

In this topic, are you able to:

- label and describe** the internal and external structure of the eye?
- describe** the pupil reflex in response to bright and dim light?
- describe** the process of accommodation when viewing near and distant object (with reference to components of the eye)?

The external structure of the eye

Structure	Function
Eyelids	<ul style="list-style-type: none"> • Movable fleshy flap of skin which protects the cornea from excessive damage • Prevents excessive light from entering it when eye is partially closed (squinting) • Spreads tears over the eyes so that dust can be wiped off when blinking
Eyelashes	<ul style="list-style-type: none"> • Stiff hair that shield the eye from dust particles
Tear gland	<ul style="list-style-type: none"> • Gland lying at corner of upper eyelid which secretes tears to: <ul style="list-style-type: none"> ○ wash away dust particles ○ keep the cornea moist for atmospheric oxygen to dissolve ○ lubricate the conjunctiva which helps to reduce friction when the eyelids move

<p>Conjunctiva</p>	<ul style="list-style-type: none"> • A thin transparent layer covering the sclera and is continuous with skin of eyelids <ul style="list-style-type: none"> ○ A mucus membrane which secretes mucus to keep the front of the eyeball moist
<p>Iris</p>	<ul style="list-style-type: none"> • A circular sheet of muscles, which <ul style="list-style-type: none"> ○ contains a pigment that gives the eye its colour ○ controls the amount of light entering the eye by two sets of involuntary muscles - the circular and radial muscles
<p>Cornea</p>	<ul style="list-style-type: none"> • A dome-shaped transparent layer which is a specialized form of conjunctiva <ul style="list-style-type: none"> ○ helps to refract or bend light rays into the eye
<p>Pupil</p>	<ul style="list-style-type: none"> • A hole in the center of the iris which <ul style="list-style-type: none"> ○ allows light to enter the eye

The internal structure of the eye

Sclera	<ul style="list-style-type: none"> • Tough, white <u>outer</u> covering of the eyeball (continuous with the cornea) <ul style="list-style-type: none"> ○ protects the inner parts of the eye from mechanical damage ○ also supports and maintains the shape of the eye
Choroid	<ul style="list-style-type: none"> • <u>Middle</u> layer of the eyeball • Pigmented black to prevent the internal reflection of light • Contains blood vessels that carry oxygen and nutrients to the eyeball while removing metabolic waste products
Lens	<ul style="list-style-type: none"> • Transparent, circular and biconvex structure • Changes its shape or thickness in order to refract light onto the retina
Ciliary body	<ul style="list-style-type: none"> • Contains ciliary muscles • Control the curvature and thickness of the lens

Suspensory Ligament	<ul style="list-style-type: none"> Attaches the edge of the lens to the ciliary body
Aqueous chamber	<ul style="list-style-type: none"> Space between the lens and the cornea, which is filled with aqueous humour, a transparent watery fluid Keeps the front of the eyeball firm Refracts light into the pupil
Vitreous chamber	<ul style="list-style-type: none"> Space behind the lens which is filled with vitreous humour, a transparent jelly-like substance Keeps eyeball firm Refracts light onto the retina
Retina	<ul style="list-style-type: none"> Innermost layer of the eyeball Layer on which images are formed Contains light-sensitive cells known as photoreceptors - rods and cones Photoreceptors connected to nerve ending from optic nerve
Optic Nerve	<ul style="list-style-type: none"> Nerve that transmits nerve impulses to the brain upon stimulation of the photoreceptors
Fovea/yellow spot	<ul style="list-style-type: none"> A small yellow depression where images are focused Contains cones but not rods Enables a person to have detailed colour vision in bright light Fovea centralis is where vision is the sharpest

NOTE: Cornea, Aqueous Humour, Lens and Vitreous Humour has a common role - refract light rays onto the retina.

Photoreceptors in the Retina

Cones	Rods
<ul style="list-style-type: none"> • Three types of cones containing different pigments: red, blue and green cones • Each type of cones <u>absorbs light of different wavelengths</u> and together, they enable to see a variety of colours • Cones <u>do not work well in dim light</u> 	<ul style="list-style-type: none"> • Rods are more sensitive to light than cones • They enable us to see in dim light, but only in black or white • Contain a pigment called visual purple

How does the iris control the amount of light entering our eyes?

- The iris is controlled by two sets of involuntary muscles - the radial and circular muscles
- The muscles are antagonistic to each other - when one contracts, the other relaxes

In Bright Light	In Dim Light
<ul style="list-style-type: none"> • Circular muscles contract • Radial muscles relax • Pupil constricts • Reduces the amount of light entering the eye 	<ul style="list-style-type: none"> • Circular muscles relax • Radial muscle contract • Pupil dilates • Increases the amount of light entering the eye

What is a pupil reflex?

- It is a reflex which involves the pupil changes size as result of changes in light intensity
- Involves receptors and effectors

How is an image formed on the retina?

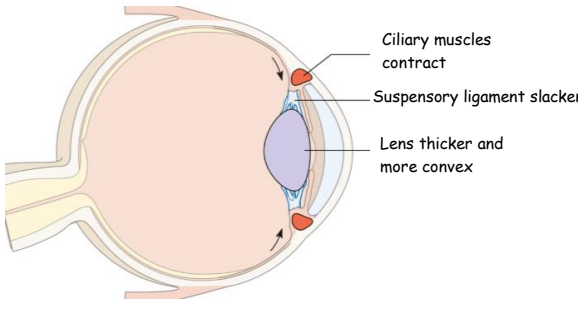

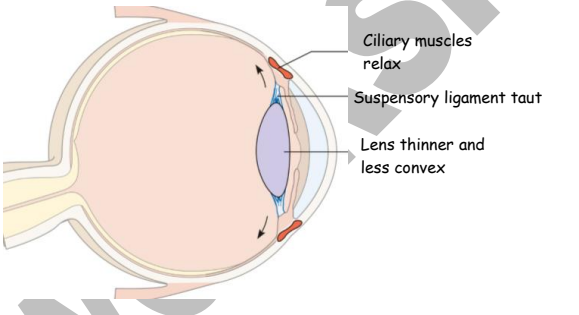

What is the role of the brain in vision?

- Image formed on the retina is inverted, laterally inverted and smaller in size than the real object
 - This means image is upside down within the retina, but the brain makes it upright
- The brain has corrective function
 - In the case of the blind who have their sight restored, objects appear upside down to them at first
 - The brain will learn how to correct the images that fall on the retina

What is focusing?

- Focusing or accommodation is the adjustment of the lens of the eye so that clear images of objects at different distances are formed on the retina
- In focusing, the thickness or curvature of the lens is adjusted
 - This allows the light rays to be focused on the retina, hence enabling a clear image to form on the retina

Viewing NEAR objects	Viewing DISTANT objects
 <p>Ciliary muscles contract</p> <p>Suspensory ligament slacken</p> <p>Lens thicker and more convex</p>	 <p>Ciliary muscles relax</p> <p>Suspensory ligament taut</p> <p>Lens thinner and less convex</p>
<ul style="list-style-type: none"> • Ciliary muscles contract, relaxing their pull on the suspensory ligaments • Suspensory ligaments slacken, relaxing their pull on the lens • Lens become thicker and more convex, decreasing its focal length • Light rays are focused on the retina • Photoreceptors are stimulated • Nerve impulses are transmitted to the brain, which is interpreted by the brain that allows the person to see the object 	<ul style="list-style-type: none"> • Ciliary muscles relax, pulling on the suspensory ligaments • Suspensory ligaments become taut, pulling on the edge of the lens • Lens become thinner and less convex, increasing its focal length • Light rays are focused on the retina • Photoreceptors are stimulated • Nerve impulses are transmitted to the brain, which is interpreted by the brain that allows the person to see the object

NOTE: Focal length is the distance between the middle of the lens to the point of focus on the retina.
