The Impact of Pollution on Asthmatic Patients of California

Sharanya Sharma

March 22, 2023

Abstract

The purpose of this report is to foster the curiosity of how pollution affects the health of people in California. The California Office of Environmental Health Hazard Assessment (OEHHA) dataset includes data on the number of asthmatic people in each county of California, as well as the concentration of various pollutants. We will specifically look at 3 specific pollutants, and more intensely, we will look at how they affect the effects on asthma. With a series of tests, we determine that the level of pollutants can significantly affect the number of asthmatic people in California, as well as the idea that the big number of asthmatic people throughout California is significantly different.

Introduction

Over the years, the increasing use of fossil fuels, burning of petrochemical gasses, and mass deforestation has caused the pollution of the air we breathe to increase drastically. Pollutants such as carbon dioxide, methane, and nitrous oxide are formed from the burning of fossil fuels, they are trapped within the Earth's atmosphere and disrupt solar radiation, thereby increasing the Earth's temperature (Tarantino 2022). This is the cause of global warming and climate change. Pollutants such as ozone, PM2.5, and benzene that are produced and preserve the Earth's surface are dangerous to the health of humans. Certain consumables are more prone to air pollution because of the disproportionate balance of pollutants released into the environment during the production of these consumables (Ritchie et al. 2022). In 2021 the OEHHA, designed several graphical summary of air pollutants and their effects on communities across California. By using demographics information from the 2010 and 2020 census, as well the 2010 California Communities Environmental Health Screening Tool (CalEnviroScreen), they were able to identify the disproportionately burdened by pollution (OEHHA 2022). In addition to pollutants, the study analyzed the areas affected with diseases most commonly associated with pollution, such as asthma and cardiovascular disease. In this report, we will be investigating the OEHHA's dataset on the number of asthmatic people throughout California. According to the California Air Resources Board's State Implementation Plan Health, Fine chemicals, dust, soot, and metals that compose pm2.5 may worsen lung function or medical conditions such as asthma (CARB 2022). Using the OEHHA's dataset, we will be investigating the current sample of 1000 data points in California. We will then perform a series of tests and a combination of them can be used to predict the amount of asthmatic patients in California. In addition to this, we will compare the big number of asthmatic people throughout California to the number of asthmatic people. This is significant because it is the amount of asthmatic people, making a difference in the data.

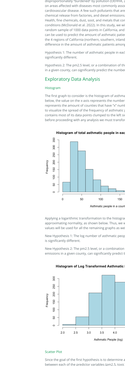
Hypothesis 1: The number of asthmatic people in each region (northern, southern, inland, coastal) is significantly different.

Hypothesis 2: The pm2.5 level, or a combination of the pollutant with toxic chemicals and diesel emissions in a given county, can significantly predict the big number of asthmatic people in California.

Exploratory Data Analysis

Histogram

The first graph I created is the histogram of asthmatic people. For each vertical bar on the histogram, the height of the bar is the count that represents the number of asthmatic people in a county and the frequency represents the amount of counties that have "n" number of asthmatic people. In this manner, we are able to visualize the data and the distribution of the asthmatic people across California. Notice that this histogram contains most of its data points clumped to the left side, resulting in a right skewed histogram. Therefore, without proceeding further with any analysis, we can predict that the mean > median.



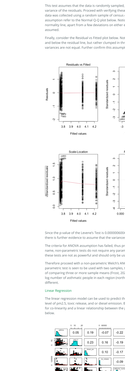
Applying a logarithmic transformation to the histogram results in a bell curve shape, which is ideal for approximating normality, as shown below. Thus, we will continue our hypotheses as the big asthmatic values will be used for all the remaining graphs as well.

New hypotheses 1: The log-mean of asthmatic people in each region (northern, southern, inland, coastal) is significantly different.

New hypotheses 2: The pm2.5 level, or a combination of the pollutant with toxic chemicals and diesel emissions in a given county, can significantly predict the log number of asthmatic people in California.

Scatter Plot

Since the goal of the first hypothesis is to determine a predictive, we must consider the relationship between each of the predictor variables (pm2.5, toxic mass, and diesel) and the big asthmatic people. As all the variables are numeric, a scatter plot would best represent a visualization of the data.



The first scatter plot of log-asthmatic number of people to pm2.5 level shows the most comparatively linear relationship between the 3 variables. The second scatter plot of log-asthmatic number of people to toxic result in a similar value of r, thus implying that the log-asthmatic number of people may not have much correlation with the pm2.5 level. The second and third plots representing log-asthmatic number of people to toxic and diesel, respectively, have a relatively similar correlation coefficient, however, the toxic scatter plot has a slightly stronger linear trend. Therefore, we can predict that the log-asthmatic number of people in a county will be more likely to have a higher concentration of toxic chemicals in the air.

Boxplot

Finally, the boxplot allows for a comparison between the distributions of the log number of asthmatic patients within each of the 4 regions of California. The thick black line in the middle of each distribution represents the median log-asthmatic number (pm2.5). The 50% of the data lies above the first, and 50% of the data lies below the third quartile. The 25% of the data lies between the first and the median, and the interquartile range (IQR) is the 50% of the data between the first and the third quartile. The 25% of the data lies below the lowest ("min"). In an area known as the "whiskers". Values even further than this boundary are represented by individual dots, or outliers.

Looking at the boxplots below, inland and North seem to have a relatively similar median and range of log-asthmatic number of people. However, the coastal and South regions have a higher median and IQR range, implying that there is a greater variation of the log-quantity of asthmatic people in each of these asthma areas. Since the southern boxplot has 2 outliers on the lower end of values, this suggests that certain counties in the South region have a significantly lower number of asthmatic people. Additionally, the coastal region has a relatively high IQR range, implying that the region's range with the lowest log-asthmatic median value, implying that the counties in the coastal region have the largest variation of the log-quantity of people of with low or dark-low asthma.

Statistical Methods

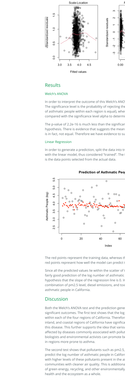
ANOVA

The ANOVA test is used to compare the means of multiple samples of different by defining. For the next part of the statistical analysis, we will use a one-way ANOVA test to determine if the mean log-number of asthmatic people in each region (northern, southern, inland, coastal) is significantly different. The test will provide information about determine whether there are statistically more asthmatic people in a certain region of California compared to another.

This test assumes that the data is randomly sampled, has normally distributed residuals, and equal variance of the residuals. Proceed with verifying these assumptions before conducting the test. Since the data is collected by the OEHHA, we can assume that the data is randomly sampled. Next, we will look at the residuals of a simple linear model to find a mean to fit the data and explore if the same hypothesis that the log-asthmatic number of people in each region (northern, southern, inland, coastal), is significantly different.

Linear Regression

A simple linear regression could be used to predict the log-number of asthmatic people depending on the pm2.5, toxic, or diesel values, and to detect emissions. Before performing the regression model, we must test for co-linearity and a linear relationship between the predictors and the response variable using the graph below.



Checking for co-linearity, the absolute correlation values between the predictors (pm2.5 level, diesel emissions, and toxic release) and the response variable (log-number of asthmatic people) are all much less than 0.95. Therefore, there is no co-linearity between the predictors and the response. This passes the co-linearity assumption.

Checking the relationship of the predictors with the log-number of asthmatic people, my plots appear to be relatively linear. Therefore, the linear relationship assumption is met. Now, we can proceed with the linear regression model. Before we can interpret the results of the model, we must check the assumptions of the linear regression.

Proceed with developing 4 models. Diesel has the highest correlation value with log-asthma of 0.2, the first model will be diesel. The second model will be pm2.5 and toxic, and the final model will be the interaction of all three predictors. In the end, we will compare the three models and choose the appropriate predictor. We will consider Akaike's Information Criterion (AIC) and Bayes' Information Criterion (BIC). Additionally, we will look at the adjusted R^2 and the RMSE of the model to the data with a prediction interval.

	df	AIC	BIC	r_{adj}	$adj.r_{adj}$
fit_true	3	1427.07	1441.70	0.04	0.04
fit_pm2	3	1427.05	1441.68	0.04	0.04
fit_final	5	1426.28	1444.82	0.05	0.05

Looking at the AIC and BIC values, it appears that the third model with all three predictors has the lowest AIC value of 1426.28 with a close second lowest BIC value of 1426.82. In addition to this, the adjusted squared value is 0.05 highest, implying that the percentage of variation in the data explained by this model is comparatively the best.

Finally, we will look at the residuals of the linear model. Since the variance is not random or scattered above and below the residual line, but rather clumped in three distinct linear patterns. This suggests that the variance is not constant. Therefore, the assumption of a linear regression variance with a constant is fail.

Since the p-value of the Shapiro-Wilk Test is 0.000000000000, which is much less than the standard 0.05, there is further evidence to assume that the variances are in fact not equal.

The criteria for ANOVA assumptions have finally been proceed with a non-parametric test. Implied by the name, non-parametric tests do not require parameters or assumptions. However because of this, these tests are not as powerful and will require a higher level of assumptions for a regular test like.

Therefore proceed with a non-parametric Welch's ANOVA test. Although typically the Welch's non-parametric test is used for comparing the means of 2 samples, it can be extended to the comparison of the three predictors in the model using the Welch-James statistic. Therefore, the null is the same hypothesis that the log-number of asthmatic people in each region (northern, southern, inland, coastal), is significantly different.

Linear Regression

A linear regression model can be used to predict the log-number of asthmatic people depending on the pm2.5, toxic, or diesel values, and to detect emissions. Before performing the regression model, we must test for co-linearity and a linear relationship between the predictors and the response variable using the graph below.

Checking for co-linearity, the absolute correlation values between the predictors (pm2.5 level, diesel emissions, and toxic release) and the response variable (log-number of asthmatic people) are all much less than 0.95. Therefore, there is no co-linearity between the predictors and the response. This passes the co-linearity assumption.

Checking the relationship of the predictors with the log-number of asthmatic people, my plots appear to be relatively linear. Therefore, the linear relationship assumption is met. Now, we can proceed with the linear regression model. Before we can interpret the results of the model, we must check the assumptions of the linear regression. Proceed with developing 4 models. Finally, we will look at the residuals of the linear model. Since the variance is not random or scattered above and below the residual line, but rather clumped in three distinct linear patterns. This suggests that the variance is not constant. Therefore, the assumption of a linear regression variance with a constant is fail.

Since the p-value of the Shapiro-Wilk Test is 0.000000000000, which is much less than the standard 0.05, there is further evidence to assume that the variances are in fact not equal.

The criteria for ANOVA assumptions have finally been proceed with a non-parametric test. Implied by the name, non-parametric tests do not require parameters or assumptions. However because of this, these tests are not as powerful and will require a higher level of assumptions for a regular test like.

Therefore proceed with a non-parametric Welch's ANOVA test. Although typically the Welch's non-parametric test is used for comparing the means of 2 samples, it can be extended to the comparison of the three predictors in the model using the Welch-James statistic. Therefore, the null is the same hypothesis that the log-number of asthmatic people in each region (northern, southern, inland, coastal), is significantly different.

Results

Welch's ANOVA

In order to interpret the outcome of this Welch's ANOVA test, consider the significance level alpha of 0.05. Since the p-value is much smaller than the significance level, there is strong evidence that the log-mean number of asthmatic people within each region is equal to 0 or it is false. Therefore accept the true null above as compared with the significance level alpha to determine the result of the Welch's ANOVA test.

The p-value of 2e-16 is much less than the significance level 0.05, implying that we reject the null hypothesis. There is evidence that suggests the mean log-number of asthmatic people within each region (coastal, inland, north, south) is different. Therefore we have evidence to support our original hypothesis.

Linear Regression

In order to generate a prediction, split the data into training data and test data. The training data will be fit with the linear model. Also constructed "Control" data. The control data is then compared to the test data, which is the data points selected from the actual data.

The red points represent the training data, whereas the white points represent the actual data. Hence, the red points represent how well the model can predict the test data points.

Since all the predicted values lie within the scatter of the actual data, the regression model demonstrated a good fit. Additionally, the prediction interval of the model is relatively small, which is a good sign. This is due to the hypothesis that the slope of the regression line is 0. In other words, there is little evidence to suggest that a combination of pm2.5 level, diesel emissions, and toxic release can significantly predict the log-number of asthmatic people in California.

Discussion

Both the Welch's ANOVA test and the prediction generated from the regression model resulted in significant conclusions. The first test shows that the log-mean number of asthmatic people are different within each region (coastal, inland, north, south). Additionally, the second test shows that a combination of pm2.5 level, and toxic release and diesel emissions have significantly different effects on asthmatic people diagnosed with this disease. This further supports the idea that communities in California are disproportionately burdened by pollution and asthmatic people. Although the data is from 2010, the results still provide ideologies and environmental activists can utilize to promote health and well-being by focusing on pollutants in regions more prone to asthma.

The second test shows that pollutants such as pm2.5, toxic release, and diesel emission can significantly predict the log-number of asthmatic people in California. Therefore, there is evidence that communities with high pollutants, such as the Central Valley, Los Angeles, and the Bay Area, are the main communities with poor air quality. This is additional information ideologists can use to encourage the use of green energy, recycling, and other environmentally friendly initiatives for the betterment of human health and the ecosystem as a whole.

Since the ANOVA test was conducted using a non-parametric Welch's test, limitations lie with the power of the test. Non-parametric tests are not as powerful as regular tests, and therefore, the results of the test may not be reflective of the true population. Another limitation is that the data is not up to date by the time the most accurate representation of the current ecosystem status.

If given more time, I would explore ways to make the regression model equal and use the standard ANOVA test for results instead. Perhaps this may result in a more powerful, thus more convincing test result. Since this data is collected by the OEHHA, I would also explore ways to collect data myself. Perhaps I could collect data on other states or countries and different ways to measure pollutants. Additionally, I would explore the area and resources to conduct this test via a global scale, perhaps the results would be more applicable to anyone reading my report.
