Noninvasive tracking of gene transcript and neuroprotection after gene therapy

J Ren¹, YI Chen¹, CH Liu¹, P-C Chen², H Prentice², J-Y Wu² and PK Liu¹

Gene therapy holds exceptional potential for translational medicine by improving the products of defective genes in diseases and/or providing necessary biologics from endogenous sources during recovery processes. However, validating methods for the delivery, distribution and expression of the exogenous genes from such therapy can generally not be applicable to monitor effects over the long term because they are invasive. We report here that human granulocyte colony-stimulating factor (hG-CSF) complementary DNA (cDNA) encoded in self-complementary adeno-associated virus-type 2 adeno-associated virus, as delivered through eye drops at multiple time points after cerebral ischemia using bilateral carotid occlusion for 60 min (BCAO-60) led to significant reduction in mortality rates, cerebral atrophy and neurological deficits in C57black6 mice. Most importantly, we validated hG-CSF cDNA expression using translatable magnetic resonance imaging (MRI) in living brains. This noninvasive approach for monitoring exogenous gene expression in the brains has potential for great impact in the area of experimental gene therapy in animal models of heart attack, stroke, Alzheimer's dementia, Parkinson's disorder and amyotrophic lateral sclerosis, and the translation of such techniques to emergency medicine.

Gene Therapy advance online publication, 20 August 2015; doi:10.1038/gt.2015.81

INTRODUCTION

Alzheimer's dementia (AD), an age and genetic-related disorder, affects 4.5 million Americans. The risk to develop AD and stroke can be associated in elderly people,¹ and a common pathway (p25.cdk5) leads to elevated production of amyloid protein beta in individuals with stroke and AD.² The granulocyte-colony stimulating factor (G-CSF) in patients diagnosed with AD is found to be significantly lower than age-matched people.³ G-CSF is a cytokine that stimulates growth and differentiation of myeloid precursors.⁴ The expression of G-CSF and its receptor in the microvessels of the central nervous system suggests that G-CSF provides autocrine neuroprotection in response to brain damage.⁵ In pre-clinical tests, G-CSF has been shown to pass through the blood-brain barrier by receptor-mediated endocytosis, leading to a reduction in infarct volume in rat models of acute stroke;⁶ G-CSF reduces the level of beta amyloid deposited in excess in the brain and reverses memory impairment in mice genetically altered to develop AD.⁷ In addition, studies in different animal models of stroke, Parkinson's disease and other neurodegenerative disorders have specifically demonstrated that G-CSF may protect neurons, increase blood vessel growth and improve motor function.^{8–10} A phase IIb trial has also tested the safety of G-CSF.¹¹ On the other hand, a recent clinical study demonstrated that direct injection of exogenous G-CSF protein to the vasculature of 328 acute stroke patients showed a trend to reduce infarct growth, but did not reduce mortality, infarct size or neurological score.¹² The discrepancies between clinical and preclinical responses can partially arise from different approaches used to validate the delivery of exogenous biologics and examine the molecular basis of their therapeutic effects are primarily histology based. These histological methods have limited benefit because they rely on the use of invasive

tissue sampling and, because they involve the removal of the very tissue we wish to protect, preclude long-term monitoring. To overcome these limitations we need to re-evaluate the responses using a noninvasive approach to monitor the delivery, expression of exogenous G-CSF genes and its efficacies in the central nervous system of living conditions.^{13,14}

We tested the hypothesis that a neuroprotective biologic encoded in the complementary DNA (cDNA) carried by a viral vector could be delivered at multiple time points using eye drops to forebrain ischemia model using bilateral carotid occlusion for 60 min (BCAO-60) in C57black6 mice.^{14–16} BCAO-60 does not induce significant infarct, although DNA and brain damage can be repaired.¹⁷ By encoding human granulocyte colony-stimulating factor (hG-CSF) in a replication-deficient, self-complementary adeno-associated virus (AAV) vector (scAAV2-CMV-hG-CSF) it may be possible to elicit a continuous supply of endogenous G-CSF.¹⁸ The use of the AAV2 vector, with optimally selected serotype, has proved highly valuable for efficient transduction in the central nervous system, and for rapid initiation of expression.¹⁹ For example, AAV2 vectors carrying exogenous genes have been used to examine transduction in brain tissue *in vivo* in models of AD, amyotrophic lateral sclerosis and Parkinson's disease.^{16,20,21}

Most significantly, we have developed two noninvasive measurements as alternatives to invasive biopsy procedures. First, we developed MR contrast agents (MR-CAs) to target unique mRNA expression of hG-CSF cDNA in the brains of living mice without biopsy. Second, we established and validated measurements to noninvasively monitor neuroprotection after gene therapy, so that these responses are consistent with hypothermia treatment (34 °C, whole-body) during cerebral ischemia, a therapeutic method that has been shown to reduce brain injury

after cardiac arrest and traumatic brain injury.^{22–24} We demonstrate this approach as an alternative to destructive sampling methods. Such assays would allow long-term monitoring of neuroprotection and continuous expression of exogenous cDNA, as gene therapy becomes translatable to clinical applications. This monitoring system will be central to evaluating the therapeutic efficacy of exogenous cDNA in the central nervous system.

RESULTS

We first characterized noninvasive measurements of cerebral damage in C57black6 mice. In C57black6 mice, BCAA-60 induces global oxidative stress, DNA damage, apoptosis, but very limited infarction in the brain.^{14,15,25,26} Figure 1a shows the protocol used for BCAA induction and longitudinal monitoring. This cerebral ischemia model is associated with severe weight loss (Figure 2a), compared to sham-operated mice at the same temperature (Figure 2b), and a mortality rate of $75 \pm 10\%$ within the first week. In common with other animal models of cardiac arrest or stroke,^{27–29} we have reported that BCAA-60 induces regional abnormal water movement (edema), as evidenced by enhanced diffusion-weighted imaging (hDWI), within the first 2 days (Figure 1b1); the regions with hDWI were localized in the forebrain and midbrain (Figure 3). To overcome the lack of measurable infarct in this BCAA model, we translated the increased hDWI to the reduced apparent diffusion coefficient (rADC), and we quantitatively measured the regions with significant rADC in the brain before and 1 day after BCAA-60 (Figure 1b2). We found volume of metabolic disturbance (VMD) is characteristically bi-phasic with a second peak appearing at >10 h, and the second peak became stable at 1–2 days with pseudo normalization toward the values before cerebral ischemia in the striatum (Figure 4). We measured DWI and VDM thereafter at 1 day after BCAA-60 (Figure 3). Without effective treatment, the brains would develop cerebral atrophy and eventual ventriculomegaly by the 4th week (Figure 1c1). Indeed, we found that lateral ventricular size increased to 4.3% post BCAA-60 significantly ($P=0.01$, Student's *t*-test, one tail) from 2.1% in sham-operated mice (Figure 1c2); atrophy measured at 4 weeks and beyond positively correlated with the estimated VMD at 1 day in living mice post BCAA-60, with a linear coefficient of 0.71.

Unlike mice with brain damage, when normal animals encounter a corner normal mice typically rear forward and upward, then turn back, in either direction, to face away from the corner and toward the open end of the setup (the corner test).^{30,31} We measured the rate of turns when normal mice faced a 30° corner (that is, turning to either the left or right) to have a rate of $50 \pm 8\%$ (symmetric and no bias) before BCAA-60. Mice were measured weekly for at least 4 weeks after the BCAA-60 procedure (Figure 1d). We observed a significant increase in asymmetric turning ($\sim 90\%$ to one side) in BCAA-60 mice.

To validate ventriculomegaly and corner tests as robust indicators of the severity of brain damage and treatment responses, we randomly treated a group of the BCAA-60 mice with whole-body hypothermia, whereby the animals were placed on ice immediately after vessel occlusion and returned to room temperature when rectal body temperature measured 34°C during the 60-min procedure (hypothermia group). Hypothermia treatment was found to significantly improve survival, from $25 \pm 10\%$ to 100%, and to have a repaid recovery in body weight loss (Figure 2c) in this group. We found that hypothermia significantly reduced lesions and cerebral atrophy in the striatum and cortex (Figures 1e and f). Furthermore, we found that this neuroprotection involved a reduction in the expression of MMP-9 (Figure 1g1 and g2). Hypothermia therapy was also associated with a significant reduction in asymmetric turning, from 0.9 to 0.58 ($P < 0.05$), a rate not significantly different from that seen in the sham operation group; these results were consistent throughout

the 4 weeks of weekly tests following BCAA (Figure 1d). Our data thus demonstrated that ventriculomegaly and performance in the corner test served as accurate indicators of the severity of brain damage in this BCAA model.

Genes carried by an AAV vector are delivered as one single-bolus dose in most gene therapies. To evaluate gene therapy using eye drop delivery, we administered a single dose of scAAV2-CMV-hG-CSF (3×10^9 plaque-forming unit; $1.5 \mu\text{l}$ to the conjunctival sac of the left eye) at 0.5 ($n=9$), 1, 2, 3, 4 or 24 h ($n=3$, each group) after the release of BCAA. Survival rate varied depending on the time of eye drop administration (that is, 78% for the 0.5 h group, 66% for the 1 and 3 h groups, 33% for the 4 h group and 100% for the 2 and 24 h groups), but in each instance it was $\sim 25\%$ survival seen in the placebo group treated with scAAV2-CMV-green fluorescent protein (GFP) similarly administered (placebo, $n=15$). Moreover, there was no significant reduction in ventriculomegaly compared with the placebo group (Figure 5a).

When we applied additional scAAV2-CMV-hG-CSF at 0.5 h, 1, 7 and 14 days after BCAA-60 ($n=7$), we observed an exceptionally high survival rate of 100%, compared with $\sim 25\%$ in the BCAA-60 without treatment group ($n=22$). The optimal window for multiple scAAV2-CMV-hG-CSF treatments after BCAA coincides with the development of bi-phasic VMD (Figure 4). More importantly, we found that multiple doses of scAAV2-CMV-hG-CSF significantly reduced cerebral atrophy (Figure 5a). Gene therapies with hG-CSF cDNA ameliorated asymmetric turning in the corner test, from 0.9 in the placebo mice (BCAA with scAAV2-CMV-GFP, placebo group) to 0.67 ± 0.1 (Student's *t*-test, $P=0.03$, one tail, $n > 5$ each group), a result not significantly different from that measured before BCAA, that is, 0.50 ± 0.08 . We did not compare the corner tests in single dose groups because variable surviving mice.

To demonstrate positive hG-CSF mRNA expression *in vivo*, we designed a phosphorothioate-modified oligo DNA with antisense sequence (AS) hG-CSF and Cy3 label (sODN-AS-hG-CSF-Cy3). After transfecting PC-12 cells with scAAV2-CMV-hG-CSF or scAAV2-CMV-GFP DNA we found PC-12 cells expressed exogenous hG-CSF mRNA 6 h after transfecting using real-time cell imaging for Cy3 or DNA-free real time-PCR (Figures 6a and c); no hG-CSF mRNA expression was found in the placebo group at any of the time points tested (Figures 6b and c). We successfully showed that secondary GFP \pm transfectants using DNA extracted from primary transfectants of the placebo group exhibit real-time expression of GFP (Figures 6d and e); these data supported a stable scAAV2 vector and its cDNA after gene therapy. Moreover, these data indicate that the sequence in the sODN-AS-hG-CSF-Cy3 will distinguish hG-CSF mRNA from the endogenous rodent mRNA.

We found that hG-CSF mRNA expression was clearly represented as unique regions of interests in the R2* map when SPION-AS-hG-CSF and magnetic resonance imaging (MRI) were acquired 3–4 weeks after BCAA (arrows, Figure 5b1). However, we observed some enhanced regions of interests in the placebo group (Figure 5b2); such noise was mainly near the injured site surrounding the ventricle with ventriculomegaly (asterisk). We used data from target-guided MRI to obtain tissue sample and validated hG-CSF antigen expression to be localized in the non-astroglial population (Figure 5c); such noise in the placebo group was negligible (Figure 5d). We showed that NeuN expressed in most small blood vessels in mice treated with scAAV2-CMV-hG-CSF (arrow, Figure 5e); in the control groups (no virus treatment or placebo) the expression of NeuN was found mostly in neuronal nucleus.

To demonstrate the route of scAAV2-CMV-hGCSF or -GFP distribution after eye drop administration, we applied non-targeting Gd-DTPA to the right conjunctival sac ($n=4$). Compared with pre-existing signal in fatty tissue (Figure 5f), we noticed a conspicuous elevation of R1 signal in the ipsilateral bulbar and palpebral conjunctiva (regions of interest near the lens, as denoted by the asterisk) as well as in

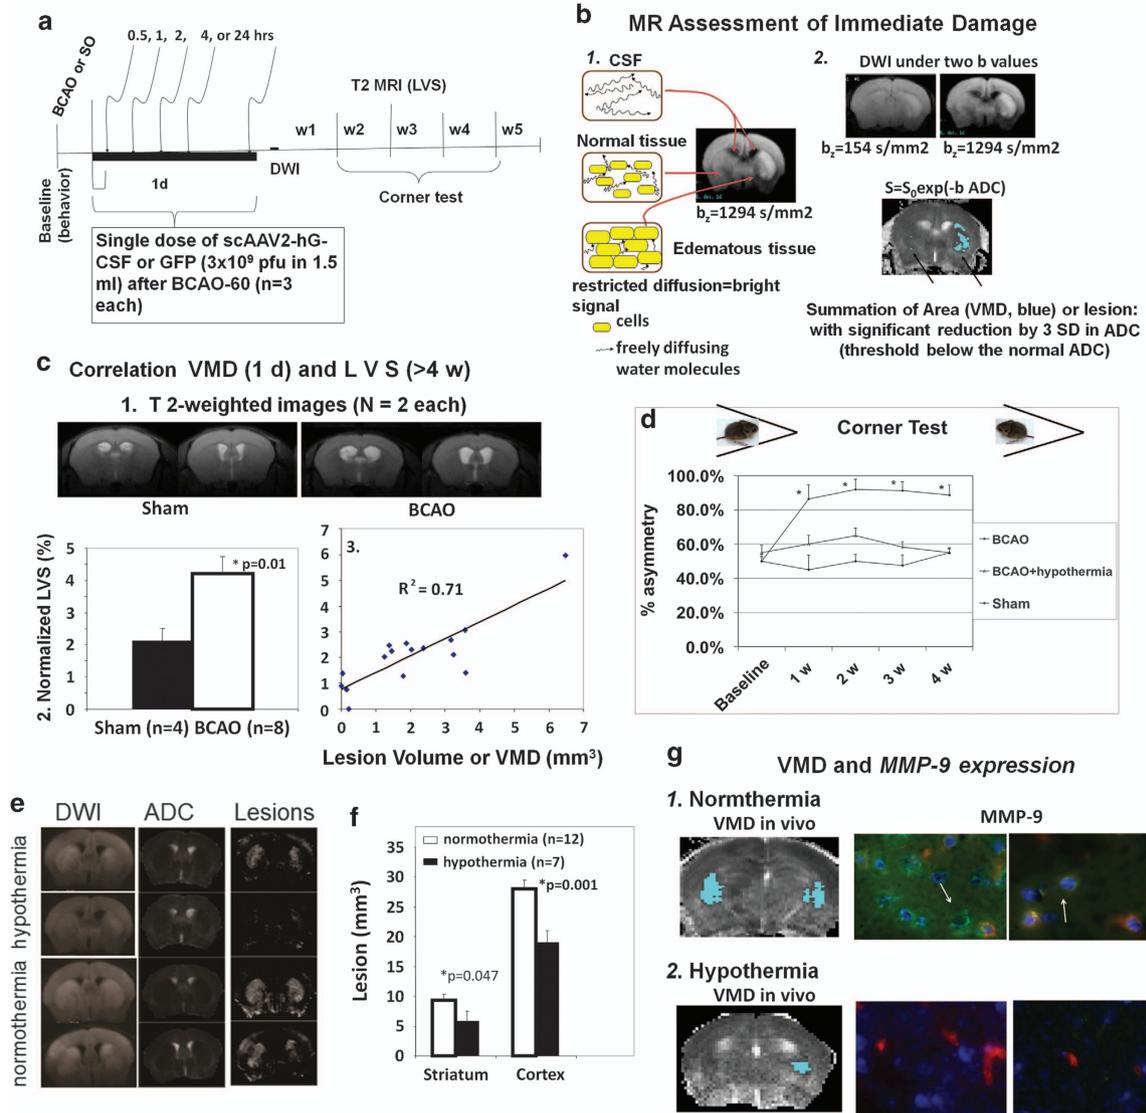

Figure 1. (a) Protocol for longitudinal monitoring of brain repair *in vivo* using MRI in mice with BCAA or sham operation. We made weekly measurements (up to 10 weeks, w10) for cerebral atrophy (ventriculomegaly) without MR-CA within 5 weeks, expression of scAAV2-CMV-hG-CSF, baseline MRI using SPION-Ran studies. The protocol can be extended to 24 weeks in some studies for leakage of the BBB using Gd-DATA. (b1) Abnormal DWI is obvious at high b -values; DWIs before and after BCAA are shown. Highlighted areas showing significant below-threshold $rADC$ after BCAA-60 represent regions of interest (ROI) for calculating the volume of metabolic disturbance (VMD, summation of all ROI of five MR slices of 1 mm each) as the lesion size (mm³). (b2) The results of BCAA-60, including abnormal water diffusion in the cerebrospinal fluid (CSF) in normal tissue as well as tissue with edema are illustrated, as detected by MRI. (c1) Representative T2-weighted images (caudal view). Enlarged lateral ventricles show cerebral atrophy without visible abnormal T2 MRI from mice at weeks 4 and 5 following sham operation and BCAA (one of five MR images from each mouse). (c2) Normalized lateral ventricular size (LVS). We measured ventriculomegaly ($n=16$) as normalized LVS (size ratio of lateral ventricle to corresponding brain volumes in percent, %). (c3) Scatter plot of LSV and VDM from mice before ($n=4$) and after ($n=12$) BCAA-60. The scatter plot shows the correlation between LVS (%) at w4-w5 post BCAA and lesion volume (VMD) in the same mice. (d) Corner test results of BCAA mice (normothermia, $n=8$ survivors of 32; hypothermia, $n=6$; sham-operation, $n=4$) when facing a 30° corner. BCAA mice without treatment showed significant asymmetric turning (~90%) beginning 1 week after the procedure and persisting for at least 4 weeks. Mice with treatment (BCAA ± hypothermia) exhibited behavior not significant differently from that seen in the sham-operated mice. (e-h) Validations of noninvasive measurements. Hypothermia treatment reversed DWI and $rADC$ (e) as well as VMD (f). The expression of MMP-9 antigen 1 day post BCAA in postmortem samples (g, arrows point to vascular MMP-9, green) validates brain lesion reduction with hypothermia treatment, shown here as normothermia (g1) vs hypothermia (g2). (Endothelia = red; nuclei = Hoechst stain).

the naso-lacrimal canal (arrow) 5–10 min after application (center panel, Figure 5f); enhanced MR-CA distribution becomes apparent in the naso-lacrimal canal on the contralateral side at 30 min. We found no MR-CA in the lens and cornea (asterisk), regions where lymphatics are lacking. We then tested the route of distribution after eye drop application in mice ($n=3$, 14 days after BCAA-60) using targeting Gd-NA-nestin (1 μ g Gd-DTPA in 2 μ l). This targeting MR-CA binds to nestin mRNA of

pericytes in the neovasculature when intraperitoneally injected to mice after BCAA-60;^{14,15} we acquired longitudinal MRI (Figures 5g1–g4). Figure 5g shows enhanced R1 signal in the brain 3 h after eye drop application (asterisks, Figure 5g1 vs Figure 5g3); in addition, we noticed R1 signal in the brain (asterisks) and retina (arrows) where the blood–retina barrier in the choroid might become permeable to MR-CA following BCAA-60. The data we have acquired support the hypothesis

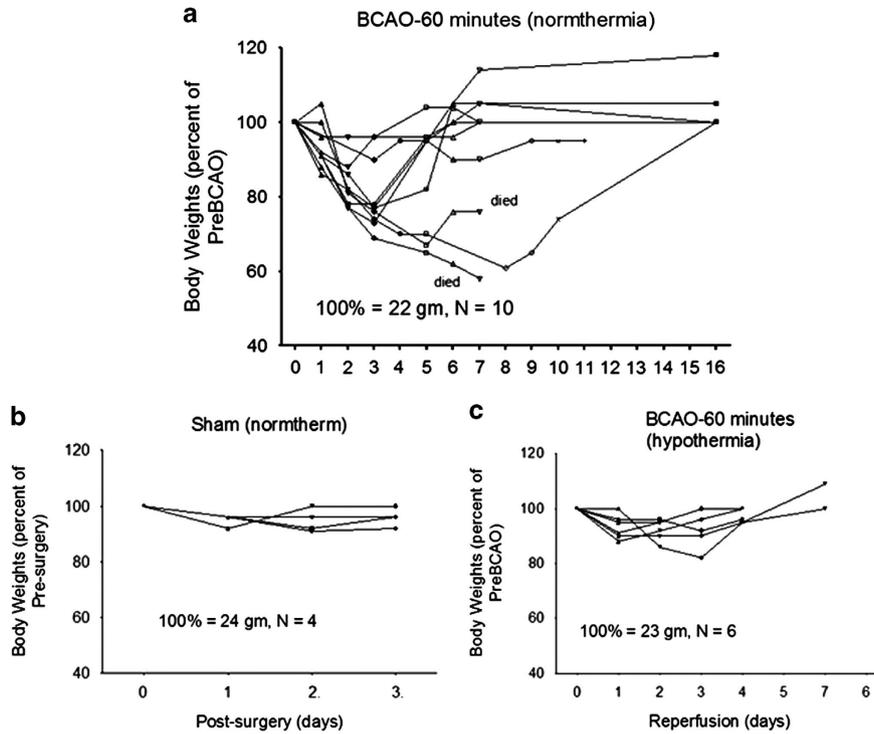

Figure 2. Changes in body weight with (a) and without (b) BCAA in the presence (c) of hypothermia treatment. Body weights of mice after BCAA were measured and recorded daily for at least 7 days after BCAA-60.

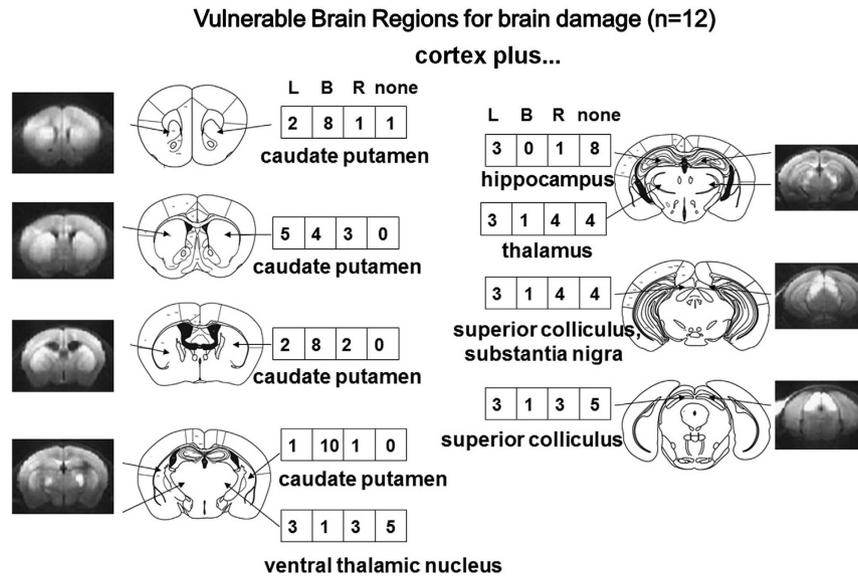

Figure 3. Summary of potential brain damage measured by MRI at the second peak of DWI or (1–2 days after BCAA-60) in C57black6 mice. The number in the box indicates the number of mice exhibiting lesion in the left (L), right (R) both (B) hemispheres (reconstructed from ref. 32). The presence of a lesion in the superior colliculus or optic tectum (midbrain) indicates BCAA effects that extend beyond the forebrain; mouse cardiac arrest-resuscitation models also show hyperintense DWI (hDWI) in similar ROI.^{27,28}

that viral vectors for treatment of BCAA-induced brain injuries can be distributed via the orbital lymphatics after delivery through eye drops applied to the conjunctival sac.

DISCUSSION

To the best of our knowledge in the area of theragnostics using gene therapy, this study is the first of its kind to demonstrate

effective noninvasive delivery of hG-CSF cDNA in scAAV-type 2 adeno-associated virus via eye drops, and to examine hG-CSF mRNA expression from neural cells in living mouse brains without biopsy. Furthermore, this study is distinct in that it tracked the neurological and histological effects of gene therapy for acute cerebral ischemia. Expression of the exogenous hG-CSF cDNA carried by scAAV2-CMV-hG-CSF and delivered through the eye conjunctiva are found to be effective in reversing neurological

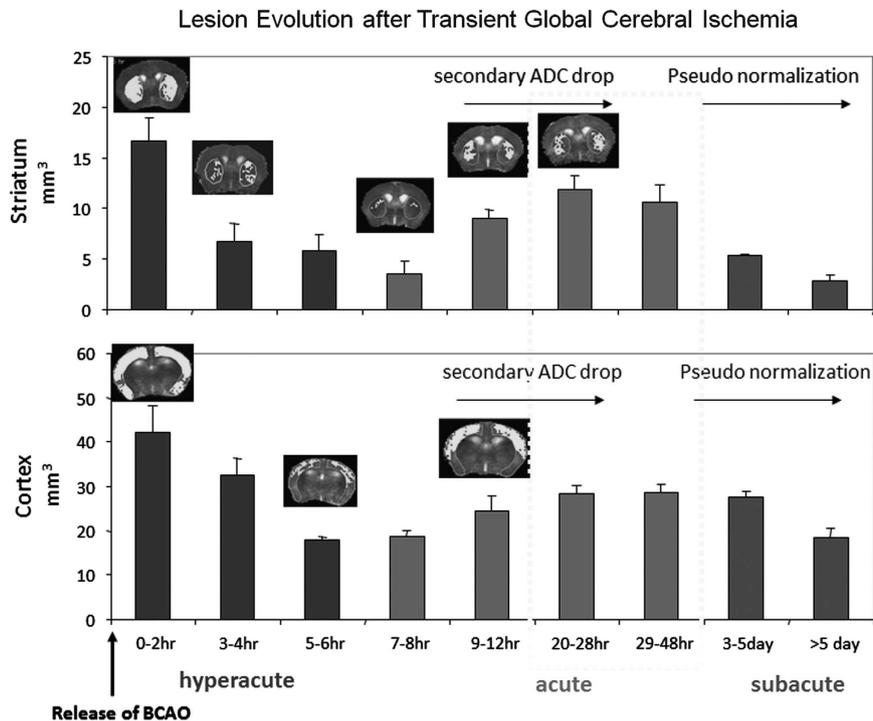

Figure 4. The time course followed for applying the AAV-CMV vector. Early brain lesions estimated by rADC below the threshold values (see Figure 1c). The threshold of ADC in normal mice ($n=6$ at different dates and different litters of mice) was established using power analysis after BCAA at normal temperature (each data point after BCAA was obtained from at least $n>4$, data adapted from our previous publication).³²

symptoms (the corner test) and ventriculomegaly in the brain after ischemia. These data lead us to conclude that repeated administration of hG-CSF cDNA in scAAV-type 2 adeno-associated viruses can protect the brain by supplying endogenous biologic of hG-CSF from neural cells during critical time after BCAA-60, leading to reductions in mortality, cerebral atrophy and the neurological deficits associated with ischemia. In mice that undergo brain repair using gene therapy is mediated by further elevation of neural progenitor cells in the small blood vessels. None of the improvements noted above was observed in mice of the placebo group. We validated noninvasive measurements used in our studies by comparing the results after hypothermia treatment. In normal mice, hypothermia may elevate DWI and reduce ADC. However, we measured rADC 1 day after hypothermia; the rADC by hypothermia in normal mice could inflate lesion estimation based on the threshold ADC leading to an over-estimated VMD in this hypothermia group (Figure 1g). Even so, The finding that hypothermia significantly reduces VMD induces less MMP-9 after BCAA-60 is consistent with neuroprotection of hG-CSF and our previous studies using MMP-9 gene knockdown in normal temperature.³²

Single doses delivered at various time points within the first 24 h after injury are found to be less effective in reversing brain damage. Our results from a single application of scAAV2-CMV-hG-CSF confirm the less-than-optimal effect of single-dose delivery of murine G-CSF cDNA in scAAV1/2 to the mouse spinal cord.¹⁶ It is also important to note that for our BCAA model there may be a window immediately after release of vessel occlusion during which uptake and distribution of hG-CSF cDNA are variable. The variability in the reduction of ADC most likely represents the change in the severity of hDWI, elevated MMP-9 expression and/or defective BBB. Therefore, the change in rADC at the second peak supports our rationale to deliver multiple doses of hG-CSF cDNA in scAAV-type 2 adeno-associated viruses. Cerebral damage and disturbance of the BBB were demonstrated by variations in the

ADC threshold, which was previously established using power analysis in a project involving 52 normal mice that underwent BCAA at normal temperature.³² The association of brain damage to the location of lesions with below-threshold ADC was supported by MMP-9 expression (Figure 1h); this association is validated by studies, from two different investigators, that used a global ischemia model with potassium chloride and resuscitation.^{27,28}

The damage that occurs in the brain in the first few hours after cerebral ischemia may reflect reperfusion, and thus exhibit as 'normalization' toward the baseline ADC, followed by another elevation of VMD in the secondary ADC drop that continues for at least 48 h. The lower lesion severity between 3 and 7 h after BCAA may explain the less-than-optimal efficacy of scAAV2-CMV-hG-CSF treatment we observed at 4 h. Therefore, although a single dose of scAAV2-CMV-hG-CSF on day 1 was found to improve survival rate, it did not reduce either cell death or neurological deficits. Indeed, repeated applications of scAAV2-CMV-hG-CSF after the initial 4-h time point ensure continuous supplies of hG-CSF in our studies. Increased blood vessel growth has been demonstrated in mice treated with G-CSF protein by showing greater numbers of bone marrow neural precursor cells in the vessels,^{33,34} and we demonstrated the same after repeated treatment. This result suggests that hG-CSF must be present during reperfusion and for at least 7 days for edema-related brain damage and neural cell death to be reversed.³⁵

We propose that the viral vector is transported through the lymphatic fluid (Figure 5f and g) to the vena cava, and then through the blood circulation to the brain, reaching the perivascular space by way of the BBB damaged as a result of cerebral ischemia.^{14,15} After the viral particles reach the perivascular space, they may be transported across the cell membrane for intracellular expression.³⁶ Another distribution route of the viral vector can be via the blood-retina barrier, which will need a retina-specific MR-CA for future evaluation.

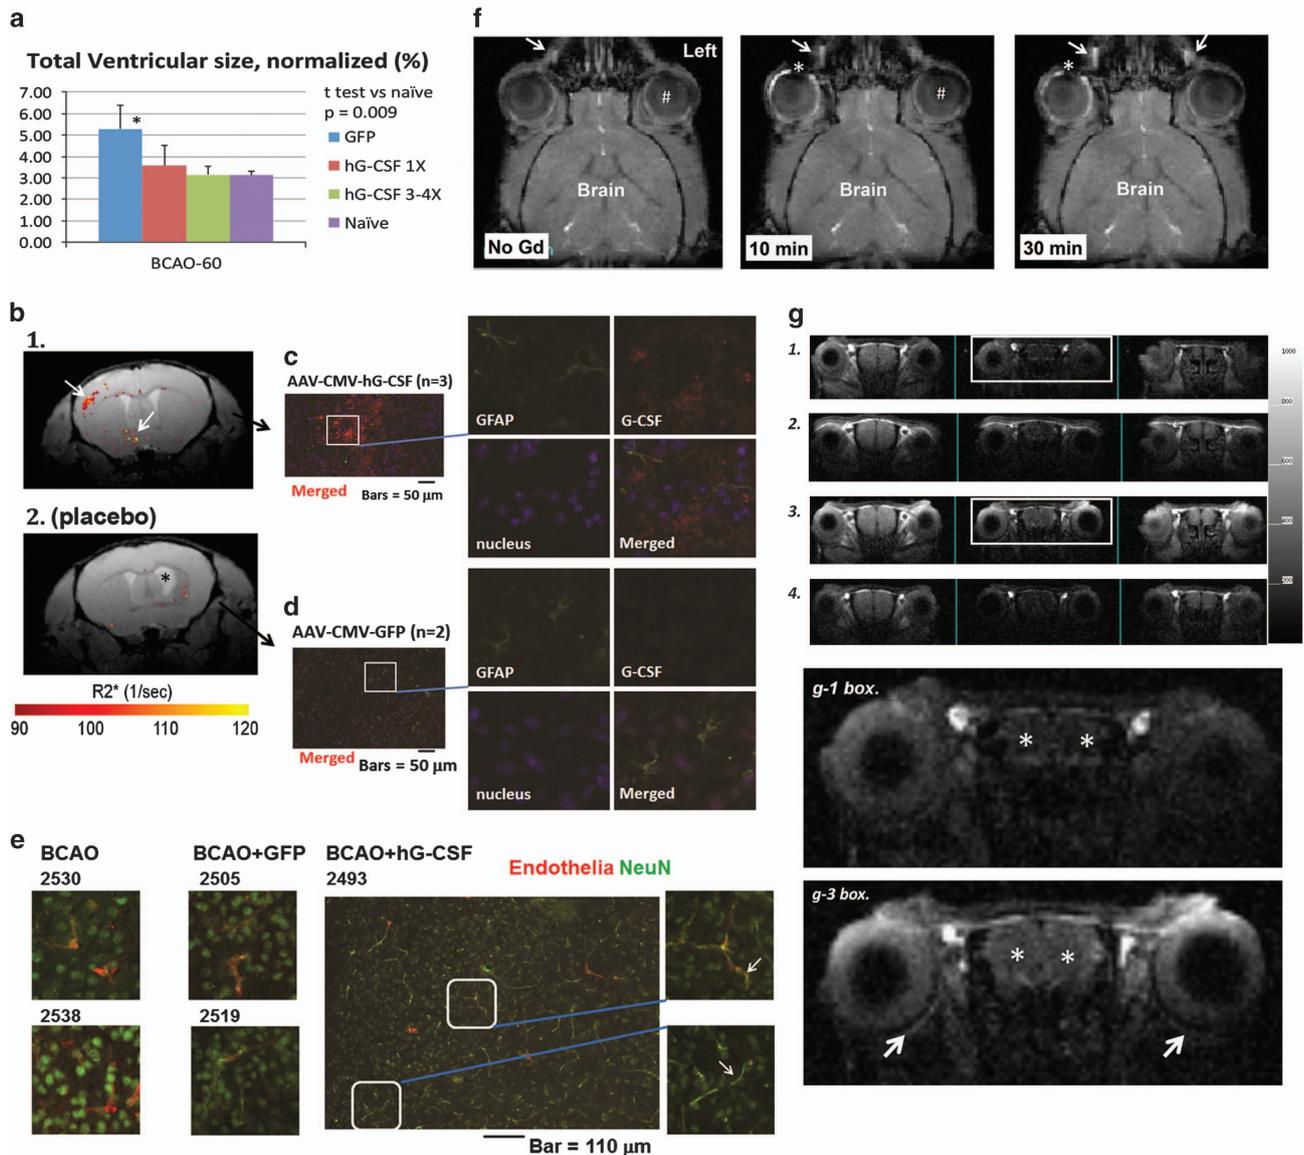

Figure 5. (a) Significant reduction in cerebral atrophy (measured during the 4th week after BCAA) in the scAAV2-CMV-hG-CSF treatment groups with multiple doses (green bar, $n=5$ survivors of 5) compared with the placebo group (blue bar, $n=7$ survivors of 28) or BCAA ± single dose hG-CSF (red bar, $n=5$ survivors of 8). (b) A unique ROI (arrow) using SPION-AS-hG-CSF 1 week after the final scAAV2-CMV-hG-CSF treatment (the 3rd week). (b1) The ROI in delta R2* maps from both the multiple treatment ($n=5$) and placebo ($n=4$ survivors of 16, b2) groups of mice. (c, d) hG-CSF expression in the proximity of the ROI identified *in vivo* (b1), with no expression found in the placebo group (b2). Mice with BCAA only did not show elevated hG-CSF expression ($n=2$ survivors of 8, data not shown). (e) NeuN expression in small blood vessels (Cy3-GSL I) in mice with AAV2-CMV-hG-CSF (BCAO ± hG-CSF, $n=3$) bar = 100 μm. NeuN expression (Cy2, arrow) occurs mostly in the neuronal nuclei of control and placebo groups (BCAO, $n=2$ survivors of 8; BCAO ± GFP, $n=4$ survivors of 16). (f) T1-weighted MRI of mice ($n=4$) before and after application of eye drops containing non-targeting MR-CA (Gd-DTPA, 500 mM in 10 μl Magnevist, Schering, Berlin, Germany) to the conjunctival sac; the distribution of MR-CA is shown in the same mouse. Arrow: the naso-lacrimal canal; #: the vitreous chamber; asterisk: lens. (g) The distribution of targeted MR-CA (Gd-nestin) in longitudinal MR acquisition ($n=2$). T1-weighted MRI was acquired before (g1), 10 min (g2), 180 min (g3) and 41 h (g4) after application of Gd-nestin (50 μg Gd-NA and 30 pmol biotin-sODN-nestin per 2 μl per mouse to one eye) in mice with BCAA-60. Arrows: choroid of the retina; * both hemispheres of the brain. Biotinylated sODN-nestin binds to NeutrAvidin (NA, Thermo, Grand Island, NY, USA) on Gd (modified from Gd-BSA, BioPal, Worcester, MA, USA) and the MR-CA targets Nestin mRNA of pericytes of neovessels after BCAA-60.^{14,15}

Our findings support the hypothesis that G-CSF reduces neurological deficits that develop in the first few days after cerebral ischemia. The corner test is one of more than five sensorimotor tests (including forelimb flexion, forelimb placing, accelerated roared and adhesive removal tests) used to assess neurological deficits in rodents. Among these tests, the corner test is regarded as 'more sensitive' in detecting deficits than the other tests because it reflects multiple asymmetries, including forelimb,

hind limb, postural and turning bias.³⁷ It has been established for mice affected by focal cerebral ischemia induced by the middle cerebral artery occlusion model; infarct volume is correlated with performance on the corner test for chronic behavioral impairments even as many as 90 days after mild focal cerebral ischemia, and whether with or without treatment.^{23,38} We confirmed here that the corner test can be used in BCAA model that does not induce infarcts. We have demonstrated here that gene delivery

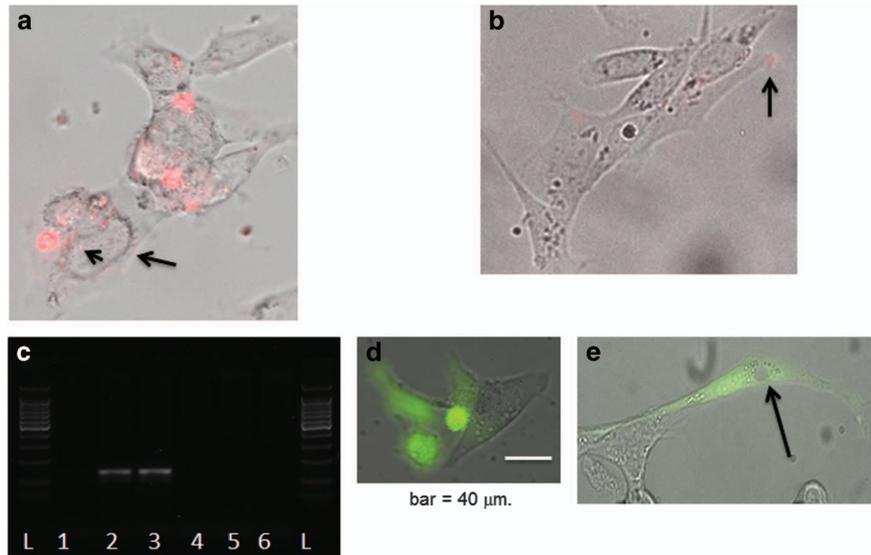

Figure 6. (a) hG-CSF cDNA transfection and mRNA expression in PC-12 cells. We transfected Cy3-sODN-AS-hG-CSF to detect hG-CSF mRNA in cells transfected with pCMV-hG-CSF; we observed signal in the nucleus (arrowhead) and peri-nucleus (arrow). (b) Few Cy3-sODN-AS-hG-CSF (arrow) retention in the cells transfected with pCMV-GFP. (c) Validation of hG-CSF mRNA expression from transfected PC-12 cells (pCMV-hG-CSF (lanes 1–3) or pCMV-GFP (lanes 4–6) at 3 (lanes 1, 4), 6 (lanes 2, 5) or 8 (lanes 3, 6) hours after transfection. Isolated RNA was treated with DNase before reverse transcription. (d) Living cells with GFP expression (Z-stack photograph, cellSens, time-lapse optical microscopy, Olympus IX83) > 3 h after transfection with pCMV-GFP. (e) Stable pCMV-GFP DNA *in vivo* for 72 h. We isolated total DNA from PC-12 at 72 h (d); we then transfected PC-12 again and detected GFP expression at 24 h after transfection. GFP is in the cytoplasm but there is no nuclear GFP (arrow).

and resulting protection of the brain can be validated without removing the brain tissue we hope to preserve. Moreover, the ability to deliver therapeutic agents through eye drops may have important implications for emergency medicine, as lyophilized viral particles can be readily reconstituted in saline and administered to cardiac arrest patients.

MATERIALS AND METHODS

Cell culture

We examined the delivery and dynamic uptake of pCMV-hG-CSF and pCMV-GFP transfection in PC12 cells (ATCC, CRL-1721) in a miniature incubator chamber (INU-UK-F1; Tokai Hit Inc., Shizuoka, Japan) on the stage of an upright microscope (Olympus, Lebanon, NH, USA), following published procedure.³⁹ All cell culture studies were repeated by two separated research staffs.

Expression of hG-CSF cDNA

The scAAV2-CMV-GFP plasmid we used in our study was a gift from Dr D McCarty (Ohio State University, Columbus, OH, USA) to Dr JYW hG-CSF 615 bp cDNA (accession number NM 172219.2) was inserted into the scAAV2-CMV-GFP plasmid by substituting hG-CSF for the GFP cDNA sequence. The new plasmid was thus termed scAAV2-CMV-hG-CSF. The scAAV-type 2 adeno-associated viruses, produced (two separate batches) by the Gene Therapy Vector Core of the University of North Carolina (Chapel, Hill, NC, USA), were generously gifted to Massachusetts General Hospital for explicit research use. Viral titers were determined by dot blot analysis. To test gene expression *in vivo*, vectors were transiently transfected using lipofectin (Invitrogen) into PC12 cells (50 cells per well) at a total concentration of 1 µg per well in a six-well dish. At 3, 6, 8 or 24 h (one dish per time point) after transfection with scAAV2-CMV-hG-CSF plasmid or scAAV2-CMV-GFP plasmid PC12 cells were harvested for RNA isolation using RNA-easy (Qiagen, Valencia, CA, USA) with the addition of RNase-free DNase before reverse transcription. We generated a primer with AS sequence (5'-AACTCGGGGAGATCCCTTCCA-3', homemade) to hG-CSF mRNA (AS-hG-CSF) and sense sequence (5'-ACTCTCTGGGCATCCCCCT-3', S-hG-CSF). A hG-CSF-specific reverse transcription product using primer AS-hG-CSF was generated using reverse transcriptase, PCR amplification and the DNA product was resolved by agarose gel (1%) electrophoresis, as described previously.⁴⁰ To analyze the duration of GFP expression

following scAAV2-CMV-GFP plasmid transfection, images were collected by time-lapse optical microscopy (Olympus IX83) from living PC12 cells. A cellSens system (Olympus) was used to reconstruct the Z-stack image from seven photos (Z dimension ± 8.82 micron with Z spacing = 1.26 microns; exposure time = 661 ms × 4.22 gain).

Animals and housing

All procedures were approved by the Massachusetts General Hospital Subcommittee on Research Animal Care, in accordance with the Public Health Service Guide for the Care and Use of Laboratory Animals. At least 10 adult C57black6 male mice were ordered from Taconic Farm (Germantown, NY, USA) each time ($n > 3$ litters at a time), 2–3-month of age (23 ± 2 gm bw), were kept in cages in a room with controlled light cycles (12 h/12 h light/dark). All animals had free access to water and standard lab chow. We conducted stratification for baseline values (MRI and corner test) to eliminate abnormal anatomical brains or bias corner test before experimentation. Mice were trained, operated on and tested in a random manner, with a blinded observer performing all behavioral testing. A numeric identifier for each mouse and was given to the examiner; the treatment was revealed at the completion of testing for data analysis.

BCAO to induce cerebral ischemia

We used the BCAA model, as described, for long-term examination of the delivery and dynamics of our therapeutic agents.⁴¹ For each BCAA experiment, we randomly selected six mice each day and arbitrarily assigned them to one of three groups (sham operation control, BCAA, or BCAA plus treatment, $n = 2$ each). The control animals underwent surgical procedures identical to BCAA, except that we did not occlude the arteries ($n = 4$). For all normothermic animals ($n = 22$), we maintained body temperature at $36 \pm 1^\circ\text{C}$ using a heating blanket, and monitored temperature with a rectal thermos-sensor, throughout BCAA. We analyzed the blood flow of the mid-cerebral artery using Doppler in all animals that underwent surgical procedures, positioning the Doppler probes to the skull during BCAA ($n = 4$ of 20); these mice were not used for further experimentation. We randomly selected animals and placed them on ice immediately after the completion of vessel occlusion; they were immediately removed from the ice when body temperature dropped to 34°C (the hypothermia group, $n = 10$). The mice were then kept at room temperature for the remainder of the procedure, before release of vessel

occlusion. The average body temperature in the hypothermia group was $34 \pm 0.5^\circ\text{C}$. We applied SCAAV2-CMV-hG-CSF, scAAV2-CMV-GFP (3×10^9 plaque-forming unit), or saline (1.5 μl) to the eye sac of the left eye after release of BCAA, at single ($n=24$) or multiple ($n=7$) time points, as indicated. By the third day after cerebral ischemia, all of the surviving post-ischemic mice exhibited spontaneous activity in their home cages, were responsive to handling and engaged in normal self-grooming behavior.

MRI protocols for diffusion-weighted MRI and gene-targeting MRI
Diffusion-Weighted MRI was performed in mice before and after BCAA following previously published procedure,³² using a 9.4 Tesla MRI system (Bruker Avance system, Bruker Biospin MRI, Inc., Billerica, MA, USA). Ventricular images were acquired using a T2-weighted spin echo sequence (repetition time/echo time (TR/TE) = 7000/25 ms, $120 \times 120 \mu\text{m}^2$ in-plane resolution and 20 slices of 0.5 mm thickness, rapid acquisition with relaxation enhancement factor 8, number of averaging = 4) on a 9.4 T system. We segmented the ventricles from the tissue using a threshold of two s.d.s (0.3% confidence interval outside of the mean) above the mean signal intensity of the entire brain slice (including the ventricles).

We have shown T2 MRI to be correlated with volume measured by the threshold ADC.¹⁴ However, BCAA-associated cerebral ischemia does not consistently induce necrosis, and SPION-hG-CSF delivered to measure gene expression may interfere with T2 MRI. Therefore, we applied threshold ADC (ADC values at three s.d.s below the average of $n=6-9$ at different dates, and examined different litters of mice). We identified VMD as brain lesions where rADC is evident in hyperintense diffusion-weighted images after BCAA, as previously described.³²

To detect hG-CSF cDNA expression *in vivo*, we generated a phosphorothioate-modified oligodeoxynucleotide (sODN) with AS sequence (5'-Cy3-sODN-AS-hG-CSF-biotin-3', homemade) to hG-CSF mRNA. Target-guided MR-CA was made by conjugating SPION-NA to all sODN at 3 nmol per mg Fe for at least 6 h at 4°C before delivery as described.⁴¹ We examined the expression of hG-CSF mRNA by acquiring MR images at 15 T (Magnex 130-mm diameter horizontal magnet with a Siemens clinical console) using SPION-AS-hG-CSF or SPION-Ran (4 mg Fe per kg, 0.1 ml, i.p) injected the night before MRI. We measured non-specific R2* changes using non-targeting binding MR-CA (SPION-Ran), and evaluated SPION-labeled gene expression in the R2* maps acquired using multi-echo gradient echo sequences: TR 800 ms, six echoes (TE = 1.94, 3.41, 4.88, 6.35, 7.82, 9.29 ms) with spatial resolution of $0.1 \times 0.1 \times 0.25$ mm. We also obtained the ventricular volume from T2-weighted turbo spin echo images acquired at 15 T (TR 3 s, effective TE 42 ms, Turbo factor 8). The total size of the segmented area (including both lateral ventricles, 3rd and 4th ventricles) was measured, normalized to the total area of the corresponding brain slices, and expressed as the ratio of ventricular volume to brain volume, in percentage.

Corner tests

The corner test, which determines an animal's asymmetric direction of turning when encountering a corner, is used as an indicator of brain injury. We used an experimental corner setup composed of two boards (with dimensions of $30 \times 20 \times 1 \text{ cm}^3$) arranged to form a 30° corner; a small opening was left along the joint between the two boards. The mouse was placed 12 cm from the corner and allowed to walk into the corner, so that the vibrissae on both sides of the animal's face made contact with the two boards simultaneously. Before BCAA procedure, we conducted behavior tests (stratification) on all mice to screen for mice with no turning asymmetry ($n > 18$). Each mouse took part in 10 trials, after which we calculated the percentage of turns to each side, recording only those turns involving full rearing along one of the boards. This stratification procedure excludes mice with 80–100% asymmetric turns ($n=4$); we included mice that turned in either direction ($n=14$) with a pretest score of 0.50 ± 0.08 . Each mouse took part in 10 trials for up to 4 weeks after BCAA.

Immunohistochemistry

Following MR acquisition, the mice ($n > 2$, each group) were put under general anesthesia and retrograde-perfused with ice-cold saline. Whole brains were removed from perfused animals and frozen in *n*-butanol on dry ice. The frozen brain tissue sections (thickness, 20 μm) were prepared and stored at -70°C before staining. The brain samples were fixed in 4% paraformaldehyde (50 ml) in 0.1 M phosphate buffer (0.1 M $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$ pH 7.4) for 10 min, and then were washed in buffer. For antigen detection, the samples were stained overnight with rabbit polyclonal

antibodies against GFAP (Z0334, DAKO North America, Carpinteria, CA, USA), G-CSF (NBP1-89894, Novus Biologicals, Littleton, CO, USA), GFP (Z0334A11122, Life Technologies, Grand Island, NY, USA), or NeuN (MAB337, Millipore, Danvers, MA, USA); all at 1/1000 dilution at 4°C , followed by fluorescein isothiocyanate-goat anti-rabbit IgG (1/1000). Vascular endothelia were stained with Cy3-griffonia simplicifolia lectin I (1/100 dilution), and nucleic acids were stained with Hoechst dye. All histological images were acquired using the same exposure time and gain, using a cellSens system (Olympus).

Statistical tests

We calculated the minimum number of animals required in each group using power analysis to achieve 85% power for a *P*-value of 0.05, or a minimum of $n=2$ viable mice in each comparison. We computed the mean and s.e.m. from the average values in each group of animals. We then compared these values using Student's *t*-test, one tail; we used the Mann-Whitney test to assess the corner test results.

CONFLICT OF INTEREST

The authors declare no conflict of interest.

ACKNOWLEDGEMENTS

We thank Dr Sean I Savitz (University of Texas Houston Medical School, Houston, TX, USA) for demonstration of the corner tests; Dr Jarek Aronowski (UTHMS, TX, USA) for sharing the hypothermia treatment protocol; Dr Chang-Ming Liu for synthesizing all sODN and Dr JS Yang for conducting real time-PCR. This project was supported by NIH grants R01DA029889 and R01EB013768, as well as by a pilot grant from the Boston Area Diabetes Endocrinology Research Center (P30DK057521-14 (J Avruch)) to PKL, NS045776 to the MGH Neuroscience Center). The MR systems used for this work were funded by NIH Shared Instrumentation Grants (1S10RR025563) awarded to the Athinoula A Martinos Center for Biomedical Imaging. The B Wellcome Trust (No.1012722) to HP, State of Florida (09KW-11) to JYW also supported this research.
