))y^N$ is pointwise continuous and monotone ($p(C)$ is continuous and monotone increasing under Assumption 1), (b) by Corollary 12 $c^*(C^T(S), \beta, R, \kappa)(d, y)$ is order continuous, and hence, (c) $\inf\{c^*(C^T(S); \beta, R, \kappa)(d, y), A_c(C^T)(s^e)\}$ pointwise continuous and increasing by Berge's theorem (as the state space is compact). Then the result follows from Dugundji and Granas ([26], p.15).

■

Proofs for Section 4

Proof of Theorem 11

We will prove the theorem using several preliminary lemmas. First, it will be shown that equation (55), when it holds with equality, generates a sequence of increasing level of debt d_+ for any d as long

as $y^T = y_{lb}$ if y_{lb} is sufficiently small. Then, using this result, we show that starting from any initial condition, the collateral constraint will bind in finite time. This lemma will be useful to show the existence of an accessible atom in the third lemma. Then, the fourth lemma shows the existence of a unique invariant ergodic measure.

From now on we will assume that assumption 1 holds. Additionally, assume that in any SCE we have $d_{t+1} \leq H$ with $H \equiv \kappa(y_{ub} + P_{ub}y^N)$. Lemma 13 will show that, once the collateral constraint is imposed, H will not bind in equilibrium.

Lemma 13 *In equilibrium when $R\beta < 1$, we have $d_{++} > d_+ > d$ for any $d \in K_2$ if the collateral constraint does not bind, $y^T = y_+^T = y_{lb}$ and $y_{lb} \in (0, \epsilon)$ with $\epsilon > 0$.*

Proof. Note that in equilibrium, WLOG it is possible to write $U'(A(c_1, c_2))A_1(x_1) \equiv u'(y^T - d + R^{-1}d_+)$. Then, under the assumptions stated in the lemma, it is clear that equation (55) can be written as:

$$u'(y^T - d + R^{-1}d_+) = R\beta \sum_{y_+^T} u'(y_+^T - d_+ + R^{-1}d_{++})q(y_+^T)$$

Where $d_{++} \in K_2$. Suppose, to generate a contradiction, $d \in K_2$ and $d_+ \leq d$. Then, as $R > 1$ for ϵ sufficiently small, we have $u'(y^T - d + R^{-1}d_+) \rightarrow u'_{ub}$, where u'_{ub} can be constructed using the definition of u' together with assumptions 1 - a1 and 1 - c and 1 - f. Then, as $R\beta < 1$, $u'_{ub} > R\beta \sum_{y_+^T} u'(y_+^T - d_+ + R^{-1}d_{++})p(y_+^T)$ which implies that d_+ is not optimal. Then, we must have $d_+ > d$ as desired. Replacing d with d_+ , we get $d_{++} > d_+$. ■

Lemma 14 *For any $z \in Z$ the sequence $\{z, \phi_1, \phi_2, \dots\}$, generated by (Z, P_φ) , will hit the collateral constraint in finite time.*

Proof. Take any $y_0^T \in Y$, $d_0 \in K_2$ and a sequence with τ elements in $Y \times Y \times \dots \times Y$ with $\{y_0, y_{lb}, \dots, y_{lb}\}$. Then, the results in section 3 imply that, as long as the collateral constraint does not bind, $d_{\tau+1}(y_\tau^T, y_{lb}, \dots, y_{lb}, y_0; d_0) = d'(y_\tau^T, d)$ and $P_\tau(y_\tau^T, y_{lb}, \dots, y_{lb}, y_0; d_0) = P(d'(y_\tau^T, d))$, where the equalities follow from applying iteratively backwards the minimal state space policy function on equations (43) and (44) together with the envelope theorem, both derived in section 3. Note that the dependence of P on y^N has been omitted. Further, if the collateral constraint does not bind, we know from section 3 that $d'(y_\tau^T, d) / P(d'(y_\tau^T, d))$ is decreasing / increasing in y_τ^T for each d . Further, $d'(y_\tau^T, d) / P(d'(y_\tau^T, d))$ is increasing / decreasing in d for each y_τ^T . Lemma 16 below formally proves these claims. Then, using Lemma 13 we know that $\{d_1, \dots, d_{\tau+1}\} / \{P_0, \dots, P_{\tau-1}\}$ is a (strictly) increasing / decreasing sequence which in turn implies that $g_t(y_t^T, y_{lb}, \dots, y_{lb}, y_0; d_0) \equiv \kappa(y_t^T + P_t y^N) - d_{t+1}$ is a strictly decreasing sequence in t . To complete the proof we must show that: i) there exists a $y_\tau^T \in Y$ such that $g_\tau \leq 0$ and ii) $\tau < \infty$.

i) Suppose the collateral constraint does not bind. Then, $d_{t+1} \rightarrow H$. By the definition of H and the fact that $d_{t+1} = d'(y_{lb}, d_t)$, we know that $|H - d_{t+1}| = H - d_{t+1} < \epsilon$ for $t \geq N_\epsilon$. For any given κ , we can take $\epsilon \equiv \kappa(y_{ub} + P_{ub}y^N) - \kappa(y_{lb} + P_{ub}y^N) = \kappa(y_{ub} - y_{lb})$. Then, $d'(y_{lb}, d_t) > \kappa(y_{lb} + P_{ub})$, which is a contradiction. Then, the collateral constraint binds. That is, $g_\tau \leq 0$ for $g_\tau(y_{lb}, y_{lb}, \dots, y_{lb}, y_0; d_0)$

ii) Simply take $\tau = N_\epsilon$.

Note that H can be defined for any $y^T > y_{lb}$ which in turn implies that ϵ can be assumed to be arbitrarily small as desired. As the initial conditions were arbitrary, the proof is completed. ■

Before stating and proving the next lemma we need some additional notation. Let $z \in Z$. Then, any solution to the system defined by equations (45) to (49) will be denoted $z(d, y^T) \equiv z = [d \quad y^T \quad y^N \quad c_1 \quad c_2 \quad p \quad m]$.

Lemma 15 *Let $J_1 \equiv Z$, where Z was defined in section 4.1. There is a point $d_* \in K_2$ with $d_{ub} > d_* > d_{lb}$ and a selection $\varphi \in \Phi$, where Φ is the equilibrium correspondence which contains all Generalized Markov Equilibria, such that for any $(y_0^T, d_0) \in Y \times K_2$, there is a sequence $\{\phi_0, \phi_1, \phi_2, \dots\}$, generated by (J_1, P_φ) , which satisfies $\phi_\tau = z(d_*, y_{lb}) \in J_1$ with $\tau < \infty$.*

First, some notation and a auxiliary lemma. Let $d'(d_0, y_{lb})$ be the policy function obtained from solving the optimization problem in the RE defined in section 3 for the unconstrained case. It can be seen from the results in section 3 that, as long as we are dealing with the unconstrained problem, $d'(d_0, y_{lb})$ is independent of prices and, thus, we can take this policy function for any c^T . Then, $\varphi \in \Phi$ satisfies:

$$d'(d_*, y_{lb}) = \kappa \left[y_{lb} + y^N \left(\frac{A_2(y^N)}{A_1(y_{lb} + (d'(d_*, y_{lb})/R) - d_*)} \right) \right] \quad (58)$$

$$U' \{A_1(y_{lb} + (d'(d_*, y_{lb})/R) - d_*)\} = \beta RE_\varphi[-d'(d_*, y_{lb})] \quad (59)$$

Where φ is defined by taking any vector $d''(y') \in K_2$ for any $y' \in Y$ such that:

$$U' \{A_1(y_{lb} + (d'(d_*, y_{lb})/R) - d_*)\} = \beta R \sum_{y'} [U' \{A_1(y' + (d''(y')/R) - d'(d_*, y_{lb}))\}] q(y')$$

Before proving Lemma 15, we need a preliminary lemma. It simply proves that, in an unconstrained framework, in partial equilibrium, more "disposable income" means more consumption and less debt.

Lemma 16 *Let $y^D \equiv y^T - d$ and $c_1(y^D)$ be a tradable optimal unconstrained consumption. Then, in any unconstrained equilibrium, $y^D > \tilde{y}^D$ implies i) $c_1(y^D) > c_1(\tilde{y}^D)$ and ii) $d'(y^D) < d'(\tilde{y}^D)$*

Proof. i) Suppose not. Then, $y^D > \tilde{y}^D$ and $c_1(y^D) \leq c_1(\tilde{y}^D)$. Then, the budget constraint in any unconstrained equilibrium implies $d'(y^D) < d'(\tilde{y}^D)$. As $c_1(y^D)$ and $d'(y^D)$ are optimal, we have:

$$U'(A_1(y^D)) \geq U'(A_1(\tilde{y}^D)) = \beta RE(-d'(\tilde{y}^D)) > \beta RE(-d'(y^D))$$

Which implies a contradiction as $c_1(y^D)$ and $d'(y^D)$ are assumed to be optimal.

ii) Let $y^D > \tilde{y}^D$ and $c_1(y^D) > c_1(\tilde{y}^D)$. Assume, in way of contradiction $d'(y^D) \geq d'(\tilde{y}^D)$. Then:

$$U'(A_1(y^D)) < U'(A_1(\tilde{y}^D)) = \beta RE(-d'(\tilde{y}^D)) \leq \beta RE(-d'(y^D))$$

Which implies a contradiction as $c_1(y^D)$ and $d'(y^D)$ are assumed to be optimal. ■

Lemma 17 *In any unconstrained equilibrium, there is a decreasing sequence of debt with increasing tradable consumption for the same level of tradable output, y^T*

Proof. Let $d'(d_t, y_t^T) = d_{t+1}$. Thus, $U'(A_1(y_t^T - d_t + (d_{t+1}/R))) = \beta RE(-d_{t+1})$. Take $\tilde{d}_t < d_t$. Then $U'(A_1(y_t^T - \tilde{d}_t + (d_{t+1}/R))) < \beta RE(-d_{t+1})$. Then, there exist $\tilde{d}_{t+1} < d_{t+1}$ with $(\tilde{d}_{t+1}/R) - \tilde{d}_t > (d_{t+1}/R) - d_t > 0$ such that $U'(A_1(y_t^T - \tilde{d}_t + (\tilde{d}_{t+1}/R))) = \beta RE(-\tilde{d}_{t+1})$. By letting $d_{t+1} = \tilde{d}_t$, $\tilde{d}_{t+1} = d_{t+2}^*$ and $\tilde{d}_t = d_{t+1}^*$, $d_t = d_t^*$, we obtain the decreasing sequence $\{d_{t+i}^*\}_i$ which generates a increasing consumption sequence $\{c_{1,t+i}^*\}_i$ because $(\tilde{d}_{t+1}/R) - \tilde{d}_t > (d_{t+1}/R) - d_t > 0$ and $y_{t+i}^T = y^T$ for all i . ■

Lemma 18 *The selection $\varphi \in \Phi$ exists.*

Proof. Lemma 16 implies that there exist $d_* \in K_2$ such that:

$$d'(d_*, y_{lb}) = \kappa \left[y_{lb} + y^N \left(\frac{A_2(y^N)}{A_1(y_{lb} + (d'(d_*, y_{lb})/R) - d_*)} \right) \right]$$

This is possible as the LHS / RHS of this equation is increasing / decreasing in d , both sides are continuous functions of d according to the results in section 3.2 and

$$d'(0, y_{lb}) < \kappa \left[y_{lb} + y^N \left(\frac{A_2(y^N)}{A_1(y_{lb} + (d'(0, y_{lb})/R))} \right) \right]$$

That is the collateral constraint does not bind if debt is non-positive.

Take any $y_0^T, d_0 \in J$ and a sequence $\{y_0^T, y_{lb}, \dots, y_{lb}\}$ of $\tau + 1$ elements. The results in Lemma 13 imply that, as long as the collateral constraint does not bind in period $\tau < \infty$ (this assumption can be imposed WLOG due to Lemma 14), there is a constant sequence of tradable consumption $\{c_{1,0}, \dots, c_{1,\tau-1}\}$ with $c_1(y_0^T, d_0) = c_{1,t}$ for $0 \leq t \leq \tau - 1$ which can be implemented as a SCE. Further, as it is shown in Lemma 16, it is possible to choose $c_1(y_0^T, d_0)$ to be decreasing in d_0 and increasing in y_0^T . Equipped with these paths we will deal with a fraction of all possible initial conditions in $Y \times K_2$. In order to deal with the rest of the space we will use 13 and the inequality nature of the Euler equation to deal with the constrained case, if necessary.

Now take $y_0^T = y_{lb}$ and $d_0 = d_*$ with $\kappa(y_{lb} + P(x_1(y_{lb}, d_*))y^N) = d'(y_{lb}, d_*)$. The existence of d_* follows from Lemmas 15 and 18. This point defines the "atom" and we must show that there exist a positive probability sequence starting from any initial condition that hits it in finite time. Intuitively, the atom will be defined as the level of wealth, d , for which the collateral constraint binds with equality at $t = 0$ for the lowest possible level of current income, y_0^T . Thus, the strategy of the proof is to show that regardless of the initial condition, it is possible to construct a positive probability path that will hit the constraint: a) later, b1) with a bigger tradable consumption level and with more debt, both today or b2) with more debt tomorrow (and not necessarily with more consumption today). Call this last point $z(d_\tau, y_\tau)$. First, note that, as the collateral constraint hits with equality in the atom, for any other path, we will have more debt but not necessarily more consumption. In any case, the euler inequality implies that $z(d_*, y_{lb})$ satisfies the system of equations which defines the GME due to the strict inequality in the primal formulation of this equation. That is, the qualitative properties of $z(d_\tau, y_\tau)$ imply, due to the inequality in the Euler equation in the primal characterization of the sequential equilibria coupled with the backwards nature of the definition of any GME, that $z(d_\tau, y_\tau)$ and $z(d_*, y_{lb})$ are both a solution to the constrained system of equations which define the GME. This last claim is proved in Lemma 18.

We will now show that the chain will hit the atom, $z(d_*, y_{lb})$, starting from any initial condition in $J = Y \times K_2$. We will proceed in 2 regions: i) $d_0 < d_*$ and $y_0^T = y_{lb}$, ii) $d_0 > d_*$ and $y_0^T > y_{lb}$. Intuitively, region i) insures, due to Lemma 16, that the collateral constraint will not bind at $t = 0$ and that initial tradable consumption is bigger than the atom level. Using Lemma 13 and 14 we will construct a positive probability sequence with increasing debt which insures the "reversion" to the atom at the time the path hit the constraint. Region ii) has 2 possible sub-regions. ii.a) $y_0^T - d_0 > y_{lb}^T - d_*$, in which case again due to Lemma 16 we will have bigger initial consumption and smaller debt when compared with the atom level. Thus, we can construct a sequence with increasing debt in an unconstrained environment using the arguments in region i) until we exceed the atom's level and revert to it when the path hit the collateral constraint. ii.b) $y_0^T - d_0 < y_{lb}^T - d_*$, in which case the consumption level is smaller when compared to the atom level due to Lemma 16. Thus, we must construct an increasing consumption sequence in order to revert to the atom. In this case there are multiple possibilities: the constraint can be bigger (ii.b.1) or smaller (ii.b.2) compared with the atom level. In region ii.b.1 an increase in consumption will take place in a constrained environment if p is not sufficiently sensitive or elastic (ii.b.1.1). Contrarily, if prices are sufficiently elastic, an increase in consumption will take place in an unconstrained environment (ii.b.1.2).

Finally, in region ii.b.2, when the constraint is bigger with respect to the atom level, as debt is also bigger we may have a constrained or an unconstrained regime. In these cases we can use the results in regions ii.b.1 to generate an increasing consumption level until we reach the atom consumption.

i) For $d_0 < d_*$ and $y_0^T = y_{lb}$, we have $\kappa(y_{lb} + P(c_1(y_{lb}, d_*))y^N) < \kappa(y_{lb} + P(c_1(y_{lb}, d_0))y^N)$ and $d'(y_{lb}, d_0) < d'(y_{lb}, d_*)$ from Lemma 16 which, using Lemma 14, implies that for the sequence $\{\phi_0, \dots, \phi_t\}$ the chain will hit the collateral constraint in $t = \tau > 0$ with $d_\tau > d_*$.

We claim that the system of equations given by (45) to (49) can also be solved by $z(d_*, y_{lb})$ and thus we have that $\{\phi_0, \dots, z(d_*, y_{lb})\}$ is an equilibrium trajectory. To prove this claim, note that from the definition of an equilibrium correspondence, we have that any d in z with $z \in Z$ that solves $U'\{A_1(y_{lb} + R^{-1}\kappa(y_{lb} + P(c_1(y_{lb}, d_0))y^N) - d)\} \geq E(m_+)$ is a predecessor of $z_+(y_+^T)$ for any $y_+^T \in Y$. As $U'\{A_1(y_{lb} + R^{-1}\kappa(y_{lb} + P(c_1(y_{lb}, d_*)y^N) - d_*)\} > E(m_+)$, equations (45) to (49) imply that $\{\phi_0, \dots, z(d_*, y_{lb})\}$ is an equilibrium trajectory as desired.

ii) For $d_0 > d_*$ and $y_0^T > y_{lb}$.

Region ii.a): $y_0^T - d_0 > y_{lb} - d_*$. As y^D is bigger in this case when compared with the atom level and we have more tradable output, $d'(y_0^T, d_0) < \kappa(y_{lb} + P(c_1(y_{lb}, d_*))y^N) < \kappa(y_0^T + P(c_1(y_{lb}, d_0))y^N)$ and we can use the arguments in region i).

Region ii.b): $y_0^T - d_0 < y_{lb} - d_*$.

Region ii.b.1): $\kappa(y_0^T + P(c_1(y_0^T, d_0))y^N) < \kappa(y_{lb} + P(c_1(y_{lb}, d_*))y^N) < d'(y_0^T, d_0)$. That is, the collateral hits at $t = 0$ with $c_1(y_{lb}, d_0) > c_1(y_0^T, d_0)$ which implies that we must generate an increasing sequence of consumption from the constrained regime. Note that when we increase tradable consumption, depending on the sensibility of p with respect to c^T , we may enter into a constrained (ii.b.1.1) or an unconstrained regime (ii.b.1.2).

Region ii.b.1.1): $1 \geq \kappa y^N R^{-1}p'$, where p' is the derivative of (45) with respect to d_+ . As $c_1(y_{lb}, d_*) > c_1(y_0^T, d_0)$ and

$$\begin{aligned} \kappa(y_0^T + P(c_1(y_0^T, d_0))y^N) &< \kappa(y_{lb} + P(c_1(y_{lb}, d_*))y^N) \\ &< d'(y_0^T, d_0) \end{aligned}$$

we have:

$$\begin{aligned} U'\{A_1(y_0^T + R^{-1}\kappa(y_0^T + P(c_1(y_0^T, d_0))y^N) - d_0)\} &> U'\{A_1(y_{lb} + R^{-1}\kappa(y_{lb} + P(c_1(y_{lb}, d_*))y^N) - d_*)\} \\ &= E(m_+; -\kappa(y_{lb} + P(c_1(y_{lb}, d_*))y^N)) \\ &> E(m_+; -\kappa(y_0^T + P(c_1(y_0^T, d_0))y^N)) \end{aligned}$$

The above inequality implies that any path in this region with $P(c_1(y_t^T, d_t)) < P(c_1(y_{lb}, d_*))$ is optimal. By setting $\{y_0^T, y_{lb}, \dots, y_{lb}\}$ we can construct an increasing sequence $\{P(c_1(y_0^T, d_0)), P(c_1(y_{lb}, d_1)), \dots, P(c_1(y_{lb}, d_\tau))\}$ converging to $P(c_1(y_{lb}, d_*))$ as desired.

Region ii.b.1.2): $1 < \kappa y^N R^{-1}p'$. In this case an increase in consumption take us to the unconstrained region. Using Lemma 17, we can generate a path $\{y_0^T, y_1^T, \dots, y_\tau^T\}$, with $y_t^T > y_{lb}$; $t = 1, \dots, \tau$, of increasing consumption and decreasing debt until we get $c_1(y_{lb}, d_*) < c_1(y_\tau^T, d_\tau)$. Then, set $\{y_\tau^T, y_{lb}, \dots, y_{lb}\}$ The argument in region i) insure that there is a finite time, $\tau + \tau_1$, such that the path hits the atom.

Region ii.b.2): $\kappa(y_0^T + P(c_1(y_0^T, d_0))y^N) > \kappa(y_{lb} + P(c_1(y_{lb}, d_*))y^N) < d'(y_0^T, d_0)$. In this case, we can be either in the unconstrained or constrained case. For the former, we can use the same arguments as in section ii.b.1.2) as we need a path of decreasing debt and increasing consumption. For the latter, however, note that by setting $\{y_0^T, y_{lb}, \dots, y_{lb}\}$ we enter into the ii.b.1) region for $t > 0$ as $\kappa(y_{lb} + P(c_1(y_{lb}, d_t))y^N) < \kappa(y_{lb} + P(c_1(y_{lb}, d_*))y^N)$ as $d_t > d_*$. ■

Lemma 19 *the results in Lemmas 13 to 15 imply that there exists a selection $\varphi \sim \Phi$ and a Markov process (J_1, P_φ) that has an accessible atom, $z(d_*, y_{lb})$, and is $P_\varphi(z(d_*, y_{lb}), \cdot)$ -irreducible*

Proof. Follows directly from proposition 1. ■

Lemma 20 Let (J_1, P_φ) be the process defined in Lemma 15. If the collateral constraint hits at time $\tau > 0$ with $d_\tau > d_*$ and $c_{1,\tau} > c_1(y_{lb}, d_*)$ or with $d_{\tau+1} > d(d_*, y_{lb})$, then $\{\phi_0, \phi_1, \dots, \phi_{\tau-1}, z(d_*, y_{lb})\}$ is an equilibrium trajectory.

Proof. If the collateral constraint binds for consumption $c_{1,\tau}$ and debt d_τ , then it must satisfy $U'\{A_1(y_\tau^T + R^{-1}\kappa(y_\tau^T + P(c_{1,\tau})y^N) - d_\tau)\} \geq E(m_+)$. The conditions in the remark imply that $U'\{A_1(y_{lb} + R^{-1}\kappa(y_{lb} + P(c_{1,\tau})y^N) - d_*)\} > E(m_+)$ as desired. Next note that

$$\begin{aligned} U'\{A_1(y_\tau^T + R^{-1}d_{\tau+1} - d_\tau)\} &\geq U'\{A_1(y_\tau^T + R^{-1}d(d_*, y_\tau^T) - d_*)\} \\ &= E(m_+(d(d_*, y_\tau^T))) \geq E(m_+(d_{\tau+1})). \end{aligned}$$

■

Lemma 21 Let (J_1, P_φ) be the Markov process in Lemma 15. Then, (J_1, P_φ) has a unique, ergodic, invariant probability measure.

Proof. Note that Lemma 15 imply that $P_\varphi^\tau(z(d_*, y_{lb}), \{z(d_*, y_{lb})\}) > 0$ with $\tau < \infty$. Given the results in Remark 4.2.1, proposition 4.2.2, theorem 8.2.1 and theorem 10.2.1 in Meyn and Tweedie ([49]) imply that (J_1, P_φ) has an unique invariant measure. As $\tau < \infty$ for any initial condition in J_1 , theorem 10.2.2 in Meyn and Tweedie ([49]) implies that the invariant measure is a probability measure. As it is unique, the Krein-Milman theorem (See Futia, [28]) implies that this measure is ergodic. ■

Supplementary Material for Section 5.1

Up to now, in this sub-section, we have been silent about optimality. Assume that for some exchange rate level, P_0 , there is a debt level d_0 which satisfies equation (49) for $y^T = y_{lb}$. That is, d_0 satisfies: $U'\{A_1(y_{lb} + R^{-1}\kappa\{y_{lb} + P_0y^N\} - d_0)\} \geq E(m_+)$. Taking into account that we are assuming that (d, p) belong to a compact set, the existence of d_0 and P_0 follows without loss of generality given theorem 3 in section 2. Note that any $d = d_0 + (y^T - y_{lb})(1 + \kappa/R)$ will also satisfy equation (49). Now, the definition of $d_2(y^T)$ implies: $d_2(Y) - d_2(Ymin) = (Y - Ymin)(1 + \kappa/R)$. As can be seen in figure 3, if any d_0 is in the locus formed by $f(p) = K(d)$ (i.e. which satisfies equation (50)) with $(d, P) \gg 0$, above the zero-consumption line $d_2(Ymin) - P(Ymin)$ line (i.e. which is above equation (51)) and satisfies equation (49), then $d = d_0 + (Y - Ymin)(1 + \kappa/R)$ is in the locus formed by (50) and above (51) but with the last equation crossing the d -axis at $d_2(Y)$. By replacing Y with $y^T > y_{lb}$ and $Ymin$ with y_{lb} , we know that d will also be feasible and optimal if d_0 is so: it will be to the right of the vertical axis, above the $d_2(y^T) - P(y^T)$ line, over the locus formed by $f(p) = K(d)$ (i.e. it will be feasible) and will satisfy equation (49) (i.e. it will be optimal). Finally, we must show that any the pair (d, P) satisfies the optimality requirement (i.e. it satisfies (49)) and find a contour in the plane in order to separate optimal from non-optimal pairs. We will start with (d_0, P_0) . Take any $m_+(y_+^T)$ from Z which satisfies equation (48) with $d_+ = \kappa\{y_{lb} + P_0y^N\}$ and any given d_{++} . Equation (60) below, when it holds with equality, defines a locus increasing in the (d, P) plane which determines optimality. Call this map $h(d, P) = 0$. Take any (d_0, P_0) over (60). Any $P \leq P_0$ is optimal because of the weak inequality in the primal optimization problem in the SCE. Thus, optimality lies below (60). Moreover, note that this locus is increasing in d_{++} . Thus, $h(d, P; d_{++}) = 0$ As can be seen from the definition of GME, $d_{++}(y_+)$ for each $y_+ \in Y$ defines a selection of the equilibrium correspondence and, thus, 1 of possible multiple GME. As the upper bound on d_{++} can be chosen freely⁵⁶. Then, there is always a value in $[d_l, d_u]$, the set which contains d by assumption, which insures optimality. That is, which satisfies:

⁵⁶For expositional purposes, in this subsection we are assuming that endogenous variables lie in a compact set. Thus, the existence of an arbitrarily large upper bound can be insured without loss of generality. However, in section 2, we showed that it depends on the bounds on marginal utility (see Table 1).

$$U' A_1 (y^T + R^{-1} \kappa (y^T + P y^N) - d) \geq \beta RE[m_+ (-R^{-1} \kappa (y^T + P y^N; d_{++}))] \quad (60)$$

Figure 4 illustrates these facts. Note that the multiple displacements of (50) in solid lines form the equilibrium correspondence of some GME for an arbitrarily large selection $\varphi \in \Phi$. That is, figure 4 below presents the full picture as it combines the feasible pairs in figure 3 with the optimal ones in $h(d, P; d_{++}) = 0$. Note that there is a fraction of equation (50) which intersects with $d_2(Ymin) - P(Ymin)$ that is depicted in light grey. This is because it evolves $d < 0$. As the level of P becomes smaller, c^T does so and it is not necessary to take debt to satisfy optimality. In other words, the light grey areas represent the unconstrained regime for $y^T = y_{lb}$. A similar argument holds for $y^T = Ymax \equiv y_{ub}$. As it is shown in the appendix for section 4 (see Lemma 16), in the unconstrained regime, tradable consumption is increasing in tradable output, while debt is decreasing in the same variable. Thus, it is possible that $d(d, Ymax) < p(Ymax - d + d(d, Ymax)/R, y^N)$, where $p(\cdot, \cdot)$ is equation (43) and $d(\cdot, \cdot)$ is the policy function for the unconstrained regime associated with the envelope m_+ . The locus formed by equation (50) which intersects with $d_2(Ymax) - P(Ymax)$ is depicted in light grey as the pair $(d + (Ymax - Ymin)(1 + \kappa/R), PYmax)$, where $f(PYmax) = K(d + (Ymax - Ymin)(1 + \kappa/R))$ may belong to the unconstrained regime given the fact that $Ymax$ can be chosen to be arbitrarily large. Further, note that there is a point for which $d(d, Y^T) = p(y^T - d + d(d, y^T)/R, y^N)$, with $Ymin < y^T \leq Ymax$ (see Lemma 14 in the appendix). Thus, as $p(\cdot, \cdot)$ is continuous and $d(\cdot, \cdot)$ are continuous and decreasing in y^T , and $c^T = Y^T - d + d(d, Y^T)/R$ is increasing in Y^T , we know that the collateral constraint will be binding for any $y < Y^T$. Thus, the desired result follows.

Numerical procedure for section 5

The numerical procedure is based on the policy function of the RE, $d'(\cdot, \cdot)$. It is computed as a solution to (18) without a collateral constraint. Then the atom d_* is computed using $d'(\cdot, \cdot)$ in (58). Note that if the process hits the constraint in period t , then $d'(d_t, y_t) > d'(d_*, y_{lb})$. Thus in order to find a regeneration point, we need:

$$U' \{c_1 (y_t - d_t + d'(d_t, y_t)/R)\} - \beta R \sum_{y'} U' \{c_1 (y' - d'(d_t, y_t) + d''(d_t, y_t, d', y'))\} \equiv f(d''(y'); d, d', y_t) \geq 0$$

$$U' \{c_1 (y_{lb} - d_* + d'(d_*, y_{lb})/R)\} - \beta R \sum_{y'} U' \{c_1 (y' - d'(d_*, y_{lb}) + d''(d_*, y_{lb}, d', y'))\} \geq 0$$

Note that in section 4 we require d'' to be independent of d, d', y . This fact implies that we can easily find d'' but there are some additional conditions which must be satisfied by paths in order to revert to the atom (i.e. consumption and debt must be greater than the atomic level). This restrictions affects the frequency at which the atom is hit. Thus, in order to improve the recurrent structure of sets and gain computationally efficiency, we modified the selection from the GME. When we allow d'' to depend on an expanded state space, we can find a stationary Euler equation for each d, y as d' has at most 2 solutions when the collateral constraint is binding.

To formally prove the existence of this selection is beyond the scope of this paper. We need to show that $f(d''(y'); d, d', y_t) \geq 0$ has a minimum in d'' for each $y'; d, d', y_t$, subject to the collateral constraint, and that the value function of this problem is equal to zero if the collateral constraint is not binding. Numerically, this selection is easily implemented and the algorithm is really fast as we do not need to compute every selection of the GME.
