Active engagement; Computer simulations; Inquiry; Project-based science; Scaffolding; Student centered

Inquiry-based learning is part of a family of instructional techniques that situate learning in meaningful problems or questions. Inquiry learning approaches focus on having students learn disciplinary knowledge, reasoning, and epistemic practices as they engage in collaborative investigations (Hmelo-Silver et al. 2007). Inquiry is organized around the questions that scientists might ask or disciplinary problems that require scientific inquiry to resolve. Inquiry approaches to learning are student centered, meaning that active engagement on the part of the student is required. The teacher's role is to facilitate learning and engagement in science practice rather than to provide direct instruction. Of central importance to inquiry-based learning are the questions being asked. Pursuing questions situates learners in the epistemic practices that are part and parcel of the science discipline (Krajcik and Blumenfeld 2006). The nature of student investigations varies with the particular scientific discipline so that investigations might involve designing and running experiments but could also involve observational or model-based inquiry.

The theoretical basis of inquiry learning builds upon important principles from the learning sciences (Krajcik and Blumenfeld 2006). This research has demonstrated that students only learn deeply when they are active agents who engage in meaning making as they interact with the world. Substantial evidence also suggests that it is critical to situate learning in real-world contexts in which learners design their research and participate in scientific practices such as observation, representation, and explanation, as well as the social practices of science. Tools play an important role in inquiry in that they can be used to support and scaffold learners as they engage in complex inquiry practices. These tools may be relatively simple, such as a magnifying glass or a ruler, or they be more complex, such as computer simulations and data visualization instruments (Eberbach and Crowley 2009; Hmelo-Silver et al. 2007; Krajcik and Blumenfeld 2006).

Long before students formally learn about scientific inquiry, they have already developed many ways of understanding and reasoning about the natural world (Duschl et al. 2007). Such naive knowledge – developed through direct everyday experiences with phenomena and through cultural transmission – offers both opportunities and challenges for learning to participate in scientific inquiry. These knowledge sources can provide a rich foundation for asking questions, for generating evidence, and even for evaluating claims about evidence. At the same time, a major challenge for students of all ages is to learn to understand and to evaluate sources of knowledge in ways that enable them to distinguish personal beliefs from empirical evidence, to connect evidence to explanations (Duschl et al. 2007), or to connect their observations of everyday phenomena to the development of new knowledge (Eberbach and Crowley 2009).

These challenges affect the development of scientific reasoning and are evident throughout inquiry. To illustrate the challenges of learning through inquiry, we briefly consider observational practice, which can be a powerful means of making sense of the world and which plays a central role in how scientists develop new knowledge (Eberbach and Crowley 2009).

Although observation is often treated as a simple skill of noticing surface features, actual systematic observation is a complex practice that coordinates disciplinary knowledge, theory, and certain habits of attention. Observational practice includes asking questions of phenomena. These questions focus attention and filter complexity; questions connect to disciplinary problems and goals throughout the inquiry process. The questions that scientists ask guide their observations and ultimately the data they record and collect. These data are often transformed into inscriptions – diagrams, graphs, and line drawings – that allow new questions to be asked of data. Transforming direct observations into multiple iterations of scientific inscriptions can be useful in shaping shared questions, making evidence explicit, and critiquing each others' theories (Lehrer and Schauble, cited in Eberbach and Crowley 2009).

There are many successful examples of inquiry-based learning that are being used in a range of primary and secondary school contexts (Duschl et al. 2007; Hmelo-Silver et al. 2007). One prominent example comes from the work on project-based science at University of Michigan. PBS, used in several large urban school districts in the United States, begins each inquiry unit with a driving question, such as "Can good friends make me sick?" These questions provide a shared context that anchors inquiry and learning of disciplinary ideas. Because engagement in inquiry practices is challenging, scaffolding is critical to supporting learners. These scaffolds are often distributed across social and material resources. Social resources include teacher guidance and peer collaboration. Material resources can include technology tools that provide guidance and contexts. These scaffolds may embed expert guidance, model disciplinary thinking, and structure complex tasks so as to reduce the cognitive load (Hmelo-Silver et al. 2007). In PBS, student investigations result in the creation of artifacts, including physical models, computer simulations, or multimedia artifacts (Krajcik and Blumenfeld 2006).

There is substantial evidence that inquiry-based learning is effective (Hmelo-Silver et al. 2007). These outcomes have included effects in a large urban district on state standardized assessments (Krajcik and Blumenfeld 2006). Moreover, this effect was cumulative (i.e., more inquiry units led to greater gains) and sustained. In a study of a large and diverse school district, Lynch et al. (2005, cited in Hmelo-Silver et al. 2007) demonstrated that inquiry-based learning environments fostered better engagement and a mastery goal orientation when contrasted with a comparison group that participated in traditional instruction. This effect was equally strong for historically disadvantaged groups as it was for non-disadvantaged groups. In a meta-analysis of teaching strategies on science achievement, Schroeder et al. (2007) found that inquiry strategies were associated with a moderate to large effect on student achievement.

To deal with the challenges of inquiry-based learning and to make complex phenomena accessible to learners, many such learning environments use computer tools to scaffold learning, support inquiry, and make complex phenomena accessible to learners (Hmelo-Silver et al. 2007). Computer-based tools can be used to provide scaffolding and set contexts for inquiry. For example, in Animal Landlord, students create a chronological sequence of behavioral components in a video clip (Smith and Reiser 1998, cited in Hmelo-Silver et al. 2007). The tool highlights the disciplinary strategies for animal behavior. In BGuile, students investigate evolution of the Galapagos finches as the software provides a database and templates to help guide learners in constructing domain-specific explanations (Sandoval and Reiser 2004, cited in Hmelo-Silver et al. 2007). In WISE, scaffolds are used to provide expert guidance (Davis and Linn 2000, cited in Hmelo-Silver et al. 2007). Other scaffolds can be used to structure inquiry tasks and decrease cognitive load. In Model-It (Krajcik and Blumenfeld 2006), a computer environment allows learners to build models of natural phenomena. The software allows learners to plan, build, or test models. Learners must engage in planning before they can build their model. Moreover, the software allows students to qualitatively model relationships that express underlying complex mathematical relations, reducing the learners' cognitive load and placing the task in their zone of proximal development. Technology can also provide contexts for inquiry. These can take the form of computer simulations, visualization tools, or video. In the STELLAR project, videos of classrooms provided a context for preservice teachers to learn about educational psychology. At the same time, scaffolds structured their video analysis around instructional planning (Hmelo-Silver et al. 2007).

Learning through inquiry offers powerful ways in which learners construct content understanding and learn disciplinary practices. This is not without challenges. We demonstrated some of this with our example of observation. Inquiry changes the role of both learner and teacher. It focuses the teacher role on guiding the learning process and learners must take increased responsibility for their learning. This increased responsibility may better prepare scientifically literate citizens who are prepared to be lifelong learners.

In-Service Teacher Education

Aik-Ling Tan
Department of Natural Sciences & Science
Education, National Institute of Education,
Nanyang Technological University,
Nanyang, Singapore

Introduction

In-service teacher education fits broadly under the category of teacher professional development. Teacher professional development can be divided into two branches – (1) in-service teacher education and (2) professional learning communities. In-service teacher education is usually formal in nature with courses or programs offered and accredited by universities or other institutes of learning. Unlike preservice teacher education that aims to prepare inexperienced individuals to teach in classrooms, in-service teacher education is specifically catered to practicing teachers with practical experiences in the classrooms. One of the objectives for in-service teacher education is to ensure currency of knowledge that teachers have in their field of practice. These knowledges can include subject matter knowledge, knowledge of and about latest pedagogical methods, and knowledge about policies and reforms.

Teaching is a complex activity that changes with the demands of the society and the world at large. These changes in societal needs and education reforms suggest that teachers' knowledge needs to be constantly updated and innovations in teachers' practices need to keep pace with changes. Further, the rapid rate of change in scientific and technological advancement suggests that the shelf-life of knowledge that an individual possesses is shortened. Hence, constant updating and upgrading is a necessity. As such, in some countries, there is legislation on the renewal of teaching certificates/accreditation. The legislation requires in-service teachers to be involved in some form of formal professional development so that they are kept abreast of changes in the educational landscape. Even in the absence of formal legislation of teaching certification, in-service teachers are also encouraged to attend some form of professional development courses. For example, in Singapore, in-service teachers have an entitlement to 100 h of professional development to enable the in-service teachers to stay relevant and current in their practice.

Forms of In-Service Teacher Education

The forms of in-service teacher education can be mapped on a spectrum which range from short-term courses to mid-term courses to long-term courses (in ways not dissimilar from Huberman's (1989) stages of career development). Some forms of in-service teacher education are:

1. Short-term in-service courses offered by universities or colleges of education. The function of these courses is to introduce and revise with in-service teachers concepts and practices that have changed. For instance, in the last 10 years, knowledge in the area of techniques for isolation of molecules have increased exponentially and hence, in-service teachers need to be updated about these latest techniques and how to use them. Further, with the growth of information technology, in-service teachers also need to be informed how they can potentially exploit the affordances of technology to enhance their classroom practices. These short-term courses are usually conducted with specific domain learning outcomes and take the form of a single workshop that can last between 12 and 36 h. In-service teachers are usually awarded certificates of participation or proficiency when they attend these courses.
2. Mid-length in-service courses are those courses which last 2–4 weeks. Not unlike the short-term courses described above, these mid-length courses are also aimed at informing teachers of the latest development and changes in educational policies or domain knowledge. Unlike the short-term courses, these mid-length courses are usually structured in such a way that will allow the participating in-service teachers to trial some of the ideas from the courses in their classrooms and to be able to share the outcomes of their enactment. These courses are usually conducted concurrently with the school academic term so that trial implementation is made possible. These mid-length in-service courses are more agentic for in-service teachers as there are opportunities for them to contribute to the knowledge pool of the course. As such, there are also opportunities for in-service teachers to form themselves into professional communities of practice (see Lave and Wenger 1998) through these courses.
3. On the other end of the spectrum are longer-term in-service courses leading to formal accreditation such as a master's or doctor of philosophy graduate degree. These long-term in-service teacher education courses are usually offered by colleges of education or tertiary education institutions with graduate schools. This form of in-service education functions to fulfil the needs of in-service teachers who like to specialize in a particular area of their practices. For instance, an

in-service teacher working with children requiring special needs may find it meaningful to pursue a master's degree program specializing in understanding and helping students with special needs. This form of in-depth study will likely increase the knowledge, practice, and professionalism of the teacher. These forms of in-service teacher education will usually require the in-service teachers to go back to school formally, and learning usually takes the form of lectures, laboratory exercises, group discussions, and readings. In many graduate programs, the in-service teacher participants are usually also required to be involved in some form of critical inquiry of their practices. Depending on the demands of legislation, societal needs, and changes in domain knowledge, the frequency and forms of in-service teacher education will vary from country to country and even within the same country.

Issues with In-Service Teacher Education

There are many issues which in-service teacher education researchers and policy makers are faced. Firstly, it is often difficult to track and measure the impact of various forms of in-service teacher education (Day 1997) and how they contribute to changing/improving the practices of teachers. The causal relationship between in-service teacher education and teacher change is difficult to establish, and hence, in-service teacher education providers find it difficult to evaluate the impact of the courses. Secondly, while in-service teacher education is important and is encouraged, taking teachers out of the classrooms results in the loss of curriculum contact time with students. This disrupts the routine and the learning of the students. As such, schools and the education system as a whole need to think of ways to provide in-service teachers with learning opportunities that result in minimum disruption to school life. In general, the in-service teacher education community needs to develop more robust means to evaluate and assess impact of in-service teacher education on both short-term as well as long-term programs and relate these to the improvements in teachers' practices and their contributions to improving educational outcomes. Systematic tracking of in-service teacher education (e.g., in the form of a personal portfolio) either for personal development or for career advancement will help.

Instructionally Sensitive Assessments (Close, Proximal, Distal Assessments)

Maria Araceli Ruiz-Primo
University of Colorado, Denver, CO, USA

Keywords

Curricular validity; Instructional alignment; Instructional validity; Opportunity to learn (OTL)

Instructional sensitivity refers to the validity of the inferences made about the ability of a test or test item to reflect or differentiate the instruction received by students, based on their performance on that test or test item. The focus of instructional sensitivity is the overlap between test and instruction. The scores produced by an instructionally sensitive test should distinguish accurately between students who have and have not been taught a given content or those who have and have not been effectively taught that content. Because of the importance of the validity of test interpretations, instructional sensitivity should be regarded as a psychometric property of the tests – as important as other psychometric properties (Polikoff 2010). Interpretations of the effectiveness of teachers' and schools' instructional practices are not valid if they are based on instructionally insensitive tests.

Two terms closely related to instructional sensitivity are instructional validity and curricular validity. Instructional validity was originally introduced by Feldhusen et al. (1976) to refer to two sources of data for evaluating the validity of test score interpretations: the specification of the knowledge or performance domain being tested and evidence that instruction on the specified domain was provided. They argued that the concept of content or curricular validity only considered the content of the test, but it did not provide information about whether and how that content was delivered to students. In 1979, McClure used the term instructional validity in the Debra P. vs. Turlington case. He defined it as "an actual measure of whether the schools are providing students with instruction on the knowledge and skills measured by the test" (p. 683, emphasis added). He defined curricular validity as "a measure of how well test items represent the objectives of the curriculum" (p. 682). It is important to note that McClure regarded curricular validity as "theoretical" and instructional validity as empirical since judgments on the latter need to be supported by evidence that the students were exposed to the knowledge and skills required to answer the test correctly. This distinction helps to appreciate that, even when a test appears to have an appropriate "fit" to a curriculum based on the content areas sampled, the fit does not ensure that students have actually been instructed on these content areas. That is, an assessment that has curricular validity may have different degrees of instructional validity across classrooms. The connection between instructional validity and instructional sensitivity is direct. Both terms focus on the need of evidence of the instruction received by students on the topics being tested. Curricular validity is part of instructional sensitivity. While instructional validity can be used interchangeable with instructional sensitivity, curricular validity cannot.

Two other terms usually linked to instructional sensitivity are instructional alignment and opportunity to learn. They are techniques to measure the characteristics of instruction to which students are exposed, and, therefore, they are not conceptually equivalent to instructional sensitivity. Instructional alignment refers to the match between the content of instruction and the content of an assessment based on teacher's reports about the content being taught and the cognitive demands with which the content was taught. Opportunity to learn (OTL) refers to whether or not students have had the opportunity to study a particular content. It is a concept introduced in the First International Mathematics Survey in the 1960s with the purpose of ensuring valid comparisons in international testing programs. While there are multiple measures of OTL, basically, they address whether certain content was covered and, in some instruments, what proportion of time is spent covering it.

An important source of deviations in defining instructional sensitivity lies on the conceptualization of the instruction students received – "what" aspect of the instruction researchers paid attention to. Two aspects of instruction have been the focus of the research on instructional sensitivity: the content being taught and the quality with which the content is taught. This difference is relevant when it comes to the methods used to gather information about the instruction that students receive.

Examining Instructional Sensitivity of Tests

There are three major categories of methods for examining instructional sensitivity (Polikoff 2010): statistical, instruction-based, and judgmental. Statistical methods focus on item statistics based on students' responses to items. One especially important item statistic is the pretest-posttest difference index (PPDI) proposed in the 1960s. PPDI is the proportion of students (p value) passing the item on the posttest minus the proportion of students passing the item in the pretest. The difference in pre-instruction and post-instruction scores is considered as an indicator of instructional effectiveness. PPDI is considered to be a robust indicator because it allows detection of the effects of instruction (on different tests and with different samples of students), it is easy to implement and understand (as gain scores), and its use in item selection for tests leads to a better ability to distinguish between students who have and have not received instruction (Polikoff 2010). Other item statistics involve the use of item response theory (IRT). One of them is ZDIFF, the normalized difference between IRT-based item difficulty estimates on the pretest and the posttest or from two different samples of students (see Polikoff 2010).

Instruction-based methods focus on two sources of information, students' responses to items, and some type of measure of the instruction students received. The study of the content and/or the quality with which it is delivered has used a wide variety of approaches. These approaches include multiple measures of instruction (e.g., teachers' reports about content covered or content taught/not taught, quality of instruction measured by direct observation or teacher surveys, or analysis of curriculum materials), multiple research designs (e.g., comparing expert teachers vs. less expert teachers), and multiple analytic methods for examining the link between instruction and performance (e.g., simple comparisons of means, regression, IRT, hierarchical linear modeling – HLM). Studies using instruction-based methods have produced conflicting results about instructional sensitivity (Polikoff 2010).

Judgmental methods use experts' judgments about tests and test items. Judgments can target (1) the alignment or congruence of the test items with learning goals, targets, or objectives (henceforth learning goals) using a simple rating of yes/no/unsure; (2) the appropriateness or suitability of test items to measuring certain learning goals using a rating scale; (3) the correspondence of items to learning goals; (4) the curricular learning goals test items appear to assess; and (5) the clarity with which the curricular learning goals tapped by a test help teachers to understand what is being assessed. Unfortunately, little to none empirical support exists about the effectiveness of examining instructional sensitivity by focusing on any of these targets.

Developing Instructionally Sensitive Tests

All the methods and approaches mentioned above focus on examining the instructional sensitivity of extant tests, not the development or instructionally sensitive tests. Recently, an approach for developing instructionally sensitive tests has been proposed (Ruiz-Primo and Li 2008). The approach generated by DEISA (Developing and Evaluating Instructionally Sensitive Assessments) project builds on the notion of variations in the proximity of assessments to the enacted curriculum (i.e., close, proximal, and distal; see Ruiz-Primo et al. 2002). At a close level, assessments are curriculum sensitive; they are close to the content and activities of the curriculum. At a proximal level, assessments consider the knowledge and skills relevant to the curriculum, but their contexts (e.g., scenarios) differ from the one studied in the unit. At a distal level, assessments are based on state or national standards for a particular domain. Close assessments are assumed to be more sensitive than proximal or distal assessments to the impact of instruction. Proximal assessments are assumed to pose greater demands on students than close assessments; to achieve in these assessments, students need to transfer what they have learned to new contexts – which is likely to happen only if they have received high-quality instruction. Distal assessments tapped learning goals most likely differ from the goals of the curriculum students learned. Large-scale assessments are distal; they are assumed to be less sensitive to the instruction received by students.

The DEISA approach proposes the idea of "bundles of triads" to develop test items. Each triad has one close item and two types of proximal items, one near proximal and one far proximal. (Since distal items are selected from state, national, and international large-scale tests, they have not been the focus of the project, which focuses on test development.) A triad is used to (1) establish, based on information on student performance on the close item, whether the learning of the concept, principle, or explanation model took place after instruction and (2) to manipulate different contexts with the two types of proximal items in a way that some evidence can be obtained on how able students are to transfer their learning as a result of the instruction. Regarding the items' questions, items with different distances to the enacted curriculum are produced through variations on the question they pose, their cognitive demands, and their contexts. Near proximal and far proximal item questions may be less familiar to students, compared to the questions studied in the curriculum, yet they tap the same content or inquiry process. Regarding the items' cognitive demands, near proximal and far proximal items are designed to require students to go beyond what was studied in the curriculum, for example, by requiring students to use a pattern of reasoning that differs from that used in the curriculum activities (e.g., if a science curriculum examines causes of erosion, near proximal and far proximal items may ask about factors that can contribute to reducing erosion). Regarding the items' contexts, near proximal and far proximal items have different scenarios from those used in the curriculum. For example, aspects of the scenarios that are changed may involve organisms, variables, and levels or values of variables.

The DEISA approach has been empirically evaluated through four iterations with different science curricula. Available evidence indicates that the DEISA approach can be used to obtain information relevant to developing items that can be sensitive to the quality of instruction students received.

Information about the content and the quality of instruction to deliver the content was collected through videotapes, interviews, questionnaires, and focus groups. Information based on the PPDI and group comparisons indicates that the approach enables developers to construct items that vary in instructional sensitivity. Remarkably, on average, the effect sizes of the difference between pretest and posttest scores across the tested science modules are consistent with the distance of the items: ES close items = 0.95, ES near proximal items = 0.71, ES far proximal items = 0.30, and ES distal items = 0.41. Results about the pattern linking quality of instructional and students' performance are mixed; different measures of quality of instruction had led to different patterns. These results are consistent with findings from other studies using measures of quality of instruction (see Polikoff 2010).

Importance of Instructional Sensitivity

Accountability tests are largely instructionally insensitive mainly because, due to the sampling procedures used for large-scale testing, very little of what is taught is tested. As a consequence, test results reflect socioeconomic status, general ability, or maturation rather than effective instruction. As Popham and Ryan (2012) suggested, "Clearly, if the tests being employed in these evaluations [to evaluate success of schools] are not up to the job, then many of the resultant evaluative decisions about the effectiveness of schools and teachers will be mistaken. Mistaken decisions about the caliber of schools or teachers, of course, will have both short-term and long-term harmful effects on the quality of education we supply to our students" (p. 1).

Test developers should provide empirical evidence about instructional sensitivity with the same care as it is done for other aspects of validity or of the tests (e.g., discrimination and difficulty). They should plan ahead of time for studies to gather the necessary information. If nothing else, at least statistical approaches to measuring instructional sensitivity should be used (e.g., PPDI and ZDIFF) to provide such evidence.

More research is needed to better determine the link between quality of instruction and student performance. For now, we do know that there is a wealth of evidence indicating that instructional sensitivity is an important characteristic of criterion-reference assessments that, if not met, can threaten the validity of decisions made based on tests.

Integrated Curricula

Grady Venville
Graduate School of Education, University of Western Australia, Crawley, WA, Australia

Keywords

Cross-disciplinary; Interdisciplinary; Thematic; Transdisciplinary

Definition

Most curriculum documents around the world are structured around subjects that are derived from disciplines. The subjects provide order and authenticity to the nature and scope of the knowledge to be taught and learned in schools. Curriculum integration is about teaching and learning processes that cross the traditional disciplinary or subject matter boundaries in some way. Integration can occur between broader subjects such as history and science, for example, students could learn about the history of the development of human understanding of gravity. Integration can also occur between closer disciplines within science, for example, students could learn about both mechanics and anatomy through investigations of bird flight. Some curriculum documents highlight the importance of integration, and others ignore it altogether. There are a number of alternative terms that are used to refer to integrated curricula, for example, cross-disciplinary, interdisciplinary, and transdisciplinary. All these terms refer to a curriculum that bridges the boundaries of the traditional subjects in some way. There are a number of educational programs and comparatively new subjects that are inherently integrated. For example, environmental science is a topic that bridges the boundaries of traditional subjects by including subject matter from chemistry, biology, and physics as well as other disciplines including economics and politics.

Approaches to Integrated Curricula

While curriculum documents and schools are most often structured around traditional discipline-based subjects, there are a number of examples of different approaches to curricula reported in the literature that can be considered integrated. An overview as well as an in-depth analysis of case studies of these approaches is presented in Rennie et al. (2012a). Examples of different approaches include a thematic approach, a community-based issue approach, and a problem-based approach. Each of these approaches has something other than the subjects that drives what is taught and learned.

A thematic approach to integrated curriculum is popular in elementary and middle schools. Teachers and/or students select a theme of interest or importance to them around which all teaching and learning activities are organized. Examples of themes might include dinosaurs, the Olympics, and junk food. Teachers plan a number of activities that utilize skills and/or knowledge from a number of subject areas that are linked to the theme in some way. A thematic approach to curriculum often finishes with a special event, like a fair or an open day, where parents and other students and teachers are invited to come and see or participate in the learning.

Another example of an approach to integrating the curriculum is to focus on a community-based issue, event, or locality such as the health and well-being of local indigenous people, the ecology of a local lake or mountain, or a local industry such as a mine site or fishing industry. Through this approach, discipline-based knowledge is used to understand and explore the problem as necessary. For example, considerable chemistry may be used to investigate the solutes in a local lake and the different types of pollution from a local mine site. From a social science perspective, the importance of a lake or a mine site to the people who actually live in the town or city may be investigated.

In high schools, problem-based approaches to curriculum are often used to focus on issues that are of particular relevance or interest to youth. For example, problems such as teen pregnancy, binge drinking, or natural disasters can be the driving force behind the curriculum, and the students themselves may make decisions about which aspect of the problem they will use to develop their knowledge and understanding. Students often plan and conduct investigations in an inquiry-based manner to answer their research problem and then communicate their findings to other members of the class.

The Paradox of Integrated Curricula

The term “curriculum integration” can be considered to be paradoxical when we think about knowledge in our everyday environments. Knowledge outside of schools and educational institutions is not divided up into disciplines or subjects; it is of course integrated. The paradox, therefore, is that when we refer to integrated curricula, we are talking about bringing together something (the subjects) that is in fact always together in the real world. Ever since educational institutions first began, however, knowledge has been divided into compartments so that it was easier to investigate, understand, and communicate from generation to generation. Through a long history, the disciplines have developed great bodies of knowledge, and it is within the disciplines that the most powerful and useful ideas have come to fruition. Each discipline has its own way of understanding knowledge, its own traditions, language, symbols, methods of inquiry, and methods of communication. These factors have enabled disciplines to become authoritative and enduring; however, they remain human constructs.

It is a consequence of the influence and validity of the knowledge available through the disciplines, that the associated subjects provide the structure for almost all curriculum documents worldwide. In almost all school curriculum documents, major subjects include English (or the relevant language), mathematics, history, science, and physical education. Within science, the subdisciplines (biology, chemistry, physics, and sometimes geology and astronomy) are almost always present.

The State of Knowledge in the Global World

The state of knowledge in this age of globalization has resulted in many people rethinking how our curriculum documents are structured and how we can better engage students in learning activities that require them to be able to think and work across disciplinary boundaries. The state of knowledge toward the end of the twentieth- and the beginning of the twenty-first centuries seems to have shifted to more complex, integrated, and holistic issues and problems facing our planet and humanity. These problems and issues are not confined within one discipline, and solutions require people from a number of disciplines to bring their knowledge and expertise to bear. Furthermore, understanding these problems requires knowledge from a number of disciplines. An example of one of the problems is climate change: a global issue that can be informed and understood from a number of disciplinary perspectives including physics, chemistry, biology, geology, history, economics, geography, politics, and so on. Human population growth is another global complexity that may be better understood and informed through multiple disciplinary perspectives. Cutting-edge research also often involves experts from a number of disciplines. For example, advances in forensic science have been driven by knowledge from anthropology, chemistry, computer imaging, geometry, geography, dietetics, and other subdisciplines. Another example is research into endangered species which often involves conservation biologists, geneticists, and ecologists looking at the biological aspects of a particular plant or animal but also mathematicians and computer programmers who can use the information to conduct important population modeling based on a range of variables. It is questionable whether compartmentalized curricula in schools enable young people to appreciate global complexities and cutting-edge research of this nature.

The Dilemma of Integrated Curricula

The current status quo in schools throughout the world is to compartmentalize the subject matter taught and learned into subjects based on disciplinary knowledge such as science, history, mathematics, and English. On one hand, this provides students a wealth of foundational knowledge in highly respected disciplines that are easily examined and are accompanied with high status. Passing discipline-based subjects like physics and chemistry provides students with the power to pass high-stakes entrance exams and gain entry into prestigious universities as well as providing career trajectories into highly remunerated occupations such as medicine, law, and engineering. On the other hand, restricting students' learning to within the disciplines can be considered to prevent their access to powerful ways of thinking that are not available from within one subject. For example, learning to think from different perspectives and in creative ways is said to be enhanced through an integrated curriculum. Learning important facts and information in chemistry about acid rain is one thing, but being able to apply that understanding to real-world contexts and create arguments and debate issues around acid rain extends that learning. Students also are better engaged by a curriculum that is more grounded in the everyday, integrated world and the problems and issues that are relevant to them. Integrated subjects, however, are difficult to define and difficult to assess in quantitative ways. The dilemma with regard to integrated curricula faced by teachers, parents, and students is that learning within the discipline-based subjects is likely to support and facilitate them making rapid progress through the educational pipeline; however, learning restricted to these same subjects is likely to confine their learning to narrowly defined skills and knowledge that is not very helpful or easily applied in the real world.

Student Learning Within Integrated Curricula

Student learning through integrated curricula is more difficult to measure than learning through discipline-based approaches to curriculum. One reason for this difficulty is that students often work independently or in small groups, and their work is idiosyncratic and not uniform across the whole class or the whole year cohort. It is, therefore, inappropriate to test specific types of knowledge when students are engaged in an integrated curriculum because different students often learn different things.

Integrated curricula are not common; therefore, the education community has not necessarily developed the types of tests and assessments that may give a clear indication of the learning that has occurred. For example, students experiencing an integrated curriculum may learn about ratios in mathematics and apply that knowledge to a genetics problem. The transfer process and application to a real-world problem may be something the student has learned; however, it is difficult to test their ability to transfer knowledge in an exam situation.

Another example of the type of learning that is more likely to occur through an integrated curriculum is that students learn to use different sources of information to help them solve problems, as is common in the real world. For example, students may be working on a project for which they need to know how to apply Ohm's law to get the maximum amount of power from that of a solar-powered boat. They may learn that asking their teacher, a knowledgeable friend, or parent for information, accessing information from the Internet or a textbook, and doing their own investigations and trials are all legitimate ways to help them understand these types of processes in the real world. But it is very difficult to test students' ability to use different sources of knowledge, or how they make judgments about the quality of knowledge from different sources in an exam context. Of course this type of assessment is not impossible; it's just much more difficult, less valid, and less reliable than current approaches to discipline-based examinations that educators have developed and trialed over many years.

Other learning that occurs in integrated curricula is said to be less about discipline-based knowledge and more about aesthetics, communication, and collaboration. For example, students may learn how to work with other people who bring different points of view and different knowledge to a problem. They need to be able to communicate with these people and to collaborate and negotiate in order to problem solve and move forward with whatever project it is that they are working on. These types of knowledge and skills are less tangible and less reliable for educators to measure, and this means that in competitive, exam-driven educational environments, integrated curricula often have less value and less status and are considered to inculcate *soft* concepts and *everyday* knowledge.

The perspective that integrated curricula do not contain *hard* or *valuable* knowledge misses entirely the point that through integrated curricula, it is possible for students to learn disciplinary-based knowledge, but in addition, they are more likely to learn the skills that will enable them to apply that knowledge in different contexts. They are more likely to learn to collaborate with people and utilize each other's skills and abilities; they are more likely to be able to think from different perspectives, to weigh up the pros and cons, and to make decisions; and they are more likely to be able to communicate their thoughts and findings to a range of audiences. These qualities may not help students to pass discipline-based exams, but they are much more likely to help young people to develop into better researchers, better employees, better thinkers and decision makers, better communicators, and ultimately better citizens.

The Challenges When Implementing Integrated Curricula

The biggest challenge to designing and implementing an integrated curriculum is that curriculum documents are usually written around the disciplines and are assessed through the disciplines. This means that the content that has to be taught and the various modes of teaching and assessing often are discipline specific. It is difficult for teachers to map the things that students learn through an integrated curriculum onto the discipline-based curriculum documents to ensure that all the contents, skills, and values that students are required to learn have been addressed.

Another challenge when implementing integrated curricula is that high school teachers usually have specializations in one discipline area. Even if they are a science specialist, their own education means they are likely to have strengths in subdisciplines such as chemistry, physics, biology, or geology. Teachers often are uncomfortable teaching outside their area of expertise, and research has shown that when they do, they tend to rely more on traditional, teacher-centered approaches commonly referred to as "chalk and talk."

An integrated curriculum often requires teachers to collaborate with teachers with expertise in another field. In high schools where there are subject-based departments, often in different buildings and on different timetables, collaboration can be very challenging. Extra money often is required to allow teachers the time they need to get together and plan, to change their programs and teaching activities, and also to incorporate field trips and guest speakers. Block time often is required in the school timetable to allow for the nonclassroom-based activities that are frequently part of an integrated curriculum.

Parents, principals, and community members are usually more familiar with the traditional subjects and understand and value them better than subjects that are more integrated. When teachers try to implement an integrated curriculum, it may not be well understood by major stakeholders, and it has been shown that they may disapprove or not look favorably on these subjects.

High-stakes exams require students to memorize a lot of information from a particular content domain, and this forces teaching into narrow aspects of the curriculum and into more teacher-focused approaches. This means that integrated approaches to curriculum are often ignored, particularly around exam time.

One of the major challenges for integrated approaches to curriculum is that due to their very nature, they challenge the status quo of discipline-based approaches to education and the power and status that accompanies discipline-based subjects. Everything to do with education revolves around the subjects. There are subject-based professional learning programs, the architecture of schools is planned and built to accommodate the subjects, teachers are qualified to teach subjects, and school departments are based on subjects. These are powerful mitigating factors that work against the implementation of integrated curricula.

Within schools, the status of discipline-based knowledge is defended and lauded by those who belong to the discipline-based community. Integrated curricula can be seen as a threat to the high status of subjects like science and the subdisciplines of physics, chemistry, biology, and mathematics, for example. Integrated approaches to curricula may be seen to break down the walls that delineate strongly defined areas of knowledge and to erode the identity and status of the people who belong to the discipline-based communities of teachers.

Facilitating Integrated Curricula

One way to conceptualize curricula for the future that addresses many of the concerns raised above is to view approaches to curriculum from a Worldly Perspective (Rennie et al. 2012b). A Worldly Perspective reflects a holistic view of knowledge, grounded in students' experiences, relationships, and contexts. Disciplinary knowledge is an important component of this holistic view, and from a Worldly Perspective, the integrated and disciplinary paradigms should be considered together, overlapping rather than mutually exclusive. A Worldly Perspective encourages educators to balance a discipline-based and an integrated view of knowledge in curriculum. It also encourages connection between local and global themes and issues in curriculum. This balance between integrated and disciplinary approaches to curriculum and connection between local and global themes and issues challenges more traditional ways of making judgments about knowledge and approaches to curriculum. From a Worldly Perspective, the better a curriculum demonstrates these aspects of balance and connection, the more powerful the curriculum, and the more intellectual power it provides to those who have access to it (Rennie et al. 2012b).

While the Worldly Perspective is a powerful way to reimagine curriculum, a number of practical steps also need to be implemented at the school and classroom level to support a curriculum that is consistent with the Worldly Perspective. These practical steps can be put under four broad categories including shared purpose, collegial relations, norms of improvement, and structure. Implementing and sustaining an integrated approach to the school curriculum requires changing the context of schooling and addressing factors in each of these four broad categories. This requires including an integrated curriculum in the shared ideas about the purposeful educational direction of the school and documenting these shared ideas within the school mission and vision statement and other relevant documents and garnering administrative and community support for that direction. Collegial relations between teachers need to be addressed so that mutual sharing, assistance, and joint effort are valued and honored and become part of the normal practice in the school. This may involve the establishment of stable teams or small groups of teachers who work together in a cross-disciplinary way on aspects of the curriculum. Changes need to be made to the way teachers seek to improve their practice, that is, they may have to focus less on feedback from state or national testing results and focus more on outcomes displayed by their students in the classroom context. Teachers need to understand the holistic direction the school is taking, their role within that direction, and they should focus on improving their practice to serve the school vision. Finally, structures within the school need to be changed so that they support the other three conditions. This may involve changing the timetable to give more flexibility, providing time for teachers to work together as teams, rearranging the seating and other work arrangements for teachers and students to better facilitate communication, revisiting assessment and rewards processes, or rebuilding or refurbishing parts of the school or classroom to reconnect with the outside environment and the local community.

Keywords

Thematic; Transdisciplinary

The term “integrated science” is often used as a synonym for interdisciplinary and unified science, which may be applied generally to any curriculum effort in which two or more previously separated science subjects are combined (Showalter 1975). The effort, according to Brown (1977), may be characterized as a collaboration among, a blending with, or a fusion of a number of “subjects” traditionally taught separately. Thus, the meaning of integration in various types of integrated science is different. An integrated science course may be characterized by a focus on processes of scientific inquiry, or a wish to cater for the interests of pupils, or it may be a course structured around topics, themes, or problems that require a multidisciplinary approach. Brown (1977) identified four groups of meanings of integration in science: (1) as the unity of all knowledge, (2) as the conceptual unity of the sciences, (3) as a unified process of scientific enquiry, and (4) as interdisciplinary study. Examples of each of these meanings can be found in the history of the development of integrated science curricula. *The Conceptually Oriented Program in Elementary Science (COPES)* in the United States, for example, has four conceptual schemes: the structural unity of the universe, interaction and change, degradation of energy, and the statistical view of nature. *Science – A Process Approach*, also from the United States, uses scientific processes as the basis of integration. Integrated science curricula with an interdisciplinary approach often emphasize the interaction between science and society (e.g., *Science and Technology in Society* (SATIS) in the United Kingdom).

According to Blum (1991), there are two clusters of arguments that are used to advocate integrated science at the secondary school level. The first includes epistemological and methodological arguments while the other includes psychological, pedagogical, societal, and practical arguments. For a given integrated science curriculum, there may be a wide range of reasons why it has been chosen in preference to traditional separate science curricula. Brown (1977) also developed a classification system of arguments for integrated science, which comprises six factors: (1) outcomes demanded by society (e.g., provision of scientists, informed lay population, informed political leadership), (2) resource constraints (e.g., accommodation, equipment, time, teachers), (3) political constraints (e.g., common-core course for all pupils, national assessment system), (4) conditions for effective learning (e.g., pupil security, motivation, interest), (5) conditions for effective teaching (e.g., teachers' interests, competence), and (6) constraints imposed by the subject (e.g., unified nature of scientific enquiry). These various arguments are associated with a range of influences and choices which operate at either macro or micro levels in society or both. This classification system can be used to analyze the arguments used for any given integrated science curriculum.

Two dimensions of integration were also put forward by Blum (1991). One is "scope," which refers to the range of disciplines and fields of study from which content has been used in an integrated science curriculum; the other is "intensity," the degree to which the subject matter has actually been integrated. Six categories of "scope" were suggested by Blum (1991): (1) within one of the classical natural sciences (e.g., botany and zoology in biology), (2) between two close natural sciences (e.g., chemistry and physics as physical science), (3) between the natural sciences (and perhaps also mathematics), (4) between basic and applied sciences and technology, (5) between natural and social science, and (6) between science and humanities or arts. Blum suggests that, along with the dimension of "intensity," integration can proceed from "coordination" (independent subject programs taught simultaneously), through "combination" (with major units organized round headings taken from the different disciplines), to "amalgamation" (a particular "issue" forming the unifying principle).

The integrated science curriculum developed in China from the 1980s to the beginning of the new millennium can be used to illustrate the concepts of "scope" and "intensity" (Wei 2009). Aiming to integrate biology, chemistry, and physics in the junior secondary school, this curriculum belongs to the third category of "scope," i.e., "between the natural sciences." The "intensity" of this curriculum was different at its two stages of development. At the first stage, at the provincial level in the 1980s/1990s, the aim was "integration within science subjects." At the second stage, at the national level at the beginning of the new millennium, "integration beyond science subjects" became the aim, and themes that cut across subjects, such as scientific inquiry and nature of science, were used to integrate the curriculum content (Wei 2009).

Interactive Exhibits

Sue Allen
Allen and Associates, Newcastle, ME, USA

Definition and Background

There is general agreement among museum professionals and scholars that the key feature of an interactive exhibit (or “interactive” for short) is reciprocity: as a visitor uses the exhibit, it responds in some way. This distinguishes it from more traditional exhibits that may be read or observed but do not change physically in response to visitors’ actions. The simplest interactives respond in only very limited ways, such as revealing more information to visitors when a flap is lifted or initiating a mechanical process when a button is pushed. More typically, however, interactive exhibits include mechanical, optical, magnetic, or electrical components that can be moved, connected, and adjusted in a broad variety of ways. Interactives often include some kind of interpretive labels that guide visitors and orient them to the goals of the exhibit; these typically include instructions or challenges, questions or hints, explanations, and a connection to daily life. While interactives are often referred to as “hands-on” exhibits by the public, that phrase is something of a misnomer, since even a static exhibit may be available for touching, while an interactive exhibit is truly responsive to visitors’ actions.

Interactive exhibits are not new – visitor-activated models date back at least to 1889 in Germany – but they became widespread in the 1970s and 1980s with the growth of children’s museums and science centers in countries such as Canada and the USA. Since then, they have become common in all kinds of museums and both indoor and outdoor public spaces around the world. With the advent of computer technologies, interactive exhibits have become even more open-ended and adaptable.

Contributions to Science Learning

Various theoretical frameworks have been used to classify and assess the kinds of learning that interactive exhibits seem to support. Among the more common are constructivist theories that characterize cognitive learning, sociocultural theories that emphasize visitors’ participation with others using language and tools, and various psychological theories that focus on affective and motivational dimensions of learning.

In terms of cognition, interactives have shown evidence of contributing to visitors’ understanding of scientific content: particular scientific concepts (such as gravitational force), principles (such as conservation of angular momentum when a spinning person changes her rotational inertia by pulling her arms closer to her body), observable features (such as the structures of genetically modified worms), or the behavior of a system of components (such as the way artificial muscles move the legs of a robot). The way a visitor uses the exhibit can also make a difference: for example, there is evidence that children who play with an interactive exhibit in an investigatory way show greater learning of scientific content goals than those who engage in fantasy play at the exhibit.

Interactives have been shown to elicit a range of scientific and engineering practices, as visitors spontaneously engage in exploring, questioning, investigating, designing, and building. However, such practices are not equally supported: the most frequently observed learning behaviors by visitors are usually action-oriented (such as manipulating the exhibit and seeing what happens), while more reflective behaviors such as generalization, argumentation, and conclusion are considerably rarer.

Research has also shown the importance of human facilitation in aiding learning at interactives. Typically parents will support children, focusing their attention, explaining how the exhibits work (especially often to boy children), and drawing connections to similar real-world experiences as well as formal science ideas. Parents of young children tend to either sit back or take over, so exhibit labels can help by suggesting ways they can contribute and support their children.

Finally, it is well established that interactive exhibits are extremely attractive to museum visitors and tend to sustain their engagement for a longer time than non-interactives. Even in institutions with live animals, visitors often seek and talk about their interactions with the animals; this is a likely contributor to the popularity of touch tanks in aquariums.

Design Challenges

Apart from considerations of greater cost, ongoing maintenance, and safety concerns, interactives are among the most challenging learning materials to design successfully, because they need to work without the presence of a "teacher" who can guide activity and circumvent problems if visitors become lost, confused, or stuck. Typical design tensions include:

- Degree of complexity: Interactives that support deep and extended exploration are often complex or have multiple components, but such complexity may easily confuse visitors when they first use the exhibit.
- Source of authority: The more open-ended an interactive exhibit, the more authority visitors have in creating and interpreting their own experiences. On the other hand, a more limited set of configurations allows the museum to anticipate visitors' actions and create a label that includes canonical science content voiced with institutional authority.
- Target audience: While exhibit designers may have a particular audience in mind, interactives are likely to be used by museum visitors of literally all ages, abilities, and backgrounds. Designing for a particular age or ability level may easily create unintentional barriers to other types of visitors.

Sometimes these challenges have been resolved by creating a hierarchy of salience so that simple actions are obvious at first and others discovered later. Another successful approach has been to segment the functionality of the exhibit into similar stations so that a social group of visitors can each do personal investigations but still be watching and learning from each other (Fig. 1).

What Makes Effective Interactive Exhibits?

Various researchers have created lists of features that support learning at exhibits more generally. For interactives more specifically, some of the key design recommendations (summarized by Gammon, below) include: clear feedback from the exhibit in response to visitors' actions, few control mechanisms and no requirement of a particular sequence for these, control mechanisms that match visitors' expectations (e.g., dials should work either clockwise or anticlockwise), and use of clear and concise labels near visitors' point of attention as they use the exhibit.

Interactive Exhibits, Fig. 1 Multiple stations allow visitors to easily make drawings in the sand on individual spinning disks while also supporting and learning from each other (Photo courtesy of the Exploratorium)

For interactives to deeply engage visitors in lengthy and self-directed inquiry, such as that aligned with Dewey's vision of education in schools, the most successful designs seem to be quite open-ended, with some combination of compelling phenomena, intriguing challenges, and aesthetically beautiful changes or small components that support combination and construction.

Social engagement has been extensively studied as a pivotal means to science learning and an end in itself. With interactive exhibits, just talking with other visitors increases the amount of exploratory behavior and hence greater understanding of the exhibit. When available, skilled facilitation by a docent or other staff member can further extend and deepen learning. For example, with a little coaching in how to generate productive questions and verbalize interpretations of the results, a staff member can coach both family and field trip groups to engage in longer, more collaborative, and more coherent investigations. Staff can also use their conversations with visitors to change the quality of the talk, such as increasing the amount of ecological discussion within a group exploring at a touch tank.

Despite general guidelines such as these, interactives are so diverse in their goals, designs, audiences, and configurations that it is critically important for designers to pilot test them with users during development.

Current Trends

Interactive exhibits are still at the frontier of changing exhibit designs. Among the trends over the last decade are the following:

- greater support for simultaneous use by social groups of visitors (such as large exhibits with several sides and components) rather than a solo individual;
- increasing use in supporting visitors to share their views on an issue (such as projection tables that present an issue and invite visitors to vote);
- more supports for reflection (such as an embedded video camera that asks visitors to create an illustrated story of their experience using the exhibit);
- blurring of boundaries with other types of experiences and media. Examples include

Interactive Exhibits, Fig. 2 Visitors create an immersive geometrical structure (Photo courtesy of the Exploratorium)

Interactive Exhibits, Fig. 3 "Bug Rug" at California Academy of Sciences, where visitors interact with a simulated jungle floor (Photo courtesy of Snibbe Interactive)

including large-scale immersives with embedded interactive components (such as a climbable structure made of movable geometric pieces), interactives created in virtual reality (such as a musical staircase made entirely in Second Life), dioramas with interactive components (such as an animal diorama incorporating touchable fur or the noise-making structure of a rattlesnake), aquariums with touch tanks (supporting handling of live animals in carefully structured ways), or augmented reality focused on social interaction (such as a floor projection of an animated ecosystem that changes in response to visitors' movements) (Figs. 2 and 3).

Interactives are rich drivers of creative learning assessment methods as well, supporting rich data streams of video and audio recordings, interviews, and observations at many scales of space and time. This is probably because their open-endedness and support for group learning mimic the complexity of real-life settings, their use by diverse publics demands excellent interface design, and their hybridization with other forms of multimedia requires the development of multimedia embedded assessment tools.

Interactive Science Centers

Mike M. Gore
Australian National Centre for the Public
Awareness of Science – A Centre for the
Australian National Commission for UNESCO,
The Australian National University, ANU
College of Mathematical and Physical Sciences,
ACT Canberra, Australia

The concept of interactive science centers emerged during the 1960s in Europe and North America; many consider that the Exploratorium in San Francisco marked the beginning of this development. Since this time, they have proliferated worldwide and have been recognized as an important source of informal learning. Interactive science centers have several fundamental differences from museums. Museums are concerned with scholarly research and the management and protection of artifacts. Interactive science centers, on the other hand, have always been about experimentation. Unlike conventional museums, they actively encourage their visitors to handle the exhibits. Interactive science centers contain purpose built exhibits, not objects. These custom built exhibits are crafted in such a way as to provide the visitor with a kinesthetic task that concerns and illustrates a scientific principle. The task may involve handling, looking, hearing, or even smelling. Interactive exhibits are frequently very simple, and this is extremely important, as it cannot be assumed that all visitors will be appropriately and equally skilled at manipulating the exhibit and understanding the implications of such manipulation.

The value of interactivity has emerged from research during the 1980s and 1990s in the areas of both formal and informal science learning. In the world of formal education, the growing constructivist movement placed a high value on experiential learning. The belief that science knowledge is constructed through personal experimentation is at the core of constructivist philosophy.

At the same time, however, increasing attention was being paid to the “problem” of the understanding of science by a broader public. Through large-scale surveys, such as those claiming to measure scientific literacy, the public came to be regarded as lacking in their understanding of science. This so-called deficit model (described by Brian Wynne 1991) was important in the late 1980s, because it was believed that enhanced general science literacy would result in greater economic prosperity, greater appreciation of scientific research, and greater participation in democratic decision-making (discussed in Stocklmayer et al. 2001). Thus efforts to bring science to the public through interactive experiences were a natural and timely development. In more recent times, this deficit model has been deeply criticized and subsequently discarded, but its legacy of science centers remains, with modified goals for exhibit interaction which are more about experience and attitudes than "education" (Stocklmayer and Gilbert 2002).

Another important difference between a museum and a science center is that the latter almost always has explainers or "docents." These people play two main roles. They talk with visitors about the activities, explaining the science and encouraging them to reflect on the experience. Explainers put a human face on the science on display. Second, their presence tends to reduce maintenance costs as they keep a watching brief on visitor behavior. In many cases the explainers are drawn from enthusiastic retirees or students.

Because of the limitations of both funds and labor, interactive exhibits tend to be simple. Simple exhibits are cheap to construct and cheap to maintain. The costs of construction and maintenance have resulted in few science centers featuring interactive exhibits in the areas of chemistry and biology, not only because they are expensive to maintain but because of safety issues. Partly because of these constraints, science centers have generally concentrated on ideas taken from physics. Physics provides an almost limitless source of ideas from which to make cheap, simple, and durable interactive exhibits. Translation of these design principles into other disciplines is a contemporary challenge for science centers.

Interactive science centers began to emerge on the world scene in the 1980s, in a very small way. By the first decade of the twenty-first century, however, there were 2,400 centers in seven world regions, visited by almost 300 million people every year. Across the world, science centers have come to share the same status as museums and art galleries, and many are afforded national status. They complement and add to the formal science education experience, usually working closely with the formal sector. The mission of most, however, is not to "educate" in the formal sense. It is to inspire, interest, challenge, and delight visitors and thus affect their appreciation and knowledge of science.

At the Science Centre World Congress held in Cape Town, South Africa, these institutions resolved to:

Encourage the establishment of science centers and museums in parts of the world where they are lacking.

Support a policy of investment in science, technology, and innovation in response to global economic and financial challenges.

Partner with formal education, arts, business, policy makers, and media where relevant.

Strive to address cross-generational science and technology-related problems that are relevant to local, regional, and global communities and to develop programs that allow the general public to contribute actively to the resolution of these problems.

Continue to develop programs that promote awareness of the multicultural roots of science and the value of indigenous knowledge systems.

Continue to develop partnerships to promote science awareness and engagement across cultural, political, economic, and geographical boundaries.

Conduct further research that measures the efficiency and effectiveness of their programs and to act on this information in order to improve their efficiency and impact.

Further promote dialogue between scientists and the general public so that public opinions on science and technology can be heard and incorporated into decision-making processes.

Further promote creativity, invention, and innovation that lead to more sustainable life styles.

Work together to ensure that they share their joint experience and knowledge of the most effective methods of engaging with science and technology with other local, regional, national, and international bodies that promote science and technology awareness.

Interactive White Boards

Sara Hennessy
Faculty of Education, University of Cambridge,
Cambridge, UK

Main Text

The interactive whiteboard (IWB) is an increasingly popular educational technology and can be found in approximately one eighth of all K-12 classrooms worldwide (34 million teaching spaces). IWBs are found in 85 % of UK classrooms, and their prevalence is rapidly increasing in many other countries. IWB technology combines a large, touch-sensitive electronic board with a data projector, specialized software, and a computer (which drives the projector and runs the software). The projected computer image is visible to a class and allows direct input via finger or stylus. Thus objects and texts can be easily moved or transformed by teachers or students, allowing experimentation, revision, and feedback on student work and a wealth of interesting interactions amongst teachers and students. All drawings, screen captures, or other objects can be stored and retrieved in future lessons, allowing for a continuous thread of interactions across many class sessions or even school years. For example, one teacher progressively built up – over six lessons – a representation of the photosynthesis cycle using images of its components, revisiting earlier elements in each subsequent revision (see http://t-media.educ.cam.ac.uk). Comparing artifacts such as concept maps produced at the beginning and end of such a lesson sequence allows a powerful means of illustrating to learners how their thinking has progressed.

The IWB acts as a focal point in many classrooms for interaction with a wide range of digital media resources. These include texts, photographs, multimedia presentations, animations, simulations and models, interactive diagrams, databases, graphs, tables, web pages, audio and video files, etc. Tools provided as part of the IWB software package include those for annotating text, highlighting, drawing, hide and reveal, resizing and zooming, and saving (storing and retrieving) IWB contents. These functions can help to draw attention to salient features of a representation or process. A key strategy is for teachers or students to publicly interpret a display. For example, one teacher introduced the process of gaseous exchange at the alveoli (the primary gas exchange unit of the lungs) by annotating a diagram, animating it, and then describing it to help pupils develop a powerful mental image of a dynamic process. The IWB can be effectively combined with other peripherals such as a document camera (also known as a "visualizer"), where objects placed beneath the camera stand appear on the screen, or even a standard digital camera. Such peripheral cameras can be used to display critique or compare pupils' work or experimental results or to project an image as a task stimulus. A teacher might compare different flowers, for instance, so that students can critique common or disparate features.

While teachers may emphasize "hands-on" use of the IWB by learners as being important for learning, cognitive engagement must also be prioritized. Hands-on use is motivating but can become mundane unless carefully orchestrated. Digital "artifacts" – objects or texts collaboratively produced and manipulated by teachers and learners – can play a pivotal role in supporting learning. For example, a collective representation of the knowledge that is developing in the class can be displayed on the IWB, serving as a rich resource for further teaching and learning. Interaction with digital artifacts can make new ideas available by making them accessible to collective scrutiny and iterative development. These artifacts can be simple constructions; research shows that advanced or "whizzy" uses of the IWB technology are unnecessary for learning.

The IWB is well suited to support interactive teaching (Thomas and Cutrim Schmid 2010), as contrasted with traditional "whole-class teaching" in science, where technology has tended to use computers for demonstration purposes. The IWB offers a fluid "shared communication space" where teacher and students can explore ideas together, pose questions, and reconcile scientific and informal ideas. Different ideas can more easily be juxtaposed, explored, connected, and compared, highlighting strengths and weaknesses. With proper levels of preparation, teachers can use the IWB to support reasoning activities such as visualizing or modeling a science problem or process, planning experiments or projects, and argumentation. The process of helping students respond to peers' ideas can be designed as part of the activity itself, for example, by helping students progressively build up a food chain, each student can add a link in turn and communicate their reasoning. Creating concrete representations of ideas and receiving feedback allow learners to engage in productive reflections concerning their own explanations and others' critical perspectives. In sum, the use of IWBs to develop and support student engagement with such external "knowledge objects" can serve to highlight differences between perspectives and deepen classroom dialogue.

Teachers require professional development in order to learn to use IWBs for such dynamic, collaborative approaches to science instruction. One research team at Cambridge University has developed a multimedia professional development resource to support classroom dialogue using the IWB (http://dialogueiwb.educ.cam.ac.uk) with accompanying book (Hennessy et al. 2014). Teachers learn to cultivate a comfortable and supportive atmosphere for dialogue. Adolescents, in particular, may be quite self-conscious and hence reluctant to come to the IWB.

The advent of remote input devices (tablets, wireless mice) reduces exposure and releases the teacher from the front of the room. This approach of integrating technologies, where students use handheld computers or remote pointers to interact with IWB content, can add new strategies to engage *everyone* in learning activities. For example, students could work on arranging their own paper mini-diagrams that replicate the IWB image (e.g., composing the photosynthesis equation or matching terms and definitions/functions), justifying their own arrangements to peers. One learner could then arrange the ideas on the IWB with others verifying the diagram. Prediction could engage a whole class, e.g., through working with peers to formulate a theory about how the structural features of alveoli facilitate gaseous exchange. The IWB can also act as a focal point for class discussion of displayed observation data, helping students in a variety of different constructivist learning processes for science: noticing and resolving divergence, considering additional avenues for reflection or observation, grouping ideas together to generate insights about a new topic, reflecting on data or hypotheses, brainstorming limitations to current approaches, or proposing new inquiries (Fong et al. 2012). Discussions carefully facilitated by the teacher are essential to support learning.

Finally, new IWB features, technologies, and forms of interaction are emerging. For example, horizontal multiuser "tabletop" boards can support collaborative learning within and between groups (Higgins et al. 2013). Teachers can centrally manage student tables and project them onto the vertical IWB. As ever, educators must harness new tools purposefully. Rather than just another form of "supplemental technology" that is ignored or used for conventional instruction, the IWB can be a transformative addition to the science classroom, if pedagogy is the driving force in its application.

Interests in Science

Debra Panizzon
Faculty of Education, Monash University,
Clayton, VIC, Australia

Keywords

Interdisciplinary; Student interest in science

How Is Interest Defined?

Generally speaking, interests are perceived as psychological traits that activate individuals to respond to external activities, events, or objects. It is interest that highlights an individual's personal orientation and responsiveness to a particular activity or experience. So how does this translate to student interest in science? According to the Organisation for Economic Co-operation and Development (OECD), the organization that designs and implements the Programme for International Student Assessment (PISA), the student who shows interest in science:

- Demonstrates curiosity in science and science-related issues or endeavors
- Pursues additional scientific knowledge and skills for intrinsic purposes using a range of methods and resources
- Seeks information about science-related careers

Why Is Student Interest Considered Important?

Over the last two decades, student interest in science has become a prime focus of attention as it is often used in educational policy to explain the consistent decline in student uptake of science-related subjects in many countries. Clearly, this trend is economically important for stakeholders given that declining enrolments in science subjects in secondary schooling have a flow-on effect to universities and ultimately the future workforce. Compounding the issue is an opposing trend in some developing countries like India, China, and Korea where students actively seek degrees in science, technology, engineering, and mathematics (STEM) as a means of ensuring a reputable career that provides economic security over the long term (OECD 2008). For many teachers, policy personnel, and educational stakeholders, there is a perception that it is a lack of student interest in science that is causing this decline in the uptake of science in many countries.

What Is Known?

Research does suggest that interest is a motivator for students to undertake deeper thinking and cognitive engagement in a task, activity, or experience. One of the largest international studies to explore student interest in science was the Relevance of Science Education (ROSE) project convened by Svein Sjøberg from Norway. Some of the key data from this study of 14- to 16-year-old students in over 30 countries indicated that students in western countries demonstrated greater interest in science topics that were rarely taught in school (e.g., existence of life outside of Earth), while students in developing countries preferred more traditional topics, such as chemicals, properties, and reactions. Complicating these differences further were significant gender variations that emerged in relation to specific science topics. For example, female students in most countries were interested in topics around health, medicine, the human body, beauty, and aesthetics (e.g., eating to keep healthy and fit), while male students preferred topics that were technical, electrical, mechanical, or volatile in nature (e.g., explosive chemicals) (Sjøberg and Schreiner 2010).

Similar results emerged from the PISA attitudinal survey conducted in 2006 with 68 % of students across 57 participating countries demonstrating greater interest in topics aligned with human biology and less interest for topics related to astronomy, chemistry, physics, and plants. However, what was different with PISA was that 87 % of students with minimal interest in school science topics recognized that science in general was important to society. This point suggests that students distinguish between their interests in school science and science as viewed in the media or in the world around them. As synthesized by Peter Fensham (2006), school science for many students is viewed merely as the transmission of knowledge and content from a textbook having little actual relevance to their everyday lives.

So, what can be gleaned from what is known currently? Clearly, there appear to be some topics in science that generate greater student interest than others, although this does vary between students from western (OECD) and developing countries. Furthermore, there does appear to be a gender preference around these topics, which is more pronounced in some countries. But these variations in student interest are not a recent phenomenon with much of the earlier research in science education identifying similar variations and fluctuations (Ainley et al. 1994; Fraser 1978). The bottom line is that there does not appear to be any substantive difference in the levels of student interest now and 30 years ago.

There is little doubt that interest is a motivator. However, to date there is no causal link evident in the research between students' interests in science (school or science generally) and the likelihood they will continue in science-related pathways, even though there is a perception prevalent in broader society that such causality exists. Research around students' choices in science highlights many confounding factors that influence subject selections at the secondary and tertiary levels of education with interest being only one contributory factor to the decision to engage or not with science.

Internet Resources: Designing and Critiquing Materials for Scientific Inquiry

Ghislaine Gueudet
CREAD, ESPE Bretagne, University of Brest,
Rennes, France

Keywords

Collaborative work; Evaluation of resources; Internet; Quality of online resources; Science inquiry

Introduction

In twenty-first century science classrooms, teachers and students are frequently engaged with Internet resources: lesson plans, digital textbooks, various kinds of software, videos, and much more. There is, in particular, a profusion of online resources for the teaching and learning of science. This raises important questions about the design of online resources that are effective and engaging, and how educators can evaluate the quality of items they find. This entry discusses criteria for evaluating such resources in terms of their relevance for science inquiry learning. It presents a set of criteria for evaluating resources, with a focus on the nature of the inquiry tasks that those resources can support and their link to authentic science practices.

Evaluating the Quality of Online Resources for K-12 Science Inquiry

Assessing the quality of online resources for inquiry science learning is a complex matter, which has been studied by science and mathematics education researchers (Linn et al. 2003; Kim et al. 2007; Gueudet et al. 2010; Trouche et al. 2013). The assessment must take into account the ease of use of the resource, and the scientific accuracy of its content, but also its didactic or pedagogical relevance. This paper emphasizes the evaluation of the adequacy of the resource with regard to inquiry-based teaching and learning, as defined by science education research.

A review of the science education research literature reveals the following dimensions for the assessment of the quality of online resources:

- *Appropriate tasks for students*: offering students appropriate environments and tasks to get them engaged in scientific inquiry, addressing students with well-defined tasks to motivate, construct, and refine knowledge.
- *Appropriate language*: the language used in the online resource should be adapted to students' knowledge, and scientific language should be introduced carefully.
- *"Hands-on" elements*: "hands-on" activities are central in an inquiry process and can be proposed virtually.
- *Link to authentic scientific practices*: a goal of inquiry-based science teaching is to provide students with authentic learning activities through problem-based situations.
- *Integration of digital media*: online resources offer the possibility of integrating several technological tools such as simulations tools, modeling tools, videos, etc. Many research works underline the importance of presenting knowledge through a large variety of representations to foster students' learning during their inquiry process.
- *Scaffolding for students*: inquiry-based tasks can be difficult for students, because of the autonomy they require. It is well known that for a teacher, helping the students and preserving at the same time the inquiry is complex. The same holds for an online resource, playing here a part of the role of the teacher.
- *Scaffolding for teachers*: many studies emphasize teachers' lacks of technological, scientific, and didactical knowledge concerning

inquiry-based science teaching. Online resources can offer scaffolds on such issues.

- *Collaborative work for students and teachers*: from a student's point of view, studies outline the need for activities that engage students in pairs or groups to conduct argumentation and construct explanations in science inquiry. From a teacher's point of view, studies underline the importance of giving teachers time for collective activities in order to enhance evolution of their practices and their professional development.

Taking into account these dimensions, the design of an online resource, or the assessment of its quality, will require somewhat different guidelines, according to the context of learning (domain, type of user, etc.). The next section presents several comment aspects that characterize the quality of resources: scientific content, scaffolding offered, and possibilities of collective work.

Scientific Aspects

In addition to matching the desired science content goals, Internet resources should include the following features that are related to scientific content:

- *Clarity of objectives and appropriate tasks*: in order to support students' scientific inquiry, activities and materials must present comprehensible and challenging problems or questions.
- *Rich scientific content*: an online resource can present scientific content in diverse ways: written texts, graphs, diagrams, images, animations, hypertexts, or any combination of those media. It can present recent results of science research, adapted to students' level, or more summary forms of information. In general, a variety of representations of scientific concepts is supportive of science inquiry.
- *Articulation of empirical evidence and concepts*: in order to foster science inquiry, learning materials must enable students to fully experience science concepts within physical and virtual learning environments and to make connections between their understandings and a variety of conceptual models. Activities include critiquing evidence and arguments or comparing solutions.
- *"Hands-on" activities, including virtual manipulations*: many inquiry-based activities allow students to investigate questions using empirical data through direct or virtual experiments and manipulations. Online resources can support data collection, data analysis, dynamic modeling, or experimentation with simulations of scientific phenomena.
- *Introduction to scientific language*: introducing science concepts using a vernacular language before using scientific terms can improve students' science learning and understanding as well as their use of scientific language (Brown and Ryoo 2008).
- *Epistemic value*: the resources must propose situations likely to support the introduction of new scientific concepts.

Scaffolding Aspects

There are important aspects of Internet materials for K-12 science inquiry that are concerned with "scaffolding" student and teachers. Scaffolding is defined as a form of support that allows a user to achieve certain activities or applications that might otherwise be out of reach (Quintana et al. 2004).

Many ICT resources include scaffolding for student learning as a matter of design. The following aspects of scaffolding should be considered in evaluating such resources:

- *Conceptual scaffolds*: the resource should provide different representations (formulas, figures, animated pictures) that support "sensemaking" and conceptualization.
- *Strategic scaffolds*: in order to manage their scientific inquiry, students need to understand the ways scientists approach and solve problems in their disciplinary fields. Strategic scaffolds help them determine how and when the resource could be used for inquiry.

- *Procedural scaffolds*: the resource must provide structure and support for complex tasks and functionality, embedding guidance to allow students to succeed with minimal errors.
- *Metacognitive scaffolds*: students may benefit from support to engage in reflection and assessment of their investigations, allowing them to monitor their own progress and develop an accurate sense of self-efficacy.
- *Argumentation scaffolds*: argumentation scaffolds help students justify and evaluate their ideas, potentially for purposes of discussion or debate with peers. Activities that engage students in "talking science" (Lemke 1990) are an important part of IBST.

The criteria mentioned above are also relevant for teachers, who can take cues from the student scaffolds. In addition, the following aspects are directly relevant to supporting teachers as they develop lesson plans or enact them in classrooms:

- *Analysis of inquiry*: an important aspect of support for teachers is concerned with a thoughtful analysis of the materials (with a specific focus on the precise knowledge at stakes), conducted by their designers, concerning how students may understand, misunderstand, or make effective use of the materials. Such analysis could be provided as a supplement (i.e., "for teachers only") to the materials.
- *Discussions of K-12 applications for learning and assessment*: a resource can include some discussion for teachers about how students may work with the resource during the different parts of the lesson (individual work, group work, precise role for each student), time management, and expected output from students (on the computer and on paper). Easy access to student work is essential for the teacher, as well as a discussion of assessment norms and practices.
- *Lesson plans and starter activities*: the way that teachers introduce a resource or activity to students can have a serious impact on its likelihood of success or efficacy. Ideally, resources should contain some discussion about how they should be introduced, in terms of strategies for engaging students in the task, problems or misconceptions that may be encountered, and so on.

Scaffolds for teachers can take diverse forms, including supplemental pages, teacher communities and social networks, or videos of classroom enactment. Classroom videos are helpful, if they are associated with appropriate indications about what can be drawn from these videos.

Collaborative Aspects

Two kinds of collaborative aspects contribute to the quality of a resource for science inquiry. First, the resource should permit or support collaborative work of students and teachers. Second, students or teachers should be able to contribute to the further design or content of the resource.

- *Collaborative work of students or teachers*: an online resource can include recommendations or supports for collaboration among students, interactions with teachers, or even interactions with scientists. Collaboration supports can be synchronous or asynchronous, including discussion forums, wikis, annotations, or other collaborative features. Resources can also support the organization of student groups or the collaboration of teachers with students, peers, teacher professional development specialists, or scientists. Supports for collaboration can include schedules, prompts, or tools (e.g., online discussions) as well as scaffolds to support the use of those elements (e.g., a set of common vocabulary that supports discussions of a lesson).
- *Contribution of the users to the design of the resource*: some online resources provide students with the possibility of integrating their contributions, through votes, tags, or elaborations, into the resource itself. For example, they might submit an inquiry report online,

which could be shared with other users of the resource. They might also add votes, comments, Web links, or other scientific resources. Teachers could add to a resource by contributing lesson plans, opinions, or suggestions that could inform other users or the resource designers.

Conclusions

As the Internet matures from a static resource of links and “pages” to a more dynamic, social environment where users contribute content (e.g., Wikipedia, YouTube) or network socially, there will be new forms of online resources for science inquiry and new opportunities to support K-12 students and teachers. The various qualities delineated here should serve science educators in their efforts to design, develop, evaluate, and apply such resources.

Interpretive Centers

Michael Brody
Curriculum and Instruction, Montana State University, Bozeman, MT, USA

Keywords

Nature center; Science centers; Visitor center

Interpretive centers are informal education venues in which a place of interest such as a state/provincial park, wildlife preserve, historic building, or archaeological site is designed to afford the general public an opportunity to better understand the natural or cultural heritage of the site. Interpretive centers are site-specific linking *place-based* educational approaches with public informal learning settings. Often the interpretive center, sometimes referred to as a visitor center, utilizes a variety of approaches to public understanding including diverse media such as video displays, instructional kiosks, interactive computer simulations, or movie theaters. Often center employees such as park rangers, curators or natural resource managers conduct interpretive education programs for visitors. It is not uncommon for centers to include souvenir or gift shops. Nature centers often have a visitor or interpretive center dedicated to educating people about nature and the environment. In addition technological, engineering, or science research sites may have a public visitor/interpretive center for public outreach. They seek to educate and raise awareness of their innovative activities. As such, interpretive centers are very accessible to the general public in urban, suburban, and rural areas and often attract tourists visiting an interesting geographical or historical area.

The original characterization of interpretive centers is as a site for communication to enhance understanding of heritage and create meaningful links of intellectual and emotional connection to natural and cultural resources. This traditional view of the centers derives from Freeman Tilden's *Principles of Interpretation* (Tilden 1957) focusing especially on relating content in meaningful ways to the visitor's own experience leading to emotional connection, thought, and further questions about a subject or site. This perspective is closely aligned with cultural heritage interpretation.

A more recent conceptualization of interpretive centers in the context of natural science education is a place of informal science learning (Committee on Learning Science in Informal Environments 2009) where all ages of people come to spend time in *free-choice learning* activities. Informal science learning settings similar to interpretive centers include museums, aquaria, zoos, botanical gardens, and science centers. Recent innovation in museum programs has led to science centers where interactive, hands-on exhibits may encourage visitors to experiment and explore and interpret the content or site in their own context and experience. The research and educational practice related to interpretive centers and science education is blended into the diverse types of informal science learning environments.

On one end of the informal learning spectrum are visits to parks or gardens where there may be no specific educational structure or agenda for the visitor. In the broad and diverse informal learning context, we also see the organized and planned nature of museum dioramas or interactive exhibits focusing on educating the public about a specific or narrow set of concepts. Interpretive centers and their education programs are found somewhere between these two ends of the informal learning environments spectrum and thus are influenced and informed by the work in both unstructured and structured informal settings.

In the modern context of interpretive centers as informal science learning environments, recent efforts have been made to better understand the nature of learning activities that occur there to better inform design, delivery, assessment, and evaluation of interpretive programs. Much of this work is in the form of evaluation reports on specific programs and is reported as part of education program evaluation literature.

Typically the audience for interpretive centers is the general pubic, however, we often see educational programs targeted at more specific groups such as after-school and camp programs for children or topical programs for adults with special interests. In these contexts, science learning is seen as a dynamic interaction of both formal and informal learning across people's life span.

Because interpretive centers must address the needs of the general public, issues of population, class, race, diversity, socioeconomic status, and special needs are addressed in research and professional-related literature. Interpretive center programs are typically designed for all ages but may be adapted for narrow age groups such as preschool or elder hostel programming. This connection of interpretive centers to diverse audiences and their needs helps to inform science education in general.

The research literature related to interpretive centers is found in a diverse collection of journals, reports, books, and other online literature well beyond the typical science education literature. Journals addressing museum programs and informal learning often include articles related to interpretation. There are professional journals addressing studies of visitors, learning environments as well as interpretation. Journals focused on environmental education also include topics related to interpretive centers.

Research around interpretive centers has been strongly influenced by the free-choice learning (Falk and Dierking 2002) literature. Originally focusing on describing the nature of the experience of visitors/learners, recent research has advanced our understanding of the personal and social aspects of informal learning over time. This ecological view of learning has proven beneficial in understanding the holistic nature of learning in and around interpretive centers.

As in most of science education, the future of interpretive centers will be influenced by the nature of emerging teaching and learning technologies, especially as they relate to public audiences and the delivery of educational programming through portable devices.

Interventions, Gender-Related

Jane Butler Kahle
Teacher Education, School of Education, Health and Society, Miami University, Oxford, OH, USA

Beginning with Alison Kelly's (1985) research, scholars have identified and practitioners have implemented interventions that address girls' interest in, attitudes about, and success in science. Originally, gender-related interventions addressed equity issues in curriculum and in classroom interactions. Early interventions were based on Mary Budd Rowe's (1986) studies of *wait time* and *tinkering time*, on Kenneth Tobin and James Gallagher's (1987) identification of *target students*, and on Kelly's analysis of gender differences in spatial ability. Curricular materials that are focused on relationships as well as rules involve people as well as machines; use pragmatic, not dogmatic, approaches; view the world as a network, not a hierarchy of relationships; emphasize the aesthetic as well as analytical aspects of science; and focus on nurturing living beings as well as inanimate things are gender-related interventions (Small 1984).

Inquiry instruction is an intervention that enhances the achievement as well as the interest of all students in science. Inquiry in science classrooms is defined by engaging with authentic problems, raising appropriate questions, using evidence, justifying claims, and applying appropriate representations (Battey et al. 2007).

Gender-related interventions have moved from ones that address covert actions or materials to more subtle ones such as *gender-related incidents* and *gender lore*.

Kansatsu

Ken Kawasaki
Philosophy of Science Education, Kochi
University of Technology, Kochi, Japan

Keywords

Incommensurability; Science education in the non-West; Worldview

Traditionally, Japanized Buddhism developed meaning for the term "kansatsu" over more than a thousand years. In this context the most reasonable English translation of the term is "contemplation" that strongly implies empathy with objects (Kawasaki 2002). However, this Japanese term "kansatsu" acquired an additional meaning in the context of learning science in the second half of the nineteenth century as Western scientific ideas came into Japan. Since then, science educators have simply assumed that "kansatsu" is identical with "observation." However, that assumption produces a clear complication because the meaning "observation" conflicts with the meaning that "kansatsu" already has in the Japanese language. The source of this complication lies with Japanese science educators having little understanding of language-culture incommensurability induced by the assumption. In brief, the assumption originates in their ignorance about the arbitrary nature of linguistic signs (Culler 1988, p. 19). If Japanese science educators realize the assumption they are making, they will be able to find a way to overcome the complication and then to minimize it.

In this entry, the complication and a way of overcoming it are briefly described. The description will be applicable to non-European communities where science education is based on the translation of scientific concepts from European languages into students' first and non-European languages (Kawasaki 2010).

In Japan science education is conducted in the Japanese language, which is both students' and teachers' first language. In this language setting students inevitably understand "kansatsu" according to the context of the Japanese language. Moreover, owing to science educators' assumptions of equivalence with "observation," very few of them realize the contradiction between the acquired and the original meanings or the incommensurability between "kansatsu" and "observation." Thus, it is almost impossible that "kansatsu" conveys what "observation" originally means in English contexts in the science classroom.

As indicated in the foregoing, "kansatsu" is no more "observation" than "contemplation" is. The term "observation" leads observers to objectify objects, whereas "kansatsu" connotes empathy with objects. These outlooks on objects are opposite to each other.

This incommensurability reflects differences between the Western scientific and the Japanese worldviews. As a general rule, a worldview is

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

potential and a social system of norms: what outlook on this world people should have in their community. As is well known, the Western scientific worldview is based on the dichotomous worldview, which opposes the world of ideas against the phenomenal world, to use Platonic terms. The term "observation" signifies the first step to bridge the gap between these two worlds. In such intellectual activities, scientific objects are objectified (Kawasaki 2002).

By contrast, "kansatsu" acquires its meanings from the Japanese worldview. This worldview has never established such a dichotomous position (Kawasaki 2002). When science teachers use "kansatsu" without realizing the incommensurability, students accept it as a Japanese term and then learn the outlook innate in "kansatsu." Consequently, they cannot conceive "observation." In addition, owing to their assumption, science educators cannot realize this discrepancy. What actually happens to the science classroom in Japan is far from being scientific: Science teachers remind students of what "kansatsu" traditionally signifies and stimulate students to have empathy with their scientific objects.

A strategy for overcoming the complication is not difficult: science educators' awareness of the difference in worldview needs to be raised. However, there is difficulty in implementing this strategy. The curriculum for prospective science teachers in Japan has excluded goals and content aimed at cultivating a comparatist mind and epistemological reflections on what is unwittingly known, what is unwittingly known about "kansatsu" in the present case.

If the comparatist mind was so cultivated, science teachers would be much more likely to understand "kansatsu" against the backdrop of "observation." This understanding would liberate science teachers from confusing "observation" with "kansatsu," and it would become possible for students to develop an appropriate understanding of "observation" that symbolizes the scientific way of thinking, then science.

Science teachers' explanation of the incommensurability can be properly called metalanguage if it is accepted that a language entails a worldview inherent in the language (Kawasaki 2010). An issue that needs discussing in science education research in Japan is the way to enrich such metalanguage. However, science educators are still unaware of the incommensurability because of a widespread lack of a comparatist mind or an understanding of the arbitrary nature of linguistic signs.

It is also very significant to examine the collocation of "kansatsu" with another Japanese term "shizen" translated as "nature." Just as "kansatsu" conveys a critical meaning in the Japanese belief system, so "shizen" conveys another critical meaning – in the Japanese worldview the word refers to "supernatural" (Kawasaki 1996). So clearly, when science teachers use the word as meaning "nature," they are causing the same complications for and confusions in students. And then further complication comes from science educators using the phrase "shizen no kansatsu" to mean the same as the English phrase "to observe nature." Regardless of this incommensurability between the two phrases, science educators have accepted, without comparatist mind, that the phrases are identical.

It is not difficult to envisage the confusion stemming from the science educator belief that the phrases are identical. On one hand, the English phrase encourages the objectifying of natural things and the careful watching of them; on the other hand, the Japanese phrase encourages having a form of mystical empathy with the supernatural embedded in natural things in contemplating them.

This science educator belief characterizes "rika," a Japanese counterpart of school science, and keeps students away from a real understanding of scientific concepts. Conversely, this situation implies the way to minimize the complication. If science educators can realize that foreign language education is filled with metalanguage, the following slogan well expresses the way to overcome the complication: Science education should be associated with foreign language education (Kawasaki 2010).

Knowledge About and Understanding of Science, Assessment of

Beverley Bell
Professional Studies in Education, University of Waikato, Hamilton, New Zealand

Assessing students' science learning with respect to knowledge is done for a variety of purposes: formative, summative, and for accountability purposes (Bell 2007). It is the purposes for generating the assessment data which determines what kind of assessment task will be used. For example, written examinations and tests are most often used for assessment of science knowledge learning for summative purposes, as this produces a storable record. Oral conversations between teacher and student are often used for assessment of scientific knowledge for formative purposes, as the feedback and feedforward can be given while the student learning is occurring.

A key aspect of assessing students' learning of scientific knowledge is to assess the extent to which students are able to use their newly acquired knowledge in situations other than the ones in which they learned the knowledge. The distinction between recall of knowledge and the use of that knowledge is made. For example, if students learn about the concept of food chains in the context of the backyard vegetable garden, to what extent are they able to use their newly constructed knowledge to answer assessment questions on food chains in the wild or in the marine environment, as well as in the vegetable garden?

Assessing students' knowledge of science may also be an assessment of their competence in using the science knowledge to reason and solve problems. For example, if the students have learned the science knowledge that one categorizing characteristic of insects is that they have six legs, can the students use this knowledge to decide if a worm, butterfly, centipede, spider, and crayfish/lobsters are insects or not?

The communication format of the assessment tasks may be oral, written with pen and paper, or online using ICT technologies, such as computers, iPads, and iPhones. For example, assessment of knowledge for formative purposes is often done orally in classroom teacher and student conversations. Assessment of science knowledge learning using multiple choice tests may be done online.

Assessing students' science knowledge learning may be done using a variety of assessment tasks (New Zealand Ministry of Education 2012):

Multiple choice tests
Open-ended question items, asking for the student to describe, discuss, explain, and draw
Matching exercises
Essays
Questionnaires
Predict-observe-explain tasks
Completion tasks
Observation of student work books or small group discussions
Interviews
Conferencing
Performance tasks

Projects
Posters
Portfolios of student work
Laboratory reports of practical work
Brainstorming
Concept maps
Puzzles
True-false statements
Student questions
Student learning journals, blogs
Student presentations
Problems solving

When teachers design an assessment task, the following need to be taken into account (Atkin et al. 2001):

- What learning goal is being assessed?
- What criteria will be used to judge the quality of the student work?
- What are the quality indicators of validity and reliability or trustworthiness
- Is it a group or individual assessment task?
- Is this assessment equitable, that is, can all students attempt the assessment or are they restricted by, for example, disability, culture, and gender?
- What kind of data does it give? How will the assessment data be recorded and analyzed? And by who?
- How long will it take to administer? That is, how manageable is it?
- What kinds of teacher judgements are needed to make sense of the data analysis?
- Will the assessment data analysis give you information about what to do next to further increase student learning?
- Is moderation appropriate?

When choosing an assessment task from government or commercial banks of assessment resources, the following additional concerns need to be addressed:

- Country and/or culture of origin, that is, which curriculum is the assessment task aligned with?
- Is the assessment task standardized and norm-referenced for students in your country?
- How much training is needed before it can be used?

Collective inquiry; Knowledge building; Knowledge communities

Main Text

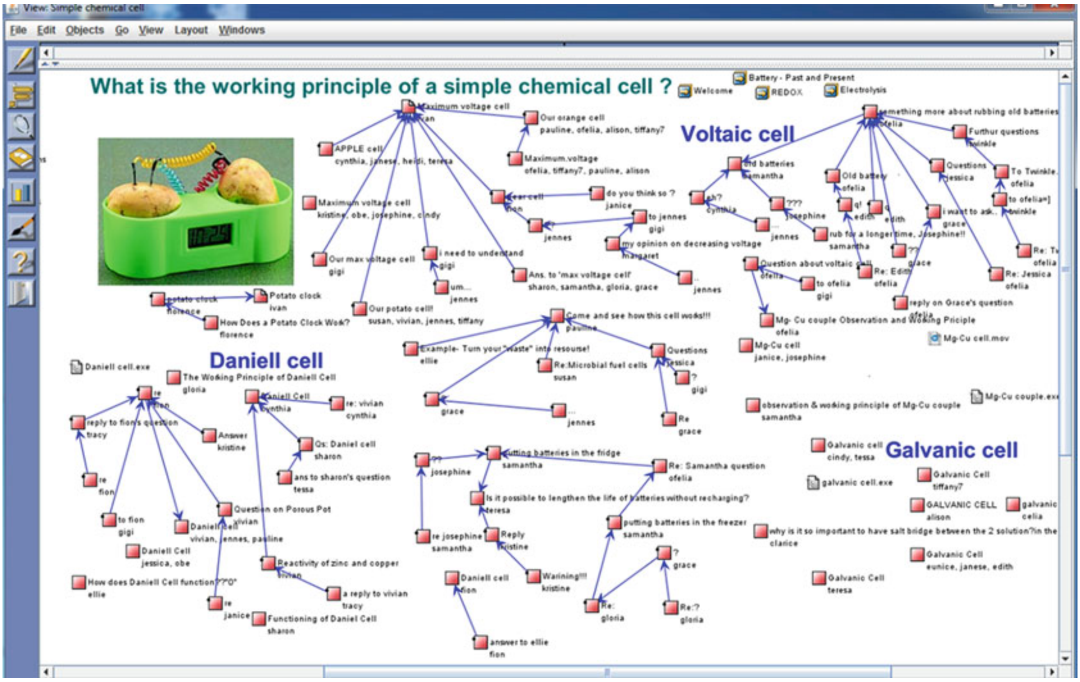
In recent decades, it has been the goal of many science curricula and projects to develop inquiry-based learning in science classrooms. Many such projects, often of short duration, involve students' learning from inquiries and investigations, exploring science phenomena firsthand, carrying out experiments, practicing scientific skills, and applying scientific ideas in new situations. However, critics have pointed out that these approaches fall short of what scientists actually do, as theories emerge within a sustained community of inquiry and knowledge exchange. In classrooms, scientific inquiry is often limited to sequenced activities designed to meet predetermined goals and fixed standards, rather than helping students to develop authentic scientific practices within a community of their peers.

What Is the Knowledge-Building Community Model?

The model of Knowledge-Building Community, developed by Marlene Scardamalia, Carl Bereiter, and colleagues, takes a different approach by focusing student inquiry on the challenge of collectively advancing the knowledge of their community. Knowledge building, the "production of knowledge that adds value to the community" (Scardamalia and Bereiter 2003, p. 1370), fosters the kind of productive knowledge work found in scientific communities, foregrounding the *discourse* by which lines of inquiry are set, explanations are proposed and tested, and the community's overall progress is evaluated. Knowledge building is fundamentally concerned with ideas, particularly the *improvement of ideas*, in a community. In knowledge building, students contribute their ideas to a public space – a computer-supported collaborative learning environment called Knowledge Forum® – where they become shared objects of inquiry, investigations, and progressive discourse. Much like how scientists generate new knowledge, science students can develop the capacity to create and improve ideas that add value to the community. For example, they may formulate problems and put forth ideas, propose an explanation for a given phenomenon, suggest how their idea may be related to other ideas, or how an idea can be tested and modified in building a more coherent theory.

Knowledge building generally refers to how students co-construct knowledge and understanding via discourse, and KBC draws several distinctions among elements that commonly occur in similar community-based models. First, a distinction is made between learning – changes in students' mental capacities and personal understanding – and knowledge building, the improvement of public knowledge (Scardamalia and Bereiter 2003). If learning is a practice in which a community's intellectual heritage is *passed on* to a new generation, then knowledge building *extends* that intellectual tradition. As Scardamalia and Bereiter (2006, pp. 97–98) put it, students in KBCs "come to see themselves and their work as part of the civilization-wide effort to advance knowledge frontiers." When considering students as engaging in a "knowledge-creation culture," it is important to underscore that students are not expected to make new major discoveries, but they can and do engage in knowledge-creation dynamics and regularly make discoveries that are novel in their communities and go beyond what is contained in the sources they study and school curriculum.

A second distinction is made between "belief mode," which emphasizes *argumentation*, and "design mode," which focuses on *progressive problem solving*. While argumentation is currently central to science education, the KBC model postulates that in addition to helping students make claims, justify their beliefs, and use evidence, science educators can also incorporate "design-mode" thinking, as is common in scientific communities. Design mode helps students to view ideas as conceptual artifacts (similar to scientific inventions), which can be continually improved upon by themselves and others. Designing is an open-ended activity, in the sense that it does not have an obvious endpoint but rather serves to advance collective knowledge to a state that is more coherent and powerful in explaining science phenomena. By contrast, belief-mode discourse is more closed and commonly oriented toward persuading others of the merit of an idea, without necessarily improving the idea itself. The KBC model



Knowledge-Building Communities, Fig. 1 A Knowledge Forum view for collective inquiry and scientific discourse

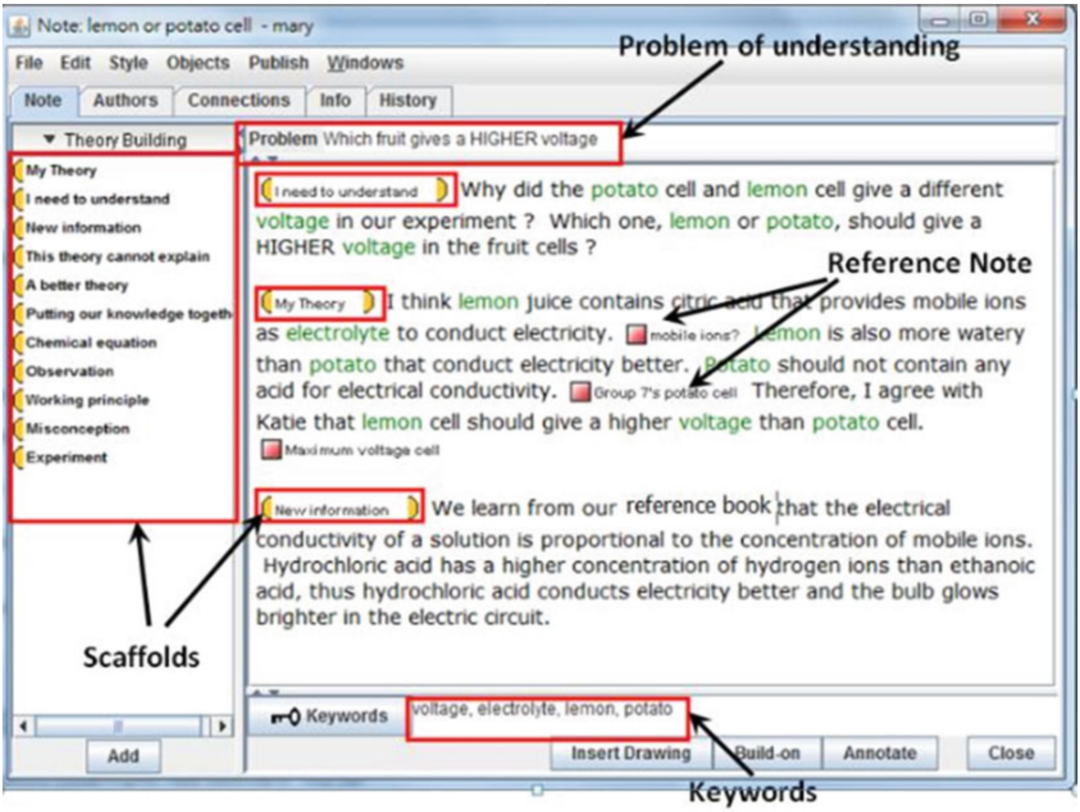
focuses on design mode for theory building to help students engage in the complex processes of knowledge creation. Thus, knowledge building goes beyond merely helping students to develop conceptual understandings, by engaging them in the creation of new knowledge within a community context.

Pedagogical and Technological Support

Technology environments help to support knowledge building by maximizing student agency and empowering students to take up collective cognitive responsibility in advancing their community knowledge. In a typical knowledge-building classroom, students record and work their ideas using Knowledge Forum, including online and offline discourse in which they formulate problems (e.g., "Why do leaves fall?"), propose theories, identify relevant information, construct explanations, and examine different models to help them revise their theories. Working with their teacher, students may conduct experiments to test hypotheses, read to understand difficult information, engage in "knowledge-building talks" to tackle problems emerging from the discourse, and work collectively to advance their theories. Knowledge Forum thus serves as an objectification of the community's advancing knowledge. Using networked computers, students can simultaneously add notes to the database, search or comment on existing notes, or organize notes into more complex structures.

Unlike online forums for discussion or information sharing, Knowledge Forum is designed with the explicit epistemic commitment to help students advance their ideas and focus on *idea improvement*. Features of Knowledge Forum include:

- *Views and notes*. A *view* is a communal area for collective inquiry where students post their questions and ideas and others will "build on" as initial ideas are advanced (Fig. 1). *Notes* can be placed on the view, where lines between the note icons indicate interactions, and students can navigate across different views.



Problem Which fruit gives a HIGHER voltage

I need to understand Why did the potato cell and lemon cell give a different voltage in our experiment ? Which one, lemon or potato, should give a HIGHER voltage in the fruit cells ?

My Theory I think lemon juice contains citric acid that provides mobile ions as electrolyte to conduct electricity. 🟥 mobile ions? Lemon is also more watery than potato that conduct electricity better. Potato should not contain any acid for electrical conductivity. 🟥 Group 7's potato cell Therefore, I agree with Katie that lemon cell should give a higher voltage than potato cell.

🟥 Maximum voltage cell

New information We learn from our reference book that the electrical conductivity of a solution is proportional to the concentration of mobile ions. Hydrochloric acid has a higher concentration of hydrogen ions than ethanoic acid, thus hydrochloric acid conducts electricity better and the bulb glows brighter in the electric circuit.

Keywords voltage, electrolyte, lemon, potato

Knowledge-Building Communities, Fig. 2 A Knowledge Forum note with features to support metacognition

- *Metacognitive prompts*. These are scaffolds that help students frame their ideas, during note writing, such as: "I Need to Understand," "My Theory," "New Information," "A Better Theory," and "Putting Our Knowledge Together" (Fig. 2). Students may also use the *problem* tag to highlight their note as being problem centered, and *keywords* for domain vocabulary and search.
- *Linking and rising above*. Tools that help make conceptual progress visible include the opportunity to link views and to create *rise-above views* for emergent questions. When writing notes on Knowledge Forum, students can create *rise-above* notes or add other notes as *references*, much as scientists use references to build on existing ideas and create an integrated web of ideas.
- *Assessment tools*. These have been developed to support students and teachers, including applications that generate information about contribution, social networks, vocabulary growth, and idea improvement (Fig. 3).

International Research

Since the 1990s, the KBC model has been implemented in primary and secondary science classrooms in some 20 countries, illustrating how elementary children can engage in a knowledge-creation approach, how maximizing student agency can bring about knowledge creation, and how principles, rather than scripted activities, are key to emergent knowledge work and sustained classroom innovation (Zhang et al. 2009). The KBC model has also been successful in Asian secondary classrooms despite their emphasis on high-stakes examinations, where teachers have adapted the KBC model to allow students to

Implications for Science Education

The KBC model, in line with National Science Education Standards in the USA and other countries, focuses on scientific literacy and inquiry beyond the simple acquisition of knowledge, processes, and skills. Specifically, the KBC model advocates an agenda for developing a -knowledge-creation culture in science classrooms. In contrast to conventional lecture, laboratory experiment, and inquiry approaches that focus on structured activities, KBC advocates scientific epistemology and commitment, sustained pursuit of idea improvement, theory building, progressive discourse, and collective growth. This emphasis on epistemology aligns well with increased recognition of the importance of students' understanding of nature of science.

Inquiry-based approaches like KBC face many challenges, including the current K-12 science standards that result in curriculum sometimes described as being a "mile wide and an inch deep." Ultimately, applying the KBC model in science classrooms is a matter of fundamentally shifting teachers' and students' epistemological understandings. Substantial research and development has progressed among a widening community of researchers and practitioners, resulting in advances in the pedagogical, technological, and social infrastructure for KBC.

University of Leeds, Leeds, UK

Keywords

Affective value; Experiments; “Hands-on”; “Minds-off”; Open-ended investigations; “Recipe” style tasks

One of the features of science education that sets it apart from most other subjects taught in school, perhaps the distinctive feature, is that it involves practical lessons that are, in general, undertaken in specifically designed and purpose-built laboratories. Yet although teaching in the laboratory is widely used in many countries (Lunetta et al. 2007), its educational value remains unclear, with any agreement on this being dependent upon the term “educational value” remaining very loosely defined. Indeed, despite teaching in the laboratory being both widespread and well established (Bennett 2003), research findings regarding its effectiveness in terms of developing conceptual understanding, practical skills, as well as its affective value remain, at best, ambiguous (Abrahams 2011).

However, if, as Plato suggests, the world can be divided into a world of ideas and a world of physical realities, then there is a broad consensus that a fundamental purpose of laboratory teaching in school science is to help students bridge the divide between these two disparate worlds. In essence, effective laboratory teaching provides a link that enables students to understand the world around them in terms of abstract scientific ideas.

Yet teaching in laboratories is not a single, clearly defined, process but rather involves various strategies that include experiments, investigations, discovery, and “recipe” style tasks, all of which can be referred to under the broad overarching heading of “laboratory work” (or “labwork”). Here, the essential difference between the different strategies can be thought of in terms of the degree of “openness” or “closure” of the task – that is, the extent to which decisions regarding the activity are made by the student and/or the teacher. At one end of this continuum are closed “recipe” style tasks in which the teacher sets out what is to be done, how it is to be undertaken, and how the data are to be collected, analyzed, and presented. At the other end of that continuum are open investigations in which students determine what they want to investigate, how they will carry out the task, as well as deciding upon the data to be collected and how this data will be analyzed and presented.

While open-ended investigations do occur in school science lessons, much teaching in school laboratories regularly involves the use of recipe style tasks in which students, generally working in small peer groups, follow a combination of teacher and/or task instructions. This widespread use of recipe style tasks appears to owe more to

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

the relatively short nature of most practical lessons and the fact that teachers often want to ensure that their students successfully produce and see the desired phenomena rather than a belief that open-ended investigations might be less effective in developing conceptual understanding or specific practical skills. Another possible reason for the frequent use of recipe style tasks is that teachers' preferences for various types of practical work are informed by curriculum targets and the associated methods of assessment. At present, the skills that those types of investigations develop are not sufficiently recognized in the current assessment criteria to warrant their widespread use.

In an ideal situation all teaching in the laboratory would be synonymous with learning in the laboratory, but, to a certain extent, much laboratory teaching focuses far too narrowly on the unthinking production of a particular phenomenon and/or data set. As a consequence a substantial proportion of teaching in the laboratory can be categorized as "hands-on" but "minds-off." Indeed, many teachers are seemingly still convinced of the merits of the, by now largely discredited, "discovery-based" approach to learning in which "doing" with, and "learning" about, ideas are seen to emerge of their own accord simply from the successful production of a phenomenon. Indeed, despite its widespread use and the high esteem with which teaching in the laboratory is held by many teachers, there is little unambiguous evidence to show that, as currently used in many schools, laboratory teaching is any more – or any less – effective in developing conceptual understanding than other, non-laboratory-based, approaches to the teaching of science.

Furthermore, despite claims about its very positive affective value and the large amount of time spent teaching in the laboratory, there remains, unfortunately, a disappointingly low number of students opting to pursue science in the post-compulsory phase of their education. Yet despite this apparent contradiction, many teachers adhere to the view that student motivation towards school science (and many of them would also argue towards science in general) is in some basic way to be seen as being proportional to the amount of laboratory teaching they receive. Such views arise as a result of teachers mistakenly assuming that students' claims to like laboratory teaching are symptomatic of their liking of science as a subject rather than, in many cases, simply reflecting a preference for teaching in the laboratory as opposed to other forms of science teaching (Abrahams 2011). Indeed, the focus on "hands-on" and "minds-off" has tended to mean that much laboratory teaching requires little by way of cerebral engagement. Such a recognition goes some of the way to explaining its relative popularity among students, particularly those who have no interest, or intention, in pursuing science post-compulsion and who would, given the choice, prefer not to be learning science at all.

One positive consequence of the focus on "hands-on" teaching in the laboratory is that it has, through the widespread use of closed recipe tasks, become an extremely effective means of getting students to do, within the often limited time available, things with objects and materials in order to see what the teacher wanted them to see. Indeed, students are frequently able to recollect qualitative procedural details of what they did with a high degree of accuracy, albeit if not with much understanding. Yet despite the effectiveness of much laboratory teaching in terms of getting students to do what the teacher wants with objects and materials, it is much less effective in getting students to learn about ideas, and part of the reason for this lies in the disproportionate amount of whole-class laboratory teaching time devoted to procedural instructions.

Few can doubt that laboratory teaching is, and will remain, a core feature of science teaching, and yet if it is to become as effective in developing conceptual understanding as it currently is in producing phenomena, then change is necessary. That change requires those using it to relinquish their discovery-based approach in favor of a hypothetico-deductive one in which laboratory teaching needs to be designed with the explicit aim of helping to "scaffold" students' efforts to form links between the domain of objects, materials, and phenomena and the domain of ideas.

Laboratory Reports

Reuven Lazarowitz
Department of Education in Science and
Technology, Technion City, Haifa, Israel

Keywords

Cognitive and affective domains; Content science-oriented; Inquiry-oriented; Science technology and societal issues

Over the past several decades, we have seen the development, implementation, and evaluation of three generations of high school science curricula: (a) content science-oriented, (b) inquiry-oriented, and (c) problem-oriented (see Lazarowitz 2007). These generational movements are accompanied by changes in science content knowledge, pedagogical content knowledge, textbooks, and modes of teacher instruction. Each of these changes had implications for the nature of laboratory work and the way in which lab work is reported by students.

To illustrate the nature of these changes and their impact on laboratory reports, I describe three generations of biology curricula in Israeli schools.

Content-Oriented Curriculum in Biology

In this first generation, the biology content was presented as a body of knowledge, organized systematically around topics such as invertebrates and vertebrates in zoology, lower and higher plants in botany, and the human body. Each organism was presented in a sequence of morphology, anatomy, physiology, growth, development, and reproduction and introduced with a short description of the cell structure and function. Microbiology, genetics, ecology, and evolution were complimentary subjects. Biology laboratories aimed at learning about organisms and their classification, with the physiology aspects discussed as far as the knowledge in chemistry and physics permitted. Each textbook depicted a sequence from cells to multicellular organisms at different levels of biology organization from the molecular level to the organism. The modes of instruction were expository. Teachers lectured and asked questions, while students listened and sometimes were allowed to ask or answer. Student–student interactions and the process of inquiry rarely occurred.

We can conclude from this description that listening and memorization skills were emphasized rather than learning skills such as seeking knowledge, exchanging ideas, and taking responsibility. The nature of laboratory work was essentially aimed at proving what had already been learned in the classroom. Laboratory reports were used to report results based on a few physiological experiments and microscopic work, drawing cells, and anatomic structures. The reports mainly drew on cognitive levels of knowledge and understanding, with little room for students to record personal thoughts, ask questions, or think critically. Reports were related to past learning, rather than future plans or scientific explorations. Generally, lab reports from this generation of curricula did not include higher cognitive levels such as application, analysis, synthesis, and evaluation (Lazarowitz and Tamir 1994).

Inquiry-Oriented Curriculum in Biology

The late 1960s saw a second generation of high school science curricula based on the concept of inquiry. This approach, rooted in the educational theories of Dewey and Bruner, was developed by Schwab and Brandwein in their landmark book, *The Teaching of Science as Enquiry* (1962). These ideas were later incorporated in Schwab's book, *Biology Teachers' Handbook*, which is considered to be the foundation for the inquiry-oriented curricula, the Biological Sciences Curriculum Study (BSCS).

The content knowledge of the BSCS textbooks was based on the seven levels of biological organization (see, Schwab 1963), emphasizing the teaching of concepts and principles in biology. Teachers were asked to create learning environments, facilitating a process of student/teacher interaction where students had to "search and seek" for knowledge using inquiry skills such as scientists use in their research. In the laboratory, students were required to use skills such as identifying problems, forming hypotheses, planning and experimenting, collecting data, analyzing results, presenting them in tables and graphs, and planning and designing of new experiments. Students were asked to draw conclusions, infer and identify new problems, and read graphs and tables.

The inquiry-oriented curriculum in biology required a new approach to assessing students. Rather than simply repeating facts and information, students had to show in their laboratory reports how these inquiry skills had been applied. Students were expected to demonstrate the use of higher cognitive skills, critical thinking, and problem-solving and affective skills such as responsibility in the learning process. Lab reports were a vehicle for building a body of knowledge on a scientific topic and bridging content from previous laboratory experiences to new laboratory work (Lazarowitz 2007; Lazarowitz and Tamir 1994).

The Problem-Oriented Curriculum in Biology

Since the 1990s, new approaches in science curricula have taken into consideration the heterogeneous nature of students in terms of learning styles, cognitive stages, abilities, choices, preferences, and needs (see Yager and Hofstein 1986). Broadly based on the science, technology, and society (STS) movement, this curriculum generation saw students introduced to science through problem-based thematic material, with units such as Human Health and Science; Ionizing Radiation: Uses and Biological Effects; and Microorganisms.

The laboratory reports from this generation were based on the inquiry demands depicted earlier, with an additional emphasis on societal issues, requiring teachers and students to relate to the affective as well as the cognitive domains. Often students were required to consider both sides of an argument about the use of science and technology in society, such as the use of ionizing radiation in medicine, agriculture, and the food industry vs. its use in war. These and other considerations such as social justice required students to use different kinds of skills in their reports, including problem-solving, argumentation, communication, debate, and the critical use of evidence.

Conclusion

Alongside the three science curriculum generations in the late twentieth century and the early twenty-first century, we have seen several trends in students' laboratory reporting. The first trend is from lower- to higher-level cognitive demands, from reporting and restatement of facts to application, synthesis, and evaluation of scientific ideas. The second trend is towards a better appreciation and explication of the processes of science. Here, students are asked to demonstrate and explain how scientific inquiry proceeds. The third trend – emerging from an understanding of the importance of students' needs and connecting science and technology with society – has tapped into students' affective as well as cognitive skills.

In sum, these trends have resulted in students taking on more responsibility for their own laboratory work, as well as employing the entire range of cognitive, meta-cognitive, affective, and problem-solving skills in reporting their lab experiences.

Introduction

There is general agreement that the laboratory provides science students with unique learning experiences. The laboratory utilizes manual and intellectual skills, which are in some measure distinct from those used in non-laboratory work. A comprehensive review of the literature, conducted by Lazarowitz and Tamir (1994), summarized the aims and objectives of laboratory work. These authors suggested that laboratory work be structured under the following main headings: understanding of concepts, acquiring habits and capacities, gaining practical skills (including planning and design of a practical exercise, performance, organization, analysis and interpretation of data, and application to new situations), appreciating the nature of science, and developing attitudes. Whether these aims and objectives are attained, and the form of laboratory work conducted, depends very much on teachers' instructional goals and whether students are provided with genuine opportunities to be involved in laboratory experiences. In addition, the attainment of these objectives is monitored and regulated by the context in which the laboratory exercise is taking place, by the students' characteristics (abilities and motivational patterns), and by the laboratory manual (guide) which very often dictates the type (and form) of activity that will be conducted (e.g., inquiry-type activities as opposed to confirmatory-type experiments, the degree of open-endedness of an activity, and whether the experiment will be conducted by the students individually or in collaborative groups, or presented as a teacher's demonstration). Also, often, the form of laboratory work and the type of activities conducted are based on logistical constraints such as the availability of equipment and materials and the length of the activity.

Forms of Laboratory Work

The two most common organizational structures for the laboratory are teacher demonstrations and experiments conducted cooperatively or individually by the students.

Teacher Demonstrations

The advantage of demonstrations is that the teacher is in control and so able to explain the dynamics and purpose of the experiment in a step-by-step fashion. In addition, the teacher can focus students' attentions toward particular aspects of their observations. When compared to student-led experiments, demonstrations are lower in cost, more economical of time and equipment, less hazardous, generally safer, and more ordered (in terms of directing thinking processes). The way the demonstration is conducted is related to the goals of the experiment(s) and to the type of skills to be developed. For example, if the goal is to develop students' abilities to observe, there may be an advantage to using larger and more accurate demonstration equipment rather than the small-scale equipment available for students' own experimentations.

Student Experimentation

Students' laboratory activities can be classified into four types: confirmatory, inquiry, discovery, and problem-based. Domin (1998) suggested that experiments can be classified according to the type of results obtained from the activity, the approach to the activity (inductive or deductive), who wrote the activity (teacher or students), and who performed the activity. Other researchers (Herron 1971; Pella 1961) suggested categorizing experiments according to their degrees of open-endedness. "Open" in this sense means that the experiment is performed entirely by the student, and "closed" means that it is directed entirely by the teacher. A confirmatory experiment is considered closed when the students perform an experiment that is planned by the teacher. This confirmatory approach is deductive and the results of the activity are known beforehand to both the teacher and the students. By contrast, an inquiry experiment is considered open when the students plan how it will be carried out. This approach is inductive and the results are not known in advance by the students (and in some rare cases, not even by the teacher).

Laboratory Work, Forms of, Table 1 Levels of discovery in the science laboratory

Level of discovery	Problems	Ways and means	Answers
Level 0	Given	Given	Given
Level 1	Given	Given	Open
Level 2	Given	Open	Open
Level 3	Open	Open	Open

Laboratory work may differ in the amounts of responsibility assumed by the learner and the teacher. Several methods have been suggested to analyze (and construct) the types of laboratory activities used in science education, based on assignment of responsibility. Herron (1971), for example, proposed multiple "levels of discovery" which he analyzed according to whether the problems, ways and means of discovery, and answers were "given" or "open" (see Table 1).

Hofstein, Abrahams, and Kipnis (2013) suggested a more elaborate approach to the division of labor in the laboratory between students and their teacher. The traditional confirmatory laboratory and the inquiry laboratory represent two opposite approaches that differ in terms of the role of the student and teacher, the skills that are used and developed during the activity, and the degree of open-endedness of the activity.

The Role of the Students and Teacher in the Laboratory

In the traditional confirmatory laboratory, the teacher plans the experiment, poses the questions during the lesson, and provides detailed procedural instructions regarding the activity. In contrast, the inquiry laboratory is student-centered. In such a laboratory, the students ask the questions, plan the experiment, and control their activities during the laboratory class. The discovery experiment represents another way of organizing the lab. When conducting a discovery experiment, the students perform the experiment according to the teacher's instructions, gather the data, and draw their own conclusions.

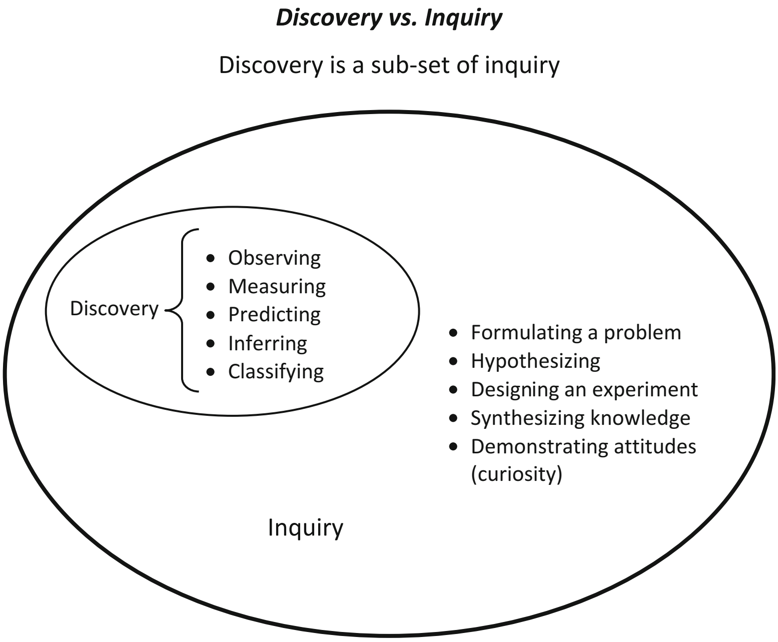
Laboratory Work, Forms of, Table 2 Learning skills involved in confirmatory and open-ended experiments

Learning skills	Confirmatory-type experiment	Open-ended-type, inquiry experiment
Conducting an experiment according to the teacher's instructions	✓	✓
Asking questions		✓
Formulating research questions		✓
Constructing a rational hypothesis		✓
Designing an appropriate inquiry experiment		✓
Conducting the experiment that was planned by the students		✓
Organizing the results	✓	✓
Analyzing the results	✓	✓
Drawing conclusions	✓	✓
Summarizing the experiment's procedure	✓	✓

A laboratory activity can therefore be classified according to the division of responsibility between the students and their teacher. Based on the teacher's aim and/or objectives, teachers can retain or transfer responsibility of some or all of the elements relating to an experiment to the students. Table 2 provides a useful tool for aligning the practical activity to meet the needs and characteristics of each particular class.

Discovery and Inquiry Laboratories

Many science educators use the terms discovery and inquiry interchangeably. Others see discovery as a subset of the inquiry process involving observing, classifying, measuring, predicting, and inferring. Under this definition, inquiry is a broader concept incorporating the additional processes of investigating a problem, hypothesizing, designing an experiment, gathering data, and drawing conclusions. For a schematic presentation of the relationship between discovery and inquiry, see Fig. 1.



Laboratory Work, Forms of, Fig. 1 Skills involved in discovery and inquiry laboratories

The Teacher's Objectives and Behavior in the Classroom Laboratory

The teacher's involvement and behavior during laboratory activities are very important and should not be overlooked. The teacher provides organizers and an environment which affects whether or not the students will reach certain instructional goals and develop the necessary knowledge and skills. The magnitude of the teacher's influence is often related to their overall teaching style. Furthermore, teaching style tends to be consistent regardless of the form of laboratory activity conducted. Deductive-oriented teachers teach practical work authoritatively, while more inductive science teachers use investigative, inquiry-oriented methods of instruction.

Using ICT in the Science Laboratory

Since the early 1980s digital technologies have become increasingly visible in science classrooms and in school science laboratories in particular. There is some evidence that the use of appropriate technologies in school laboratories can enhance learning of important scientific ideas and encourage the development of important high-level learning skills. Inquiry-empowering technologies (Hofstein and Lunetta 2004) may assist students in gathering, organizing, visualizing, interpreting, and reporting data. Some teachers and students also use new technology tools to gather data from multiple trials over longtime intervals (Dori et al. 2013). When teachers and students use these technologies properly to gather and analyze data, students have more time to observe, reflect, and construct conceptual knowledge that underlies their laboratory experiences. Also, using appropriate high-level technology tools can enable students to conduct, interpret, and report more complete, accurate, and interesting investigations. In summary, there is emerging evidence that the integration of ICT tools in the science laboratory is a promising and positive development.

Argumentation; Inquiry; Investigations; Large-scale assessment; Performance tasks

Laboratory investigations have been a critical component of science education for well over a century. Laboratories were designed to complement more traditional classroom work in order to provide opportunities for students to participate in the cognitive, physical, and social processes of scientific investigation and inquiry. Laboratory experiences were intended to enhance students' understanding of content and provide a learning environment in which students could learn how to use laboratory tools and materials, carry out investigative reasoning, and participate as part of collaborative teams. Thus, laboratories have been designed to be opportunities to learn about both the content and processes of science.

As the nature of scientific investigations has evolved and expanded, so too have laboratory experiences, leading to a recent definition: "Laboratory experiences provide opportunities for students to interact with the material world (or with data drawn from the material world), using the tools, data collection techniques, models, and theories of science" (National Research Council 2006). Advances in technology have broadened the kinds of tools and data that can be used by students in laboratory studies. Such advances no longer limit laboratory experiences to the constraints of the classroom. Students are now able to perform labs using computer simulations, access vast databases of information, or make observations by controlling remote equipment such as automated, high-powered telescopes.

There is a consensus that well-designed laboratory investigations can support student learning if they are based on clear learning goals and are incorporated into the overall science instruction, integrate science content and processes of science, and encourage student reflection and discussion (National Research Council 2006).

Despite these recommendations, research consistently has found that the implementation and impact of laboratory investigations has been quite limited. In many classrooms, students learn how to carry out laboratory procedures but engage in very little reasoning that is central to scientific inquiry. For the most part, students do not pose research questions, design investigations, or build, revise, test, or evaluate scientific models and arguments. Instead, the dominant profile of classroom laboratory investigations is one in which students use tools to make observations and gather data to verify established findings. Frequently, the laboratory experience is episodic and disconnected from ongoing science instruction. Given the general lack of well-designed laboratory investigations, there has been little evident impact of laboratory investigations on student learning. However, there is research that demonstrates positive effects on learning science subject matter when laboratory investigations are well designed and incorporated into the curriculam (National Research Council 2006). In such curricula, laboratory investigations are included along with discussion and lecture and are integral to the learning process. The investigations are used throughout the instructional unit and ask students to develop, test, and verify their ideas regarding the content being taught. Student reflection is stressed throughout the integrated unit, as students are asked to assess their own learning, describe the process they used to construct their ideas, and make sense of their findings.

A number of factors to explain the general disconnect between recommended and observed laboratory practices have been identified. Many teachers do not have sufficient preparation in science and science education to foster inquiry in their students. School organizations and structures can impose constraints that make it difficult for students to pursue research questions that require more time and/or space than the schedule or school setting allows. State science standards and assessments often focus on the learning of specific content at the expense of scientific reasoning and related inquiry processes (National Research Council 2006).

Assessments of laboratory investigations take many forms. In classrooms, teachers assess students as they proceed through the investigation, most often assessing their abilities to carry out procedures, use tools, collect data, and record results. Teachers often conduct a summative assessment of laboratory investigations that includes an evaluation of written and/or oral presentations (Hofstein & Lunetta 2003). In most cases, students are assessed on the extent to which they carry out procedures and are able to verify established science content. However, there is a large set of curriculum and research-based efforts that have designed assessments of investigation skills in which students are expected to develop scientific questions based on observations, arguments, models, and explanations as part of scientific inquiry. In many of these cases, the assessments are a culmination of integrated curricular units in which concepts and inquiry processes are developed simultaneously and students use inquiry processes to develop their understanding of science content.

Two of the most visible instructional programs that assess laboratory investigations are the International Baccalaureate® (IB®) and Advanced Placement® (AP®) programs. Across different science subject areas, IB students are expected to complete an inquiry project and display their understanding of science content through the application of scientific methods, techniques, and explanations. In subjects such as physics, students are also expected to collaborate with students from other schools as a way of emulating a scientific community. The AP science program curricula are currently under revision in order to create a greater balance and coherence among content, inquiry, and reasoning skills. Newly designed assessments in biology ask students to demonstrate evidence of an integrated understanding of conceptual knowledge and scientific practices in particular biology domains.

Laboratory skills have also been the subject of national and international large-scale assessments of student achievement. In general, these assessments have been able to evaluate only a subset of laboratory investigation skills. These assessments typically do not assume that students have studied any particular curriculum and are completed in a relatively short time span. The assessments have varied, however, with regard to the inclusion of performance tasks as well as traditional test item types such as selected-response or short-answer questions.

In the USA, the National Assessment of Educational Progress (NAEP) has used performance tasks to measure science inquiry skills in 4th, 8th, and 12th graders. Earlier versions were conducted with kits, while current versions take advantage of computer simulations (National Center for Education Statistics 2012). Both the earlier and current versions measure process skills of science investigation such as recording and identifying patterns in data, evaluating conclusions based on empirical evidence, and controlling variables to determine the effects of different independent factors. These assessments have been thought of as logical reasoning tasks as all content knowledge is provided to the student within the assessment problem. Students do not need to bring or use any conceptual understanding of particular areas of science in order to successfully solve these problems.

International assessments such as the Programme for International Student Assessment (PISA) and the Trends in International Mathematics and Science Study (TIMSS) also have assessed inquiry in 15-year-olds and fourth and eighth graders, respectively. TIMSS has included a small set of performance tasks as well as short-answer and multiple-choice items that also focus on process skills of science investigation (Gonzales et al. 2008). PISA also contains items aligned with the goals of laboratory learning such as understanding science investigations and interpreting evidence and conclusions. Taken together, these large-scale assessments have focused on processes of science inquiry but have not measured how well students have been able to develop and use investigations to enhance scientific knowledge.

The quality of instruction and assessment of laboratory investigations is related to what students learn from such investigations. The success of laboratory investigations depends on the extent to which they are supported by clear learning goals that emphasize scientific reasoning, content, and processes and are integrated in a strong science curriculum. Despite many promising models and demonstrations, most students (e.g., in the USA) are not yet experiencing laboratory investigations that provide as much attention to the reasoning and content of science as they do its processes.

Introduction

Considerations of the roles of language in learning science are not restricted to some particular frameworks or ways of learning. Rather, these considerations encompass unlimited types of social interactions, in both online and offline environments, in formal and informal contexts, involving participants from those so young they are just beginning to learn to talk to those so mature they are the most expert in their field on the planet. Thus, the issue of language and learning science is a topic of investigation not only in science education but also in a wide range of areas including social studies, humanities, and science itself. There is a long and extensive literature focused on language and the learning of science and already many reviews of this work. These reviews have been written from a range of perspectives on the form of language involved (from the specifics of student understanding of particular words used in science to the ways modes of science-related language use such as "argumentation" contribute to science learning) and from a range of perspectives on the forms of learning to which the language is contributing (from language as the tool for transmitting science information to language as an interpretive form of learners' sense making of science and its interactions with society). Given this diversity of perspectives and the number of existing major reviews of research concerned with language and learning science, including whole books, this entry seeks to include a somewhat different approach by attempting to frame these issues in new ways and from perspectives emerging in the twenty-first century. In the first major section (immediately below), there is an outline of the extensive past work, with reference to the more significant extant reviews – this section could be characterized as considering "language and science learning" from within the field of science education. Then the remainder of the entry, the second major section, considers "language and science learning" from quite different perspectives that are currently largely beyond the field of science education.

Language and Science Education: The Range of Science Education Approaches

Publication and citation data (and research, see Fensham 2004, Chap. 15) suggests a rapid increase from around 1990 in the general recognition by science educators of the fundamental importance of the nature of language use in the science classroom. However, research on language and its impacts on how science is taught and learned, and even what science is taught, was taking place in the early 1970s, very early in the development of the discipline of science education.

Understanding of Specific Words

In the early 1970s, a then young science education researcher at Monash University, Paul Gardner, began an extensive research program in which he developed multiple choice items to investigate the levels of student understanding of specific science-related words in Australia, the Philippines, and Papua New Guinea. The words were both "technical" (i.e., in Gardner's terms, physical concepts such as "force" and "mass" and "mole," names of elements and minerals, apparatus, and so on) and "nontechnical" (i.e., again in Gardner's terms, words that are not specific to science but that are frequently used in science contexts with precise science meanings; examples are "random," "predict," "theoretical," "initial"). Later in that decade, Gardner undertook a similarly comprehensive study of student understanding of "logical connectives" (i.e., words or phrases that link between ideas and are central to science arguments and discussions; examples include "therefore," "conversely," "if," "moreover," "further," "thus") and explored understanding when used in both everyday and science contexts. These studies revealed surprising (and disturbing) lack of student understanding of a wide range of words that were at that time being habitually assumed by most science teachers in most parts of the world to be clear to their students. Later studies of understanding of single words have produced similarly disturbing findings, particularly the work in Scotland of Alex Johnstone, work that had substantial impact throughout the UK. Summaries of all this work and its methodologies are given in Wellington and Osborne (2001).

Studies of students' understandings of what Gardner termed "technical words," words such as "energy" or "igneous" or "friction," are fundamentally impossible to differentiate from studies whose stated purpose is to probe students' understandings of science concepts such as "energy" or "igneous" or "friction." This is well illustrated by reports of both probes of student understanding and of student meanings for specific words in the extensive work of the Learning in Science Project in New Zealand (see, e.g., the iconic book by Osborne and Freyberg (1985)).

Broader Science Education Approaches to Investigating Language and Science Learning

The work of the Learning in Science Project, noted just above, is a clear example of the ways in which the growing prominence of constructivist perspectives impacted on almost all areas of scholarship in science learning, including the use and impact of language. As considerations of constructivism became broader in scope via recognition of the sociocultural dimensions of learning, so did perspectives on language and science learning, in particular through the embracing of the ideas of Vygotsky and the centrality of language in all learning by scholars such as the late Phil Scott.

Sutton (1992, 1998) was among the early scholars to seriously argue the need to consider language and its use in science classrooms in terms of students and their interpretations and personal meaning making and the need to reduce the existing strong focus on considering language only as a means of transmitting knowledge. Sutton used the history of science and the ways scientists of earlier times communicated their evolving ideas with each other as a central plank in his arguments. Carlson's (2007) review of research in this area explores a number of new perspectives, including extending Sutton's arguments and use of past communications between scientists into the roles of language in enabling participation in communities of practice.

Research on language and learning more generally also impacted on science education thinking in particular as science educators embraced language ideas from other contexts. Very influential in this was the work of Barnes (e.g., 1976) on the nature and use of language in classrooms, in particular his demonstrations of the powerful positive impact on student learning of personal and conversational interactions between student and teacher and the inhibiting role of rigid and formalized communication structures. These contrasting uses of language he described as "transmissive" and "interpretive" use of language. There are significant links between these arguments of Barnes and the use of the writing of scientists in earlier times by Sutton to make the same fundamental points.

The extensive research on literacy in general has also impacted on language and science education in particular. At one level this has resulted in the dramatic and very rapid increase in concerns with "scientific literacy"; this is addressed elsewhere in the encyclopedia. The more significant of these forms of impacts on language and science learning have come from another source – scholarship in linguistics. As Fensham (2004) has noted "[b]ecause science has developed such a specialised set of conceptual words and its own dialect for internal communication, it is not surprising that, sooner or later, scholars with a general interest in linguistics would turn their attention to the discourses of science and of science classrooms" (p. 203). Of course, being scholars of linguistics, these researchers published in linguistics journals. Lemke, circa 1980, appears to have been one of the first science educators to see the potential of this work and to bring it into science education domains (e.g., Lemke 1990). Lemke has also been a major figure in the ongoing debates about the nature of and interactions between literacy, scientific literacy, and science education and has again used methodologies from the field of linguistics in his work in this area (e.g., Lemke 2004).

More recently there has been an increased emphasis within science education on explorations of the ways the language forms of science per se. These are matters that first attracted the attention of linguistics many decades ago, and can be used to foster school learning of science and about the processes of science. A significant proportion of this work has been focused on argumentation and its use in classrooms to foster learning of and about science. The essential logic of this broad approach is that, just as science considers new ideas and whether or not to accept them via arguments based on evidence, so too should science education be concerned with helping students learn to argue a position from available evidence (and so learn about the concepts relating to the evidence and the ways evidence is gained and used in science). Researchers have explored the consequences for learning of argumentation approaches via verbal and written arguments, from perspectives ranging from cognitive to sociocultural and with ages from primary school to graduate teacher education students (see, e.g., Enduran and Jiménez-Aleixandre 2007).

The entry now moves to possible ways of considering language and learning science that come from beyond the discipline of science education, including outlining developments in linguistics research perspectives that have previously been embraced (e.g., Lemke).

Language and Science Education: Approaches from Beyond Science Education

Language and its role in learning science can be studied by taking into account a wide range of perspectives: determinants that facilitate the processes of decoding new knowledge, the mode of communication (particularly, but not only, since science is transmitted by a range of channels), and the relation between language and science per se. In addition, given the diverse fields of studies devoted to producing and receiving scientific data, any division into domains can also be treated as the categorization of linguistic notions. Moreover, the rapid development of neuroscience and the growing interest in cognitive studies lead to new opportunities for and very different approaches to studying the relation between language and learning science.

Domains of Investigation

The relationships between language and both science education and science per se can be considered by analyzing different linguistic domains of investigation. Language can be perceived, among others, through the prism of sociolinguistics, psycholinguistics, and neurolinguistics – all developments from the earlier linguistics frames that researchers such as Lemke brought to science education. For example, sociolinguists are interested in the way social factors shape the way scientific communication is conducted. On the other hand, psycholinguists pay attention to biological and psychological determinants of learning science. And neurolinguists, different again, focus on the relation between brain functions and neuronal characteristics and their implication for learning and using languages. Moreover, linguistic issues can be studied through the prism of phonetics, morphology, semantics, syntax, or pragmatics. Thus, attention can be paid to morphemes, words, and structures as well as their role in learning. In addition, language in learning science can be approached from the perspective of different areas of research, such as chemistry, physics, biology, and mathematics. Thus, it is possible to focus, for example, on the language and learning of science in the field of physics, by studying how the selection of linguistic tools may determine the understanding of the mathematical formulas that describe the central relationships in physics. These approaches may be connected with similarities and differences in the ways of learning science in various domains and how selected linguistic tools impede or delay the processes of knowledge flows. In addition, it should be noted that learning science is of course not restricted to some types of context. Although it is often associated with formal learning, schooling, or training, in classrooms or lecture halls, acquiring scientific knowledge often takes place in informal settings, such as interactions with colleagues, watching TV, participating in Internet discussions, using some scientific equipment in daily life, etc. (See many entries in this encyclopedia. For example 'Learning science in informal contexts', 'Social networking', 'Technology for informal and out of school learning of science', Television) Researchers investigate the languages used in scientific and science education interactions.

These investigations may explore scientific communication from the perspective of languages used in knowledge learning or the use of specialized languages, genres, or registers in any form of scientific communication. A multilingual approach can be adopted, by investigating the notion of major and minor languages in scientific discourse. For example, some researchers investigate the dominance of English in publishing scientific materials in science in this now de facto global language. The English language is also now increasingly becoming the language of science teaching in countries where English is not the daily language, particularly (but not only) in senior high school levels. The set of complex learning issues associated with learning science in an unfamiliar language – assumptions of learner bilingualism, issues of code switching, etc. – have been the subject of considerable research from within science education in many parts of the globe (see, among many examples, Amin 2009).

Researchers are also interested in the types of texts and channels of communication used in disseminating science itself, as well as increasingly in the teaching and learning of science. For example, the way science is coded determines the possibilities for decoding information by learners. Such studies may focus on online and offline methods of learning science and the linguistic tools used in standard and novel schooling and tutoring.

Translation and Teaching Language for Science: Learning science for many learners also involves working with texts that are translated versions from the source language of scientific texts. Translators have to take into account intercultural differences in coding and encoding science. This encompasses culture-specific preferences as far as knowledge creation and perception are concerned. It involves the methods of encoding (e.g., the level of formality) and the way scientific issues are presented (e.g., the use of passive and active voice). In addition, translating scientific texts involves taking into account the likely level of knowledge among the target audience. In the case of scientific products, such as media programs, scientific entities have to undergo the process of localization to the local market and cultural, technical, and linguistic needs. In addition, learning science is connected with, e.g., teaching foreign languages to scientists and others interested in learning new scientific information (Bielenia-Grajewska 2012). Language for science involves the selection of materials in the target language that meets the needs of learners as far as their level of knowledge, profession, and specialization are concerned.

Neuroscience: The field of neuroscience offers the possibility of providing a detailed and deep analysis of how science is perceived, understood, and used by diversified users. Although learning science is mainly recognized through the prism of education, learning science can also be investigated through other lens, including a range of subdisciplines of neuroscience (Bielenia-Grajewska 2013). For example, in neuromarketing researchers are interested in how purchasers understand scientific data in promotional materials and how the coding of science in advertising determines customer purchasing. Focusing on the linguistic level of neuromarketing, research may concentrate on checking the method of communication and the way it shapes the attitude of customers towards the product and the brand. Noninvasive methods are used in a range of neuroscience areas. For example, functional magnetic resonance imaging (fMRI), a neuroimaging tool using magnetic resonance, is employed in studies to observe brain performance. An individual lies still in a machine for 60–90 min. In the first stage of an experiment that lasts 6–15 min, anatomical scans of the brain are performed. In the later stages, a subject is asked to respond to a stimulus visible on screen. During these activities, it is possible to observe which parts of a brain are active. Later these scans are compared with the anatomical scans performed during the first stage of an experiment. This technique can be used to observe how scientific concepts are perceived by learners and how different forms of linguistic representation determine their scientific cognition.

Methodologies

There is a range of methodologies applied to research on language and learning science and a range of domains and types (as just discussed) to be considered. The focus of investigation can be on issues as varied as culture, communication, or networks in the processes of perceiving and learning and can use qualitative or quantitative approaches.

Text and Talk: Critical discourse analysis (CDA) is an approach used in interdisciplinary research, in which both text and talk in different social situations are observed, by taking into account political, social, and cultural factors shaping the communication. The scope of CDA may vary, depending which aspect of language and learning science one wants to investigate. In a micro approach, one may investigate how the selection of a given word in a text facilitates or hinders the processes of learning science. A meso approach deals with the “middle” dimension of investigating text or talk, taking into account, e.g., content and its role in disseminating scientific knowledge; potential studies include investigation of the structure of a text, its internal division into paragraphs, and the use of punctuation marks to divide information chunks. At a macro level, one may research such concepts as the policy of scientific organization and popularization of scientific products. In addition, CDA allows the study of how literal and figurative tools of linguistic interaction may facilitate the understanding of scientific data. Thus, an analysis of how science is learned can be conducted by use of literal language and symbolic discourse. In addition, the relation between language and learning science can also be studied by paying attention to the nonverbal components of communication. Thus, it is possible to investigate pictorial dimensions of science discourse from micro, meso, and macro perspectives, by, e.g., presenting how the type of fonts (micro approach), the use of pictures or drawings to accompany texts (meso), or the visual dimension of scientific informational campaigns (macro) determine the way science can be perceived by learners. Nonverbal studies can be enriched with investigations of multimodal communication and the semiotic aspects of modern online scientific discourse.

Culture and Communication: Ethnomethodology embraces the study of cultural factors and how these shape the way people communicate. It can facilitate the discussion of how people from different cultural backgrounds encode and decode scientific issues. An example of using the enthomethodological approach is translating scientific data, for example, into a language that is linguistically and culturally distant from the source tongue. Another approach – communication accommodation theory (CAT) – is a cross-disciplinary framework developed by Howard Giles to explain how adjustments in communication are created and how they influence communication flows and distance between discourse participants (e.g., Giles and Soliz 2014). CAT is applied in various disciplines and is used in different contexts to study the ways people change their behavior in communication. As far as learning science is concerned, the approach can be used to show how participants in scientific discourse adjust their linguistic tools to each of the level of interlocutors, type of audience, and topics in focus.

Memetics: A meme is a small element of cultural information. Memes may include, among others, words, concepts, songs, and fashion. Similarly to genes, memes are reduplicated in population (although while genes are reproduced biologically, memes are reproduced culturally). The power of this analogy is reflected in the development of memetics, a theory of an evolutionary model of cultural information transfer. Memetics is visible in the professional life of scientific academics. When a researcher learns an interesting concept himself or herself, he/she repeats the concept among colleagues and students (Dawkins 2006). Learning science can be perceived through the perspective of memes, for example, the introduction of scientific terms into standard languages. When individuals use terminology related to science on an everyday basis, the terms become elements of standard discourse. Memetics can also be used for discussing the translation of scientific texts. Some terms become very popular in the target audience, whereas the unpopular ones do not “infect” new users and die out after some time. Another reason for the rapid duplication of some scientific memes and the quick process of acquiring new terms is the growing role of technology in modern life.

Networks

Network theories are of increasing importance in modern science. The place of language in learning science can also be examined through the prism of grids and lattices. Actor-network theory (ANT) considers both living and nonliving entities, stressing their role in creating and sustaining the performance of a studied entity. For example, in the case of any organization, one may examine the importance of human actors (managers, employees, and customers or students) and nonhuman network participants (computers, faxes, telephones, or furniture) in creating and sustaining discourse. ANT studies have investigated how diversified participants, such as learners, teachers, and scientists, shape the way science is learned. This has been used in work on communities of practice. Since ANT focuses on semiotics as well as the relations between language and learning science, ANT studies also investigate the role of symbolic discourse in coding and decoding knowledge, including the role of metaphors (both verbal and pictorial) in transmitting scientific data.

Other network approaches can be used in investigating the relation between language and learning science. One example is social network analysis (SNA), an approach that views social relationships by analyzing nodes and ties between individuals. Focusing on the linguistic dimension of gaining new knowledge, the perspective of SNA offers the study how social relations shape scientific communication, especially in terms of learning science. One of the applications is to study the transfer of data in homophilous and heterophilous networks. Linguistic homophily can be perceived in terms of selecting similar expressions or communication styles, being often the result of similar background, professional experience, or social factors. On the other hand, heterogeneous social networks rely on using different linguistic codes in communication, represented, e.g., in the adoption of different names for the same notion depending on one's cultural or professional background. The types of linguistic networks have also implications for learning science. For example, homophilous linguistic networks facilitate learning science by relying on a common set of linguistic tools, in principle easily perceived and understood by all participants in knowledge exchange (poor learning outcomes can often be at least partly explained by a science learner not understanding the linguistic tools assumed to be common and understood by the teacher). Although heterogeneous linguistic networks may involve diversified communicative instruments and strategies employed in creating and disseminating science, this diversity can enhance one's interest in science by drawing one's attention to scientific issues presented in different ways.

Considerations of Learner Differences

Types of Learners: Individual characteristics of learners impact on how scientific communication should be adjusted, for example, which linguistic tools seem to be more effective in explaining science to the youngest audience, or how can one best tailor communication to facilitate understanding of new technology among the older generation. The identity of a learner is not fixed, and it is to a large extent context dependant. For example, a learner may be a teacher in some situations, and teachers are very commonly also learners. Thus, the way he/she communicates depends on the role played in a given social interaction.

Gender and Age: Another field of investigation may encompass how gender determines learning science. For example, genderlect styles theory by Deborah Tannen (e.g., Tannen 1996) focuses on differences in the ways men and women communicate. As far as learning science is concerned, researchers are interested how male and female scientists create information and later how the perception and acquisition of science depend on one's gender. In addition, methodologies are selected by taking into account the age of learners (e.g., teaching preschool children, students and learning, mature learners). Thus, the linguistic dimension of learning science is connected with examining how age determines the selection of linguistic repertoire and how the language dimension of science should be tailored to meet the possibilities and expectations of a studied age group.

Learner Identity: The way learners are viewed can be considered through the idea of "identity," a broad concept encompassing such dimensions as individual and professional identity. Individual identity includes issues such as mother tongue and family background, while professional identity includes issues such as professional background, specialized education. The "identity" of a learner can be studied through the perspective of language, thus leading to the concept of "learner linguistic identity." This has particular relevance in the present context by showing how one's identity determines the way science is perceived and acquired by linguistic tools.

Verbal Representations of Science

Lexical Perspective: The lexical dimension of learning science encompasses studies of how the selection of nouns, adjectives, verbs, and pronouns shapes the way individuals perceive and learn scientific concepts. The semantic dimension is characterized by differences in terminology used and the level of specialized terms applied in discourse. Terminology refers to the important aspects of coding and decoding knowledge; in order for scientific terms to be understood, terms should possess one meaning that denotes one scientific aspect.

Grammatical Perspective: A grammatical approach takes into account both morphological and syntactical issues. The link between learning science and morphology concentrates on studying how morphemes, the smallest element of meaning, determine the way science is shaped and understood. For example, the research may focus on the use of prefixes or suffixes in shaping scientific concepts. Syntactical implications for learning science are connected with showing how the principles governing sentences determine the way people perceive and understand science, including the use of tenses and their role in perceiving science. In addition, the use of conditionals shapes the probability of scientific events happening. Another important tool in shaping the attitude is the use of passive voice. Passive voice serves different functions in creating and understanding the language of science, for example, in stressing that the doer of the action is unknown (and thus irrelevant), in highlighting that it is difficult to assign the responsibility for a given action to one person, or perhaps in just focusing on the completed experiment or task rather than the action undertaken.

Nonverbal Representations of Science

Nonverbal representations encompass the use of pictures, drawings, and graphs, often to accompany the verbal form of scientific communication. These are often used to illustrate a given idea or to add additional information that cannot be explained adequately by using the verbal form exclusively. There are also symbolic tools used to disseminate scientific knowledge. An example is a pictorial (visual) metaphor that shapes the way science is perceived. Various linguistic tools are used to disseminate science among specialists and among laymen.

Channels of Communicating Science

Language and learning science can also be studied by taking into account the channels used for communicating science. Thus, language can be studied by observing language in offline and online communication as well as in differences in communication devoted to laymen and to professionals. For example, the language used in online communication is characterized by short forms, abbreviations, and an economical character as far as the selection of complicated linguistic repertoire is concerned. With the laymen-professional dichotomy, differences can be observed both at the semantic and syntactic levels. Complex syntax and compound terminologies often lead to misunderstanding and lack of interest among learners.

Language in Teacher Education

Marissa Rollnick
Marang Center for Research in Mathematics and Science Education, University of the Witwatersrand, Johannesburg, Gauteng, South Africa

Introduction

Language is central in science teacher education from several points of view: (i) the appropriate use of language strategies in teaching science which need to be modeled by teacher educators and (ii) the importance of language awareness of the preservice teachers themselves as teachers of language and science. Each is considered in detail below.

Language Strategies

At the most basic level, the choice of language strategies is connected to the realization of increasing diversity of linguistic backgrounds of learners in schools. In developed countries this is due to immigration from other countries, and in developing countries, the indigenous population are often learning through a language other than the one they speak at home. According to Yore and Treagust (2006), teachers have been compelled to help students navigate among three different languages – home language, instructional language, and science language. Most learners confront this problem when they move from either their primary language or nonstandard English at home to academic English science language in school. In doing this, preservice teachers need to consider the use of appropriate discourse when they explicitly teach students to talk, read, write, and do science. Once these language abilities are in place, they can be used to learn science content. Where teachers share a common language with their learners, code switching has proved to be a valuable resource for constructing meaning in multilingual classrooms as it offers additional possibilities for richer communication. Code switching is a term used to refer to changing language seamlessly while talking, often in mid-sentence. Although teachers hold differing views about code switching, it can offer an effective way to establish meaning in classrooms where the teacher and the students are able to communicate in the same language and is especially useful when either the learners' or teacher's English vocabulary is limited, making it difficult for them to reformulate ideas in the language of instruction. Code switching can facilitate the establishing of meaning by providing a linguistic and cultural bridge to understanding. Sometimes only a word or two is necessary to provide an English term where the word does not exist in the local language. Preservice teachers need to be alerted to the use of code switching in teaching and its function.

Language Awareness

Two theoretical perspectives have dominated research on language in science. Some researchers examine its use from a cognitivist perspective, while other researchers approach it from a sociolinguistic point of view, enriched by contributions from a situated cognition perspective. Historically, the focus of cognitive psychology has been on words and concepts in the text, while the focus of the situated cognition perspective has been on the discourse employed and its relationship to the learner's social situation. Gee's (2005) use of concepts of life world language and academic social language highlights the distinction between everyday language and the language of science. His emphasis is on the acquisition of academic social language by learners who use the language of learning and teaching as their main language. According to Gee, learners must be able to use academic social language, or they will not access the scientific community of practice. Various characteristics of scientific discourse distinguish it from everyday discourse. For example, a phrase like, "cold temperatures may result in death due to cell destruction by freezing or complete desiccation of plant tissue" can be translated into life world language as "plants will freeze to death in cold weather because their cells will dry out." Such a translation changes the focus such that it has changed from a process (the effect of the low temperatures on plant cells) to the effect on an object (the fate of the plants). Thus, for learners to acquire scientific discourse, texts need to use the language of scientists. Preservice teachers need to become aware that using language involves both accessing discourse and producing discourse, so listening and reading would require accessing discourse, while speaking and writing are the primary means of producing discourse. Teacher education and professional development involve the promotion and facilitation of inquiry science teaching and scientific language teaching among preservice and in-service teachers who have little personal experience in multilingual teaching environments, either as a learner of science or as a teacher of science. Thus, both preservice and in-service education require explicit language instruction. The challenge is to convince science teachers that language is an essential part of doing and teaching science. Activities promoting this view would involve integration of language issues and strategies into methodology courses rather than offering separate language courses. This process requires work on awareness as well as competence.

Large-Scale Assessment

Gabriela Noveanu
Curriculum, Institute for Educational Sciences,
Bucharest, Romania

Keywords

Large scale assessments; NAEP; PISA; TIMSS

Large-scale assessments are focused on entire education systems and lead to a better understanding of teaching and learning as well as the factors that contribute to constrain or promote achievement. Large-scale assessments provide a feedback to policy makers, researchers, and practitioners who are interested in enhancing educational quality being informed about structures and processes across the various level of education system that limit students' learning acquisition (Greaney and Kellaghan 2008). Their role consists in monitoring trends in achievement over time. The results of a national/international assessment can help identify the magnitude and the influence of various factors which can be handled to provide a better practice in the classroom and to an efficient distribution of resources. The data are usually collected by tests and questionnaires and refer to the students' achievement in the context of their home, classroom, and school environment. The process involves a sample of students of a particular age or grade level who answers multiple-choice and constructed response items.

Programme for International Student Assessment (PISA) is a cyclic internationally standardized assessment, launched by the Organization for Economic Co-operation and Development (OECD) and jointly developed by participating countries (OECD 2012). PISA is designed to collect information through 3 years assessments that allow trend analysis. These surveys are implemented in more than 40 countries and economies being typically administered to 4,500–10,000 students who are 15-year-olds and are enrolled in formal education. PISA aims to provide a new basis for policy dialogue and for collaboration in defining and implementing educational goals through insights into the background factors that influence the development of skills and attitudes necessary for adult life. PISA measures knowledge, skills, and attitudes that cover the domains of reading, mathematics, and science within an internationally agreed common assessment framework based on a dynamic model of lifelong learning. The term "literacy" is used to encapsulate this broader concept of knowledge and skills. PISA's content reflects moving beyond the school-based approach towards the use of knowledge in everyday tasks and challenges emphasizing on the mastery of processes, the understanding of concepts, and the ability to function in various situations. Test items are a mixture of multiple-choice and constructed response items and are organized in groups based on a passage, diagram, or table setting out a real-life situation. Students' outcomes are then associated with students' home background, their approaches to learning, their learning environments, and their familiarity with computers. Two-thirds of students across OECD countries scored between 400 and 600 points, so scales have an average score of 500 and a standard deviation of 100 for each domain. These scale scores represent degrees of proficiency in a particular domain. PISA 2000 defines five levels of proficiency in reading by dividing the literacy scale into five bands. PISA 2003 builds upon this approach by specifying six proficiency levels for the mathematics scale, while PISA 2006 specifies six proficiency levels for the science scale. The PISA provide three main types of outcomes: basic indicators illustrating a baseline profile of the knowledge and skills of 15-year-old students; contextual indicators showing the relationships between such skills and important demographic, social, economic, and educational variables; and indicators on trends revealing changes in outcome levels and their distributions and in relationships between student-level and school-level background variables and outcomes.

Trends in International Mathematics and Science Study (TIMSS) is an ongoing comparative study launched by the International Association for the Evaluation of Educational Achievement, (IEA) which is an independent, international cooperative of more than 60 national educational research institutions and governmental research agencies (Olson et al. 2008). TIMSS is a global endeavor directed by IEA's TIMSS and PIRLS International Study Center at Boston College and provides information about the educational context and achievement of students in a current cycle, while it measures trends from earlier cycles of TIMSS in 1995, 1999, 2003, 2007, etc. TIMSS aims to inform about learning outcomes and about the educational contexts in which students achieve these contributing to a deep understanding of educational processes within individual countries and within a broad international context. TIMSS reflects the latest advances in large-scale comparative assessments of mathematics and science. The assessment framework shows the structure of mathematics and science curricula and provides a tool for comparing and contrasting curricula from different countries. The assessment is administered to representative samples of students from the fourth grade to eighth grade of formal schooling, counting from the first year of primary school (ISCED 1). Each student is administered a single booklet, each one including two blocks of mathematics items and two blocks of science items assembled according to a rotated design and also a questionnaire asking questions about their home and school environments. The math and science teachers of the tested students respond about characteristics of the class, instructional activities, the topics covered during the lessons, and their education, training, and opportunities for professional development. The principals are asked about enrolment and school characteristics, school organization, staffing and resources, as well as the school environment. TIMSS reports on a wide range of topics and subject matters. The 30 different scales (overall achievement, content domains, and cognitive domains for the fourth and eighth grades) are designed to provide reliable measures of student achievement across the trend cycles of the TIMSS assessments. Reporting metric is established by setting the average of the mean scores of the participated countries to 500 and the standard deviation to 100. The achievement levels are established at four cut scores on the mathematics and science scales. TIMSS offer data that can be trusted for important decision making based on comparisons among countries.

National Assessment of Educational Progress (NAEP) is a project of the US Department of Education's National Center for Education Statistics (http://nces.ed.gov). It represents the largest nationally representative and ongoing assessment of America's students in mathematics, reading, science, writing, US history, geography, and the arts and civics for the 4th, 8th, and 12th grades. NAEP examines the relationships between students' performance and various factors. The content to be assessed captures a range of subject-specific knowledge and thinking skills needed by students. NAEP administers tests for different subjects (such as mathematics, science, and reading) in the same classroom, also measuring performance gaps which is done by adding more test questions at the upper and lower ends of the difficulty spectrum. It uses a set of cut scores on the scale that defines the lower boundaries of basic, proficient, and advanced levels. NAEP results are based on representative samples of students; therefore reported average scores and percentages are estimates for the entire population. This assessment provides results on subject-matter achievement, instructional experiences, and school environment for the populations of students and groups in public and private schools. The results are reported only when they are statistically significant and are intended to initiate dialogue among policy makers, educators, and the public.

Useful Controversies

The use of the term Latino/Latina – just like any other identity-related term – is crammed with controversy; and so it should be. The controversies associated with identity terms are in essence the force that urges us to seek better understanding and respect for the labels with which people choose to identify, as well as the community/communities within which they place themselves. This also holds true for the identity labels (and community associations) they choose to reject. Therefore, this entry does not to provide a neat definition that will dispel controversies, nor it provides a one-size-fits-all term. On the contrary, this entry adds to the richness of these useful controversies in hope that the insights shared here will inspire us to continue exploring identity labels and the meanings human beings attach to them and, by doing so, to come to truly recognize the boundaries that define our own sense of self.

Assigned Versus Appropriated Identity Terms

One place to start the discussion is by making a distinction between identity labels assigned by government agencies or others for the purpose of sorting, testing, placing, and categorizing groups of people vs. the labels that individuals choose to call themselves. The term *Latino* (male noun)/*Latina* (female noun) *or Latino/Latina for short* is particularly interesting because it has been appropriated by the peoples of Latin American countries to embody a sense of cultural pride, brotherhood, and sisterhood across the continent. Understandingly, some may disagree with this statement and the apparent oddity of grouping billions of people from the Americas (many of whom speak languages other than Spanish like French, Portuguese, Patois, and numerous indigenous languages and dialects) into such a broad category (Alcoff 2005). Nevertheless, there are common historical and cultural strands that bind Latinos/Latinas together as a distinguishable ethnic group. For example, I was born in Venezuela, and in this country every child undergoes a rigorous indoctrination into Venezuelan history and cultural pride. From elementary and all throughout high school, we are taught about the struggles of indigenous peoples, former slaves, and creoles to end 300 years of Spanish rule over Venezuela and the rest of the continent. There is much shared pride across Latin American countries that united to fight off the Spaniards in long and bloody liberation wars. From an early age, we are taught about the exploits of Simon Bolivar – a Venezuelan Creole born into wealth and who dedicated his life to liberate Venezuela, Colombia, Ecuador, Peru, Panama, and Bolivia (named after him) from Spanish colonialism. One of Bolivar's main ideals was to see a continent united, free from slavery and oppressive foreign rule. In fact, in 1826, Bolivar convened the Congress of Panama and invited all the leaders of the new American States in an effort to strike a treaty of mutual collaboration and defense against foreign powers. The Congress of Panama evolved several years later into what today is the Organization of American States – arguably, the most important inter-American organization in the continent (http://www.oas.org). This is just one of many potential examples of how a spirit of unity is deeply ingrained in the historical DNA of what it means to be a Latina/Latino. This is not to ignore the ongoing conflicts and resentment felt by many Latinas/Latinos as they see their countries' resources ravaged by more powerful continental neighbors, but that is another story for a different book.

To summarize, individuals who call themselves Latinos/Latinas invoke a sense of cultural pride and unity across the continent. This is not the sentiment, however, for many Latinos/Latinas who are designated as *Hispanic* by government agencies. In fact, many of us reject this neocolonial term, and this is the focus of the next section.

Hispanic Versus Latino/Latina

Elsewhere (Rodriguez 2004), it is mentioned that the term Hispanic is offensive to those who prefer to call themselves Latino/Latina as explained above. Generally found basic definitions of Hispanic are "of Spain" or "of Spanish descent." In our view, referring to Latinas/Latinos as Hispanic makes as much sense as calling people from the USA or from India *Britannic* just because they were born in a former colony of Great Britain. It is interesting to note that the USA is the only country in the world to categorize Latinos/Latinas and other individuals with Spanish surnames under the invented category of Hispanic. Indeed, the term Hispanic was appropriated by the US Office of Management and Budget (OMB), and in 1978 it released Directive No. 15 to categorize as Hispanic all individuals who were "of Mexican, Puerto Rican, Cuban, Central or South American or other Spanish culture or origin, regardless of race" (Office of Federal Management and Budget 1997). This directive sought to better monitor and control the increasingly growing population of "Hispanics" after the previously existing quotas for immigration of people from Central and South America and the Caribbean were eliminated in 1965 (Alcoff 2005).

The US Government promptly drew criticism from various scholarly and civil rights organizations since the OMB did not base its classification on existing scientific or anthropological scholarly work, nor did this agency provide clear distinctions between terms (such as, "race" vs. "origin," American Anthropological Association 1997). Another controversial component of Directive No. 15 was the decision to designate Hispanics as the only identifiable "ethnic group." In other words, the OBM required all government agencies to use four race categories, Black, White, Asian or Pacific Islander, and American Indian or Alaskan Native, as well as to use two ethnic categories, Hispanic or Not Hispanic. The rationale for classifying Hispanics as an ethnic category instead of a racial one was because Hispanics can be of any race (Idler 2007). It is very important to point out here that OBM – as well as many similar government agencies around the world – continue to misuse the biological concept of race when referring to human diversity, and what these agencies mean by "race" is the oversimplified and colonial sorting of people according mainly to their skin color. This issue is further developed below, but here it is possible to find common ground with the OBM in the use of the term Hispanic as an ethnic category instead of a racial one. Hispanics (Latinas/Latinos) are a very mixed ethnic group. In fact, a colonial term previously used to refer to Latinos/Latinas was *mestizo/mestiza* (meaning of mixed parents, i.e., European and indigenous parents, or indigenous and Black (slave) parents, or Black and European parents). Thus, a Latino/Latina may appear to be White (European) and a member of the predominant culture in Canada or the USA, yet this individual speaks only Spanish and is ethnically associated with the Latina/Latino culture. In any event, we Latinos/Latinas inherited our dark skin color from our ancestral parents (either the indigenous peoples of the Americas or African slaves or their descendants). Any other shades of skin color in between we owe to our ancestral European parents.

One would have thought that the OBM would have recognized the oddity of continuing to use a colonial system for classifying individuals according to skin color when they were forced to create a new category in order to monitor the population growth of Hispanics. Unfortunately, this was not the case, and the OBM responded to the criticism of its standards for the classification of people by mostly keeping the *status quo*. There were some changes adopted, however, as part of the revision process of Directive No. 15 that was culminated in 1997. Of relevance to this entry, OBM adopted the suggestion to change the term “Hispanic” to “Hispanic or Latino.” Furthermore, “Hispanic or Latino” or “not Hispanic or Latino” remained as the only two ethnic categories. The colonial emphasis of skin-color sorting was softened by changing “Black” to “Black or African American.” The term “White” remained unchanged.

Race Versus Ethnic Group

In the introduction to this entry, it was mentioned that controversies associated with the use of identity terms (either chosen by an individual or assigned by government agencies) are to be expected and in fact useful. However, we could leap forward in the conversation if government agencies were to use scientific research (both biological and anthropological) to provide arguments in support of selected terms to classify our rich human diversity. For instance, it would be useful to finally do away with the misuse of the biological concept of race. In other words, there is no such a thing as distinct races within humans as a species – we all belong to the same race or species – *Homo sapiens*. The minor variability in tones of skin, eye, and hair color and other physical features are not enough to – biologically speaking – differentiate us as distinct races. The misuse of the concept of race – based on superficial characteristics – for sorting, controlling, and discriminating purposes is a colonial leftover in our collective psyche and discourse, which consistently points out to the desperate need for more cross-cultural education in our schools. While racism does exist and persist, this is a social construct; race, on the other hand, is a biological construct based on scientific facts, and there is no excuse for its misuse by government agencies. A more appropriate term to classify (and to celebrate) human diversity in general is “ethnicity.” Ethnicity is defined here as an individual’s choice to associate with a group of people, or ethnic group(s), through common history, cultural practices, and language(s). It is important to stress the importance of an individual’s choice in identifying with an ethnic group because, for example, an individual’s country of origin may be China and that individual may have Asian features, but if that individual grew up in the USA exposed predominantly to Latino and Chinese cultural practices, then that individual may choose to call himself Latino Chinese. In our view, this designation says a lot more about whom that individual is than that person being forced to choose only the category of “Asian” or “Chinese” according to government agencies’ standards. One can easily appreciate the need to follow well-established and agreed-upon categories across agencies and schools for monitoring and research; however, it would be much more useful to document what ethnic group(s) individuals choose and the rationale for their choices. After all, what is the main purpose of a country’s census and of monitoring that country’s changes in population? To make individuals’ fit into convenient preselected (colonial) categories, or to gather meaningful data on individuals to serve their needs? Would it not be more scientifically accurate and informative to gather data on individuals’ own choices for ethnic group(s) association and to explore how trends in these associations change over time, as well as to seek understanding of how new ethnic group associations emerge?

Answering these types of questions will not only help us to better understand and appreciate why some individuals, for example, choose to call themselves Latino/Latina instead of Hispanic, but it will also help us to recognize and celebrate the continuing *mestizaje* (mixing) of our rich cultural and ethnic diversity.

Learning Cycle

Janet Carlson
Stanford Graduate School of Education,
Center to Support Excellence in Teaching,
Stanford, CA, USA

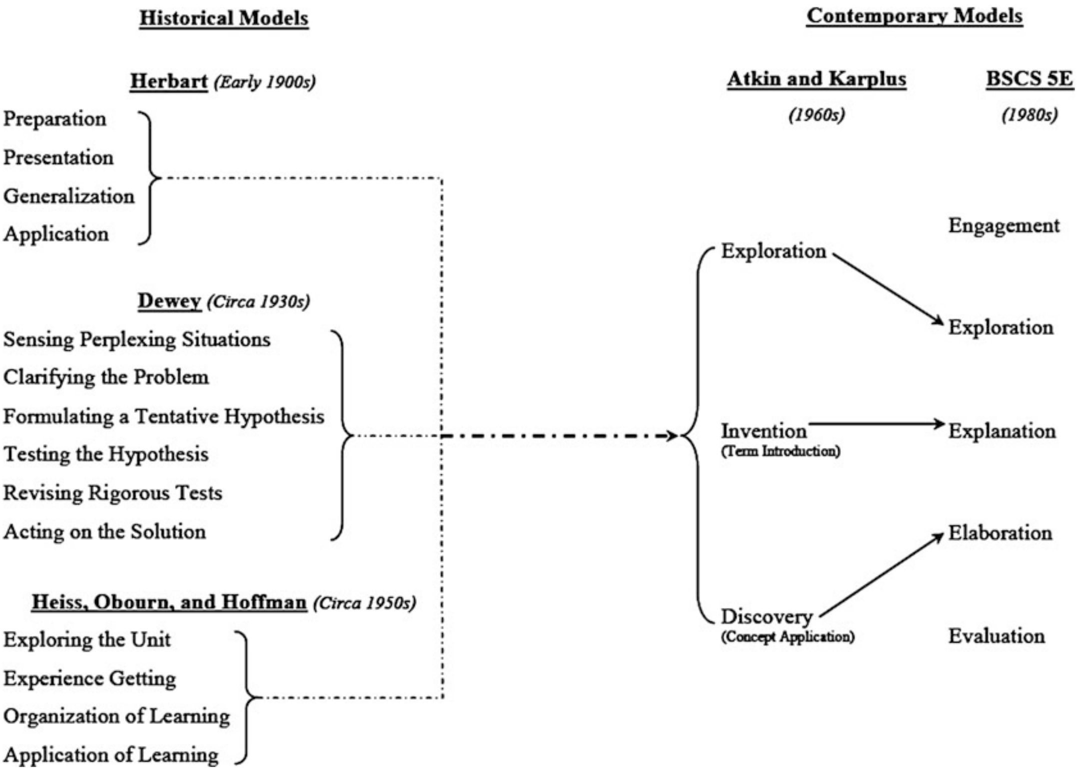
What is a Learning Cycle?

A learning cycle is a term given to describe a particular sequence of instructional emphases designed to promote conceptual understanding. The word "cycle" refers to the repetition of the emphases or phases of the instructional pattern each time a new concept is introduced. An idea related to learning cycle is the instructional model. An instructional model is another lens for considering learning. Rather than thinking in terms of what is happening directly in the learner's mind, an instructional model focuses on the actions taking place in a classroom or a sequence of written curriculum materials to promote a certain set of cognitive activities within the learner's brain to promote the understanding of a key concept.

History

Although the idea of learning cycles and instructional models is not new, their application and use has increased dramatically since the early 1990s. An historical review of this area shows that learning cycles were part of the discussion of educational reform in the United States as early as 1909. Both Johann Herbart and John Dewey wrote extensively about changing instruction by considering the learner's ideas early in the learning process. In 1950, a variation of John Dewey's instructional model emerged in textbooks on science methods for beginning teachers by Heiss, Obourn, and Hoffman. These authors labeled their idea as a "learning cycle" and based it on Dewey's idea of a "complete act of thought," i.e., that reflection must follow observations in order to form a deliberate and complete thought about the phenomenon observed. The work of all these writers strongly influenced the first era of major curriculum reform in science education in the United States in the 1960s. However, the idea of a systematic approach to instruction did not gain widespread acceptance until the development of the elementary project known as the Science Curriculum Improvement Study (SCIS), which incorporated the learning cycle developed by J. Myron Atkin and Robert Karplus. (See Fig. 1 for an overview of the relationship of these various approaches to learning cycles and instructional models).

Karplus began connecting the developmental psychology of Jean Piaget to the design of instructional materials and the teaching of



Learning Cycle, Fig. 1 Origins and development of instructional models

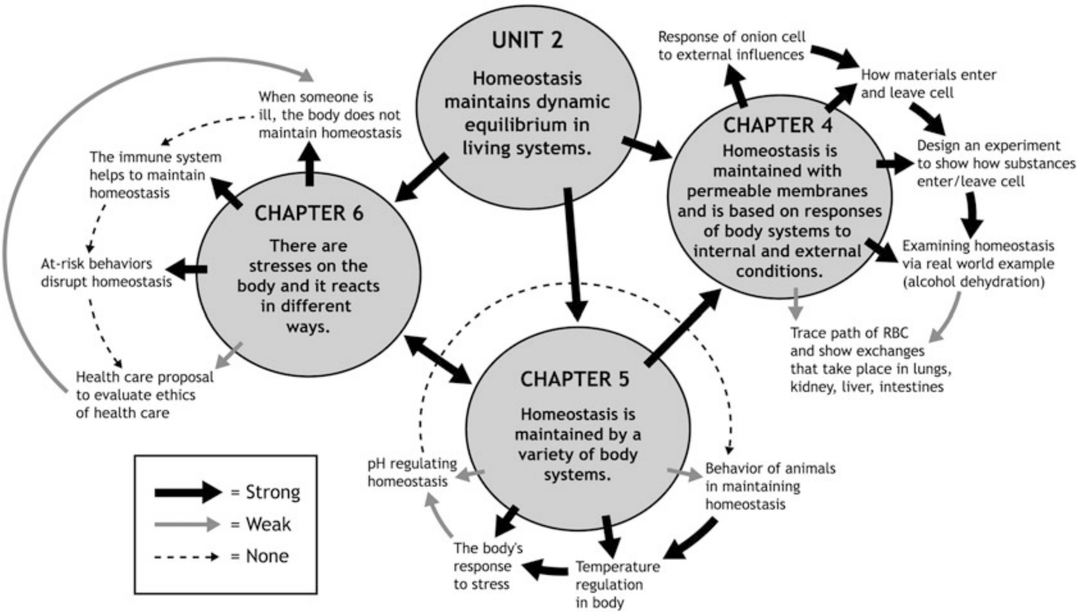
science. Atkin shared Karplus's ideas about teaching science to young children. Eventually, they collaborated on a model of *guided discovery* in instructional materials. Karplus continued refining his ideas and the instructional model as he tested different instructional materials and observed the responses of elementary children. By 1967, Karplus, in his work with Herbert Thier and the rest of the SCIS development team, used these ideas and observations to define the three phases and sequence of the SCIS learning cycle as *exploration*, *invention*, and *discovery*.

During the exploration phase, students have relatively unstructured experiences in which they gather new information about a particular science concept. Then students move to the invention phase in which they invent a formal statement about the concept. Following the exploration, the invention phase allows for the interpretation of newly acquired information through the restructuring of prior concepts. When students are in the discovery phase, they apply their understanding of the new concept to another novel situation. During this phase, the learner continues to develop a more sophisticated level of cognitive organization and attempts to transfer what he or she has learned to new situations.

Initially, the SCIS learning cycle used the terms *exploration*, *invention*, and *discovery* to identify the phases and sequence of the model. In the 1980s, Anton Lawson and others (Lawson 1995) modified the terms used for the learning cycle slightly, to *exploration, term introduction*, and *concept application*. Despite these changes in terminology, however, the key ideas informing what is expected of learners and teachers are essentially the same.

The BSCS 5E Instructional Model

The SCIS learning cycle was the foundation for the 5E Instructional Model that the Biological Sciences Curriculum Study (BSCS) developed,



Learning Cycle, Fig. 2 An example of concepts and science ideas within a curriculum unit

which is probably the most popular version of the learning cycle used in the United States. It is also used in England, Singapore, and regions of China where Teachers Without Borders works. BSCS developed the 5E Instructional Model in the mid-1980s during work supported by a grant from IBM to conduct a design study that would produce specifications for a new science and health program for elementary schools.

In its earliest documentation, the BSCS model had five phases identified by the nouns: *engagement, exploration, explanation, elaboration, and evaluation*. This model was intentionally built from the foundation of the SCIS learning cycle and the earlier models.

Today, the 5Es of the BSCS model are more often known by their verbs: engage, explore, explain, elaborate, and evaluate. This shift came about as the curriculum developers and professional development providers continued to emphasize the role of the student in the learning process, which is driven by this instructional model.

For the language of the BSCS 5E Instructional Model to make sense, it helps to know how BSCS uses terms such as "concept," "topic," and "scientific idea." BSCS refers to a "concept" as complete sentence that describes a relationship among ideas. For example, "homeostasis" is not a concept when stated alone, just a scientific idea without context. For a learning experience, the idea needs to be articulated in the context of other ideas such as this: "Homeostasis is the set of processes that maintain dynamic equilibrium within living systems." Figure 2 is an example of how concepts and ideas are articulated within a curriculum unit and supported by learning experiences. This visual may be useful for understanding how words such as "concept," "topic," and "idea" are used in descriptions of the BSCS 5E Instructional Model.

Table 1 provides a summary of each phase of the BSCS 5Es and a description of the type of classroom activity that supports each phase. It is important to note that the primary function of this instructional model, as with other instructional models based on learning cycles, is to help students develop an understanding of key concepts and ideas such as those in Fig. 1. While BSCS applies the instructional model to the learning of science, the model can be applied to other disciplines to help teachers consider how to structure their instruction to support the learning of key ideas or concepts.

Learning Cycle, Table 1 The BSCS 5E Instructional Model

Essence of phase	The student experience facilitated by teachers and/or curriculum materials will emphasize the following types of mental engagement
Engage	
Mental engagement in a key concept	Students consider a question that directly aligns with the major concept
	Students are encouraged to articulate their current thinking about the scientific idea
	Students are reminded that their ideas may change, grow, expand, or develop
	The classroom culture is developed in a way to support students so they are ready to revisit their ideas once they have examined more evidence
Explore	
Opportunity for inquiry experiences that provide a common experience for all learners in the classroom so later they can contribute to the development of an explanation	Students make predictions or pose a question about a specific phenomenon related to a major scientific concept
	Students collect and use their own data (or data from others) associated with the major scientific concept
	Students are challenged to think critically about the data (e.g., quality and quantity)
	Students begin to make sense of the data
	Students are challenged to consider their current thinking in light of their earlier thinking, which may include posing questions or looking for inconsistencies
Explain	
Students construct scientific explanations	Students have multiple opportunities to connect their ideas and classroom experiences (including those from the previous engage and explore lessons) to make sense of new information
	Students have experiences that offer opportunities for them to examine currently accepted scientific ideas and compare those to their own ideas so that they construct and/or revise their own explanations from evidence
	Students' thinking is challenged by teacher and peers, especially those whose ideas are not aligned with current scientific thinking, including opportunities for students to revisit their preliminary thinking in light of new information provided in the readings or class discussions
Elaborate	
Students have the opportunity to transfer understandings to new contexts. Students may begin to make abstractions or generalizations pertaining to the major concept of the unit	Students consider another scientific question related to the major concept. The question should be an opportunity for students to expand their understanding into deeper or broader contexts
	Students use data associated with the question
	Students think critically about the data (e.g., quality and quantity) with more sophistication because they are using their new information and experiences
	Students use their new knowledge to make sense of the data
	Students expand their understanding by constructing or revising an explanation based on their new experiences and what they have learned previously, especially in the explore and explain lessons
Evaluate	
Both teachers and students have opportunities to assess understanding	Students demonstrate their current understandings and abilities associated with the major concept of the unit
	Include components for self, peer, and teacher evaluation

Effectiveness

The research on learning cycles, including the BSCS 5E Instructional Model, does not tell a single story (Bybee et al. 2006). One general finding across 30 years of research in elementary through college settings is that students who learn using instructional materials based on a learning cycle learn about the same with respect to traditional academic content knowledge as their counterparts who learn the same content via more traditional instruction dominated by lectures in which information is transmitted and lab experiences in which students follow very specific directions to verify an expected or known outcome. While the research results regarding the effectiveness of learning cycle and instructional model approaches in general are mixed, there are also numerous studies that show better academic gains for students who were taught using a learning cycle approach and no studies where students in learning cycle settings do worse than those in traditional settings. What is particularly significant is that students learning from a learning cycle approach typically show better results than students learning from more traditional instruction as regards the persistence of learning, as measured by delayed posttests of students' understanding of science concepts. This means that students who learned via a learning cycle approach did not just learn the key words or labels of science, but understood the relationships among topics and ideas and that understanding was persistent. Similarly, the research shows more positive attitudes and better understanding of the nature of science and scientific inquiry among students in classes where a learning cycle approach is used compared with those results among students in classes where a traditional approach is used (Wilson et al. 2010).

Learning Demand

John Leach
Centre for Education and Inclusion Research,
Sheffield Hallam University, Sheffield, UK

Definition and Origins

Learning demand is a tool to characterize the nature of differences between the conceptual scientific content to be taught in a sequence of science lessons and the likely knowledge of students of a given age and prior instructional experience at the start of teaching.

Since Piaget's pioneering work, it has been known that people (and particularly children and adolescents) explain natural phenomena in predictable ways that are often at odds with accepted scientific explanations. Between the 1970s and 1990s, a significant amount of research was conducted to document, characterize, and theorize young people's explanations of natural phenomena explained by concepts in school science curricula. This work also showed the ways in which young people's characteristic ways of thinking influenced the outcomes of school science teaching. By the mid-1990s emphasis in the research community had moved away from the documentation of young people's explanations as an end in itself towards the design of science teaching. By the early part of the new millennium, an increasing number of studies were appearing which explicitly addressed the design and evaluation of science teaching sequences and learning environments. For a fuller account of the development of the literature on the design of teaching for conceptual understanding in science, see the entry on "▶ Evidence-Informed Practice in Science Education."

John Leach and Phil Scott (University of Leeds, UK) developed the notion of learning demand in 1995, as set out in Leach and Scott (2002). The initial stimulus for the work was comparing characterizations of the explanations of young people aged 5–16 about selected ecological concepts with the explanations demanded by the school curriculum. The focus quickly moved towards developing a tool to inform their work on designing and evaluating teaching sequences about specific scientific content at a fine-grain size. A social constructivist perspective on science learning informed their work. Following Bakhtin, school science was assumed to be a social language in itself. Science learners were assumed to have an "everyday" social language through which the phenomena and events of science lessons were understood. This "everyday" social language is often contradictory to the social language of school science. Furthermore, as students are exposed to the social language of school science, their "everyday" social language develops – though not necessarily into the social language of school science that is the target of the curriculum.

Learning demand compares the social language intended to be developed by students at the end of a given teaching sequence and the social language that the students characteristically use at the beginning of instruction. The purpose of identifying learning demands is to bring into sharper focus the intellectual challenges facing learners as they address a particular aspect of school science. Learning demands contrast the conceptual tools (including the ontology on which the conceptual tools are based) and the epistemological underpinnings of the social languages of school science, with the social language of students prior to instruction.

The identification of learning demands is illustrated through the example of introducing English students (aged 11–13) to a model of energy transfer via an electric current, where current is conserved and energy is transferred in resistive parts of the circuit. The social language of school science was identified from official curriculum documents as being built upon conceptualizations such as:

- Current as a flow of charge
- Current as the means of energy transfer
- Current as being conserved
- The supply of energy as originating in the electrical cell
- Energy being transferred in resistive elements of the circuit

These conceptualizations rest on ontological assumptions about the nature of current, charge, and energy. Studies of the research literature on young peoples' characteristic explanations, however, suggest that their social language is likely to include conceptualizations and ontology which contrast with the social language of school science, such as:

- Batteries run out
- Electricity makes things work
- Current, electricity, volts, and power are the same kind of thing
- Electricity/electric current flows

In addition, the scientific social language is based upon epistemological assumptions such as the need for one explanatory model to explain all electric circuits, whereas the research literature suggests that 11- to 13-year-old students may not assume that this is the case.

Use of Learning Demand as a Design Tool

In 2009, Ruthven and colleagues defined the purpose of design tools as coordinating and contextualizing theoretical insights on the epistemological and cognitive dimensions of a knowledge domain for the particular purposes of designing teaching sequences and studying their operation at a fine-grain size. Learning demand is one design tool used to illustrate the argument; others include a didactical situation and didactical variables (Brousseau), knowledge distance and modeling relations (Tiberghien and colleagues), and communicative approach (Eduardo Mortimer and Phil Scott). Design tools are defined as being theoretically embedded in intermediate theoretical frameworks (such as, in the case of learning demand, social constructivism) and grand theories (such as, in the case of learning demand, sociocultural accounts of meaning-making as proposed by Vygotsky, Bakhtin, and Wertsch).

Examples of Use

The concept of learning demand has been used by researchers and doctoral students at the University of Leeds over a number of years in the design and evaluation of teaching sequences in various conceptual areas. In 2006 Leach, Scott, and colleagues reported on three case studies where an analysis of learning demands was drawn upon explicitly to inform the design, implementation, and evaluation of three teaching sequences for lower secondary school students in England. For two of the three case studies, there is clear evidence that after teaching students were better able to “speak the social language of school science” than comparable peers who had followed their school’s usual teaching approach.

Ph.D. studies which have drawn upon the notion of learning demand in the design and evaluation of teaching have been carried out in the following conceptual areas and countries:

Chemical kinetics (Turkey; Uganda)
Differentiating physical and chemical change by the use of a simple particle model of matter (Saudi Arabia)
Plant nutrition (Saudi Arabia)
Electrochemistry (Malaysia)
Energy (Cyprus)

In each case, there is evidence that students following the designed teaching sequence perform significantly better in post-teaching tests than comparable peers who follow the school’s usual teaching approach.

Learning Environment Instruments

David Zandvliet
Simon Fraser University, Vancouver, Canada

Keywords

Classroom environment; Student perceptions

Research and evaluation within the context of science education traditionally relies on assessment of academic achievement and other valued learning outcomes. However, these educational measures do not give a complete view of students’ educational experience. In particular, students’ perceptions of their school experience are also significant. Researchers have made considerable progress over the past 40 years in both conceptualizing and assessing determinants of the psychosocial learning environment in classrooms and schools (see Fraser 2012). This has in turn led to development and validation of a variety of robust instruments that measure the learning environment in a range of contexts. Early learning environment instruments include the Learning Environment Inventory (LEI) developed by Herbert Walberg (1979) and the Classroom Environment Scale developed by Rudolf Moos (1979).

Using students’ perceptions to describe educational contexts is at the core of what learning environments research does. However, other approaches to studying educational environments can involve naturalistic inquiry, ethnography, case study, or interpretive methods. Defining classroom environment in terms of the shared perceptions of students has the advantage of characterizing the setting through the eyes of the participants themselves and for capturing data which a researcher might otherwise miss or consider unimportant. Students can be said to possess a unique vantage point for making evaluative comments about classrooms as they have typically experienced different learning environments and spend enough time in a class to form accurate impressions. What follows is a sample of instruments that have been developed and validated for specific learning contexts.

Sample Instruments

This section describes a small subset of instruments that study unique learning environment perspectives in order to give the reader a flavor of the diversity of studies possible in this growing field of inquiry.

Questionnaire on Teacher Interaction (QTI)

The QTI was developed from research begun in the Netherlands focusing on the nature and quality of interpersonal relationships between teachers and students. Drawing upon a theoretical model of proximity (cooperation-opposition) and influence (dominance-submission), the instrument assesses student perceptions of eight aspects of teacher behavior using items with a five-point response scale ranging from never to always. Typical items are as follows: “She/he gives us a lot of free time” (student responsibility and freedom) and “She/he gets angry” (admonishing behavior).

Science Laboratory Environment Inventory (SLEI)

Because of the uniqueness of laboratory settings in science, an instrument suited to assessing the environment of science laboratory classes was developed. The SLEI has five scales (each with seven items) and a five-point Likert-type response scale. Typical items are “I use the theory from my regular science class sessions during laboratory activities” (integration) and “We know the results that we are supposed to get before we commence a laboratory activity” (open-endedness). The SLEI was initially field tested and validated with a sample of over 5,447 students in 269 classes in six different countries (the USA, Canada, England, Israel, Australia, and Nigeria), then later cross-validated with classes in Singapore and Australia.

Constructivist Learning Environment Survey (CLES)

In the constructivist view, meaningful learning is a cognitive process in which individuals make sense of the world in relation to the knowledge they have previously constructed, and so, the sense-making process involves active negotiation and consensus building. The CLES was developed to assist researchers and teachers to assess the degree to which a classroom learning environment is consistent with this constructivist epistemology and to assist teachers to reflect on their assumptions about knowledge and to reshape their teaching practice.

What Is Happening in This Class (WIHIC) Questionnaire

The WIHIC questionnaire added some continuity to the field of learning environment research by combining modified versions of the most salient scales from a wide range of preexisting questionnaires with additional scales added which addressed some emerging and contemporary educational concerns (e.g., equity). The WIHIC has a class form (which assesses a student’s perceptions of the class as a whole) and personal form (which assesses a student’s personal perceptions of his/her role in a classroom). The final form of the WIHIC contains seven (eight-item) scales and has been used extensively in its original or modified form in studies worldwide (Fraser 2012).

Place-Based Learning and Constructivist Environment Survey (PLACES)

The Place-Based and Constructivist Environment Survey (PLACES) is an example of a recent questionnaire. It was created in order to assist in the description of environmental education settings and was developed in two stages. First, a pilot study was conducted by adapting scales from established inventories such as the WIHIC and SLEI and others such as the Science Outdoor Learning Environment Instrument (SOLEI). A total of eight scales were referenced. After this exploratory work, a more robust instrument for use in place-based environmental education settings was developed, including such unique factors such as environmental interaction or community involvement.

Conclusion

The brief descriptions provided here for selected learning environments give only a flavor of the breadth of learning environment instruments that have been created for research across a wide variety of settings. Although the study of learning environments has its roots in science education, its conceptual framework provides for an important and often overlooked perspective on the educational experience. As such, new instruments are also available for studies in contexts such as ICT-rich environments and sustainability related education practices.

Learning in Play-Based Environments

Jennifer Sumsion
School of Teacher Education, Charles Sturt University, Bathurst, NSW, Australia

Introduction

Understandings about learning in play-based early years' education contexts (for children aged from 6 weeks to 8 years) have become increasingly diverse and complex in recent years. Many early years' learning and curriculum frameworks developed in countries around the world over the last decade or so reflect a shift away from *developmentally appropriate practice* that closely linked children's learning capacities to their developmental "stage" and advocated child-centered approaches that primarily involved teachers responding to children's self-initiated interests and self-directed play. Especially in predominantly European-heritage countries, play is still considered essential to children's learning. However, conceptualizations of play, and views about the extent to which, and ways in which, teachers should engage in children's play vary widely. The following discussion identifies some new understandings about learning in play-based contexts and flags some associated debates.

Very Young Children Actively Engage in Learning in Play-Based Contexts

A growing body of contemporary research in naturalistic contexts shows that babies and toddlers (aged up to 2 years) actively participate in early years' settings in much more sophisticated ways than was often previously realized. Much of this research (e.g., Berthelsen et al. 2009) illustrates the babies' and toddlers' interest in developing relationships with peers and adults and the wide range of strategies they use to do so. Their learning is relational in that it occurs within relationships. Very young children, like their older counterparts, learn by actively participating in their social and cultural worlds (Berthelsen et al. 2009). These worlds provide many opportunities for babies and toddlers, in their day-to-day lives, to encounter, engage with, and learn about aspects of literacy, mathematics, and science and about other social, cultural, and physical phenomena that typically fall within the scope of curricula.

Curriculum and learning frameworks are increasingly inclusive of babies and toddlers. They raise a range of issues about very young children's learning (as opposed to the more traditional focus on their development) in early years' settings that require further investigation. Research in naturalistic settings also highlights babies' and toddlers' capacities to take the initiative, to engage purposefully in learning, and to sustain intense concentration for long periods. Increasing recognition of the sophistication of babies' and toddlers' learning has generated debate about terminology, such as the term "infant education and care." The importance of positive and caring relationships for babies' and toddlers' learning is not disputed. Rather, debate focuses on whether the term education adequately reflects and encompasses caring relationships. Conversely, does the stand-alone use of the term "care" do justice to the complexity of babies' and toddlers' learning and sufficiently convey educators' responsibilities for fostering that learning in play-based contexts?

The Importance of Teacher Involvement in Play-Based Learning

Powerful evidence of the importance of active teacher involvement in children's play-based learning has been provided by the influential UK study, the *Effective Provision of Preschool Education* (EPPE) (1997–2003), and later extended to the *Effective Pre-School and Primary Education 3–11* (EPPE 3–11) Project (1997–2008) (http://eppe.ioe.ac.uk/) and the related study *Researching Effective Pedagogy in the Early Years* (1997–2003) (https://www.education.gov.uk/publications/eOrderingDownload/RR356.pdf). These studies generated the term "sustained shared thinking," which refers to at least two people working together in ways that require them to draw on their intellectual resources – for example, to solve problems, clarify concepts, evaluate activities, and extend narratives. Each person engages with the thinking of the other participants to co-construct new understandings. Crucially, all participants are involved in extending thinking and developing new understandings (Siraj-Blatchford 2009). These landmark studies have prompted many subsequent rich accounts of sustained shared thinking in early years' settings that illustrate joint involvement of children and adults and children and their peers in child- and adult-initiated play-based learning.

Drawing on the work of Russian psychologist Lev Vygotsky, Fleer (2010) provides another, complementary, way of theorizing the pedagogical role of play in concept formation. She proposes the term conceptual play to refer to the play that assists children to develop scientific or other academic concepts. Fleer suggests that the teacher's role is to analyze children's play and to discern key moments in the development of their understandings. The teacher can then seize the opportunity to frame the play activity conceptually in ways that encourage children to think about the concept.

Fleer (2010) made the point that simply providing opportunities for children to play with a range of interesting materials and objects is unlikely to lead to scientific learning. In illustration, she described a group of preschool children playing with colored water and plastic tubes, funnels, containers, and bottles with pump dispensers. The teacher anticipated that playing with these materials and objects would enable the children to develop scientific understandings (e.g., about the density of substances and how they mix). The children, however, developed a play script that involved making medicine to treat a "Humpty Dumpty" soft toy that repeatedly fell from a wall. While they used materials and objects provided by the teacher, their play did not lead to conceptual learning. The teacher did not participate in the children's play and was not concerned about what some would see as a lost opportunity for learning. Rather, she valued their imaginative play. Fleer speculates about what learning may have happened had the teacher intervened in the children's play script. For example, the teacher could have commented that as Humpty Dumpty kept falling off the wall, the medicine was clearly not working and suggested that the children experiment by mixing substances to create a range of different medicines. Fleer's vignette provides a glimpse into the ongoing debates about different types of play, their respective contributions to children's learning, and the degree to which is it appropriate that choices about play are negotiated between children and adults (Wood 2010).

Play-Based Learning Can Exclude Some Children

A different set of concerns and debates about learning in play-based contexts focuses on claims that play can easily be romanticized or seen as unequivocally beneficial. But as Wood (2010) and Grieshaber and McArdle (2010) argue, along with many other critical and post developmentalist theorists, play can both mask and highlight complex power relations, for example, in children's interactions that lead to some children being routinely excluded on the basis of gender, ethnicity, social class, sexuality, ability/disability, or any other kind of difference. Play-based settings can also inadvertently exclude for children from cultures where play is not particularly valued as a vehicle for learning. Uncritical acceptance of long established, unquestioned assumptions about play can therefore have profound implications for the efficacy of play-based learning contexts for different children. Differential access to participation in play, in turn, can have profound social justice implications.

On the other hand, play dynamics can provide a valuable context for involving children in discussions of diversity, difference, inclusion, exclusion, and social justice. In doing so, they can pave the way for building more inclusive play-based learning environments and creating more equitable learning opportunities.

Conclusion

In summary, learning in play-based contexts raises complex issues that require ongoing consideration. Play-based environments are not a panacea. They present many potential pitfalls but if these are reflexively, creatively, and respectfully negotiated, they can be rich with possibilities for learning.

Learning of Science – A Socio-Cultural Perspective

Cory Buxton
Faculty of Educational Theory and Practice,
College of Education, University of Georgia,
Athens, GA, USA

Keywords

Cognitive; Cross-cultural; Discourse; Diversity; Identity; Learning; Place-based; Sociopolitical

The study of science learning from sociocultural perspectives has largely focused on the question of how students from culturally, socioeconomically, and linguistically diverse backgrounds can all be engaged in science learning in ways that allow students to make personal connections between their own lived experiences and core science content and practices. Researchers have addressed this question using a range of theoretical perspectives, including a cognitively based perspective, a cross-cultural perspective, a sociopolitical perspective, and other emergent perspectives. Proponents of these varied perspectives share the belief that connecting students' cultural and linguistic experiences to the practices of science is central to students' science learning; however, the specific approaches proposed to best achieve this goal differ.

Proponents of a cognitively based perspective have done research grounded in cognitive science that often focuses on students' scientific reasoning and classroom argumentation (e.g., Warren et al. 2001). These scholars have generally argued that students' ways of knowing and talking can be viewed as continuous with scientific practices and that if teachers identify and incorporate students' cultural and linguistic experiences as intellectual resources for science learning, then students will come to view themselves as successful science learners and members of a science learning community.

Proponents of a cross-cultural perspective have done research grounded in multicultural literature that often focuses on students' cultural norms, beliefs, and practices. These scholars have generally argued that students who lack sufficient background in the scientific "culture of power" (e.g., Western modern science) may possess cultural beliefs and practices that are discontinuous in some ways with scientific practices and school science norms (e.g., Lee et al. 2007). This research often proposes that teachers make the norms of school science explicit and help students learn to cross cultural borders between home and school while aiding students in maintaining their cultural and linguistic identities.

Proponents of a sociopolitical perspective have done research grounded in critical theory that often focuses on power relations. These scholars have generally argued that science itself can and should be reconceptualized to better incorporate the worldviews of people from marginalized groups (e.g., Calabrese Barton 2001). Findings from this work include the value of science learning that builds trusting relationships between teachers and students so that students come to see their teachers as allies in a struggle against oppression rather than as part of an oppressive system. In this way, more students come to engage in science in socially transformative ways.

Other emergent sociocultural perspectives on science learning include a focus on science learner identities (Carlone and Johnson 2007), the role of third (or hybrid) spaces in science learning (Calabrese Barton et al. 2008), and place-based approaches to science learning (Buxton 2010).

What Are Learning Progressions?

Children come to school with powerful ways of making sense of the world around them. Their ways of reasoning work in familiar situations; however, this naïve reasoning is often not scientifically accurate and may not hold up when students encounter phenomena that their reasoning schemes cannot explain. A central goal of K-12 science education throughout the world is to support students in moving from their initial ways of reasoning about the world to more coherent scientific reasoning that fuses science practices, crosscutting concepts, and disciplinary core ideas that hold broad explanatory power (e.g., National Research Council 2011). However, even after over a decade of formal science education, many students leave high school still using their initial sense-making schemes to explain the natural world.

Developmental psychology, sociocultural theory, science education, and other domains provide rich insights into how students learn and why they may not develop coherent scientific explanations about the natural world. However, until recently it was rare for these domains to inform one another. In addition, again until recently, these research studies have largely not influenced science education policy, commercial curricula, or large-scale assessments. This may be in part because many research studies are limited in duration and scope. Studies in science education often focus on student learning in a single unit with no connections across years or disciplinary core ideas; many developmental psychology studies are done in laboratory contexts without a classroom instructional component, thus making the findings difficult to apply to school settings; and sociocultural studies often have limited sample sizes and are focused on specific groups of students, making generalization difficult. Thus, there is a need for frameworks that can merge the findings from multiple domains to build a more powerful and coherent understanding of how students learn in the long term. Learning progressions provide this structure.

Learning progressions, in their current form, have developed rapidly over the last 15 years (primarily through research and development in the USA). Learning progressions bring together research findings from these different domains (e.g., developmental psychology, science education, psychometrics) and fuse them to build a more coherent structure for understanding how students learn. Learning progressions have been defined as, "descriptions of the successively more sophisticated ways of thinking about a topic that can follow one another as children learn about and investigate a topic over a broad span of time (e.g., 6–8 years). They are crucially dependent on instructional practices if they are to occur" (NRC 2007, p. 214).

Learning progressions do not represent just a scope and sequence of topics to be learned or facts to be added to students' repertoires. Rather, learning progressions represent a hypothetical framework that (a) links the ideas that students bring to school (at lower levels of a learning progression) with the socio-scientific ideas that students need from schooling to be knowledgeable citizens (at the upper level of a learning progression) and (b) illustrates pathways and of increasing sophistication in student reasoning about disciplinary core ideas (the middle levels of the learning progression).

Design and Essential Features of Learning Progressions

Through incorporating both a top-down (the structure of the discipline) and bottom-up (what we know about how students learn) design process, learning progressions combine ideas from multiple disciplines to provide a coherent framework for describing the development of students' knowledge and practice (Alonzo and Gotwals 2012). Learning progressions prioritize disciplinary core ideas and practices that are generative and worth focusing on for extended periods of time. As part of the top-down design of learning progressions, scientists and science educators identify disciplinary core ideas, crosscutting concepts, and science practices based on the knowledge needed for understanding socio-scientific issues and promoting scientific literacy. What separates learning progressions from other frameworks is that they also prioritize how students learn these disciplinary core ideas, crosscutting concepts, and science practices. A logical decomposition of the core ideas by scientists may not necessarily represent the paths that students take as they learn the content. Thus, learning progressions also include a bottom-up process based on empirical studies of students' sense-making processes and the nature of students' thinking as they develop more sophisticated understandings.

While learning progressions may differ on some aspects, most current research on learning progressions use similar frameworks and essential components to describe learning progressions. Corcoran et al. (2009) identify five essential components of learning progressions: (1) learning targets or end points, (2) progress variables, (3) levels of achievement, (4) learning performances, and (5) assessments.

Learning targets or end points, also known as upper anchors, are based on knowledge needed to participate in society in a scientifically literate way. These learning targets result from a deliberative process that includes (a) an understanding of the core disciplinary ideas, (b) social aspirations for citizens of a just and technologically sophisticated society, and (c) science education research that produces empirical evidence about the intellectual resources that students bring and the ways that they respond to appropriate instruction.

Progress variables identify the aspects of disciplinary core ideas, crosscutting patterns, and science practices that are present in some form at all levels of achievement, so that their development can be traced across levels. The development of progress variables is an iterative process (i.e., employing both a top-down and bottom-up process); they are derived partly from theories about how knowledge and practice are organized and partly from empirical research on student reasoning.

Levels of achievement are patterns in learners' disciplinary core ideas, crosscutting concepts, and science practices that extend across progress variables. This is a key part of the learning progression hypothesis – students' performances for different progress variables will be aligned in predictable ways. As with progress variables, the development of levels of achievement is iterative; they are based partly on research about what constitutes higher and lower levels of performance and partly on data about students' actual performances. It is mainly in the levels of achievement where the bottom-up approach to learning progressions is important because learning progressions do not impose normative models of understanding science on student learning. Using the bottom-up approach helps define the middle or intermediate levels of the learning progression.

Research shows that students' intuitive ideas about the natural world can sometimes be barriers to more sophisticated understandings. However, learning progressions also search for some of the intermediate ideas students have that may be productive stepping-stones on the way to scientific understanding. These intermediate stepping-stones may not resemble the scientifically correct idea in that they are either a gross simplification (e.g., genetic information specifies the structure of proteins) or even scientifically inaccurate (e.g., equating weight with mass), but may be conceptually productive steps in the process of moving from naïve ideas to more sophisticated scientific reasoning (Duncan and Rivet 2013). Students' naïve ideas, then, are not just seen as misconceptions that need to be replaced, but are recognized as students' ways of making sense of the world around them and bases for further learning. Thus, these ideas can be used as leverage points to engage students with the scientific ideas and to help students restructure and reorganize their intuitive ideas into scientific theories.

Learning performances are the specific practices characteristic of students who are at a particular level of achievement and reasoning about a particular progress variable. Describing specific learning performances is at the core of the learning progressions hypothesis: the learning performances should provide specific predictions about student reasoning and student learning that can be tested empirically. Thus, it is through learning performances that we can link the learning progression framework to empirical data from assessments and teaching experiments, enabling us to test the learning progression hypothesis.

Assessments provide tasks that allow students to reveal their reasoning about the progress variables in the learning progression. Initially, researchers attempt to match student responses to the framework and use these responses to provide information to iteratively refine the levels of achievement (or even the whole progress variable) defined in the learning progression. Once the learning progression has validity evidence underlying it, student responses can be used to place students at particular achievement levels, which can provide stakeholders with information about these students' understandings.

While learning progressions often lay out levels of increasing sophistication of students' abilities to use disciplinary core ideas and scientific practices, this does not imply that students' learning necessarily follows a linear path. Rather learning progression levels represent patterns in students' ideas as they become more sophisticated. By providing this framework that lays out students' ideas that range from naïve to more sophisticated, learning progressions illustrate the range of ideas students may have around disciplinary core ideas, crosscutting concepts, and science practices. These frameworks, then, can guide the development of standards, assessment, instruction, and professional development.

The Role of Instruction

Researchers agree that students will not move up a learning progression without instruction and that traditional instruction may not allow students to reach the desired upper-level understandings (learning targets) for meaningful engagement with socio-scientific ideas and practices. However, the role of instruction in defining a learning progression varies among research projects. In some projects, learning progressions are designed to illustrate what is possible for students to achieve with specific instructional experiences. In these learning progressions, researchers document how experiences allow students to engage with the disciplinary core ideas and crosscutting concepts through scientific practices and how these experiences shape learning such that students can develop more sophisticated understandings. The curricula, then, become part of the argument for the validity of the learning progression in that researchers can document that, with specific instructional experiences, students are able to reach more sophisticated reasoning and move to higher levels in a learning progression. Researchers can examine the pathways that students take as they develop more sophisticated understanding after engagement with the curricula, and this can inform how the intermediate or middle levels of the learning progression are defined.

Other learning progression researchers do not tie their learning progressions to specific curricula or instructional strategies. Rather, they begin with the implicit ideas that students bring to school and the upper levels or socio-scientific ideas we aim to have students achieve. The initial research tends to be cross sectional in examining how students reason at different levels across grade bands. These cross-sectional patterns in student responses, then, become part of the argument for the validity of the learning progression. Researchers then can design instructional experiences to help students move up the learning progression, documenting the progression that students take on their way to more sophisticated understandings.

The learning progression hypothesis suggests that although the development of scientific knowledge is culturally embedded and not developmentally inevitable, there are patterns in the development of students' knowledge and practice that are both conceptually coherent and empirically verifiable. Through an iterative process of design-based research, moving back and forth between the development of frameworks and empirical studies of students' reasoning and learning, we can develop research-based resources that can describe those patterns in ways that are applicable to the tasks of improving standards, curricula, and assessments.

Using Learning Progressions for Multiple Purposes

While there are certain similarities for all learning progressions (e.g., including the five essential components and beginning with students' ideas and moving toward more sophisticated and integrated understandings), there are certain choices that developers of learning progressions make in the design process. Many of these decisions are based on the purpose of the learning progression. Two important applications of learning progression research are (a) standards and large-scale assessment and (b) classroom learning and formative assessment.

Standards and Large-Scale Assessment

Past standards documents in the USA have included too many topics and separated "science processes" or inquiry from content. Although some standards sequenced the topics (e.g., AAAS Atlases), these sequences were based mainly on a disaggregation of disciplinary ideas, rather than on understandings of how students learn. The National Research Council's Framework for K-12 Science Education (2011) and the USA's Next Generation of Science Standards (NGSS) seek to use learning progression research as the basis for coherent progressions of knowledge and practice across the K-12 range. A top priority of NGSS was to provide coherent grade-band end point learning progressions such that students build deeper knowledge over time. The incomplete development of learning progression research meant that these aspirations were realized better for some topics than for others.

In order to inform standards such as NGSS and large-scale assessments based on these standards, learning progressions must describe how disciplinary core ideas, crosscutting concepts, and science practices develop over long time frames (e.g., multiple years or even K-12). Since learning progressions that can inform standards need to emphasize larger themes and patterns in how students learn these ideas, they tend to have a larger grain size, meaning that they do not include as much detail about student understanding at particular points in time. In addition, the differences among levels of achievement will likely be large, capturing major shifts in worldview or reconceptualization of key ideas.

The role of incorrect or incomplete stepping-stone levels for standards is controversial. Many would argue that there is not a place for inaccurate ideas in standards documents; rather these end-of-grade-band intermediate levels should represent conceptually accurate, but less sophisticated understandings of disciplinary core ideas that build to the upper anchor end point at the end of schooling. Thus, there is often a tension between the empirical results of learning progression research (which can show the value of noncanonical knowledge and practices as stepping-stones) and the general expectation that the contents of standards documents and large-scale assessments should be scientifically accurate.

Classroom Learning and Formative Assessment

Similar tensions can arise in classroom contexts where teachers should recognize productive (but inaccurate) stepping-stone ideas, but may still expect scientific accuracy in summative assessments. There are also differences in "grain size" between learning progressions that support standards development and learning progressions that are useful for classroom learning. Large learning progressions that stretch over grade bands are necessary to ensure coherence across K-12 education and to provide a vision for supporting students to achieving upper-level understandings. However, these broad learning progressions may not be as useful for classroom teachers as they think about responding to specific student ideas that arise in a classroom discussion or in embedded assessments, and they may not provide the support for designing activities for day-to-day or week-to-week use.

Thus, smaller, more focused, learning progressions may be helpful for developing classroom-level curricula and formative assessment. These more focused learning progressions will cover less information and the difference between levels of achievement will be smaller – identifying smaller changes in students' conceptual networks rather than large-scale restructuring. In order to ensure coherence with the larger learning progressions, these learning progressions should use the larger learning progressions in order to specify grade-band end points as their upper levels and zoom in to examine the nuances in learning to identify the middle levels or stepping-stones. Unlike learning progressions for standards, the intermediate levels for these smaller learning progressions may include the inaccurate, but productive, ideas that help students move toward upper-level understanding.

There has been significant work on learning progressions for shorter time frames that has implications for curricula and formative assessment. Researchers have used these learning progressions to develop curricula to build on students' intuitive ideas and provide structured activities that help students engage with the disciplinary core ideas through science practices. These learning progressions provide the structure for sequencing learning opportunities such that students work with specific phenomena that build more sophisticated understandings.

Learning progressions are also valuable for classroom formative assessment. By providing a model that portrays students' ideas as ranging from less to more sophisticated rather than as right/wrong, learning progressions can illustrate the range of student ideas and potential approaches to moving students forward. Since teachers often struggle to identify the range of ideas that students bring to the classroom, learning progressions can provide a structure to help teachers anticipate students' ideas and plan for how to work with these ideas. In addition, when these learning progressions are coupled with other educative tools, the learning progressions can provide a scaffold for teachers for how to provide feedback to students based on where they are on a given learning progression and can help identify ways to modify their instruction to support students in moving to upper-level understandings.

The Potential of Learning Progressions

Learning progressions of the form discussed in this entry were originally proposed as a way to bridge the gap between research and large-scale standards, curricula, and assessment programs. Because developers and researchers work under different design constraints, connections between them have rarely happened. Standards, curricula, and large-scale assessment programs need frameworks that describe learning in broad domains over long periods of time. Researchers, on the other hand, are required to develop knowledge claims that are theoretically coherent and empirically grounded. In general researchers have been able to achieve theoretical coherence and empirical grounding only for studies of learning over relatively short time spans (usually a year or less) in narrow subject-matter domains. So, faced with a confusing welter of small-scale and short-term studies, most developers have understandably based their frameworks primarily on logic and on the experience of the developers rather than empirical studies.

Current work on learning progressions has been motivated by optimism that we may be ready to bridge the gap – to develop larger-scale frameworks that meet research-based standards for theoretical and empirical validation. As such, learning progression work suggests worthwhile modifications to current procedures for developing standards and large-scale assessments. A conceptually coherent framework is an important step as the first draft of a learning progression. When researchers and developers use that framework to develop assessments and teaching experiments, and then use the results of those assessments and teaching experiments to revise the framework, we are on our way to empirically based models that can guide practice in new and more powerful ways.

Smaller grain size learning progressions can also support classroom learning and formative assessment. When they are linked to larger-scale learning progressions, they can support teachers' ambitious teaching and subsequent student learning toward important socio-scientific ideas.

Introduction

"Learning progressions" in science is generally defined based on the statements written at *Taking Science to School*: *Learning and Teaching Science in Grades K-8* (National Research Council [NRC] 2007) and subsequently at *Learning Progressions in Science*: *An Evidence-Based Approach to Reform* (Corcoran et al. 2009). Synthetic definition about learning progressions (hereafter LPs) addressed in common at the two reports is:

- Descriptions of the successively more sophisticated ways of thinking about and using core scientific concepts and practices
- Empirically grounded and testable hypotheses about children's learning pathways with appropriate instructional practices
- Learning pathways that children can follow one another over a broad span of time

Since the above formal addressing, there have been many studies on LPs, and at the same time, various perspectives on LPs itself and approaches to developing LPs have appeared among researchers. Thus, when we meet diverse studies related to LPs, we need to ask questions about the criteria that help to judge which LP studies are more complete and less flawed than others.

The criteria for assessment of LPs can be derived from each sentence of the definition of LPs. The first sentence allows us to assess LPs in terms of what and how LPs describe. This criterion includes selecting the topic of LPs, setting up the lower and upper anchors, and organizing the intermediate steps of LPs. The second sentence of the above definition of LPs provides two more criteria for assessing LPs: one is how to refine and validate LPs with appropriate assessment tools and measurement model and the other is how to connect instructional practices with learners' development in LPs. The last sentence of the definition of LPs gives us a criterion, how to decide the grain size of LPs.

Before looking ahead detailed discussion about assessing LPs, it would be helpful for readers to understand the above four criteria when being compared with the seven questions proposed by Duschl et al. (2011) for guiding and understanding LP research.

1. How and on what grounds have the researchers arrived at the selection of the core idea for the LPs?
2. What, if any, connections are there between the knowledge domain topic and science practices?
3. How have the researchers established the lower anchor and the accessibility of the starting point/place for the LPs?
4. How have the researchers established the upper anchor and the abstractness of the ending point/place for the LPs?
5. How, if at all, do the targeted instructional pathways/sequences serve to mediate children's learning toward the upper anchor?
6. How, if at all, do the researchers refine the LPs?
7. What, if any, alignments exist between curriculum, instruction, and assessment?

Learning progressions are generally grounded in iterative assessments that generate the evidence of children's learning pathways. Therefore, more appropriate and of high-quality LPs should show validated evidence of learning pathways as well as clear and exact assessment processes. In the next sections, it is discussed what and how LPs describe in terms of core ideas of LPs, lower anchor, intermediate steps, and upper anchor of LPs. Then an exemplary way of validation and refinement of LPs is introduced. Finally, description about the grain size of LPs and concluding remarks will follow.

Quality and Appropriateness of Learning Progressions

According to Duschl et al.'s (2011) findings, the topics in many LP studies were usually selected from and set by reviewing already established disciplinary sequences or standards and curriculum documents. Additionally, in many cases even if not all of LPs, science contents and science practices are not integrated with each other as a focused topic of LPs. The intent and goal of LPs, however, are to facilitate learners to achieve increasing levels of sophistication with using science knowledge in doing cognitive, epistemic, and social practices of science. Thus in order for more complete and less flawed LPs, the identification of foundational knowledge as a core idea of LPs needs to be clearly described. Foundational knowledge is a specific knowledge to assist and advance learning pathways of reasoning and understanding. For example, an LP for evolutionary thinking (Lehrer and Schabuble 2012) identified the foundational knowledge of change, variation, and ecosystems and conjoined using the knowledge with the practices of representation and modeling.

Lower anchor is the beginning point of an LP that represents the concept and reasoning children bring with them to school. Upper anchor is the ending point of an LP that represents societal expectations or values about what society wants children to understand at the end of LPs. Lower anchors in many LPs used to be macroscopic events or children's folk and naïve accounts related to their everyday experiences. This kind of lower anchors is easily observable, measurable, and accessible to lower-grade learners. In other cases, however, the lower anchors of LPs, which are based on curriculum documents and start at a higher grade, not kindergarten or elementary levels, are often to be at a more complex place or level. The latter cases have challenges regarding what extent children feel at ease to the lower anchors. Thus for being more complete

LPs, lower anchors should be more accessible to learners at the beginning point.

The upper anchors, in contrast, give rise to the issue of abstractness which is about the extent of complexity of targeted learning goals. Upper anchors show various forms depending on the targeted ending grade of the LPs. In one case, upper anchors tend to target college readiness. In other cases, upper anchors show the levels of knowledge and practices based on curriculum/standards documents or indicate early grades' learning goals based on scientists' own canonical conceptions. If a learning goal of LP is too sophisticated, then the upper anchor becomes too abstract or is beyond the boundaries of outcome learning expectations for children to achieve such lofty abstract goals. Thus, stronger and more complete LPs have to pay more attention to whether the upper anchor seeks for highly abstracted and scientifically accurate concepts or pursues obtainable societal expectancy for a scientifically literate citizenship.

With regard to identifying learners' developmental pathways, intermediate steps of LPs, sometimes called stepping stones, play a significant role of bridging between lower anchor and upper anchor with appropriate instructional interventions. While much of current LP research describes learning pathways based on well-grounded assessment, the instructional practices that facilitate successively increased sophistication of learning are not clearly discussed. Most of LPs, if not all, gave high emphasis on elaborating children's misconceptions in describing intermediate steps based more on assessments, less on instructional interventions. Intermediate steps in those LPs are intended to validate the initial sequences of learning and often reflect the ways by which they fix children's misconceptions and set them aligned with targeted canonical understanding. Duschl et al. (2011) referred to this perspective as *misconception-based fix-it view*, which is a prevalent characteristic of *validation LPs*. On the contrary the intermediate steps of some other kind of LPs, even though in a few cases (e.g., Lehrer and Schabuble 2012), are elicited from the results of instructional interventions employed in the LP research. The lower anchors and intermediate steps in these LPs are regarded as productive intuitions for understanding the upper anchor concepts, not as misconceptions. Thus, these LPs show practical examples of instruction-assisted development in which instructional interventions mediate learners' development working with their intuitional conceptions and practices. Duschl et al. (2011) also referred to this perspective as *intuition-based work-with-it view*, which is a feature of *evolutionary LPs*. More details about validation LPs and evolutionary LPs are discussed at the concluding remarks.

Validation and Refinement of Learning Progressions

Development of LPs can be regarded as design a road map to create coherent, comprehensive, and continuous assessment systems that are interrelated with both curriculum and instruction. Berkeley Evaluation and Assessment Research (BEAR) assessment system is regarded as one of the quite suited methodological approaches to making the road maps of learning progressions, because it provides a comprehensive means for designing, evaluating, and using an assessment. BEAR assessment system also has much contributed to obtaining evidence to test, revise, and validate given hypothetical LPs with its four principles and four building blocks. Below a detailed discussion on the BEAR assessment system is addressed.

The first principle of BEAR assessment system, *developmental perspective*, is to assess the development or growth of children's understanding of particular concepts and practices over a longer period of time. This principle is operationalized by *construct map*, which is the first building block of BEAR assessment system. A construct refers to understanding of a concept or engaging in a practice that forms a substantial step in the process toward a learning goal. Thus, the construct shows a form of extension from one extreme of high quality to the other of low quality, that is, a *construct map*. In this continuum of extension of a construct, there are two aspects of construct map, a respondent construct map and a task response construct map. The former is related to where a respondent for an assessment task is located across the continuum. The latter is to show where the item responses to the tasks are located. In many LPs, the construct maps have shown only the task responses. BEAR assessment system, however, recommends depicting both respondents and task responses into one construct map. As an outset of designing LPs, construct maps can serve not only as a framework for designing assessment task items but also as a methodological base for applying a measurement model to the assessment.

The second principle of BEAR assessment system is *match between instruction and assessment*, which means the design of assessment task items should be integrated with classroom instruction. This principle is embodied by the second building block, *task item design*. There has been a variety of different types of assessment task items for describing learning pathways of LPs, e.g., ordered multiple-choice items, asking open-ended written responses, or clinical interviews. Whatever the type of task items, BEAR assessment system recommends that designing assessment items be matched to the construct maps. For example, each of the answer options in an ordered multiple-choice item is aligned with the developmental levels of children understanding described in a task response construct map. Likewise, children responses from open-ended questions or clinical interviews are coded into categories consistent with the levels of a construct map. The other and more significant consideration is the degree of match between instruction and assessment during the process of LP development. In spite of emphasis on instruction in BEAR assessment system, there is very few LP applying instructional practices to designing assessment items. Black et al. (2011) suggest a good way to align instruction and assessment, which is to develop teaching material and assessment task items at the same time. They also recommend the assessment tasks to be embedded into classroom activities as formative assessment. Considering instructional practices in developing LPs is a crucial element for more complete and less flawed LPs.

The third principle of BEAR assessment system is *teachers' management of assessments*, in which a teacher makes consistent scoring and interpretation of children's responses to an assessment. This principle is represented by the third building block, *outcome spaces*. Outcome spaces are meant by scoring guides for children responses to assessment task items. The scoring guides are in some cases (e.g., multiple-choice items) simply to assign numeric scores to each response to assessment items but in other cases (e.g., open-ended questions or clinical interviews) are to provide annotated examples for coding and categorizing children responses. In order to get a sound LP, it is very important to obtain the validity and reliability of outcome spaces.

The fourth but the most important principle of BEAR assessment system is *evidence of high quality*, which is to ensure comparability of consistent measure with various assessment tools across time and context. This principle is actualized through the fourth building block, *measurement model*. The measurement model connects scored or coded responses with the particular locations of a construct map, so that science educators or teachers can make inferences about children's learning and development. BEAR assessment system employs *Wright maps* from Rasch model as a measurement model to interpret outcome spaces of an assessment and link them with a construct map. Rasch model is a kind of one-parameter logistic model of item response theory, which estimates the probabilities of respondent proficiencies to solve assessment items compared with item difficulties. Figure 1 is a Wright map of the author's study of learning progression for water cycling with ordered multiple-choice items. The numbers arranged vertically at the leftmost of Wright map are marked out in logit (log odds unit) scale, which determine the relationship of the construct to the probability of response. On the left side of Wright map, "x" stands for two children who have specific proficiency level at its point. On the right

Learning Progressions, Assessment of, Fig. 1 An example of Wright map (Reproduced with permission of the Korean Association for Science Education) side of the map, each answer option of the ordered multiple-choice items is located according to its difficulty. According to the location of each item in the Wright map, four conceptual levels among item options are differentiated. In doing so, a conjectural learning progression for water cycling could be elucidated.

Four building blocks described so far make an iterative cycle when they are applied to developing LPs. Therefore, the measurement model and its product should be employed again to revise the initial construct map, and the whole processes of developing LPs rotate again.

Grain Size and Time Spans of Learning Progressions

Learning progressions are defined as hypothetical pathways that children can follow one another over a broad span of time. Therefore, learning pathways of LPs consist of several levels with relevant time spans. The grain size of LPs refers to the amount of knowledge, skills, and ability included in each level, so that LP researchers can propose assessment items to elicit children understanding and classify children into specific levels based on the contents of each level. The grain size of LPs is also related to the distance between the levels, that is, the extent of attainment required to progress from one level to the next upper level (Alonzo and Gotwals 2012). Consequently, LPs with broader and longer time spans (e.g., K to 6 or K to 8) usually have a larger grain size than the shorter time-spanned LPs (e.g., a weeklong instructional unit). LPs with fine-grain size focus on specific and narrow conception or practice (e.g., sinking and floating), require assessment items related to a specific phenomenon in one context, and can distinguish minute differences of children's learning performances with much more detailed information used in diagnostic assessment. By contrast, coarse-grained LPs show increased amount of knowledge and practices along the more sophisticated levels, represent a greater accomplishment for moving from lower level to higher level, and require assessment items about different phenomena to characterize children thinking across contexts. The amount of contents in each level and the aspects of progress to be captured between the levels vary depending on the purposes of LPs. Thus, the grain size of LPs is to be decided by the use of LPs whether large-scale assessments, standards framework, or for a teacher's instructional units. For more complete and less flawed LPs, the balance between setting the amount of knowledge or practices in each level and capturing key differences to distinguish children's performances should be properly maintained. This balance can be achieved by iterative LP research design and empirical testing that refine the levels of LPs.

Concluding Remarks

To be a meaningful learning progression, it is very important to capture children thinking or practicing and its development accurately. An exact assessment and reliable interpretation of outcomes from the assessment provide critical information for revising and validating the learning pathways of LPs. The quality and appropriateness of LPs can be achieved by selecting foundational knowledge as a core idea of LPs, maintaining appropriate accessibility of lower anchor and abstractness of upper anchor, and applying instruction-assisted development to the description of intermediate steps. Four building blocks with underlying principles of BEAR assessment system are a useful and strong way for validating and refining a LP based on the perspective of construct map.

Duschl et al. (2011) marked out two types of LPs, validation LPs and evolutionary LPs. *Validation LPs* are to confirm or validate preliminary established teaching and learning sequences with assessment tools. Instructional interventions in validation LPs are designed to revise the original learning sequences adopting misconception-based fix-it view of conceptual change model. Thus validation LPs are regarded as top-down and theory-driven LPs. *Evolutionary LPs*, on the contrary, typically begin with pilot assessments to explore and identify successive patterns in children's understanding of concepts and practices. Delineating a construct map based on the successive patterns is a way to obtain evidence of evolutionary development of children learning. Evolutionary LPs also establish a conjectural pathway of learning based on the consequences of instructional experiments across multigrades adopting intuition-based work-with-it view of conceptual change model. Thus, evolutionary LPs are regarded as bottom-up and evidence-driven LPs. Duschl et al. (2011) argued that only the evolutionary LPs can articulate plausible incremental learning pathways with instruction-assisted development and can be complete, at least near complete, and appropriate LPs.

Learning for Life

A growing body of evidence supports the assertion that learning occurs in settings and situations outside of school, as well as across time and a variety of settings (Falk and Dierking 2010). This increased appreciation of free-choice/informal learning is affording learners increasing choice and control and is a worldwide phenomenon. Although this type of learning has traditionally been referred to as informal learning, Falk and Dierking coined the term free-choice learning almost 20 years ago to capture the core idea behind this paradigm shift – a recognition that people not only learn every day throughout their lives but that learning is, first and foremost, a learner-centered, not an institution-centered, phenomenon. Free-choice learning is guided by a person's needs and interests and is nonlinear, self-directed learning. People engage in free-choice learning throughout their lives to find out more about what is useful, compelling, or just plain interesting to them.

Science learning is an important part of this educational shift. People engage in science learning every day and across their life spans – at home, at work, and while out in the community; much of this learning is free choice. In a typical day, for example, a person might surf the Internet in a library to track down information about arthritis, attend an amateur astronomy club meeting, watch a nature documentary on television, or interact with exhibitions on robotics at the local science center. All represent free-choice learning experiences, the most common type of learning in which we engage throughout our lives. The senior citizen who has been an avid bird watcher across his/her lifetime, keeping a life list of birds, going on trips focused on bird watching, reading as many books and magazines as possible, as well as watching documentaries on birds, is also an example of a lifelong free-choice science learner.

A recent study by the National Research Council on learning science in informal environments (Bell et al. 2009) reinforces the abundant evidence that free-choice learning activities, even everyday experiences such as a walk in the park, contribute to people's knowledge and interest in science. For example, adults visit settings such as national parks, science centers, and botanical gardens to satisfy their intellectual curiosity as well as to fulfill a need for relaxation, enjoyment, and even spiritual fulfillment (Falk 2006). Adults take their children to these settings because they feel such experiences are worthwhile, educational, and fun and that they and their children learn about science in the process.

Adults also encourage their children to participate in a wide variety of after-school and extracurricular experiences, including scouting and summer camp experiences, many of which also support free-choice science learning (e.g., McCreedy and Dierking 2013). Adults and children also learn while engaged in personal investigations, through civic organizations and active leisure pursuits. Similar motivations and findings can be ascribed to watching science-related television, using the Internet to access science-related information, and engaging in science-related hobbies and special interest groups such as birding, gardening, and hiking.

This paradigm shift suggests that to effectively understand science learning, one must situate it within the context of lifelong learning. The most important aspect of this perspective is that science learning is viewed as a natural and fairly common result of living within a science-rich world, an activity and outcome of everyday life. Over the course of a lifetime, a person constructs his/her understanding of the world by connecting and building upon experiences they have in school, at work, and in informal/free-choice learning settings and configurations. This cumulative process not only involves learning facts and concepts, though important, but also includes changes in interest, awareness, skills, behavior, attitudes, beliefs, habits of mind, and feelings and emotions (Bell et al. 2009). Such learning may result because the learner was "primed and ready" for transformation through previous experiences or because unique experiences are so powerful that significant changes result.

Although free-choice learning significantly contributes to what is learned in an individual's lifetime, currently it represents a fraction of the learning research literature. Exacerbating this situation, the research is scattered across many disciplines and subdisciplines, with few efforts to consolidate, situate, and synthesize it within an overall framework. Fortunately, a growing body of research is providing evidence for such learning. If one looks at basic and applied research, what is revealed are three, essentially independent lines of investigations, which evolved during the last quarter of the twentieth century: (1) how people learn in out-of-school institutional settings like museums and libraries; (2) how people learn through media-mediated experiences (e.g., television, gaming, Internet); and (3) how people learn through nonformal learning, particularly as it occurs in unstructured/cultural contexts.

Institutional Settings

Museums One of the first settings in which free-choice learning was seriously investigated was the museum. For example, in the 1930s, Arthur Melton, under the direction of Yale professor Edward Robinson, conducted two landmark studies of behavior and learning in art museum settings. Then, as today, these psychologists viewed museums as useful laboratories for studying learning – free-choice yet structured environments. With the notable exception of the groundbreaking book, Unobtrusive Measures in 1966, which utilized a number of examples from nonschool institutional settings, it was nearly

40 years before additional serious research was conducted in these settings.

Beginning in the mid-1970s and building momentum through the 1980s, a series of investigations were conducted on learning in institutional free-choice settings; many of these were doctoral dissertations. By the 1990s and into the 2000s, research on learning in these venues had become commonplace, particularly in science museums. There were important studies over the last 15 years, some again dissertations, including multiyear studies of family learning in science museums and ethnographic research on the role of museums in supporting family's long-term learning, the investigation of children's science concept development in a children's museum, the impacts of school field trips to museums and of visits to zoos and aquariums on visitors' and staff members' understanding of conservation, as well as investigations into identity and the long-term impact of visits (Falk and Dierking 2013).

Another avenue in which free-choice learning has been observed is through community-based institutions/organizations such as Boys & Girls Clubs, scouts, YMCAs/YWCAs, etc. Most often these efforts focus on families, youth, and children living in poor urban or rural communities; many are recent immigrants for whom the mainstream language is not their first. Most of these learning opportunities involve in-depth programming in the community in which participants live, however often complemented by programming within a cultural institution such as a museum. Research suggests that these efforts are extremely effective when integrated with trusted community-based organizations that share a common goal of supporting families, youth, and communities. Much of the research has focused again on science, finding that after participating, families and youth better understand processes of science and its importance, develop enriched conceptual understanding and a stronger sense of science's role in their daily lives, and appreciate that science is not about "getting the right answer" but wondering, asking questions, and experimenting. Two common outcomes for programs with museum components include an increase in museum interest and/or attendance, at least in the short term, and positive changes in participants' perceptions of museums. These programs also help participants understand that museum programs offer fun and comfortable ways to share quality time together. Since many programs focus on families, outcomes for adults are also observed; for example, they include increased parental awareness and involvement in their children's (and their own) learning, as well as a better understanding that learning is not just for children but for them also and that learning together as a family can be enjoyable and rewarding.

Although efforts also often try to engage families in other kinds of free-choice learning outside the program, these impacts are much less commonly observed. Community events may encourage active participation, but it is difficult to encourage parents to continue activities with children at home. Participants do identify a main benefit as "expanded horizons" or "exposure to culture." The evidence that is available suggests that families engage in learning experiences that build on the program, including related conversations at home and family visits to other similar places. There is still insufficient data to determine whether impacts from these efforts are lasting. For instance, in programs encouraging museum use, it remains to be seen whether use continues once the program ends.

Libraries These societal trends are also directly influencing libraries, and as with museums, staff and researchers are attempting to better understand library users. Most libraries know "why" the public uses them, appreciating that they have long been viewed as beneficial to children and considered to be safe and educational places. In fact, a recent report concluded that libraries positively contribute to youth development. Over two-thirds of parents say they take their children to the library, and a common reason adults say they visit is for their children. Early experiences with visiting libraries may be a factor in adult library use, as is the case in other free-choice learning environments such as museums and zoos.

Adults alone or visiting with children primarily visit libraries to borrow books and use reference materials, much of this science focused. Accordingly, libraries have worked extremely hard to understand how to meet their users' resource needs. Many libraries strive to enhance the public's information literacy, and considerable research has been conducted on how libraries can best respond to the wide range of information needs of the public. This research has been used to assist users in more effectively accessing the information they seek; however, there have only been a few efforts to assess the impact of public libraries and to understand how access to library resources directly influences users' learning needs, generally, and their science learning needs more specifically.

Researchers have found that people feel libraries contribute to their quality of life as a source of educational (98 %) and cultural (84 %) enrichment and entertainment (87 %) and are important because they are free (48 %). In a 2001 Institute of Museum and Library Services (IMLS)-funded impact study, Counting on Results (http://www.lrs.org/documents/cor/manual2.pdf), over 5,000 library users in 20 states completed mail-in questionnaires related to various service categories – basic literacy, business, and career information, library as a community hub, and so on. Over half of those responding (56 %) said they used the library for self-directed learning; however, the methodology did not allow researchers to probe this aspect of library use in any depth. Other studies have assessed library programs' outcomes and impacts on participants, but the focus of the studies was primarily on the impact that established library programs, such as adult literacy programs and homework help, had on the individual and did not specifically probe impacts of self-directed learning activities.

An environmental scan conducted by the Online Computer Library Center (OCLC; http://www.oclc.org/en-AU/reports/escan.html) in 2003 suggested that libraries are poised to reassert themselves as core lifelong learning institutions by capitalizing on their primary assets as "trusted" and "safe" gateways to information. The scan also identified three characteristics that those who use libraries desire: self-service, seamlessness, and satisfaction. The study suggested that an important step in this transition is to redefine the library as an active hub of personalized, free-choice learning, shifting from being dispensers of information, to becoming facilitators of the personal learning journeys of their users. To do so effectively, though, libraries must better understand the public's perceptions of their institutions and how they are used (or not used) for lifelong, free-choice science learning.

A 2007 study explored whether a more personalized approach to serving library users is a useful framework for the library community (Falk et al. 2007). Findings revealed seven common identity-related library user motivations that are similar to Falk's identity-related visitor motivations for museums. This study recommended the development of a set of "bundled" offerings and strategies enabling libraries to meet the identity-related needs of a wide variety of users, including frequent, occasional, and infrequent users. As recent research in museums has shown, most visitors rarely explicitly share their needs or even can fully articulate them; arguably the same is true for library users. Also, museum research has demonstrated that although visitors familiar with museums may be able to seek out a specific resource, those less familiar often are unaware of the broad range of offerings available, making them functionally nonexistent. These research findings reinforced this; even frequent library users mentioned offerings that they wished the library had that were in fact, available. If savvy library users are unaware of possible offerings, one can only imagine that new audiences, such as newly arrived immigrants and other underserved groups who may not have historically used libraries as resources, might also be unaware.

Media

The early days of research on media were dominated by studies of television, in particular related to issues such as media preferences, health (e.g., impact of television viewing on vision), and social concerns (e.g., impact of television on violence and consumer behaviors). By and large these topics dominated research in this area for decades. However, starting in the late 1970s/early 1980s, a number of investigators, in particular those studying Children's Television Workshop Sesame Street programs, began a series of comprehensive investigations into the impact of television on children's learning and cognitive development. Although the focus of a majority of these investigations continued to be the impact of television on children's school achievement, a smattering of these studies focused on learning impacts beyond schooling – including issues such as generalized literacy, creativity, and children's self-regulation and self-esteem.

More focused studies of media impacts have been conducted in the last decade, particularly studies of media in general, and specifically television, and more recently the Internet. Much of this research has focused on public understanding of science. Studies in this area basically fall into three broad categories: (1) generalized investigations that document the differences and consequences between learning in and out of school, (2) studies that have focused on the role of media in shaping public understanding of science, and (3) studies that have investigated more fine-grained impacts of media use. These studies have identified television as the most frequently used science information source – especially information about the environment – even though most citizens and social scientists question the reliability of some of the information provided. In 2006, the Pew Research Center's Pew Internet and American Life Project (http://www.pewinternet.org) reported that the Internet had replaced television as the primary source of the public's science information.

A range of more fine-grained investigations of science learning and media use have also been conducted. These include how public television programs influence children's problem-solving behavior; young children's viewing behavior and information-acquisition skills such as sequencing, patterning, and creative thinking; and, more recently, efforts to determine how digital media can be used as effective learning tools.

Despite its obvious importance, over time research into the role of media in supporting free-choice learning has remained at a relatively modest level. We know that television and the exploding arena of new media including the Internet, video games, iPods, and handheld devices have a tremendous impact on the public, with evidence that children and adults learn a great deal from their use. Relative to the importance of these media in society though, the quantity of research on their impacts on free-choice learning remains inadequate. In particular, with the spread of the Internet and the growing ubiquity of wireless mobile networks, a new generation of informal/free-choice learners, many young, are growing up in a "wired" world. Referred to as "millennials" (i.e., graduated high school in 2000) and sometimes called "digital kids," these youth are avid consumers of traditional media, electronic games, and Web-based information. In the United States in 2002, more than 78 % of children between 12 and 17 years went online. This has grown to 95 % in 2013 (http://www.pewinternet.org/Reports/2013/Teens-and-Tech.aspx). These youth use digital tools in their everyday activities not only for communication, school assignments, way finding, and play but also to create and exchange personally meaningful messages, tools, and digital media products across distributed social networks and online communities. Raising the ante even more, digital media production and free Web-based authoring tools enable youth to create multimedia stories, join online hobby communities, and create personally meaningful virtual objects in 3D online worlds, thus providing these learners even more ways to personalize and control their own learning. While using these tools, millennials are developing habits of multitasking, comparing multiple information sources, and trying out new virtual identities. They also gather, design, critique, synthesize, and develop movies and other digital products, all requiring technical expertise and digital fluency skills and competencies such as an understanding of design approaches and new representational practices.

Though Internet and online media use by youth is more commonly documented and researched during school hours, one would expect these tools to be used even more outside school, given that youth have more free time and opportunities for technology access through libraries, friends, and Internet cafes. This would seem to suggest that investigations into how these tools are used by youth during their out-of-school time would represent a fruitful arena in which to conduct research. Currently, though, there are no systematic longitudinal studies of youths' cumulative experience with digital media from childhood to adulthood or setting to setting nor an understanding of the cumulative effects of digital media upon cognition, learning, and development. This means there is little understanding of the role these tools play in supporting independent/free-choice (and compulsory) learning among youth. When the majority of practice and interaction occurs in extended virtual social worlds across multiple physical and online settings outside formal confines, research can be challenging, but it is critical that we begin to tackle the challenge. The realization that learning spaces do not exist in isolation is important in an age in which technologies make it not only possible but increasingly likely, and even natural, for learners to not be confined to a particular learning space. When such seamlessness becomes the norm rather than the exception, it is important for researchers to understand how different learning experiences and spaces are connected as part of a wider learning ecology, rather than merely focusing on what happens within a particular learning space, be it formal or informal.

Nonformalized Learning

In the mid-1970s, Scribner and Cole (1973) wrote a seminal paper that argued for increased emphasis on investigating learning outside the formal education system. According to Scribner and Cole, virtually all the research and theorizing about learning up to that point had focused upon schooling which they felt in the industrialized world in particular was a very specific lens, emphasizing didactic, rational, and "scientific" approaches to learning. They pointed out that much of learning occurred in everyday situations, and rather than being viewed as an ineffective substitute for formal learning, these typically culturally situated and often modeled forms of learning were quite effective.

Scribner and Cole's ideas inspired a whole line of investigations dominated by social psychologists, anthropologists, and sociocultural researchers, fostering a small but steady range of interesting studies occurring over the past 30 years. Arguably, the greatest contribution of this line of research has been the documentation that sophisticated learning takes place in communities without formal learning instruction. Particularly important has been the work of Greenfield and her colleagues in rural Mexican communities demonstrating the sophisticated learning of weaving skills (Greenfield and Childs 1991). Other studies have investigated the use of everyday arithmetic by housewives while grocery shopping and Brazilian street children's everyday mathematical abilities (Saxe 1988). Building on this model, free-choice learning researchers have begun to study learning in everyday settings such as family learning in the home.

Overall, investigators working in this area have been able to document two very important claims relative to learning. The first is that informal modes of learning are extremely powerful and pervasive. Equally important, researchers in this area have pointed out that a major premise of formal education, namely, that it is the best strategy for teaching generalizable and transferable knowledge, is significantly flawed. Investigators have been able to demonstrate that all learning is contextual, not merely that learned outside of school. This suggests that what school children learn in formal educational settings is strongly tied to the nature of that setting and not necessarily generalizable beyond that educational context.

Discussion

Several conclusions from this review of free-choice science learning are warranted. First, considerable research has been conducted in all three of these areas – institutions, media, nonformal – and other areas also, though of far more modest scope and scale. That said, until very recently, the interactions between these three main lines of research have been relatively few, with little cross-fertilization of ideas, methods, or findings. As these brief reviews point out, there is a tremendous need to foster collaboration between these lines of inquiry. Researchers and practitioners in these communities have been investigating similar questions yet in many cases using different approaches and frameworks for study, and much has been missed historically by the lack of communication among them.

There is much to learn from the diverse perspectives and approaches each group has taken and much to be gained in the future if these lines of research were more closely aligned. As educators strive to develop public interest, knowledge, and understanding, they need to be aware of the vast number of ways, ages, and places in which persons learn across their lifetimes. In the twenty-first century, free-choice learning institutions such as museums, libraries, the Internet, and broadcast media, to name but a few, are assuming an ever more prominent role in lifelong learning. These experiences represent important, in fact essential, ways that people learn and most importantly contextualize their science knowledge and understanding. As learning researchers and educators in the twenty-first century, it is critical to move beyond rhetoric to recognize, understand, and learn how to facilitate free-choice learning as a powerful vehicle for lifelong learning – not as a nicety, or a supplement to the learning engaged in at school and university, but as an equally essential component of lifelong learning. To not understand and embrace this form of learning as a valuable component of education in the twenty-first century is to seriously impede one's ability to enhance learning.

To enhance lifelong learning effectively, three aspects of this enterprise must be considered: (1) awareness and recognition of the learning infrastructure in each community, (2) the need to create a corresponding infrastructure for education and research that supports the facilitation of this type of learning and its connections to other forms of learning, and (3) a clear vision of the research directions that will be most fruitful and productive.

The Learning Landscape. Although it is not a large conceptual stretch to envision a complex community infrastructure of science learning resources that supports and facilitates the learning that takes place there, it is quite another thing to understand how it actually functions on the ground for learners. This basic learning infrastructure already exists in almost every community, including traditional constituents such as schools and universities, print and broadcast media, libraries, museums, zoos, aquariums, community-based organizations, and the workplace. However, increasingly these institutional constituents are being supplanted by noninstitutional, more fluid entities such as hobby groups and social networks, both virtual and physical. Currently, there is little understanding of how this learning infrastructure functions and how the various components intersect and interact. As the historical distinctions between formal and informal education are increasingly blurring, it is essential to better understand the basic nodes of the learning infrastructure and how these nodes interconnect from community to community. In short, investigations about the structure and functioning of the learning landscape/infrastructure should be an important element of any future research endeavor.

Historically, investigations of learning have been quite bounded. Most studies have investigated specific age cohorts, within classrooms, over the time frame of a unit or at most a school year. Even investigations of free-choice learning have typically been equally bounded, e.g., visitors to a specific museum, often a single exhibition, framed by the duration of a single visit. However, what is known about the nature of learning suggests that it is rarely instantaneous and does not occur in one place at one time; instead learning is strongly socioculturally framed and cumulative. The scope and scale of investigations need to be expanded in order to better encompass the realities of lifelong learning. This will require different methods, different questions, and different types of financial investment. It also will require new partnerships between organizations and individuals – partnerships that better reflect the actual structure and functioning of where and how the public learns.

An Ecology of Learning for Life. Throughout the twentieth century, the focus of learning investigations was top-down with a focus on instruction and curriculum. The organizing framework was that institutions should and could provide all that was necessary for an informed, literate citizenry. While there is increasingly greater openness toward learner participation in structuring learning experiences and the environments in which they take place, the learner is still basically expected to accept the package as it is offered. The learner is the consumer of a ready-made or, at best, partly customizable product.

This is not the reality of the twenty-first century. Learning in general, and science learning specifically, is increasingly becoming bottom-up, controlled by the individual and highly focused on meeting personal needs and interests. This shift has huge implications for not only how learning occurs, but how research on learning should be conducted. In the new world order, the learner's role is quite different. Although the reasons for learning may sometimes still be associated with the pursuit of formal learning objectives or career goals, the majority of self-directed independent learning will be aimed at meeting identity-related needs unassociated with degrees and employment – instead learning will be associated with hobbies, personal curiosities, or individual needs such as environmental/historical preservation in the neighborhood or responding to health issues. One approach to this perspective is the argument that learning entities at different levels of organizational complexity – ranging from the individual to the social – behave like complex adaptive systems (CAS). Thus to understand learning, it is crucially important to recognize the ecological wholeness of the learning environment and allow these entities to self-(re)organize themselves perpetually, in a Web of nested frameworks relevant to different time frames and spatial contexts for human learning.

A Clear Vision for Research. If the goal is to embrace a broader notion of learning situated within an ecological system, it is critical to identify what researchers might be looking for, where to start looking, and how to look. Two broad lines of research are envisioned. The first is a top-down view that attempts to deeply understand the structure and functioning of the ecosystem, existing, as well as potential, interrelationships between actors and agents in the learning landscape. The second is a bottom-up view that begins with the learner and attempts to deeply understand their own ecology of learning from a learner-centered perspective. Both of these lines of inquiry will require teams from multiple disciplines and will be more robust if they involve both researchers and practitioners and occur across extended time frames (5–10 years).

In conclusion, whether one uses these ideas or others, the take-home message is that future investigations of learning need to situate the learner at the center rather than the periphery of the learning process. In order to meaningfully understand what learning is but even more importantly why it happens, studies also should frame science learning within the larger ecological context of an individual's life and the learning landscape in which they live. Taken together, increasing an emphasis on free-choice science learning and its connection to other aspects of the learning landscape holds the promise for more effectively understanding and achieving measurable, long-lasting impacts on the public's understanding and interest in science, learning for personal fulfillment as well as for an informed citizenry.

Lesson Study Research and Practice in Science Classrooms

Tetsuo Isozaki
Graduate School of Education, Hiroshima University, Hiroshima, Japan

Definition of Lesson Study

The publication of *The Teaching Gap* (Stigler and Hiebert 1999), based on the TIMSS Video Study of grade 8 mathematics classrooms in Japan, Germany, and the USA, led to an interest among educators across many disciplines in Lesson Study – an important part of Japanese teachers' continuing professional development. "Lesson Study" is a literal translation of the term *Jyugyou kenkyuu*. *Jyugyou* means lesson, and *kenkyuu* means study or research. Lesson Study is a comprehensive and well-articulated approach to examining practice that many Japanese teachers engage in. The process involves a critical focus on the relationship between teaching and student learning.

Lesson Study is historically and strongly embedded in Japanese teachers' professional culture in both pre- and in-service teacher education (e.g., Isozaki and Isozaki 2011). The origin of Lesson Study can be traced back to the Meiji era, particularly the 1870s and 1880s, following the Meiji Restoration in 1867. Lesson Study was standardized by the end of the nineteenth century, and the process has evolved since then. Recently, in the USA and elsewhere, attempts have been made to theorize Lesson Study, something which had not taken place in Japan itself.

Processes and benefits of Lesson Study

Lesson Study may typically be divided into three parts: preparation, research lesson, and reflective meeting/conference. In initial teacher education, Lesson Study takes place during teaching practice in school. Student teachers are encouraged to participate in practice within a professional community that includes experienced teachers (mentors), other student teachers, and the school students themselves. The process focuses on various dimensions: what teaching involves, what the teaching profession is, how to carry out lessons under the instruction of a mentor and a university tutor, how to make a lesson plan and a scheme of work, and how to research and develop teaching materials. Student teachers observe their mentor's model lessons and attend lectures on the mentor's views of teaching and classroom management. Student teachers collaboratively make a lesson plan and also research and develop teaching materials based on discussions with other student teachers and on advice from their mentors. Student teachers take part in a reflective meeting/conference with their peers after a research lesson given by one of the student teachers. This process is repeated throughout the students' teaching practice. Through this process, student teachers gradually become familiar with the processes and benefits of Lesson Study including researching and developing teaching materials.

Preparation usually involves participants defining the problems and deciding the theme and the goal of the Lesson Study. The teachers collaboratively plan the lessons: the type of lesson, the teaching content, the focus, the teaching materials, the practical activities, the assessment of student performance, etc. One way to conceptualize Lesson Study is to see it as a process that starts with questions, whereas professional development workshops often start with answers.

Science teachers often try to find new and appealing teaching materials focusing on investigations using practical activities. In researching and developing teaching materials and making a lesson plan, pedagogical content knowledge (PCK) plays an important role. The teacher who will give the research lesson makes and revises a lesson plan based on discussions with colleagues and advisors, e.g., consultant teachers of a local board of education and university professors. In general, a lesson plan includes the objectives; the main scientific ideas of the unit; student characteristics, including their prior knowledge and preconceptions; the overall scheme of work; and the structure of the 1-h lesson which includes a description of what might happen during the hour. Assessment tasks, including criteria and methods to be used during the whole unit and for every lesson, are added to the plan (see Fig. 1).

The 1-h lesson structure described in the lesson plan format is basically divided in three columns: time and phase, students' activity and learning with anticipated student responses, and teacher's activity including assessment tasks. Students' activity and learning are always at the core of teachers' professional judgment and pedagogical decision making. As a result, the lesson plan provides the teacher and observers with a platform that includes the scientific and educational values implicit and explicit within the lesson.

The teacher gives the research lesson in the classroom based on the lesson plan developed by the above process. Other teachers use the revised lesson plan as a guide for their comment on and critique of the lesson. They collect data and take notes focusing on the teaching and on student learning. The other teachers sometimes move around the laboratory to listen to what students are discussing, to observe how students are engaging in practical activities, and to check what students are writing on their worksheets. Most science teachers who give a research lesson are eager to use an inquiry-based approach encouraging students to make predictions or hypotheses, conduct practical activities, obtain data, and induce a law or principle from these data. The use of video cameras for recording the research lesson enables teachers to reflect on their teaching and to analyze the students' activities.

A reflective meeting is usually held later the same day and is based on the evidence collected during the research lesson. Outside advisors, who also observed the lesson, attend the reflective meeting in order to give comments and advice. Sharing the results through Lesson Study can be done in several ways including writing a report or a school bulletin. These documents provide a record of Lesson Study for future use.

Grade ○ Science Lesson Plan

Name of teacher:
Date and time: yy/mm/dd, time
Place: laboratory or other places
Class:

[Unit title]

[Unit objectives] Based on the Course of Study and teacher's ideas, student should know and understand, be able to, etc.

[Views of unit]

(1) Main ideas of the unit and the key teaching contents,

(2) Learners' characteristics and their prior knowledge and preconceptions relating to this unit, and classroom atmosphere,

(3) Teacher's view and ideas for instruction based on both 1) and 2).

[Assessment tasks] Criteria and methods of the whole unit and each lesson.

[Overall Scheme of work] The sequence of unit goals with the number of hours to be spent on the unit.

[Today's one-hour lesson]

(1)Title of topic

(2) Objectives of today's lesson

(3) Resources

(4) Development of today's lesson

Time and phase	Students' activity and learning based on anticipated students' response	Teacher's activity including assessment tasks and notes
(Minites) [Introduction] [Development] [Conclusion]	[Review of previous lesson] [Some questions and anticipated answers] [Practical activities and anticipated errors] [Students' presentation and anticipated results] etc.	[Points to keep in mind] [Assessment tasks: criteria and methods including supports for lower achieved students] [Safety] etc.

Lesson Study Research and Practice in Science Classrooms, Fig. 1 An example of lesson plan in Japan

Lesson Study and Professional Development

Teaching is a complex cultural activity and the classroom can be chaotic and unpredictable. Lesson Study has features similar to other forms of pedagogy of investigation in teacher education; however, it has its own unique characteristics. For example, in action research a teacher examines their own teaching and their students' learning by engaging in a research project in their classrooms, with working with colleagues being usually optional. On the other hand, Lesson Study emphasizes that the process involves collaboration with colleagues and a common focus (e.g., Stepanek et al. 2007). Therefore, Lesson Study can build effective collegial relationships in a school, and the results can be reflected in everyone's teaching. Through Lesson Study, collaboration within a professional community is seen as a useful vehicle for teachers to improve their teaching, and it can help to reduce feelings of isolation.

Lesson Study helps to foster the learning or professional community in and between schools. The approach helps to form a teacher culture which provides opportunities to share the dominant values of science education. However, the approach can be a double-edged sword: there are both benefits and disadvantages, e.g., while Lesson Study is a useful vehicle to spread an "ideal model" of teaching science which many science teachers may adopt, lessons may become more standardized and the values shared by science teachers sometimes lag behind the latest research trends. Professional growth in Japan is naturally embraced by teachers and is encouraged not only through Lesson Study but also through other learning activities which take place in the daily life of the school and through reflective conversations on scientific and educational issues among teachers. These important and traditional features are based on a professional culture which promotes effective continuing professional development.

Lifelong Learning

John Falk
Center for Research on Lifelong STEM
Learning, Oregon State University,
Corvallis, OR, USA

The nature of science learning is changing worldwide as individuals have unprecedented access to science education opportunities from cradle to grave, 24/7, through an ever-growing network of educational opportunities in and out of school. The most rapidly expanding are opportunities beyond schooling which include visits to museums, zoos, aquaria, science centers, natural area parks and preserves, television, radio, films, books and magazines, and increasingly through personal games, podcasts, the Internet, and other social networking media. A hallmark of this revolution in science learning is that collectively these organizations and tools enable a growing number of individuals to customize and take charge of their own learning. Learning can no longer be divided into a place and time to acquire knowledge (i.e., school) and a place and time to apply the knowledge acquired (i.e., the workplace). Instead, learning is increasingly appreciated to be something that takes place on an ongoing basis from our daily interactions with others and with the world around us. Individuals learn science for multiple reasons, including in order to further their careers or for personal advancement, to build social relationships, to meet external expectations, to seek escape/stimulation, and to satisfy cognitive interests and curiosities; from this perspective it can be seen that the vast majority of science learning is a free choice, in other words, "learning for the sake of learning" (Falk and Dierking 2002).

Individuals engage in various forms of science learning nearly every day – at home, at work, and while out in the community. Although considerable time and energy have been invested in understanding the public's science learning, including what people know and understand and how they come to acquire that understanding, historically most investigations have failed to recognize the contingent, lifelong, and diverse experiences that support engagement with and learning of science, in both formal and informal environments. In short, it is not the one-off, individual experiences that matter as much as the sum totality provided by those engaged in science education across the course of their life.

A number of countries have begun to advocate for the importance of lifelong learning in order to create an enriching and dynamic society. They see lifelong learning as a fundamental human right and social justice issue. As such, they view learning in general, and science learning in particular, as a process that not only enhances social inclusion, competitiveness, and employability but also active citizenship, personal fulfillment, and development.

From this perspective, science learning opportunities should be available to all citizens on an ongoing basis. In practice this should mean that citizens each have individual learning pathways, suitable to their needs and interests at all stages of their lives. The content of learning, the way learning is accessed, and where it takes place may vary depending on the learner and their learning requirements. This means that across the board, science learning opportunities need to become much more open, flexible, and responsive so that such opportunities can truly be tailored to the needs of all current and potential learners.

Basil Yeaxlee (1929) is usually credited with being the first modern writer to fully develop the idea of lifelong learning and education. He, along with fellow pioneer Eduard Lindeman (1926), provided an intellectual basis for a comprehensive understanding of the importance of supporting education as a continuing aspect of everyday life. They drew their ideas from numerous sources but were strongly influenced by the ideas of North American educational thinker John Dewey. In more recent years there has been a shift in the conceptualization and implementation of lifelong learning from notions of "continuing" education for adults (typically occurring in formal contexts) to the ideas of "continuous" education for all learners (across a wide range of settings and contexts) described in the opening paragraphs.

Longitudinal Studies in Science Education

Hanna J. Arzi
Independent Scholar, Tel Aviv, Israel

Keywords

Cross-sectional studies; Learning progressions; Longitudinal studies; Long-term processes; Research designs; Retrospective studies; Trend studies

In research terminology, the adjective "longitudinal" refers to features of research designs for studies conducted over time. Since education is a gradual process with long-term goals, such studies are essential to elucidate what happens, how, and why. This entry offers a working definition for longitudinal studies and discusses *"true" longitudinal research designs* that are the gold standard for investigating continuity and change. They are juxtaposed with complementary *trend*, *retrospective*, and *cross-sectional* research designs. The entry makes comments on published longitudinal studies in science education, and attends to the persistent issue of insufficient research-based knowledge across themes along the time dimension.

Working Definition for Longitudinal Studies in Science Education

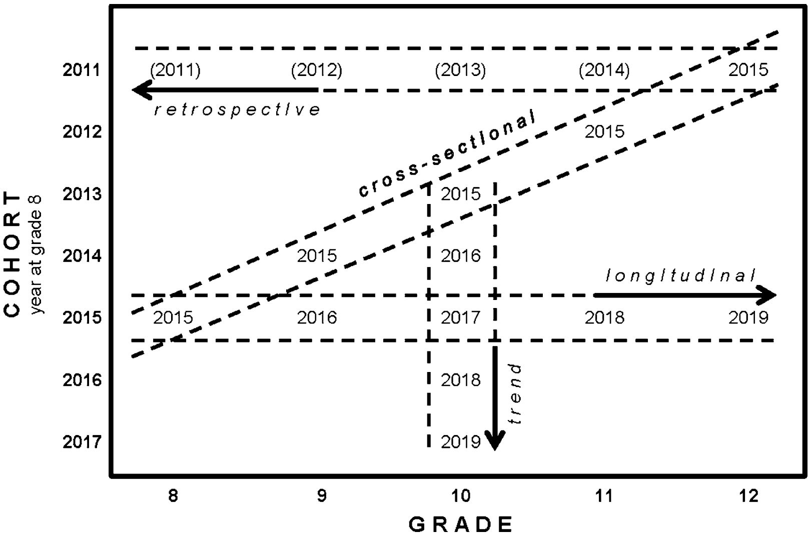
The established tradition of longitudinal studies in the behavioral and social sciences accepts a range of quantitative and qualitative designs, yet there is a sine qua non: In a longitudinal design, data on the investigated entity are collected at more than one point in time. The inclusive term "investigated entity" acknowledges that studies are not restricted to human subjects, for example, reform sustainability can be investigated through comparisons between reform-related outcomes over several years. Comparability of data over time is imperative for valid inferences on continuity and change. An extreme perspective demands identical procedures at all data collections, but this may introduce interferences and may not be possible (e.g., when instruments should be adjusted to student age). The time span of data collections depends on research questions and can reach decades, as in explorations of life-course and generational shifts in developmental psychology and sociology. In science education, an adequate minimum for categorizing a study as longitudinal is one calendar year, because during this period the boundaries of a school year are crossed and educationally significant transitions occur in regard to curriculum materials or mobility of students and teachers.

The above clarifications underlie a working definition that applies to science education: A longitudinal study collects comparable data on the same entity at least twice over a time span of at least one calendar year.

"True" Longitudinal Research Designs

In a *"true" longitudinal research design*, the same subjects are actually followed over time. Subjects are often investigated as part of a group of members with a common trait, referred to as *cohort*. In science education, cohorts usually share a chronological stage: students at the same age or school grade; teachers with similar experience or participating in a program during the same year. A study may follow more than one cohort, as happens in evaluations with experimental and control cohorts. The label *cohort designs* is sometimes used, while the label *panel designs* applies to the general case of groups that are not identified a priori by common traits, though the analysis can differentiate between age, gender, ethnicity, etc. The occasions or periods of data collection are known as *waves*; designs with multiple waves are sometimes referred to as *time series*.

The execution of longitudinal studies involves obstacles that stem from their length. Maintenance problems exist from the planning stage onward, including funding that is seldom secured for long projects and lasting participant collaboration that cannot be guaranteed beforehand. Once a study is launched, research difficulties are essentially the same as in any test-retest design, but they are amplified with time, as explained in the classic discussion of threats to validity by Campbell and Stanley (1963) that continues to be relevant across research methods. The extent to which a threat materializes depends on the particular design features, for example, interferences between successive tests increase with testing frequency, likewise, interviews in a case study with intensive researcher-participant interactions may turn into an intervention. A most bothering issue is attrition of the entry sample which is usually selective and leads to loss of comparability both within a given cohort and between initially comparable cohorts. Thus, for example, programs intended to enhance equality may seem effective just because students with lower motivation and academic achievements are more likely to be missing from follow-up waves as a result of higher rates of absenteeism, dropout, or school mobility. Despite attrition, internally valid conclusions and insights can be drawn through analysis of longitudinally matched data that attend only to participants with full data sets. Securing internal validity is crucial and overrides the risk of reduced ability to generalize. Longitudinal matching requires meticulous management of ever-growing data, which can be voluminous in qualitative studies. Storage of records is also necessary to keep options for future secondary analysis or follow-up of a seemingly completed study.



Longitudinal Studies in Science Education, Fig. 1 Research designs for hypothetical studies launched in 2015 to investigate changes over time during the grade 8–12 interval (cohorts are defined by calendar year at grade 8; years in the cohort/grade plane are periods of data collection, with retrospective data during parenthesized years)

Complementary Research Designs

Direct investigations over time with valid conclusions at both group and individual levels are possible only through true longitudinal designs. Other research designs that attend to the time dimension without actually following the same subjects can play valuable complementary roles, yet none can replace the gold standard. Figure 1 illustrates frames of hypothetical studies starting in 2015: a 5-year true longitudinal investigation of schooling from grade 8 to 12, along with complementary designs.

In *trend research designs*, data are collected from representative samples of the same population at different times. They conform to the working definition of longitudinal studies if the requirement for “same entity” is viewed broadly and includes samples drawn by the same procedures. In Fig. 1, a trend design is illustrated by the vertical sequence that encompasses grade 10 cohorts from 2015 to 2019. If the same sampling and data collection procedures are employed in the same schools, inter-cohort comparisons may reveal trends due to educational changes, demographic shifts, or historical events interacting with the results. Such trends should be considered in the interpretation of the grade 8–12 longitudinal study.

In *retrospective research designs*, data are collected at one point in time, on the same subjects, on previous periods, based on archives and human memory. In Fig. 1, the upper horizontal sequence illustrates data collection in 2015 from grade 12 backward. If the necessary data are student grades or other records from official files, then there is no difference between data collected retrospectively or in real time. Differences exist when studies concerned with meanings and processes attempt to reconstruct the past through student and teacher reports and reminiscences. Such data can be valuable, though limited in scope and reliability compared with real-time studies. In some cases a retrospective design is the only option, for example, in studies of teacher life cycles, narratives are the only source for tracing back early roots of knowledge, beliefs, or decisions to embark on a teaching career.

Cross-sectional designs do not accommodate the consensual sine qua non of longitudinal designs, since inferences on change over time are based on comparisons between data collected at the same time from different subjects across chronological stages. They provide no data on change at the individual level, and the validity of interpretations at the group level is limited by the incomparability of their different cohorts.

In the study illustrated by the diagonal sequence in Fig. 1, results of 12 graders who were 8 graders in 2011 may be inflated because they do not include students who dropped out since 2011; they may also be affected by educational interventions and events that would not happen to 8 graders from 2015 to 2019. The obvious advantage of cross-sectional over longitudinal studies is the provision of fast approximations on the long term.

Mixing of longitudinal and complementary designs has the potential to enhance investigations over time, provided that comparability is checked among the different elements. Intertwinement of retrospective data collections within longitudinal sequences can fill gaps between waves. A longitudinal study can be extended through patching of other study sequences, thus providing estimations of continuity and change over longer periods. Cross-sequential comparisons enable elucidation of trends, as has been done in large-scale cross-sectional and long-term longitudinal studies conducted periodically with nationally representative samples in the USA (e.g., Ingels et al. 2012).

Persisting Issues in Longitudinal Studies in Science Education

Publications that focus on longitudinal studies in science education include one comprehensive review (Arzi 1988) and two special journal issues with exemplary studies that provide important insights on long-term processes and outcomes and on how they were investigated (Shapiro 2004; Tytler et al. 2005). Overall, the literature does not include many research reports, and a close scrutiny reveals that the labeling of studies as “longitudinal” is sometimes permissive. Too often articles do not provide sufficient information on the research design, including actual collection and analysis of comparable data over time, which eventuates in questionable validity of inferences on the long term. Since difficulties are encountered in any longitudinal study, methodological transparency is necessary both to support conclusions and to guide further research.

The range of longitudinal research designs in the science education literature is wide, extending from descriptive case studies and follow-ups of school-based programs all the way to large-scale quantitative surveys employing sophisticated statistics and enabling further use of their databases. Longitudinal investigations can be found across areas in science education; however, since their number is limited, the thematic coverage is thin. Consequently, for example, when the notion of learning progressions emerged, again in the first decade of the twenty-first century, the existing longitudinal knowledge base was insufficient for grounding topic-specific hypotheses on extended periods. Researchers therefore turned to cross-sectional studies for quick answers, while acknowledging the necessity for elaboration and validation via longitudinal studies.

Across subjects in science education, longitudinal studies have unfolded complex long-term processes. In concept learning, for example, findings show that immediate instructional outcomes can erode, persist, or grow over time, initially undetected outcomes may appear later, and there are different patterns of individual student trajectories. Similarly, teacher learning and professional development are career-long processes with individual twists and turns that are impossible to predict from studies of beginning teachers. In reforms, too, changes take time to occur and it takes time to understand them, as promising results may fade away, but even if so, significant cumulative effects may be found years later. A single year – the required minimum in the working definition adopted in this entry – is often not enough, and an early closure of a study involves a risk of premature conclusions.

Each subject in the above examples has unique features that have been only partially explored longitudinally, or not at all, as is the case across areas in science education. The ever-existing calls for more longitudinal studies reflect their modest number and gaps between acknowledgment of importance and commitment to research which is not easy to conduct. Apparently, pressure to publish frequently and human nature to prefer short- over long-term tasks also affect the reluctance of researchers to embark on long-term adventures. The knowledge that has accumulated in science education through longitudinal studies is evidence that they are feasible and worth the effort.

Meaningful Learning

Richard Gunstone
Faculty of Education, Monash University,
Clayton, VIC, Australia

Keywords

Conceptual understanding

The term "meaningful learning" became prominent in science education through the work of the educational psychologist David Ausubel and his use of this label in the 1960s to designate learning that is in total contrast to rote learning. At its core this usage can be characterized as suggesting that, in most contexts most of the time, "rote learning is bad; meaningful learning is good." Such usage has become widespread, so that "meaningful learning" serves as a label for learning seen to be of worth, of real purpose, in a wide variety of contexts. These range from academic discussions of alternative conceptions and the need to pursue conceptual change to popular debates of educational fads (e.g., "does [some specific fad] actually lead to any meaningful learning?"). Meaningful learning has also been central in other theories of learning that have been variously influential in science education, including Wittrock's Theory of Generative Learning.

Mechanisms

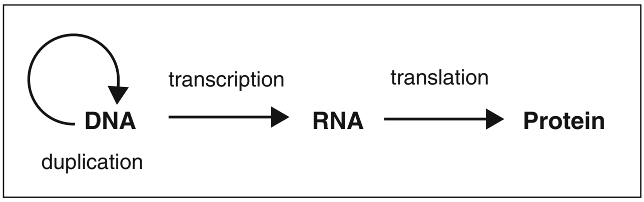
Peter Machamer[1] and Thomas V. Cunningham[2]
[1]Cathedral of Learning, University of Pittsburgh,
Pittsburgh, PA, USA
[2]University of Arkansas for Medical Sciences,
Little Rock, AR, USA

Keywords

Cognitive science; Explanations; Learning progressions; Models

A common and successful strategy for explaining something scientifically is to describe the mechanism that produces it. Mechanisms are composed of entities and activities that are, in various senses, in the world. Entities are things that behave or engage in activities. Activities are ways of working that produce phenomena. Succinctly put, "mechanisms are entities and activities organized such that they are productive of regular changes from start or set-up to finish or termination conditions" (Machamer et al. 2000,

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,



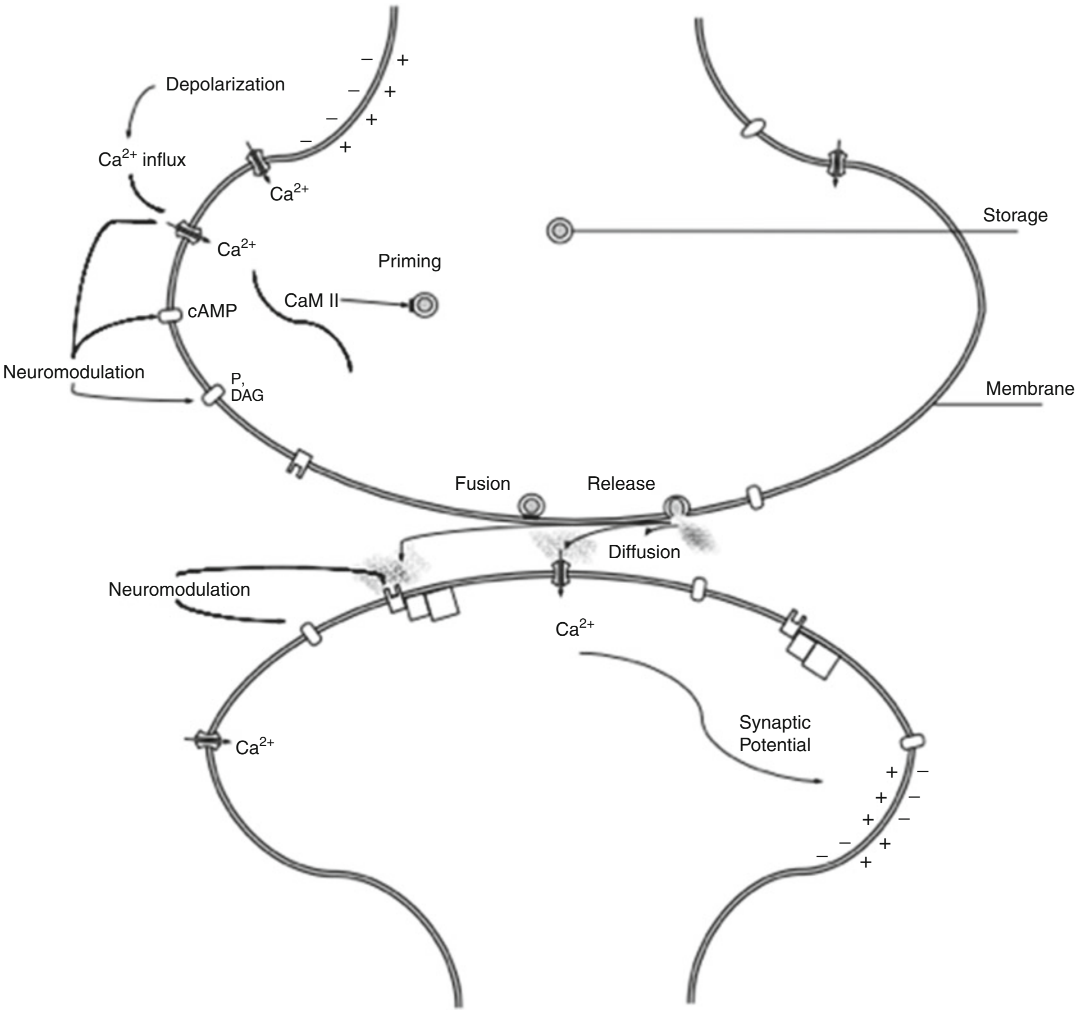
Mechanisms, Fig. 1 The central dogma of molecular biology (Redrawn, based on Machamer et al. 2000)

p. 3). Mechanistic explanations are representations (often verbal descriptions) of mechanisms.

Mechanisms may be described in varying detail. Mechanisms can never be completely described, since, given any context, there will always be more to be said about what is involved in producing a given phenomenon. Since no system is ever completely causally closed, there will always be additional entities or activities warranting inclusion. Nevertheless, we may distinguish mechanistic explanations from mechanism schemas and from mechanism sketches. A sketch is an incomplete description of a mechanism that contains many gaps or "black boxes" that cannot be filled in because of limitations in scientific knowledge; sketches are often apparent in ongoing scientific research. A schema is an incomplete description of a mechanism that contains many lacunae but where some gaps may be filled in with further details given current scientific knowledge. For example, Francis Crick's central dogma of molecular biology provides a schema for a mechanistic explanation of the uni-directionality of information transfer in biological systems (Fig. 1). A mechanistic explanation is a sufficiently filled out schema, such that our scientific knowledge fills in the gaps in a way that suffices for the explanatory needs of a field at a time and the interests of the investigators.

Let us consider some examples of mechanistic explanations, first, an internal combustion engine: a car moves because a high-energy fuel is mixed with air and burned in a special compartment so that energy is released to move a piston, which in turn moves a rod connected to other components that turn the wheels that propel a car by exerting force on the ground. We explain how a car works by providing a mechanism schema of how a drive system converts gasoline into rotational and translational motion. Yet another type of mechanistic explanation involving cars could look at the mechanisms established by legal and enforcement institutions that attempt to ensure that drivers stop at red lights, obey stop signs, put on the brakes, etc. Or, one might describe the macroeconomic relationships between gross domestic product, trade deficits, and supplies of and demands for various goods and services to provide a mechanistic description of the distribution of American-made automobiles in certain regions of the United States. To explain by describing the entities and activities that give rise to target phenomena is to explain mechanistically.

Consider, also, chemical transmission at neuronal synapses (see Craver 2009). Neurons are described as "firing together"; they propagate electrical signals from one to another as a group, in a complex, orchestrated, and poorly understood fashion that serves as the basis of the mind and nervous system. A neuron is a cell. Between each neuron lies a space called a synapse. When one neuron is stimulated, it propagates an electrical current along the length of its body. At the end point it reaches a synapse, which must be bridged to communicate with an adjacent neuron. Chemical transmission is the mechanism whereby the electrical signal from a neuron is converted into a chemical signal across a synapse (Fig. 2; cf. Machamer et al. 2000, p. 9). This neurotransmitter signal is then converted back into an electrical signal in an adjacent neuron. A textbook account of this is complex. It includes entities such as membranes, molecules, receptors, and transmitters, as well as



Mechanisms, Fig. 2 A diagrammatic summary of some entities and activities involved in synaptic transmission

activities such as depolarization, priming, fusion, and release. An explanation of how chemical transmission occurs begins with a description of which entities undergo these activities and how their doing so causes other entities to behave. Thus, the entire system is explained by showing how it proceeds from an initial condition to a later condition, resulting in communication between neurons.

In the history of the life sciences, the topic of mechanistic explanation has often been contentious, as some authors have argued there is something irreducibly special about biological systems that cannot be fully captured by them (e.g., Haldane 1913). Contemporary discussions of mechanism need not be committed to reductionism or to the claim that all mechanisms are specified at a lower level than the phenomenon being explained. For example, individual behavior at a biological or person level may be mechanistically explained by detailing an ecological, social, or cultural mechanism. So mechanisms for vision may be described, for example, in terms of chemical reactions, in terms of neuron connections, in terms of areas of the visual system, in terms of a person's cognitive capacities, and in terms of ecological and social dimensions. Thus, many mechanisms are explanatorily pluralistic.

A current trend in science education is to focus on scientific models as loci for instruction and learning (Gobert and Buckley 2000). Mechanistic explanations encompass such representations as diagrams, equations, and written description. Thus, mechanism sketches and schemata are well suited for this model-based paradigm. As the cognitive science of learning progresses, thinking about mechanisms will be central for thinking about teaching science. Just as we may describe mechanisms when giving scientific explanations, both teaching and learning may also be described mechanistically.

Cognition; Computational; Information processing; Models; Neurophysiological

Introduction

Human memory can be thought of as the capacity for retaining and recalling experience. This retention can vary from a matter of milliseconds to a lifetime, and similarly the nature of recall can vary greatly. I will qualify the discussion here to specifically consider events for which attention plays a role and where the individual has the opportunity to control aspects of their cognition for tasks such as learning.

The second half of the twentieth century gave rise to modern theories of cognition and memory, many of which paralleled the emergence of computing technologies and the broad conceptual framework of information processing. The current accepted psychological models of memory trace their roots to early work by Broadbent and later by Treisman, Atkinson and Shiffrin, Neisser, Cowan, and Baddeley in the 1960s through 1980s.

Information Processing Models of Memory

Information processing models represent mental activity as occurring in a series of stages, with starting points and feedback loops at numerous points. These models typically encompass not only memory but also those processes that bracket memory functions within a learning task context. Common across most of these models is agreement on what stages of activity take place and the belief that different stages will require differing amounts of mental resources This common model starts with sensory processing, where raw signals in the environment gain access to the brain through the peripheral sensory organs (e.g., the eyes and ears) and are received and stored in a short-term sensory store. Information in these stores might reside for one half to 4 s before decaying. Only if information is selected by attentional resources is it then interpreted through a stage of perception. Perceptual processing itself generally requires few attentional resources (i.e., is considered automatic) and driven by both ongoing sensory input (termed "bottom-up processing") and inputs from long-term memory ("top-down processing"). This speed and relative automaticity is what distinguishes perception from cognitive processes. Attentional resources may select some perceptual information for more effortful processing by cognitive functions involving working memory.

Working memory, as defined by Baddeley, consists of three core components: the verbal-phonetic subsystem, the spatial subsystem, and central executive. The verbal-phonetic subsystem itself is composed of two components: the phonological loop that represents linguistic information and the articulatory loop where words or sounds can be rehearsed. The spatial component can be thought of as a visuospatial sketchpad which represents visual information in an analog form. The verbal-phonetic and visuospatial subsystems of working memory seem to function more cooperatively than competitively when it comes to allocation of attentional resources. That is, research has demonstrated that the limited capacity of working memory can be optimized by a division of incoming information between these two encoding channels. On the other hand, the limited capacity overall of working memory means that high demands on either of these two channels will result in interference and competition between information chunks and the inability to appropriately encode, manipulate, or transfer it to long-term memory. Some research has also suggested that this model of working memory should be amended to include a kinesthetic subsystem.

Long-term memory is organizationally different, with information either stored as declarative or procedural information. Models of knowledge representation are used to better understand how long-term memory procedural information (how to do things) may interact with declarative (factual) information or episodic memory (of specific events). Physiologically, procedural knowledge primarily occurs in brain systems involving the neostriatum (a subcortical part of the forebrain, the location of essentially all cognitive and perceptual activity) while declarative knowledge primarily involves the hippocampus (also in the forebrain). Various knowledge elicitation techniques can be used to build models of an individual's knowledge structures in order to better understand what it means to be expert at a domain or how one's knowledge structures change as they learn. The term mental model or schema can be used to describe an individual's cognitive structure with regard to a concept or system. Current work on learning trajectories or progressions is used to more fully describe how these cognitive structures manifest themselves as behaviors in learning contexts. It is important to remember that while long-term memory is considered both unlimited and permanent (baring injury or disease), it does not guarantee that an individual will be able to access this information when needed for a learning task. The context in which you are attempting to recall information, the cues provided for you, and the temporal and capacity challenges put on working memory will all influence your ability to recall information in a form that is most useful.

The overarching central executive serves a number of key functions, including (1) controlling the allocation of attentional resources to incoming stimuli, (2) coordinating multiple tasks and channels of information, and (3) retrieving and temporarily holding information from long-term memory. The dorsolateral prefrontal cortex is thought to play a key role in executive-attentional functions and, by extension, working memory functionality. Because of this close connection, individual differences are best explored through a combined system of working memory subsystems and executive-attentional control.

It is not surprising that there are also likely connections between working memory capacity, executive-attentional control, and general fluid intelligence. Because many of these operations require mental resources, the attention system helps direct and allocate resources based on both automatic and conscious action. However, it is important to remember that this resource is not binary and can be divided between multiple resources. Exactly how much and under what conditions continues to be an active area of research. It follows that the mind is not simply a passive recorder of incoming streams of data, but use of the working and long-term memory systems is a dynamic process that often involves conscious cognitively effortful activity. Learning and experience both recruit and alter brain structure as memory is utilized.

Understanding the role of memory in learning requires understanding the different affordances and constraints of working and long-term memory. In this information processing model, learning is considered to involve the ways in which long-term memory has been activated and shaped, via sensory and working memory systems. Individuals will chose to execute a response (or not) based on perception and shaped by working and long-term memory. Feedback they then receive via their sensory system will help direct further activity. Working memory, true to its name, is the crucible where the examining, comparing, evaluating, and transforming representations of information take place. Information received and created here will only be available later in time if it is placed in long-term memory. The usefulness of this information stored in long-term memory depends on whether the correct information can be recalled in the appropriate context and applied to the current task taking place in working memory. Central to this model of cognition is that working memory capacity is limited while long-term memory is not and that cognitive processes are much slower and reflective than automatic, perceptual ones.

The capacity limits of working memory interact with the transitory nature of this information. Not surprisingly, the more information one attempts to hold in working memory, the faster this information is likely to decay due to less resources devoted to its rehearsal and preservation. Conversely, more information can be more effectively held for longer periods of time in working memory if adjacent units are grouped, or chunked, together by associations in an individual's long-term memory. How information is presented can either facilitate or hinder an individual's ability to group and associate information in long-term memory. However, incorrect or inappropriate (for the learning task) information learned at a previous time and retrieved from long-term memory for this current learning task can interfere with the current working memory operations.

Other Models

Early theorizing on the nature of human thought and the emergent computer revolution led to connectionist models of cognition, broadly inspired by the physiology of the brain (i.e., neural networks). Two important computational models of cognition to emerge in the 1990s that combined connectionist with symbolic (rule-based) architectures were Anderson's ACT-R model and Newell's Soar model. Computational cognitive models such as ACT-R have been the basis for a new generation of intelligent tutors being developed to assist learners though dynamic, adaptive computer-based learning environments. Newer models based on Bayesian mathematical models do not attempt to mimic physiological structure but rather behaviors observed in humans and other animals. Bayesian probabilistic methods look at how prior knowledge can form alternative structures and make inferences as to the best representation to use given the available data and context. All types of computational models can be used to understand human cognition, predict human performance in learning tasks, and build computer-based tools that assist human learning.

There has also been a long-standing interest in understanding memory and attention by directly examining the neurophysiological functioning of animals and humans. Physiologically, memory is neither a single entity nor a phenomenon that happens in a single area of the brain. Historically, the invasive techniques required for these types of studies have limited the depth of probing into human physiology. Hence, researchers have used animal models where more invasive techniques were considered acceptable, or humans already suffering from neurological injury or disease. Recent breakthroughs in imaging (fMRI and PET) and other technologies have meant that neurophysiological research and refinement of theoretical models have made considerable strides in recent years. It should be noted that theoretical models based on physiological studies of neuronal networks should be differentiated from connectionist models developed around and modeled in computer systems, as the latter are only broadly based on the functioning of the human brain. Both these forms of model are valuable since both human and machine cognition are utilized in modern educational systems.

Memory in Science Learning

A learning environment that leverages what is known about memory and attention will recognize that learners come with memory that is structured differently and with varying degrees of expertise in different conceptual domains and in ways of processing information. Such an environment will attempt to maximize learner opportunities to effectively acquire new information that shapes these memory structures and to access and utilize prior memory structures. To that end, science learning environments guided by both human and machine teachers should assess prior knowledge (memory structures) and how students are able to utilize it.

Expertise in science can be used to describe both what information is contained within long-term memory and how it is organized and utilized to chunk or organize information in working memory. Experts will have a performance advantage in their areas of expertise in terms of how efficiently and effectively they can both process information and utilize it. Novices are distinguished from experts in terms of their lack of appropriate organizational structure of information in long-term memory.

Learning in science often involves inquiry cycles that involve the introduction of background conceptual material, investigation into scientific phenomena, and then reflection on the linkage of what was investigated to the broader scientific concept. Background conceptual material needs to link new material – often presented in textual, symbolic, and visual forms – with prior memory structures. Sweller’s cognitive load theory and Mayer’s associated multimedia learning theory leverage knowledge of working memory capabilities with learning contexts such as this to provide insight into how to design multimedia content for learning. Sound pedagogical strategies will encourage rehearsal and encoding to form strong linkages with existing long-term memory structures. Similarly, well-designed investigations will also provide information through multiple modalities and facilitate linkage to prior memory structures, providing scaffolded support to guide attention to the most salient information and support its rehearsal and encoding. Finally, reflective activities allow the development of long-term memory structures that can be generalized and used in related scientific practice with similar conceptual and procedural elements.

Science education is impacted by many of the same trends in technology infusion as other educational areas. Because of this, scientific phenomena are often experienced by students virtually mediated by computer-based environments. This trend has a number of characteristics that are impacted by human attention and memory. Computer interface design needs to be mindful of the bandwidth and temporal rate of information delivery so as to not to overload working memory. However, well-designed systems can leverage the fact that information can be distributed between computer and human memory and scaffolded in ways that support learning and retrieval. Similarly, emerging technologies around intelligent tutoring systems can create parallel models of student cognition to be used to help provide guidance and support for learning. Emerging understanding of the critical role the affective state plays in attention and effective, conscious cognitive effort also has led to a better understanding as to how learning environments need to be designed to both monitor and attend to the affective and cognitive dimensions of science learners.

Metacognition and Science Learning

Gregory P. Thomas
Secondary Education, University of Alberta,
Edmonton, Alberta, Canada

Metacognition refers to an individual's knowledge, control/regulation, and awareness/monitoring of his/her thinking and learning processes. A more simplistic and less useful definition often used is that metacognition is thinking about one's own thinking. Research and scholarship in metacognition in science education typically draws on metacognition theory from educational psychology and engages and adapts that theory to address issues regarding the learning and teaching of science. Metacognition is executive, higher-order thinking that is superordinate to but that also interacts closely with the cognitive processes that students employ to construct knowledge and develop understanding via their science learning experiences. Successful science learners are consistently found to be adaptively metacognitive for the demands of their learning environments. While it might be appealing to view an individual's metacognition as good or bad, this is a simplistic notion. Rather, what might be valuable metacognition in one context or culture may be considered less or more valuable or adaptive in another, depending on the task or learning and cognitive demands of that particular context or culture. It is important to consider contextual and cultural factors when theorizing and investigating metacognition.

Developing and enhancing metacognition is congruent with existing and reform directions in science education such as conceptual change, scientific inquiry, and the use of information technology. Each of these reform directions has both commonly shared and reform-specific cognitive processes associated with them, and students should develop metacognition in relation to such cognition. For example, students should be metacognitive regarding the process of consciously considering new information against their existing scientific conceptions and theories and should be able to engage in conscious revision of their existing views in light of new information that might become available via the use of, for example, a microworld computer simulation. Further extending this example, students should be metacognitive regarding how the use of the computer technology might facilitate their learning and conceptual revision compared with, for example, the use of a textbook or a laboratory investigation. It is increasingly acknowledged that while domain-general metacognition across curricular subject areas is important, metacognition research and scholarship in the field of science education should and increasingly does account for the domain-specific science information to be learned by students and also the cognitive processes and metacognition to be employed by them to learn, understand, and employ that information and those processes within and beyond their science classrooms.

Metacognitive knowledge can be classified as declarative, e.g., definitions and/or conceptions of thinking and learning; procedural, e.g., knowing how to engage in learning and/or cognitive processes; and conditional, knowing when and why to engage particular learning and/or cognitive processes to achieve learning objectives. Science learners are all metacognitive to varying extents, but because metacognition is internal, it can be difficult to qualify and/or quantify an individual's metacognition. Much of students' metacognitive knowledge is tacit, and they often do not have a language to detail or explain their metacognitive knowledge or thought processes. This can lead to difficulty in evaluating the nature of students' metacognition and/or the impact of interventions aimed at developing and enhancing students' metacognition. It can also lead to difficulty in teaching students to be more and differently metacognitive and to be attentive and responsive to the varying demands of learning tasks and/or learning environments. Such a language of thinking needs to be taught to students and teachers.

Despite the importance of metacognition for science learning, science classroom learning environments are most often not sufficiently metacognitively oriented. The metacognitive orientation of a science classroom environment refers to the extent to which specific psychosocial factors known to assist in the development and enhancement of metacognition are evident in that environment. Improving the metacognitive orientation of a classroom environment requires that teachers make metacognitive demands on students to consider their thinking and learning processes, not just the science they are asked to learn. It also requires that students are encouraged and supported to talk with the teacher and each other about their science thinking and learning processes, that they are able to voice their views regarding the nature of the learning activities they are asked to engage in, and that they are increasingly given control over the selection and enactment of their preferred learning activities under the supervision of the teacher. Developing and enhancing student metacognition in science learning environments requires that teachers are themselves aware and knowledgeable of the thinking and learning processes required to learn and understand science in those environments. It also requires that teachers are able to incorporate the explicit teaching of metacognitive knowledge and related cognitive and learning strategies and the modeling of those strategies into their teaching settings and pedagogies.

Interventions aimed at enhancing metacognition seek to elicit metacognitive experiences in students. Metacognitive experiences are those conscious experiences that are educed in students when they reflect on and consider their thinking and learning processes, most often with reference to their learning and/or cognitive performance. They constitute key stimuli for students' revision of their metacognitive knowledge and dispositions. Interventions typically fall into one of two broad categories. The most common category of interventions involves engaging students in the use of metacognitive activities such as concept maps, Venn diagrams, and Predict-Observe-Explain (POE) or using metacognitive prompts to orient their cognition when they engage with science learning. The expectation or assumption is that students will often without prompting reflect on the use of those strategies and develop metacognition in relation to their use. The other, less common category of interventions involves explicitly inducing metacognitive conflict in students. Metacognitive conflict is analogous to cognitive conflict; however, it refers to the conflict experienced by students when they are asked to consider conceptions of learning, what it means to know and understand science, and how to know and understand science that run counter to their existing conceptions or beliefs regarding such matters. Metacognitive conflict approaches require that teachers are able to articulate increasingly sophisticated views of science and science learning to students that reflect the nature of science and science subject area disciplines. Ideally, a combination of interventions drawn from both categories would be evident in science classrooms so that students would be challenged to consider multiple means of constructing their understanding of science, what it learns to understand science, and how they can better learn and understand science. A primary goal of developing students' metacognition is to assist them to become independent, effective science learners who are able to tailor their thinking and learning processes to the demands of the science material to be learned and who can do so beyond their high school years.

Debate is ongoing regarding how students' metacognition can and should be investigated and evaluated. Two categories of methods in metacognition research are identified: online and off-line. Online methods are those employed when an individual is engaged in real time in a learning or cognitive activity. Such methods include think-aloud protocols and eye tracking. Off-line methods are those employed before or after task performance. They are typically self-report measures and include surveys, questionnaires, and interviews. Both online and off-line methods have affordances and constraints, and a researcher's selection and use of methods is guided by their epistemological assumptions, and the degree of inference they consider is appropriate in metacognition research. Online measures while targeting real-time cognition and metacognition might interfere with individuals' normal engagement in and performance of a learning task. Conversely, off-line measures while not interfering with students' real-time task engagement, cognition, and metacognitive activity are influenced by what students are aware of and/or can recall regarding their thinking and metacognition and the extent to which they can accurately report their thoughts. It may be that a combination of online and off-line methods could be employed in research studies to gain a comprehensive understanding of students' metacognition from a variety of perspectives. Further exploration of this possibility is necessary.

Priorities for future research on metacognition in science education include conceptualizing and implementing interventions to enhance students' metacognition and science learning in authentic, content-rich settings, investigations into teacher metacognition, and exploration of methods for seeking data leading to findings that can inform enhancements in science teacher pedagogy.

Metaphors for Learning

Anna Sfard
University of Haifa, Haifa, Israel

Keywords

Acquisition metaphor; Participation metaphor

Metaphors for learning are metaphors that we use, either explicitly or in an only implicit manner, to describe learning. What often appears as but an innocent figure of speech may in fact inform how we think about the topic, what we are able to notice, and what pedagogical decisions we are likely to make. Different approaches to learning may have similar metaphorical underpinnings, and therefore it is useful to categorize them according to their underlying metaphors.

In this entry, a brief explanation on the role of metaphors in our conceptual thinking is followed by a succinct survey of the metaphors for learning identified by those who studied the topic. Two of these metaphors, known as *acquisition metaphor* and *participation metaphor* and considered as arguably the primary source of all known approaches to learning, are then presented in some detail.

Metaphors as a Source of Conceptual Systems

Metaphor can be defined as a familiar word or phrase used in an unfamiliar context. We are witnessing such metaphorical use while speaking about our ideas or thoughts as "crystallizing" and about love as "burning." In both these cases, a word – *burn*, *crystallize* – has been taken from its *source* domain, that of physical phenomena, and used within a *target* domain for which it was not originally intended, that of human thoughts or emotions.

Traditionally considered to be not much more than literary gimmick, the metaphor has been recognized in the last decades as the basic mechanism through which people cope with new situations and develop original ways of thinking. Nowadays, there is a consensus that any advanced human idea, be it everyday or scientific, grows from previous concepts through the mechanism of metaphor. The American linguist George Lakoff (1993) takes these claims to the extreme when he speaks about *conceptual metaphor*, the cognitive mechanism that transforms what one already knows – familiar conceptualizations, everyday bodily experiences, and forms of activity – into new ways of thinking. Whereas ubiquitous and usually quite helpful, this mechanism becomes truly indispensable when we face new phenomena. Indeed, it is only through the use of familiar words in a new context that we can make sense of unfamiliar situations. Similar claims about metaphors are being made these days by researchers who refuse to view human thinking as fundamentally different from any publicly accessible forms of activity and prefer to consider this inner process as a special case of communicating. Within this latter approach, metaphors are said to be generators of novel discourses. This formulation brings in full relief the systemic nature of metaphors, that is, the fact that metaphor-generated target discourses tend to reproduce considerable portions of source discourses.

Whether cognitivist or discursive, the assumption that metaphors are responsible for our conceptual systems leads to the conclusion that our bodily experience is the primary source of even the most abstract of our ideas. This fact has been explicitly acknowledged by philosophers of science, who point out, for example, that his familiarity with the solar system strongly influenced Rutherford's interpretations of his experimental data as indicating the structure he hypothesized for the atom. At the same time, claims are being made about risks resulting from the systemic nature of metaphors. Unaware of their being guided by unintended metaphorical entailments, the users may be led to unhelpful conclusions. To minimize the risks, we need to be explicit about metaphors underlying our thinking. In scientific research, and in studies on learning in particular, where it is crucially important to control our language for undesirable uses, identifying hidden metaphors is not just advisable – it is imperative.

Metaphors for Learning

The ways we tell stories about learning, whether in our daily life or in research, is full of terms and phrases that disclose the metaphorical origins of our talk. This is well illustrated by common learning-related expressions such as *construction* *of knowledge*, *mental scheme*, *internalization*, *scaffolding*, *apprenticeship*, *negotiating meaning*, and *appropriation*. Because these terms have no obvious "literal" counterparts, their metaphorical nature may not be immediately visible. On closer inspection, however, one realizes that the words *construction* and *scaffolding* originate in discourses on [house] building, the word *apprenticeship* is taken from discourse on vocational training, and the first associations that come to our mind upon hearing words such as *negotiating* or *appropriating* are human activities in domains such as politics or propriety management.

Two categories of metaphors are ubiquitous in research on learning: those that help us to think about different properties or types of learning and those that offer answers to the question of what learning is. In the above list of learning-related metaphorical terms, the first category is represented by the term *scaffolding*, which refers to the support granted to the learner by a more knowledgeable person; *apprenticeship* that speaks about learning that involves the learner's and teacher's co-participation in the activity to be learned; and *internalization*, Piaget's notion referring to a stage in learning where what has been done by physical manipulations can now be done "in the head" (Piaget, 1952). The second category, that of learning-defining metaphors, is represented here by the expression *construction of knowledge*, which many writers consider as an equivalent of the term *learning*. The constructivist metaphor is clearly an alternative to the one that portrays learning as a mere *transmission* of *knowledge*. Since defining metaphors constitute the foundation on which one's thinking about learning is based, each such trope combines with some other properties–describing metaphors better than with some others. Thus, for instance, constructivist metaphor is strongly associated with *mental schemes*, *internalization*, and *transfer*, whereas none of these expressions fits the participationist vocabulary.

Our metaphors for learning can make considerable difference in the ways we teach. The constructivist metaphor, first introduced to research on human development and learning many decades ago by the French psychologist Jean Piaget, has revolutionized Western pedagogy. Its long-term impact can be felt all around the world even today. It has been influential earlier and more widely in science than in any other area of the school curriculum. For some time before the advent of Piaget's innovative ideas, instruction had been shaped by the learning-as-transmission-of-knowledge metaphor, which is deeply engraved in many languages – consider, for instance, such English expressions as "getting education" or "imparting knowledge." This metaphor pictures the teacher as the "broadcaster" and the learner as the "receiver." This vision supported the lecture-based frontal teaching that had been the dominant form of school instruction all around the world until a few decades ago and can still be found in many places. Once educators began thinking about learning as the activity of building one's own knowledge, lecturing started giving way to more active and interactive pedagogies, guided by the principle of encouraging learners to voice and develop their own ideas. Another metaphor, this time more explicit, has been coined to describe the kind of change that occurred with the transition from the transmission to construction metaphor: the teacher, rather than being "the sage on the stage," was now playing the role of "guide on the side."

Acquisition and Participation Metaphors

In spite of the considerable diversity of figures of speech that pervade our talk and shape our thinking about learning, it is possible to divide all the resulting approaches into two broad categories. Thus, for instance, although the transmission and construction visions of learning are quite different in their assumptions and implications, they can still be seen as two instances of yet another, more fundamental metaphor: the metaphor of learning as an act of taking possession over some entities – concepts, knowledge, skills, or mental schemas. This *acquisition metaphor* comes to the scholarly discourse directly from everyday expressions, such as *acquiring* or *imparting knowledge*, *having concepts*, or *getting (seeing) meaning*. The alternative metaphor is the *participation metaphor*. This trope, which originates in the sociocultural ideas of Vygotsky and his followers (Vygotsky, 1978), pictures the Learner as the peripheral participant (Lave & Wenger, 1991) in the special forms of an activity that humans developed throughout history. School subjects, such as mathematics or science, are good examples of such activities.

These two metaphors for learning differ considerably in their most fundamental entailments and in particular in those that deal with the question of what it is that changes when people learn. Whereas the acquisition metaphor portrays learning as the process of extending and transforming mental entities, the participation metaphor equates learning with changes in patterned, recurring ways of acting. The former approach, therefore, assumes a basic ontological difference between what happens inside and outside the human head, whereas the latter approach makes this distinction between internal and external processes irrelevant. In other words, the acquisition metaphor is fundamentally dualistic, whereas with the participation metaphor, the duality disappears. This basic ontological disparity has been shown to entail many other differences, either in ways in which the resulting theories view and explain phenomena or in how they inform the practice of teaching and learning and associated values (Sfard 1998).

Since the participation metaphor does not easily combine with our everyday thinking and talking about learning, the first researchers who opted for this metaphor had to be strongly motivated to be able to abandon the time-honored acquisition metaphor. Indeed, they did have a valuable insight to gain. On the basis of the acquisition metaphor, it was difficult to account either for the cross-cultural and cross-situational diversity of individual learning or for the existence of societal learning. This latter type of learning, which is widely believed to be unique to humans, expresses itself in the increasing complexity of our ways of thinking and acting across successive generations. Acquisitionist researchers, for whom knowledge to be acquired comes directly from the world and is relatively independent of social interactions, did not have means to account for those changes that transcend a single life span. By reconceptualizing learning as a process of becoming capable of acting in uniquely human ways, the participationists provide a solution to the conundrum: An individual participant may offer her own version of an established activity, and if her innovation is deemed an improvement over the former way of doing things, it is likely to spread to the entire community. In this way, human activities are constantly refined, and the innovations are passed from one generation to the next. Once adopted by the community, the reformed ways of acting will be the ones to be learned by every new member. This participationist model of learning also explains why different communities are likely to act differently in the face of similar tasks.

The difference between the acquisitionist and the participationist versions of human development, therefore, manifests itself in how we understand the origins and the nature of human uniqueness. For the acquisitionist, this uniqueness lies in the biological makeup of the individual. The adherents of a participationist vision of learning, on the other hand, believe that it is the collective life that brings about all the other uniquely human characteristics, with the capacity for individualizing the collective – for individual reenactments of collective activities – being among the most important of these characteristics.

Once it is accepted that scientific theories are but metaphors turned into rigorously told stories, those who evaluate theories become more interested in the question of whether a theory is helpful than in the query of whether it is true. Debates between adherents of different metaphors, therefore, are not about facts – about what learning *really* is – but about which of the metaphorically grounded visions of learning answers more questions in a more convincing way. The response to this query may depend on what is being asked in research. Different metaphors for learning may thus coexist, serving different areas of research for different purposes.

Microworlds

Janice Gobert
Social Sciences and Policy Studies Department,
Learning Sciences Graduate Program, Worcester
Polytechnic Institute, Worcester, MA, USA

Keywords

Simulation; Virtual lab

The term microworld was first introduced by Seymour Papert as part of the pedagogical philosophy of constructionism. To Papert, a microworld is a "…subset[s] of reality or a constructed reality so … as to allow a human learner to exercise particular powerful ideas or intellectual skills" (Papert 1980, p. 204). In this definition, microworlds are very open-ended in pedagogical style. Typically, microworlds are models of scientific or social phenomena that represent the domain-specific properties and conceptual representations of the phenomena of interest, thereby providing perceptual affordances and conceptual levers to the learner.

The degree of structure used to guide students' activities in learning environments, particularly those involving microworlds, is a topic that has been debated in science education, where some have encouraged open-ended exploration by students (as does Papert), and others have offered guidance or structure within the microworld to promote optimized learning. In our environment, Inq-ITS, we use carefully constrained technology "widgets," embedded within a broader technology learning environment to support a degree of open-endedness while also including structured guidance so that students can hone their inquiry skills (Gobert et al. 2013). These widgets, together with the artifacts students generate, serve to represent and make salient the products and processes of inquiry for the learner to support both effective monitoring and meta-level understanding of inquiry. Using microworlds, students formulate hypotheses and test them, interpret their data, warrant their claims, and communicate their findings.

In our work, we instrumented our environment and microworlds to log all students' interactions, which support real-time analyses (i.e., of the log files) based on knowledge-engineering and educational data mining techniques. This results in assessment metrics for researchers and teachers on the specific inquiry skills of interest. It also helps us scaffold students' inquiry processes in "real time" (i.e., during the microworld session).

Keywords

Adidactical; Didactic contract; Didactic milieu; Epistemic system; Symbolic forms; Teaching

In this entry, we discuss the notion of milieu as interpreted by the French educational didactician Guy Brousseau (1997). We may generally define this concept in the following terms: the milieu is the actual material and symbolic structure of the problem at stake, which one has to deal with in order to solve this problem (Sensevy 2012). Here and hereafter, the term "problem" refers in a very general way to any situation in which one has to restore an equilibrium, in the Dewean sense (Dewey 1938).

Consider this example: at primary school, students are asked to reproduce a puzzle by enlarging it, in such a way that a segment which measures 4 cm on the model will measure 7 cm on the reproduction. The pieces of this puzzle constitute the milieu that the students face for this "enlargement problem." This kind of milieu responds to three conditions:

1. *The teacher's intentions are inscrutable*. Here, the students ignore the specific teacher's teaching intentions. They concentrate on a pragmatic purpose (enlarging the puzzle), and at first they do not recognize the kind of knowledge (proportional reasoning) necessary to enable them to solve the problem. In this way, the students have to achieve certain autonomy.
2. *The relationships within the milieu are pregnant and adequate*. In enacting their activity, the students get feedbacks from the milieu, which helps them to make decisions about the strategies they use. For example, as they have to enlarge the puzzle in such a way that a segment, which measures 4 cm on the model, will measure 7 cm on the reproduction, they may decide to add 3 cm to every dimension. As a result of this strategy, the pieces are not compatible; the students may realize concretely that the additive strategy is not a good one. The milieu feedbacks are pregnant in that they focus the students' attention on the relevance of the used strategy. They are adequate, in that an effective proportional strategy in making pieces will obtain their compatibility.
3. *The knowledge at stake provides a winning strategy in problem solving*. A specific knowledge (in the puzzle case, proportional reasoning) enables students to solve the problem. In this kind of milieu, the students can examine the situation, take a decision, enact it, and judge on their own the relevance of their strategy, according to the milieu feedbacks.

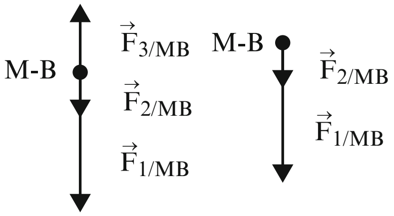
With respect to these three conditions (specially the first one), Brousseau (1997) draws attention to two fundamental features of such a milieu that he terms adidactical. First, it "lacks of any didactical intentions with regard to the students" (Brousseau 1997, p. 40). In our example, the signs provided by the pieces of the puzzle are non-intentional ones and opposed to the students' goal (enlarging the puzzle) until they use the proportional strategy. Second, designing an adidactical milieu means taking into account not only the specific knowledge this milieu has to embed but also the current knowledge system with which students will approach this milieu. This is the reason why Brousseau defined the milieu as "the system opposing the taught system or, rather, the previously taught system"

(Brousseau 1997, p. 57). In our example, students invariably act by adding 3 cm to every dimension. They face the adidactical milieu with an additive knowledge system, which provides them with their actual ineffective strategy.

Within this perspective, one may acknowledge the very nature of the teacher's work. In order to describe the teaching-learning relationship, one has to be able to call for another concept, that of didactical contract (Brousseau 1997; Sensevy 2012). The didactical contract organizes the actual system with which the students deal with the milieu. In our puzzle example, one could say that students cope with the milieu within an additive contract, which has stemmed from the previous teacher and students' joint action in mathematics. The didactical contract can be viewed both as a system of expectations between the students and the teacher and as the current students' strategic system.

One might think that the notion of milieu is specific to a certain kind of teaching-learning process. It is true in the sense that a milieu cannot be designed without taking into account the specific knowledge it embeds. But the notion of milieu has a general relevance, in that it refers to the actual material and symbolic structure of the problematic situation, insofar that this structure may provide feedbacks for the student's epistemic action. In this respect, let us consider an activity in the topic of mechanics (often taught in grade 11). This activity (Tiberghien et al. 2009; Sensevy et al. 2008) occurs while introducing the three laws of Newtonian mechanics. It aims at familiarizing students with the direction of the action and helps them to differentiate between action and motion. Then, the designers elaborate a milieu where directions of action and motion are different and observable even with common sense.

In this activity, the students have to throw and catch a medicine ball (heavy ball) and then answer a series of questions. The first one is "locate and note the moment(s) where you exert an action on the medicine ball; each time specify in which direction you exert this action on the medicine ball." For the students, it is not easy to differentiate direction of action and motion when they catch the medicine ball at its lower point, and some of them say they exert a force downward. After a while, the feedbacks of the milieu (the way their hands have "to resist" to the ball) may help them to begin to conceptualize the situation accurately. This milieu (medicine ball) has a lot in common with the previous one (puzzle). It provides some feedbacks that are more or less immediately perceived by the students (the puzzle pieces do not fit together; the hands exert a force upward). One could term these kinds of feedbacks causal feedbacks. But there are other feedback possibilities in a milieu.



Milieu, Fig. 1 Two kinds of proposals for approaching the "medicine ball" problem

Let us consider now another situation, in which the milieu is a rather complex one. After having worked on the medicine ball problem, the students have to study the whole movement of the medicine ball within a specific activity ("Aristotle or Galileo?"). The students have to analyze different students' answers to the task of "representing the forces which are exerted on the medicine ball (when it is going upward) represented by a point and noted M-B." They are asked to study two proposals (summarized in Fig. 1), composed by two annotated vectors and a text:

> One representation is correct from the point of view of the current model of mechanics (initiated by Galileo). The other representation corresponds to an intuitive analysis of the situation: according to this point of view (close to Aristotle's) there is always a force in direction of the movement.

In this problem, the students have (1) to identify which type of answer refers to an Aristotelian viewpoint, (2) to identify the systems 1 and 2 which act on the system M-B and to draw a conjecture about what the additional force represents for the students (A) and why they need to represent this force, and (3) to rely on the interaction model in order to justify the fact that this force does not model an action exerted by the medicine ball when it goes upward.

How is the milieu shaped in this situation? First, the students are confronted with a text from which they have to understand that the problem to be solved consists of analyzing two different student's responses. Second, they have to pay attention to the fact that the student's responses are vector representations. Third, while reading the text, students have to focus on a specific sentence ("according to this point of view (close to Aristotle's), there is always a force in the direction of the movement") in order to be able to work out the problem at stake. By referring to the previous sentence, they have to recognize this Aristotelian view as "incorrect." Fourth, they have to refer their analysis to the moment when the medicine ball is going up. Fifth, they have to scrutinize the two representations in order to identify which group analyzes the situation "intuitively," by drawing a force in the direction of the movement. Thus they have to consider the representation A and identify the vector F3/MB as expressing the Aristotelian viewpoint of a force in the direction of movement. They have to formulate hypotheses about the reason why the students need to represent this force. Finally, they have to justify the "fact that this force does not model an action exerted by the medicine ball when it goes upward," by applying the interaction model. According to the current didactic contract, students are supposed to recognize that there are only the earth and the air which exert an action on the ball and that both of these actions are downward.

If we compare this kind of milieu to the previous ones studied (e.g., the "feel the medicine ball" milieu), we can acknowledge deep commonalities and striking differences. In both ways the students have to decipher and take into account a set of symbolic forms (the medicine ball and the hands pressure, the different meanings in the text of the problem), which refers to the nature of the problem at stake. Then they have to inquire into this set of symbolic forms in order to institute logic relationships between them and to transform them in an epistemic system of symbolic forms. But there is also a conceptual difference between the two kinds of milieu. In the first milieu (the "feel the medicine ball" milieu), students have to experience causal feedbacks by interrogating their own body, which functions as a milieu. In the second milieu (the "Aristotle-Galileo" milieu), they have to experience rational feedbacks, by inferring new meanings from the semantic and semiotic units they put in relation.

But above these commonalities and these differences, there is a deep kinship between the two milieus. Even though the teacher's intentions can be used by the students for working out the problem, it is not possible for them to rely on this recognition to solve the problem. In order to solve it, they have to orient themselves in the milieu, then to inquire into the milieu and, in doing so, to encounter the fundamental meanings of the physics involved in this milieu. It is worth noting that the teacher's work is crucial to help the students achieve their inquiry. The art and the science of teaching could be seen as a way of monitoring the relationship between the student's work and the milieu.

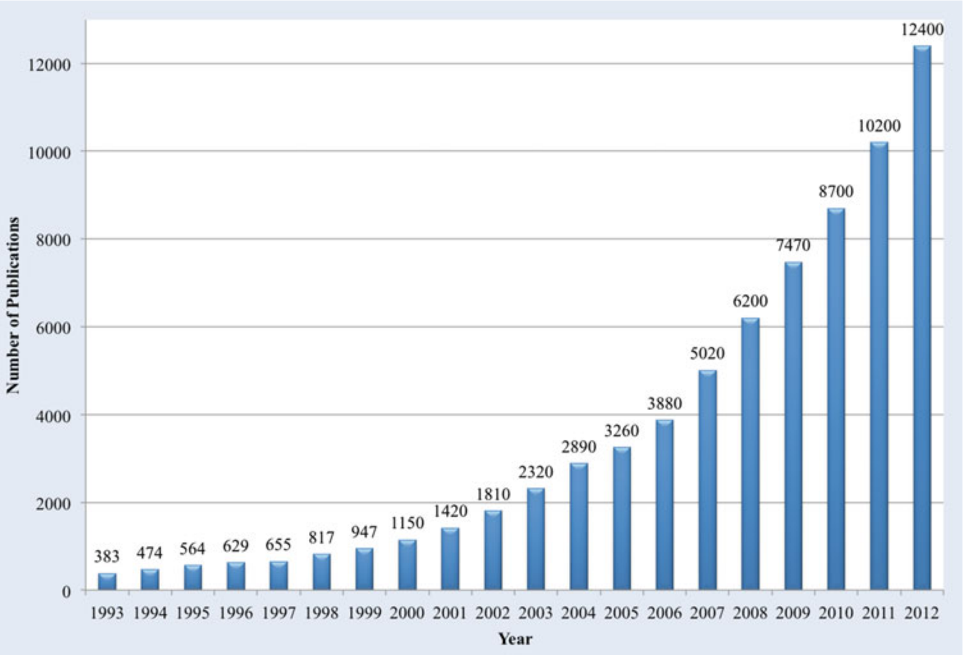
> . . . it is my fervent aspiration that our culture will pay more attention to well-being, will include strategies to promote well-being with our educational curricula and within the healthcare arena, and will include well-being within our definitions of health. These changes would help to promote greater harmony and well-being of the planet. (Davidson 2013)

In the above quote, Richard Davidson, a leading scholar and one of the pioneers of contemplative neuroscience, echoes the wishes of a growing number of like-minded enthusiasts who call for the expansion of the goals of the twenty-first century education to include promotion of wellness and sustainability. After decades of seemingly nonstop curriculum reform, much of which has focused on the production of scientists and increasing participation in science-related professions, it is desirable to revamp the goals of science education to address wellness and sustainability as well as goals that relate to the grand challenges faced by humanity. It is opportune to orient curricula to understanding the body and the mind and developing tools to afford lives as functionally literate citizens. Adapted from Buddhist traditions, mindfulness practices offer a unique opportunity to address in the classroom the cognitive and the oft-neglected affective dimensions of human ontology. As evidenced by the exponential growth of mindfulness-related publications (Fig. 1), there is widespread interest in the applicability and potential benefits of mindfulness in various fields of social life including educational contexts. This interest is fueled largely by the recent developments in the field of contemplative neuroscience that provide compelling evidence for our brain's enormous plasticity (ability to change its structure and function) and for the significance of the bidirectionality of the mind-body connection. Mindfulness training emerges as affording a number of positive changes in the brain which in turn improve the functioning of our bodies.

Mindfulness involves intentionally remembering to pay attention to the present moment experience – a disposition that defies our default preoccupation with analyzing and obsessing about the past or charting out and worrying about the future (so-called mind wandering). This present moment awareness is accompanied by a nonjudgmental acceptance of one's thoughts, feelings, and perceptions and seeing things for what they are without identifying with them. Such an accepting mindset can translate into increased levels of caring for the natural world. Mindfulness training has been linked to a range of cognitive, social, and psychological benefits to students and teachers. It supports development of self-regulatory skills associated with emotion and attention, self-representations, and prosocial dispositions such as empathy and compassion (MLERN 2012). Furthermore, mindfulness tends to decrease stress, depression, anxiety, and hostility. An increase in mindfulness may involve a higher incidence of focus, heightened awareness of thoughts and emotions and their relevance to learning, and awareness of what is happening in the moment.

Research for at least a half century has shown a relationship between emotions and cognitive focus. For example, studies indicate that positive emotions are associated with broadening of cognitive processes, and negative emotions are associated with narrowing of cognitive processes. There are numerous ways to interpret the research and associated theoretical frameworks in relation to the teaching and learning of science. However, it seems clear that the valence and intensity of emotion are salient. We conclude that it is important to be aware of the mediational potential of emotions. In terms of mindfulness, the goal is to be aware of emotions and endeavor to "let them



Mindfulness and Science Education, Fig. 1 Growth in the number of mindfulness-related publications over the last two decades. Data obtained from a search for “mindfulness” in Google Scholar

go,” making sure that they do not mediate participants’ conduct in ways that prove to be distracting and deleterious to learning. In the event that a participant decides that emotions are persisting and are adversely affecting learning, it is important to know how to intervene to sever attachments and/or reduce the intensity of the emotions.

Research on the intensity of emotions and focus has implications for teaching science. For example, consider a classroom incident reported by Tobin and Llena (2010). During a lesson on conversion of units, the teacher and several students were frustrated with most students’ performance on a recent quiz. The regular science teacher had been absent due to illness and a substitute had been teaching the class. Students were having difficulty following their substitute science teacher’s efforts to re-teach the work for which their test performance had been poor. An altercation broke out when a student leant across to clarify for another student what the teacher had said. The teacher reprimanded her for speaking while he was speaking. Almost immediately the learning environment became dysfunctional in many respects. The teacher’s anger was intense, represented through his gestures, prosody, and spoken text. Consistent with the intensity of emotion decreasing focus, the teacher was less able to attend to teaching the students about conversions from one unit to another. His oral presentation was slow, contained long pauses, and included utterances about “rude student.” Some students regarded the altercation as a performance and laughed at what was happening, regarding the text as unintelligible, an object for humor and ridicule. For the student who had been reprimanded, words such as “rude student” were inflammatory and catalyzed further outbursts, ratcheting up the intensity and distribution of high emotions.

In a very short time interval, less than a minute, the teacher endeavored to continue teaching, while at the same time he continued to refer to the student as rude and taunted her by mimicking her prosody and chanting “temp, temp, temper” as she reacted with high intensity, “you have every nerve to call me a rude student. . ..” At the same time laughter punctuated a turbulent classroom environment in which an increasing number of students’ actions were accusing and disrespectful and the teacher’s words were taunting and escalating. Laughter was polysemic, some instances possibly intended to encourage an escalation of the altercation, other instances reflecting amusement at what was happening, and nervous laughter that projected anticipation and acknowledgment that unfolding events were dangerous and cascading out of control. A key point of emphasis is that the learning environment was not mindful and the intensity of emotions focused actions away from the teaching and learning of science. Although there was widespread awareness of what was happening, there were no corrective interventions to reestablish a focus on learning science. In this context we regard it as a critical priority for science educators to use interventions, such as heuristics and breathing meditation, to create and maintain mindful learning environments.

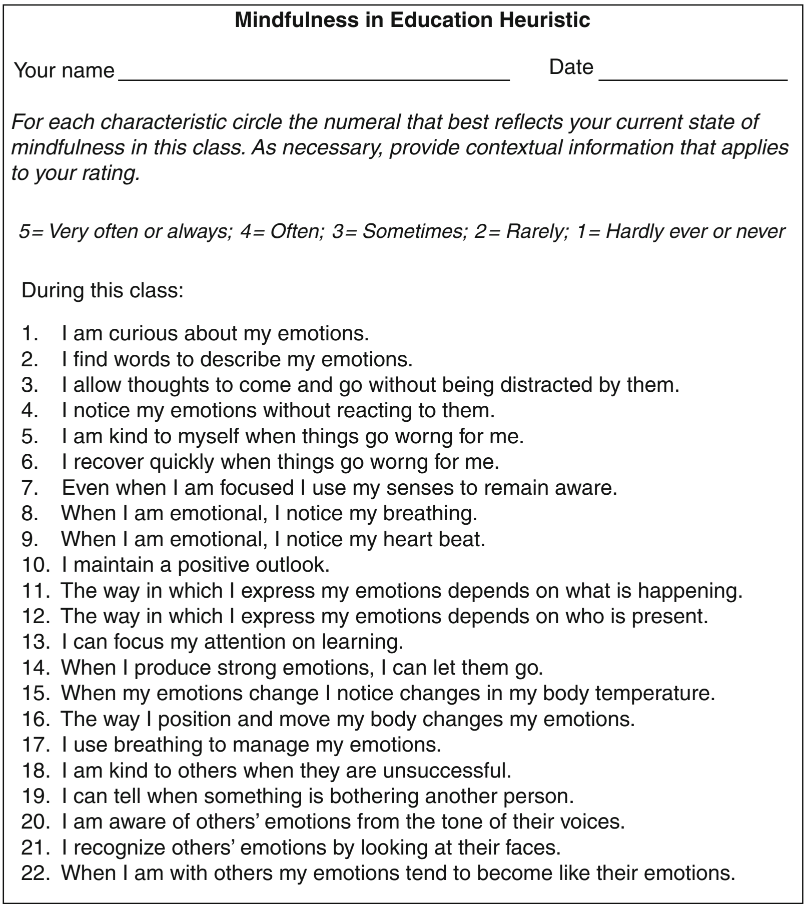
Lack of fluency in a classroom is often associated with high levels of emotional intensity and low levels of mindfulness. Of concern is the impact of sustained intense emotions on the well-being of teachers and students, a concern that is even greater in those contexts such as in the USA where there are well-documented trends associated with teacher turnover and student absenteeism. It is therefore imperative to understand and minimize undesirable negative emotions in the classroom and produce more positive emotional climates and more desirable states of wellness. The potential of mindfulness to address some of the intractable problems of education constitutes a strong rationale for the use of mindfulness-based interventions.

Cultivating Mindfulness in the Classroom: Mindfulness-Based Interventions

Over the last decade, a number of approaches to cultivating mindfulness in educational settings have been developed. Many of the programs are loose adaptations of the Mindfulness-Based Stress Reduction Program (MBSR) originally created for clinical purposes by Jon Kabat-Zinn. An alternative approach to incorporating mindfulness-based interventions into teaching and learning practices involves the use of heuristics (refer to Fig. 2 for an example of a heuristic). Consistent with the hermeneutic tradition, using a heuristic is a way of surrounding the construct with meaning through a series of statements (referred to as characteristics), each describing some aspect of mindfulness. As students or teachers read each characteristic, they select a point on the available rating scale. This process is meant to afford getting insights into one’s conduct vis-à-vis various dimensions of mindfulness. The theory that supports this intervention is reflexive inquiry (Bourdieu and Wacquant 1992) where reflexivity may be understood as becoming aware of the unaware. Because so much of what happens in social life happens without conscious awareness, reflexivity is important for actors, such as science teachers and their students, so that they can identify aspects of their practice and their supporting rationale, changing them as desirable to benefit the collective (Tobin 2012). Accordingly the use of heuristics aims at deepening awareness of self and others and of the surrounding structures. As students and teachers ponder the characteristics of mindfulness, they become aware of them and may pay attention to conduct that reflects those characteristics within themselves and each other. As the participants’ awareness of mindfulness increases, they often indicate the desire to change their conduct to more closely reflect an idea expressed in a heuristic. Consequently, changes in their conduct may become visible. Such positive changes have potential to contribute to a more harmonious learning environment. For example, students and their teachers may develop more compassionate attitudes toward self and others and learn to replace reacting with responding which may be associated with decreased incidence of aggression and bullying.

A useful feature of a heuristic is its malleability. A heuristic may be adapted to fit any educational context: a science class at different grade levels, teacher training or professional development,

Mindfulness and Science Education,
Fig. 2 Mindfulness in Education heuristic



Mindfulness in Education Heuristic

Your name ________________________________ Date ________________

For each characteristic circle the numeral that best reflects your current state of mindfulness in this class. As necessary, provide contextual information that applies to your rating.

5= Very often or always; 4= Often; 3= Sometimes; 2= Rarely; 1= Hardly ever or never

During this class:

1. I am curious about my emotions.
2. I find words to describe my emotions.
3. I allow thoughts to come and go without being distracted by them.
4. I notice my emotions without reacting to them.
5. I am kind to myself when things go worng for me.
6. I recover quickly when things go worng for me.
7. Even when I am focused I use my senses to remain aware.
8. When I am emotional, I notice my breathing.
9. When I am emotional, I notice my heart beat.
10. I maintain a positive outlook.
11. The way in which I express my emotions depends on what is happening.
12. The way in which I express my emotions depends on who is present.
13. I can focus my attention on learning.
14. When I produce strong emotions, I can let them go.
15. When my emotions change I notice changes in my body temperature.
16. The way I position and move my body changes my emotions.
17. I use breathing to manage my emotions.
18. I am kind to others when they are unsuccessful.
19. I can tell when something is bothering another person.
20. I am aware of others' emotions from the tone of their voices.
21. I recognize others' emotions by looking at their faces.
22. When I am with others my emotions tend to become like their emotions.

a cogen session (see the entry Teacher Research), etc. It may change its format (i.e., become a narrative); characteristics may be added, deleted, or altered to adequately reflect salient features of a particular educational setting. Similarly a heuristic may or may not include a rating scale associated with each characteristic. If a rating scale is included, the scale points can be written to fit the context of use. A heuristic may be completed in "one sitting" or alternatively individual characteristics may be used each day to draw attention to different dimensions of mindfulness allowing students and teachers to make personal choices about each in meaningful ways. This could be done in a variety of ways including the use of technology, cell phones, blogs, chalkboards, etc. Heuristics may be used for planning and guiding classroom activities with the purpose of facilitating adoption of practices that are characterized by mindful attention, focus, and compassion to self and others.

Breathing meditation is often an integral part of mindfulness training. Focusing on the breath allows participants to bring their attention to the present moment. It also assists with disassociating oneself from any (especially negative) thoughts and emotions. Breathing meditation may be used at the beginning of a class session to help students and teachers calm their minds and sharpen attention and focus. Using breathing meditation in a science classroom may afford exploration of the relationship between emotional feelings and respiration (the mind | body connection) and its significance for emotion regulation. Accordingly, students and teachers may observe changes in their emotional states as they practice deep abdominal breathing. Conversely, their attention may be brought to the changes in their breathing patterns (and possibly other physiological markers such as fluctuating heart rate) as their emotional states shift. Increased awareness of these connections may be accomplished through the use of relevant characteristics in a heuristic or through other techniques such as the use of oximetry (see the entry Teacher Research). Breathing meditation may be presented as a medical intervention that is associated with improvements in one's well-being. Breathing meditation may be modeled and facilitated by the teacher or by students. It may be a relatively short activity lasting between 3 and 5 min at a time. Participants may be encouraged to maintain the practice outside the classroom if they find it beneficial.

Mindfulness in Science Education

Science process skills became a visible part of the science curriculum in the post-Sputnik reform movement associated with the 1960s and 1970s. Basically, curriculum developers considered the steps of the scientific method and/or problem-solving and broke them down into skills. Different projects had different lists of process skills, in part because materials were developed around different psychological theories of learning. Prominent among these were the learning theories of Jean Piaget and Robert Gagné. Consider the 5 Es (engagement, exploration, explanation, elaboration, and evaluation), a present-day articulation of the Learning Cycle, which was based on Piaget's developmental theory and emerged in the post-Sputnik era as a framework for the Science Curriculum Improvement Study in the USA. From a sociocultural point of view, each of the 5 Es is an interaction chain (Collins 2004), that is, involving multiple interactions between individuals and social artifacts that are enacted using available structures (i.e., resources).

The quality of enactment reflects criteria such as fluency (i.e., enactment occurs just in time, is anticipatory, and is appropriate) and the extent to which others' actions are in synchrony and maintain flow. It is essential for successful interaction chains to occur in order for students to enact any of the 5 Es effectively and appropriately. The likelihood of this happening can be heightened if students establish and maintain focus and fluency while being aware of (attentive to) unfolding events that are salient to their learning. If others are involved in an interaction, for example, it is important that an actor is aware of emotional styles related to the extent to which he/she or others are expressing emotional cues. Language is an important tool for enacting process skills when actions are internal (i.e., thought), external (i.e., spoken or written), and a combination of both internal and external.

For example, the quality of enactment of a process skill concerns the words and utterances used, their prosody (e.g., loudness, frequency modulation, intonation, etc.) and proxemics (e.g., gestures, body movement and orientation, eye gaze, head tilt, etc.). Quality counts. In addition, what counts as quality will reflect the theoretical frameworks that underpin central criteria such as teaching and learning. For example, in terms of the sociocultural framework that we [the authors] adopt in our research, dialogue is central. No matter what happens to be the focus of the curriculum, we want the enactment and associated interaction chains to be characterized by dialogic inquiry. That is, as teachers and students interact, we want them to be respectful to one another, share time of talk and the number of talking turns, listen attentively to what others have to say, make sense of it, and understand its affordances in comparison to alternatives. Also, if injustices arise we expect participants to speak out in favor of corrective action. When individuals speak, they do so for the benefit of others, not just for themselves.

When science process skills were initially emphasized in science education, there were clichés to the effect that "science is a verb," "science is something that is done," and "authentic science" – meaning that what children might do, as science, would likely differ significantly from what postdoctoral researchers would do as science. It was argued that science had a role in terms of enhancing functional literacy in an increasingly technological society in which citizens have the knowledge to feel at home with the technologies they use in their lifeworlds and are not intimidated by them. The process skills learned and employed in school science, it was argued, would be available for use in different fields of the lifeworld, including shopping, working, hobbies, and consuming media. Now, more than six decades later, there is a compelling argument that students should know about healthy lifestyles and bodies, including neuroplasticity. To know, in the sense we use it here, extends far beyond just knowing the facts to include enacting healthy lifestyles and engaging in activities that transform the structure and functioning of the brain. We offer mindfulness as the process skill of the present decade.

Sound Bodies and Sound Minds

The emerging science behind the benefits of mindfulness to wellness provides support for incorporating contemplative practices into the educational arena. Mindfulness-based interventions are associated with positive outcomes for students and teachers through addressing cognitive and affective dimensions of teaching and learning. Whereas mindfulness can be a constituent of a traditional approach to science education, we regard it as a central component of a radical transformation of science education to embrace overarching goals related to wellness and sustainability. Mindfulness is a way of enacting social life that can expand learning potential and ameliorate the nature and intensity of emotions that rise and fall in the normal course of life. As part of the toolkit that individuals possess, mindfulness heightens awareness of emotions and their attachment to the ongoing conduct of social life. Given the alarming increase of violence in institutions that previously have been regarded as sanctuaries, such as schools, we regard as a priority for all humans to learn about mindfulness and to enact it in the course of everyday life, including schooling, and science education. Because science has traditionally been involved with learning about life and bodies and relationships between humans and the living and nonliving environments in which they conduct their lives, we regard mindfulness as central to a transformed science education that includes the science of learning and being in the world.

Main Text

Early in the evolution of classroom-based computing technologies, Taylor (1980) described three roles that computers could play in the classroom: tutor, tool, and tutee. In the tutor role, the computer teaches the student, a role fulfilled nowadays by Web-based tutorials, information sites, and drill-and-practice. Computers continue to be very powerful productivity tools, including word processing and organizational tools such as databases and spreadsheets. The most constructivist application of computer technologies is in playing the role of tutee, where the students actually teach the computer. One way in which computer technologies can serve as a tutee is by enabling students to construct models of what they are learning. Science educators have long recognized the importance of modeling in understanding scientific phenomena. Humans are natural model builders, constructing conceptual models of everything that we encounter in the world. The better that we understand any part of the world, the better we can model that part of the world – whether it is from science, economics, or how an automobile operates. This entry briefly describes the use of computers as mindtools (Jonassen 2000, 2006) to create models of the ideas that we are learning.

Science and mathematics educators have long recognized the importance of modeling in understanding scientific and mathematical phenomena. Psychologists have explored mental or conceptual models and how these can be represented through external models or visualizations. The models in the minds of learners can be understood as being embodied in the equations, diagrams, computer programs, or other symbolic constructs used by learners to represent their understanding. Although still a topic of research, it is clear that there is a dynamic and reciprocal relationship between our internal mental models and the external models that we construct. The primary purpose of modeling is the construction and revision of conceptual understanding – that is, conceptual change. Building explicit models of our internal conceptual models engages and supports the process of conceptual change. When we build and test external models, our internal models make progress.

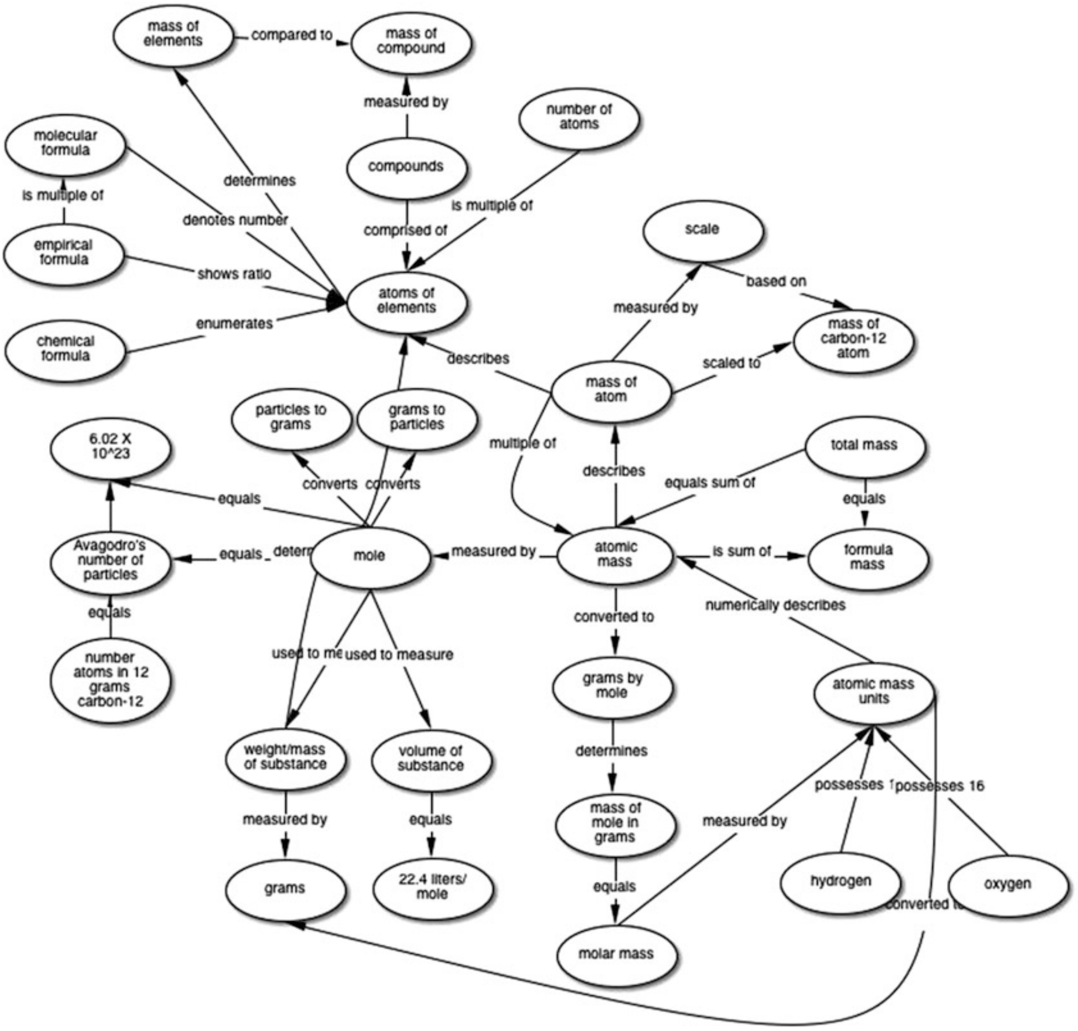
This entry introduces the notion of "mindtools," which are readily available tools for constructing syntactic and structural representations of what is being learned. Mindtools repurpose commonly used computer applications to engage learners in critical thinking and conceptual change. There are several classes of mindtools, including semantic organization tools (e.g., databases, concept mappers), dynamic modeling tools (e.g., spreadsheets, expert systems, or systems modeling tools), visualization tools (e.g., drawing or visual modeling environments), knowledge construction tools (e.g., multimedia construction and story construction tools), and conversation and collaboration tools. All of these tools may be used to construct models of what is being learned.

What Can Be Modeled

If model building serves to externalize mental models, then learners should benefit through the use of a variety of tools to model a variety of phenomena. Different models engage different kinds of thinking, and mindtools may be used to model different kinds of phenomena (Jonassen 2000).

Modeling Domain Knowledge

Domain knowledge is often presented and understood by learners in a very linear fashion, consisting of a series of facts and unrelated pieces. By modeling the domain and its structure, elements can be related to each other in complex associative maps (e.g., concept maps) or causally related systems (e.g., spreadsheets, expert systems, or system models). Concept maps are spatial representations of concepts and their interrelationships that reflect the knowledge held by the learner. Figure 1 illustrates a concept map describing molar conversion in chemistry. These representational structures can also be seen as cognitive structures, reflecting conceptual knowledge, structural knowledge, and semantic networks. As students study some domain in



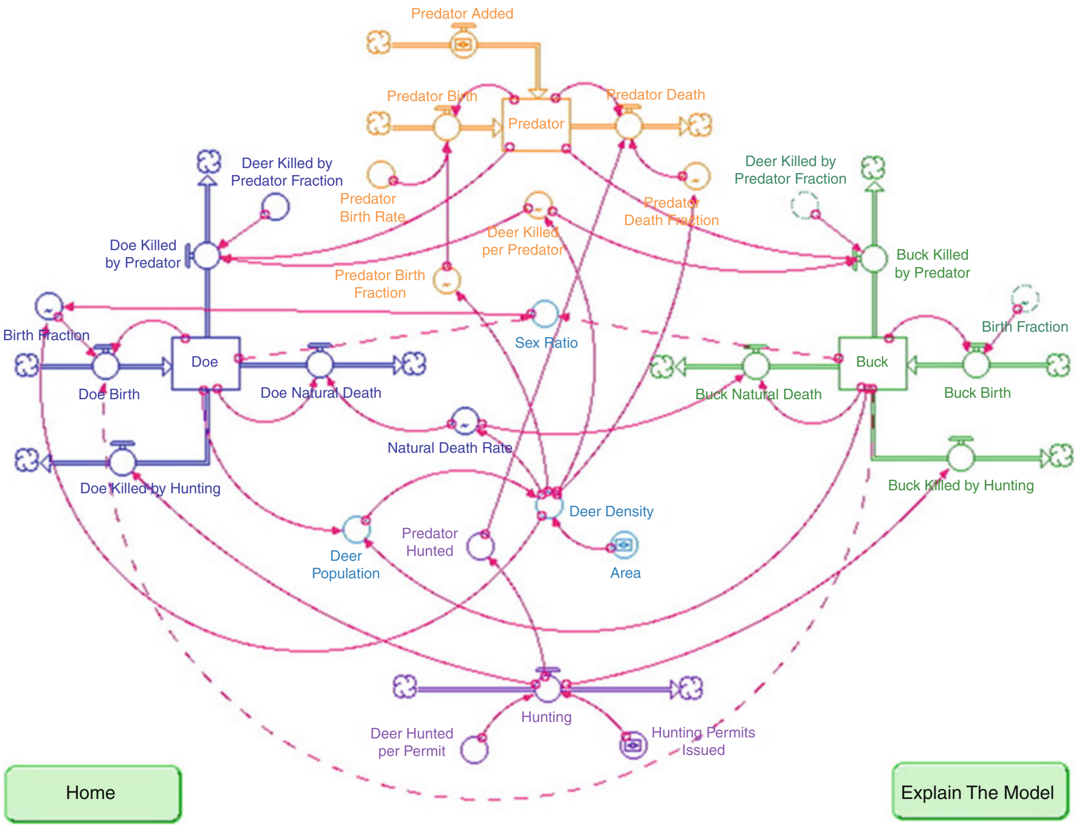
Mindtools (Productivity and Learning), Fig. 1 Concept map on molar conversion

a science course, they can continuously add to their concept maps, refine them, and even use them to reveal gaps or misunderstandings. Comparing one's concept map with others can result in conceptual change, as models constructed by other students can represent alternative structure of the same ideas.

Modeling Systems

Scientific subject matter content can be thought of in terms of coherent systems. Rather than focusing on discrete facts or characteristics of phenomena, when learners study content as systems, they develop a more integrated view of the world. Systems thinking involves understanding the world as process systems, feedback systems, control systems, and living systems, all of which can be seen as self-reproducing organizations of dynamic, interdependent parts. Systems are goal driven, feedback controlled, self-maintaining, self-regulating, and synergetic. Requiring learners to organize what they are learning into relevant interacting systems provides an opportunity to develop a more integrated view of the domain.

Systems and subsystems are defined by structural and causal relationships. Systems modeling tools, such as Stella, enable learners to build



Mindtools (Productivity and Learning), Fig. 2 System model of deer population

models that focus on systems and their internal interactions. Figure 2 illustrates a model depicting the growth and maintenance of a local deer population that was produced by high school students. In this model, we see that the deer population is a function of factors that are part of the larger ecosystems, including reproduction rates that are dependent on predation and hunting. System models show the interactions of components within a system.

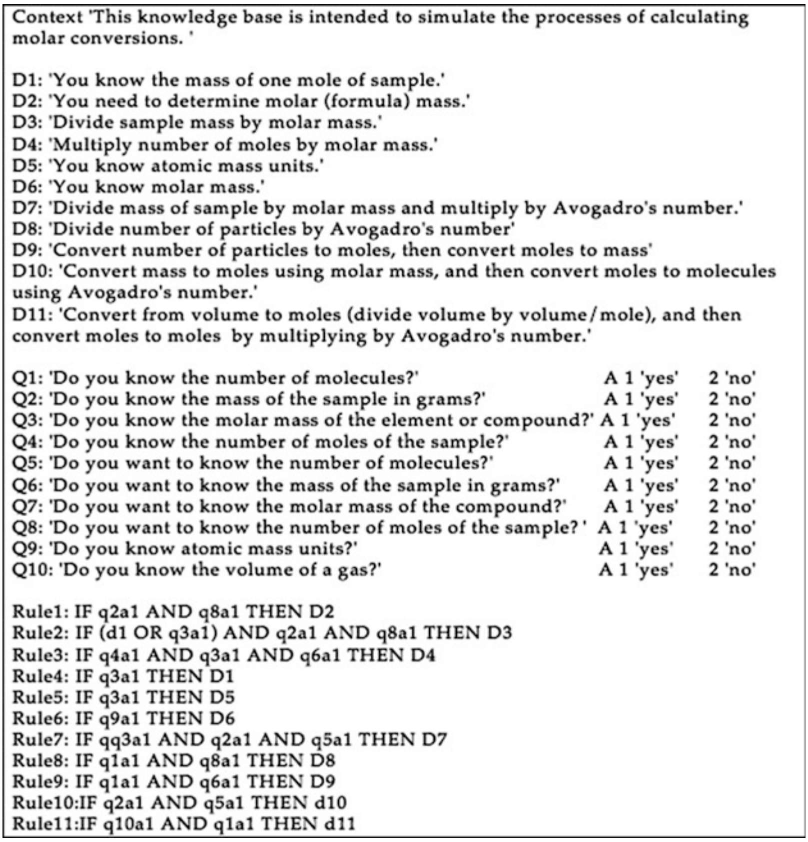
Modeling Problems

In order to solve virtually any kind of problem, the problem solver must mentally construct a problem space by selecting and mapping specific relations of the problem (Jonassen 2006). Using modeling tools to create visual or computational models externalizes learners' mental problem space. As the complexity of the problem increases, producing efficient models becomes even more important. Figure 3 illustrates the advice, factors, and rules to guide the development of an expert system knowledge base relating to how molar conversion problems are solved in chemistry. Reflecting on the problem solution process can help learners to better solve this kind of problem.

Modeling Experiences (Stories)

Stories are the oldest and most natural form of sensemaking. Cultural knowledge is often conveyed through different types of stories, including myths, fairy tales, documentaries, and histories. Humans appear to have an innate ability and predisposition to organize and represent their experiences in the form of stories and can more easily understand stories than expository texts.

An alternative modeling experience to studying content is to collect and study stories that capture relevant disciplinary experiences.



Context 'This knowledge base is intended to simulate the processes of calculating molar conversions. '

D1: 'You know the mass of one mole of sample.'
D2: 'You need to determine molar (formula) mass.'
D3: 'Divide sample mass by molar mass.'
D4: 'Multiply number of moles by molar mass.'
D5: 'You know atomic mass units.'
D6: 'You know molar mass.'
D7: 'Divide mass of sample by molar mass and multiply by Avogadro's number.'
D8: 'Divide number of particles by Avogadro's number'
D9: 'Convert number of particles to moles, then convert moles to mass'
D10: 'Convert mass to moles using molar mass, and then convert moles to molecules using Avogadro's number.'
D11: 'Convert from volume to moles (divide volume by volume/mole), and then convert moles to moles by multiplying by Avogadro's number.'

Q1: 'Do you know the number of molecules?' A 1 'yes' 2 'no'
Q2: 'Do you know the mass of the sample in grams?' A 1 'yes' 2 'no'
Q3: 'Do you know the molar mass of the element or compound?' A 1 'yes' 2 'no'
Q4: 'Do you know the number of moles of the sample?' A 1 'yes' 2 'no'
Q5: 'Do you want to know the number of molecules?' A 1 'yes' 2 'no'
Q6: 'Do you want to know the mass of the sample in grams?' A 1 'yes' 2 'no'
Q7: 'Do you want to know the molar mass of the compound?' A 1 'yes' 2 'no'
Q8: 'Do you want to know the number of moles of the sample? ' A 1 'yes' 2 'no'
Q9: 'Do you know atomic mass units?' A 1 'yes' 2 'no'
Q10: 'Do you know the volume of a gas?' A 1 'yes' 2 'no'

Rule1: IF q2a1 AND q8a1 THEN D2
Rule2: IF (d1 OR q3a1) AND q2a1 AND q8a1 THEN D3
Rule3: IF q4a1 AND q3a1 AND q6a1 THEN D4
Rule4: IF q3a1 THEN D1
Rule5: IF q3a1 THEN D5
Rule6: IF q9a1 THEN D6
Rule7: IF qq3a1 AND q2a1 AND q5a1 THEN D7
Rule8: IF q1a1 AND q8a1 THEN D8
Rule9: IF q1a1 AND q6a1 THEN D9
Rule10:IF q2a1 AND q5a1 THEN d10
Rule11:IF q10a1 AND q1a1 THEN d11

Mindtools (Productivity and Learning), Fig. 3 Excerpt from expert system rule base on molar conversion

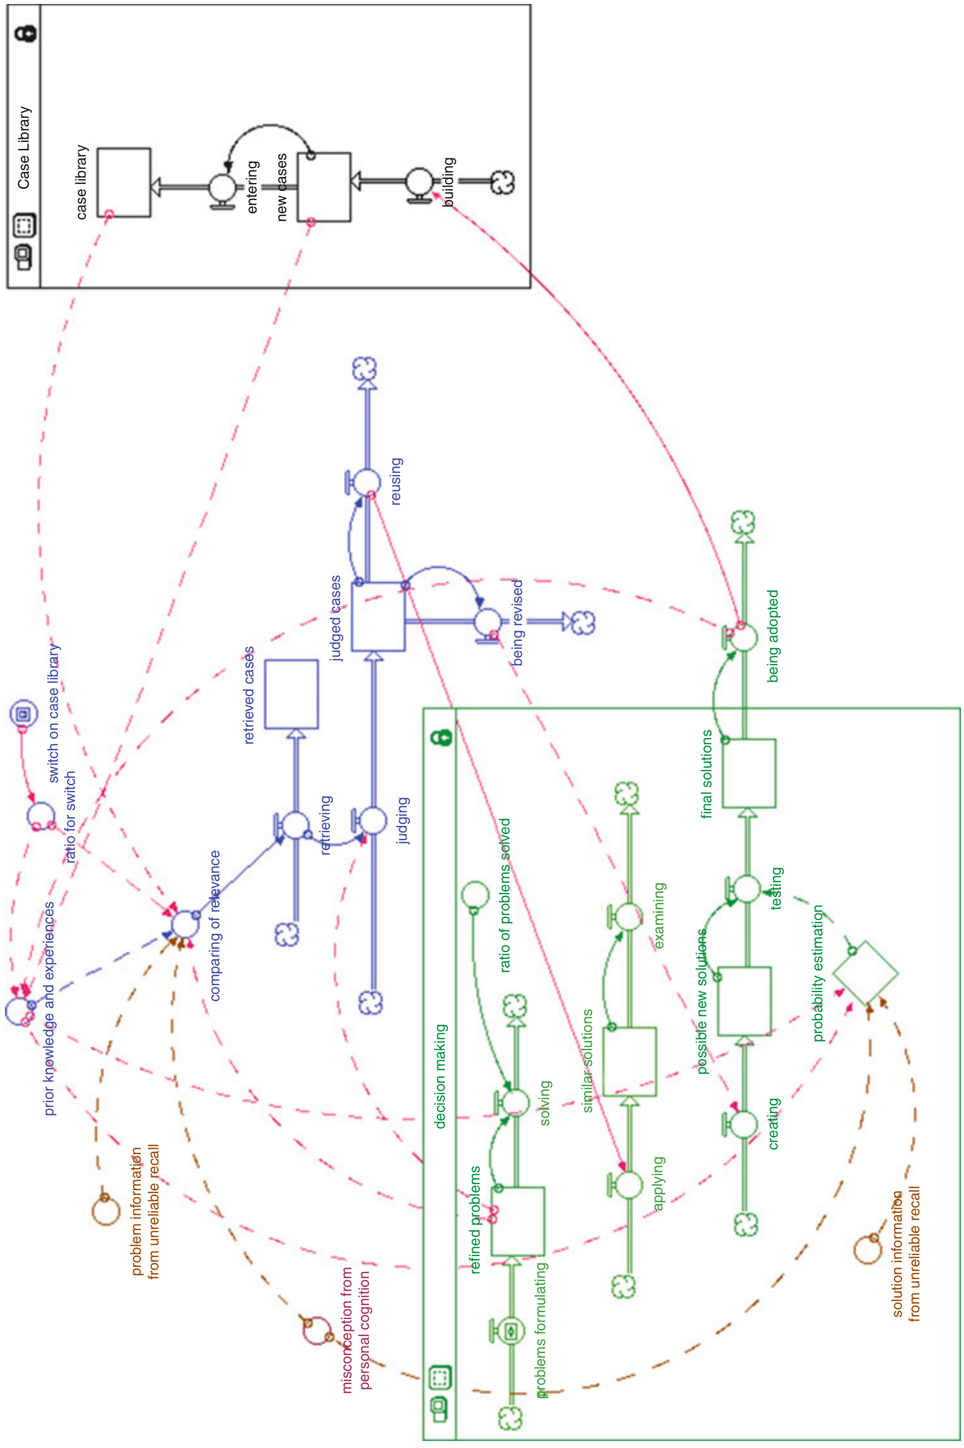
For example, we have constructed databases of stories about how engineers solve different kinds of problems, which have been collected into case libraries (i.e., databases of stories). When studying how to solve problems in any domain, students' understanding may be enriched by such stories that help them to identify the lessons learned from each problem-solving situation. This process is known as case-based reasoning – the reuse of prior experiences. Databases are a logical means for capturing and storing such stories or problem-solving cases, and the process of collecting and indexing them serves to enhance the overall intellectual resource.

Modeling Thinking (Cognitive Simulations)

Many educators have argued for an emphasis of metacognition and self-reflection by learners, having students reflect on their learning processes in order to better learn how to learn. Metacognitive reflection may be enhanced by building a model of how to engage in different kinds of learning. Rather than modeling content or systems, learners can model the kind of thinking that they need to perform in order to solve a problem, make a decision, or complete some other task. Figure 4 illustrates a systems model of decision-making that is based on the case-based reasoning theory just presented. These students developed a model of decision-making, a common form of problem solving and how it is supported by stories of prior experiences.

Why Should We Use a Mindtools Approach?

Why do mindtools work? That is, why do they engage learners in critical, higher-order thinking and facilitate conceptual change? The process of articulating what we know in order to construct a model forces us to reflect on what we are



Mindtools (Productivity and Learning), Fig. 4 Cognitive simulation of decision-making supported by case-based reasoning studying in new and meaningful ways. The common homily, "the quickest way to learn about something is to have to teach it," explains the effectiveness of mindtools, because learners are teaching the computer when constructing models. Mindtools are not intended to make learning easier. Learners do not use mindtools naturally and effortlessly. Rather, the use of a mindtools approach typically requires learners to think harder about the subject matter domain than they would by simply studying its content.

Knowledge Construction, Not Reproduction

Mindtools represent a constructivist use of technology, as they are concerned with the process of how we *construct* knowledge from our experiences. When students develop databases, for instance, they are constructing their own conceptualization of the organization of a content domain. How we construct knowledge depends upon what we already know, which depends on the kinds of experiences that we have had, how we have organized those experiences into knowledge structures, and what we believe about what we know. This does not mean that we can comprehend *only* our own interpretation. Rather, we are able to comprehend a variety of interpretations and to use them in further constructing our understandings.

Constructivist approaches to learning strive to create environments where learners actively participate in ways that help them construct their own knowledge rather than having the teacher try to ensure that students understand the world as they have been told. In a mindtools environment, learners are actively engaged in interpreting the external world and reflecting on their interpretations. This is not "active" in the sense that learners actively listen and then mirror the *one* correct view of reality but rather "active" in the sense that learners must participate and interact with the surrounding environment in order to create their own view of the subject. Mindtools function as formalisms for guiding learners in the organization and representation of what they know.

Learning *with* Technology

The primary distinction between computers as tutors and computers as mindtools was best captured by Salomon, Perkins, and Globerson (1991) as the effects *of* technology versus the effects *with* computer technology. Learning *with* computers refers to the learner entering an intellectual partnership with the computer. Learning *with* mindtools depends "on the mindful engagement of learners in the tasks afforded by these tools and that there is the possibility of qualitatively upgrading the performance of the joint system of learner plus technology" (p. 2). In other words, when students work with computer technologies, instead of being controlled by them, the students enhance the capabilities of the computer, and the computer enhances the students' thinking and learning. The result of such an intellectual partnership with the computer is that the whole of learning becomes greater than the sum of its parts.

Model of Educational Reconstruction

Reinders Duit
IPN-Leibniz Institut for Science and
Mathematics Education, Kiel, Germany

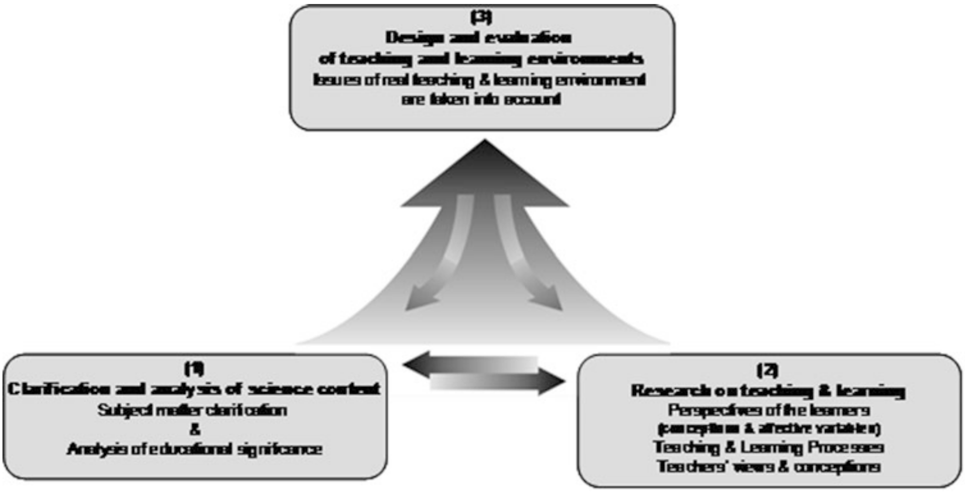
A key feature of the *Educational Reconstruction* approach is that in planning instruction – by teachers or curriculum developers – the science content to be learned *and* students' cognitive and affective variables, including their learning processes, should be given equal attention. In addition, the science content is not viewed as "given" but has to undergo certain *reconstruction* processes. The *science content structure* (e.g., for the concept of evolution) has to be transformed into a *content structure for instruction*. The two structures are fundamentally different. The first step in this reconstruction, called "elementarization" (in German, Elementarisierung), is to identify the elementary ideas that relate to the aims of instruction, taking into account student perspectives (e.g., their pre-instructional conceptions). Then the content structure for instruction has to be developed. Finally, teaching and learning settings have to be designed. The tendency of many approaches aiming at more efficient science instruction to put the major emphasis on just instructional methods should be seen as problematic.

The Model of Educational Reconstruction (MER) (Fig. 1) draws on these basic ideas (Duit et al. 2012). It is based on European Didaktik and Bildung (formation) traditions – with a particular emphasis on the German tradition (Westbury et al. 2000). It has been developed as a theoretical framework for studies looking at whether it is possible and worthwhile to teach particular science content areas. Clarification of science subject matter – including science concepts, views about the nature of science, and also the relevance of science in daily life and society – should be given substantial attention when developing instruction of a particular science content. In the past, however, often the main (or even the only) issues informing the clarification process are those that come from the structure of the science content involved. Educational issues are considered only after the science subject matter structure has been clarified.

The MER closely links analyses of the science content structure and the educational significance of parts of it, with empirical studies of students' understanding and with preliminary trials of pilot instructional modules in the classroom. It is a key assumption of the model that the curriculum developers' awareness of the students' points of view may substantially influence the reconstruction of the particular science content. The MER has been designed primarily as a frame for science education research and development. However, it also provides useful guidance for planning instruction in school practice.

The core of the model is the analytical process of transposing (or transforming) human knowledge (i.e., the cultural heritage), such as domain-specific scientific knowledge, into knowledge for schooling that contributes to students' scientific literacy. The science content structure cannot be directly transferred into a content structure for instruction. It has to be "elementarized" to make it accessible for students, but also enriched by putting it into contexts that make sense to the learners. Figure 1 illustrates the fundamental interaction between the three components of the MER. They influence each other mutually. Consequently in practice the result is a complex *recursive* step-by-step process.

The MER shares major characteristics with other models of instructional design. In French science and mathematics education, the conception of *Transposition Didactique* includes similar ideas about the process of transposing human knowledge. The MER is explicitly based on constructivist views about efficient teaching and learning environments. The cyclical (recursive) process of educational reconstruction, i.e., the process of theoretical reflection, conceptual analysis, small-scale curriculum development, and classroom research, is also a key concern of *Developmental Research*, of *Design-based research* (Cobb et al. 2003), and of other efforts to implement more evidence-informed approaches to teaching and learning in science. There is also a significant overlap with the idea of *Teaching and Learning*



Model of Educational Reconstruction, Fig. 1 The three components of the Model of Educational Reconstruction (*MER*)

Sequences as discussed by Meheut and Psillos (2004). For all such approaches, research and development are intimately linked, and the conditions of teaching and learning in instructional practices (in schools and elsewhere) are explicitly taken into account. The MER also shares major features with the *Learning Progression* approach that has developed in the past decade, primarily in the USA (Duschl et al. 2011).

In a nutshell, the MER shares major features with other frameworks of science education research and instructional design. The particular contribution of these frameworks is the idea that science content structure has to be reconstructed on the basis of educational issues, i.e., the aims of instruction and students' perspectives.

Modeling Environments

Astrid Wichmann
Education, Ruhr University Bochum, Bochum, NRW, Germany

Main Text

Modeling environments are computational tools that support learners in building dynamic or static models that represent phenomena such as plant growth, the solar system, or crowd behavior. In the context of a well-designed curricular activity, the learner creates the model by specifying objects, their characteristics (i.e., variables), and their relationships. Relationships can be specified in different ways depending on the learning environment. Modeling tools such as concept maps or causal loop diagrams allow the learner to specify relationships qualitatively. In concept maps, relationships can be specified by describing the nature of the relationship (e.g., "is a"). In causal loop diagrams, relationships are specified by polarities (i.e., "+" and "−") and include feedback loops describing how one variable causes a change of another variable, which then causes a change of the original variable. Some modeling environments allow learners to not only specify relationships but also to run the models, revealing potentially unexpected behaviors and allowing learners to test their predictions. In executable modeling environments, the learner can observe how values of variables change over time.

Modeling Languages

Executable modeling environments are different from simulation environments because of the ability to create a model of a dynamic system and to study it in a quantitative way. Executable modeling environments are based on a formalized language such as Petri nets, NetLogo, or System Dynamics, allowing the learner to quantitatively specify variables and relationships. System Dynamics, a modeling language developed by Forrester (1961), has been frequently used in learning settings. It is developed to represent dynamic systems (e.g., population growth) and to predict and understand relationships between variables (e.g., death rate and birth rate) over time. System Dynamics, like other languages, makes use of generic variable types to simulate direct and indirect effects of variables within complex systems.

Inquiry Learning

Modeling has been the focus of considerable research and is often cited as a central aspect of inquiry learning, where students actively construct their knowledge by specifying relations between variables of dynamic phenomena. For example, as part of an iterative inquiry cycle, a learner might start out with an orientation activity in which information about relevant objects or variables is sought and a research question is formulated. During an initial hypothesis activity, students would be supported in creating a model that embeds their hypothesis. In an ensuing experimentation activity, variables of a model could be modified for the purpose of testing the hypothesis. In the results activity, the produced data is analyzed and interpreted by the learner, allowing inferences. Based on those inferences or conclusions, a new hypothesis or research question could be formulated, beginning a new inquiry cycle.

Example Environments

Modeling environments are designed to work either as stand-alone tools or as activities embedded within a broader learning environment, where learners create models as part of an inquiry project. Stand-alone tools like Model-It (Krajcik and Blumenfeld 2006) or STELLA (Steed 1992) allow the learner to build executable models. They are typically integrated by the researcher or teacher, into a substantive curriculum unit, requiring careful design of activities. An embedded approach, such as employed by Co-lab (van Joolingen et al. 2005), includes a modeling activity within an overarching technology-supported learning environment. Co-lab uses the metaphor of buildings that includes different houses and rooms to guide the learner through activities of an inquiry process. The Web-based Inquiry Science Environment (WISE) (Slotta and Linn 2009) offers modeling tools in combination with notes, hints, domain information, and data visualization tools, which are provided in the context of project-based inquiry.

Applications for Learning

In its application as a learning activity, modeling has been studied in various domains, including water flow, thermodynamics, and ecosystems, and real-world phenomena such as traffic flow. Research has shown that modeling environments allow the learner to appreciate the value of models and the role that models play in science. Learners become aware that models play a role in scientific reasoning. When models no longer meet their purpose, they must be updated or replaced with better ones. This restructuring process helps learners to refine their understanding of the complex nature of scientific phenomena and the scientific inquiry process. In terms of learning outcomes, modeling environments have been shown to foster learning of complex topics. For more simple topics, other learning environments such as simulations or more traditional forms of instruction are more effective.

Modeling Teaching

Jolie Mayer-Smith
Faculty of Education, Department of Curriculum and Pedagogy, University of British Columbia, Vancouver, BC, Canada

Keywords

Modeling teaching

Introduction

Modeling is the act of sharing through explicit demonstration a particular skill, practice, activity, or way of thinking. Modeling teaching involves showcasing teaching practice, as well as the reasoning that informs, and the language that explains that practice. Effective modeling has been shown to enhance learning-to-teach science in elementary, secondary, and postsecondary settings.

Modeling teaching is a highly flexible strategy that can illustrate how to plan lessons; how to design and implement diverse instructional strategies such as inquiry teaching, lecturing, hands-on laboratory sessions, and learning beyond the classroom (e.g., in field trips and other informal contexts); and how to assess student understanding before, during, and after instruction. Modeling can also be used to illustrate the application of theory in the practice of teaching and to encourage and assist preservice teachers in acquiring skills in reflective practice (Loughran and Berry 2005).

Modeling Is a Guide, Not a Recipe

A challenge associated with the use of modeling teaching as a strategy is that any given episode can only highlight certain aspects of a topic, issue, theory, thought process, or practice. The observer or novice teacher may misinterpret a modeling episode intended to show how a topic *might* be taught, to mean this is how that topic *must* be taught. For example, modeling the constructivist teaching approach of probing prior knowledge of students for a particular science concept may be misconstrued to indicate that every science concept one teaches will require such probing. Similarly, modeling the use of teaching approaches such as concept mapping for reviewing topic "X," or role playing for promoting an embodied understanding of a particularly complex scientific process, may lead novice teachers to link the modeled teaching approach with the particular topic used in the exemplar or to broadly apply the modeled practice to topics where it will not assist with student learning.

To address this issue, it is essential that all modeling of teaching be accompanied by some conversation about the practice or practices that were modeled. Debriefing of a modeled episode needs to incorporate reflection and participation by the preservice teachers, as well as explicit discussion of the instructor's intentions or a conversation on teaching about teaching by the educators who undertook the modeling. This combination of dialogic debrief elements avoids the educator adopting (and modeling) a "teaching as telling, showing, [and] guided practice approach" (Myers 2002, p. 131).

Learning Through Modeling

Modeling of both "good" and "bad" teaching has merit, but both types of exemplars must be accompanied by discussions of practice. Modeling of poor practices with preservice teachers participating as students can provoke thinking and discussion about teaching and learning issues that may be invisible and tacit and thus missed in "good" and effective instructional exemplars. For example, modeling teaching of a laboratory activity where the required materials are not all available, are poorly labeled, or are not distributed on the laboratory bench, where safety concerns are handled cavalierly, and where students are rushing to complete the laboratory and data recording can lead to rich discussions of the important safety, organization, and learning elements of hands-on laboratory lessons.

Both the modeling of teaching and learning from that modeling require skills and practice. Novice teachers as observers of modeled episodes need skills in order to see and understand what is happening. To assist and scaffold such learning, teacher educators should establish a "safe," trusting classroom environment where talk about teaching is encouraged and happens regularly and guidelines for how to offer honest feedback in a positive and supportive manner are provided.

Conclusion

The intentional and explicit modeling of teaching, the ability to "unpack" that teaching without being didactic, and modeling the critique of teaching for the learner are complex processes that contribute to the development of teacher educators and represent a form of professional knowledge that is researched through the self-study of teaching and teacher education (Loughran and Berry 2005). Thus, modeling teaching informs not only those who are learning to teach but also those who do the modeling of practice.

Explanation; Mechanisms; Representations; Scientific reasoning

Science is fundamentally about coming to understand the world in both its complexity and amazing elegance. At its core it is about developing explanations for the workings of the natural world based on evidence. Science is a particular way of approaching the generation, evaluation, and revision of knowledge that has served as the foundation for profound shifts in our collective understandings and our manipulation of the world.

Models are viewed by many as the functional units of scientific thought. They allow the scientist to reason about a phenomenon by representing and highlighting aspects of that phenomenon that are salient to answering questions about how and why the phenomenon works the way it does. They take a small number of theoretical ideas and highlight the key relationships among them making it possible to reason with the ideas to address questions and problems in the discipline (Giere 1988). Models – sets of ideas that define relationships among various theoretical and concrete objects and processes – are ubiquitous in science. Some examples of important and familiar models include the model of the atom, the model of the particulate nature of matter, the model of plate tectonics, and the model of protein synthesis. Models function as reasoning tools that allow one to bound, explore, organize, and investigate phenomena and to develop explanations, generalizations, abstractions, and causal claims about those phenomena.

The verb modeling refers to the acts of generating, evaluating, revising, and using/applying models. Modeling is, at its core, about making sense of the world by producing and coupling theoretical interpretations and understandings with empirical measurements/observations in order to develop explanations and predictions about phenomena.

Consistent with its centrality in scientific reasoning, modeling is now recognized as a key practice that can be used to organize and structure classroom science from the elementary grades through graduate school, and likewise core disciplinary models can serve as the foundation for content organization of science education. Thus, just as models and modeling are often at the center of accounts of scientific practice, an explicit focus on models and modeling is becoming more common in science education.

Models

Models are sets of ideas about why particular classes of phenomena function the way they do. They exist on a continuum between nascent and naïve ideas in an individual's mind – often called mental or internal models – and clear and widely shared ideas that guide a community of scholars in a particular field, often called expressed or conceptual models. They provide an important foundation for scientific thought.

Models are human constructions that stipulate a set of relationships between and among observed or theoretical processes, events, and objects. Models can be used to figure out and understand how something works. For example, a model for the particulate nature of matter stipulates relationships between small bits of matter (atoms). Such a model would include the core stipulation that the matter in the world is made up of tiny, unseen particles and that those particles interact with one another in specific ways. From this model (the set of ideas about how particles behave), one can understand and explain a broad class of phenomena from phases of matter to how smell travels across a room.

The level of detail and the particular attributes of a model are dependent upon the aim of the modeler, and therefore, there may be many models for reasoning about any particular phenomenon. Take again the case of the particulate nature of matter. Depending on what the modeler is using the model for, the model may invoke a generic particle, or it may invoke those particles as atoms and molecules with particular attributes (e.g., polarity).

The model is a dynamic mental entity that can be used to explain and predict phenomena. Determining the relationships among the model ideas is what enables a model to function as a reasoning tool. Even though the word model is used in general parlance to refer to purely descriptive depictions, in science, something does not function as a model unless it can be used to reason about the underlying causes of a phenomenon. In this sense, models sit between theory and evidence.

Within a community of practice, a model must be externalized and communicated in order to undergo evaluation and be used by the community. The externalized model can take a range of representational forms depending on the aim of the modeler and the purposes to which the model is being put to in a particular context. Many models that contain the same core conception of a system can be alternatively represented in diagrammatic, narrative, and/or mathematical forms. However, it is not the expressed form that makes something a model or not; rather it is the way in which the underlying ideas are used toward a goal of sensemaking that defines a model.

Models are subject to evaluation based on conceptual as well as empirical criteria. Model evaluation based on conceptual criteria involves comparing the model to previously agreed upon theoretical ideas or other models. Typically, scientists strive for consistency among the models in their discipline such that the assumptions in one model do not violate or contradict those in another. While this is a common criterion to use for evaluation, there are some times when two contradictory models may be held by the community and used in different circumstances because each has some utility in explaining or predicting empirical data. Perhaps the most notable instance of this in physics is the continued use of both particle and wave models of light.

Empirical criteria are applied when comparing a model or the explanatory output of the model to observations and data. The scientist asks if the model is useful in explaining the data at hand, and in some cases the predictive power of the model is used to evaluate the utility of the model. It is the correspondence between the model and the phenomenon that is key to empirical model evaluation, and in that sense a model can be thought of as a representation of particular aspects of the phenomenon.

Modeling

Models are at the core of scientific reasoning. They hold the theoretical ideas of the reasoner in a clarified arrangement that allows her/him to make sense of the world. Models mediate between the more abstract and very general theoretical ideas in a field and the empirical world. The act of modeling includes developing, examining, critiquing, and using these sets of ideas. Modeling is the active process of putting discrete ideas together by stipulating the relationships between and among them. Modeling is also the act of examining the utility of the model in the face of some sensemaking need. In this case the ideas are held up and examined for their fruitfulness. This may result in particular ideas or relationships being kept as is, discarded, or modified. This analysis and revision process is one form of modeling. And finally, when a scientist is using the model and applying it in a deliberate way to a phenomenon, she/he is modeling.

Functions of Models

Models serve a variety of functions and are central to the day-to-day working and reasoning of most scientists (Osbeck et al. 2010). In some disciplines models are named with the word model and the modeling is explicit. In others the role of the model may be more implicit, but in virtually all cases there is a small set of ideas that are at the core of particular scientific activities.

Models are used in practice to define and develop questions, they often point to specific investigations and data collection needs, they form the basis of explanations and predictions, and they are key to communicating about the processes that underlie observable phenomena. Thus, models inform and mediate a range of activity in science, and in turn these activities become the basis of further model development and refinement.

Scientists alternate between interacting with the physical world and developing models that explain measurements and observations. Extant models play a key role in helping to define the scope of observations. They become important filters on the world that affect what the scientist notices and finds worthy of investigation. In this way, models that already exist in a discipline are an important element in the generation of questions worth pursuing. For example, if one was interested in explaining the existence of particular trait variations in a population of organisms, the aspects of that phenomenon that are salient would depend in large part on the models that the phenomenon was viewed through. If the investigator was operating with evolutionary models, the observations and questions asked would differ from those asked from the perspective of physiological models.

As scientists use their models to ask questions about the world, they must both incorporate and generate data in a systematic way. The model often assists the scientist in considering what kind of data would be useful, and in this way, models provide a foundation for investigations in science. Since models incorporate the current understanding of a phenomenon, they form the basis of the scientist's interactions with that phenomenon.

Once an investigation is complete, the data generated are analyzed with regard to the model, and the model is evaluated with regard to the data. That is, the scientist seeks to understand the data with regard to the model, incorporates the empirical results into the model, and uses those results to inform further refinements of the model.

Models are developed with respect to a particular phenomenon or class of phenomena. In this way many models begin in a rather specific state. However, the aim of the modeler is to explain a broader swath of the world, and thus, models developed in one context can be taken to other contexts, tested for their fruitfulness, and often revised once again. The common use of model organisms in the biological sciences is a case in point. Scientists investigate the workings of particular organisms in order to first understand how processes and mechanisms work in that species. Then they use that understanding as a basis for explaining similar attributes across a wider range of organisms. A model for a specific metabolic pathway in one species, for example, may then be revised or broadened when taking into account how the system works across several species.

Models and Modeling in the Science Classroom

In science education the term models has been used to refer to a wide class of objects. Science teachers often refer to objects in their classrooms such as plastic torsos and Styrofoam ball depictions of the solar system as models. Teachers also often talk about modeling particular behaviors for students in the sense that they show them what to do or how to do it. While these uses of the word model and modeling are legitimate uses in education, in terms of scientific practice, models and modeling take on a much more specific meaning as explicated above. Merely depicting or describing a system should not be the endpoint of activity because science is centrally concerned with understanding and exploring the mechanisms that underlie the observable world.

An explicit focus on models and modeling in the science classroom is becoming more common (Windschitl et al. 2008). Classroom teachers have crafted experiences for students that make the model-based sensemaking that scientists do accessible and attainable for children across grade levels (Schwarz et al. 2009). One curricular area that is commonly taught with an explicit focus on models and modeling is around the particulate nature of matter. This example can illustrate how classrooms can be centered on model-based sensemaking and how a focus on models and modeling can productively organize classroom activity in much the same way that it organizes scientific activity.

Imagine a middle school classroom in which the students are investigating the attributes of matter. The curricular unit begins with some concrete experiences and a focus on a few phenomena like the movement of a smell across the room, the way a drop of food coloring disperses in a glass of water, and the phase changes of water. With the assistance of the teacher, the students are pushed to wonder what it is about the nature and structure of matter that would help them explain these phenomena. Over the ensuing days, they experience more phenomena and are introduced to and develop the ideas of particles and their movements and interactions. This can play out in classrooms in a wide variety of ways, but the key feature of this experience must be that students come to a deep understanding of the various aspects of the model, that they develop and elaborate the core stipulations in the model as a community, and that they work to test those ideas against phenomena by using them to explain the phenomena that motivated their investigations.

This kind of classroom is in stark contrast to one where students are told that the world is made up of small particles, called atoms and molecules, and asked to repeat that fact on a test. On the surface these two contexts may appear similar in that in each classroom one goal is for the students to emerge with the knowledge that matter is made of particles. However, in the classroom in which this idea is presented to students in its final form and assessed as a fact, the students have not experienced using the ideas as a tool for making sense of the world nor are they likely to understand their utility in explaining phenomena. On the other hand, when the exploration of matter is motivated by asking questions about phenomena and the road to answering those questions is through clearly articulating a model for the underlying mechanisms that can be used to explain those phenomena, the students may achieve something more than simply knowing the definition of atoms and molecules. Modeling provides an opportunity for students to connect sets of ideas together, thus making it possible for them to construct a rich understanding of the phenomena in the context of an explanatory framework.

Designing classrooms that are model based involves a shift both in pedagogy and in content organization. Classrooms that are model based focus on the connections between theoretical ideas and observable phenomena and can provide opportunities for students to use models to develop explanations and engage in argumentation (Passmore and Svoboda 2012). This implies that the teacher must craft an environment in which students are active learners in a community setting and that scientific concepts are not presented as discrete facts.

Summary

A focus on models and modeling has become more prominent in science classrooms. This focus has come as science educators have made deliberate attempts to build science experiences that mirror important aspects of scientific practice. Because modeling is central to reasoning in science, it provides an important framework for engaging students in scientific reasoning. Model-focused science classrooms provide students with opportunities to make sense of the world by developing, representing, sharing, and applying models.

Morals and Science Education

Holmes Rolston III
Colorado State University, Fort Collins,
CO, USA

Science and conscience have a vital, if sometimes uneasy, relationship. Moral education demands levels of responsible agency that science education does not, owing to the shift from what *is* the case to what *ought* to be the case. Facts and causes are the domain of science and values and duties the domain of ethics; but criticism is equally requisite in both. Science and ethics alike are embedded in traditions where truths are shared through education. Ethicists often find stages in moral life; no analogous claims have been made for scientific life. Morality has to be chosen, entered into, lived, and practiced, in ways that science does not. People are responsible for their values as they are not for their science.

Astronomy is sometimes thought to leave humans lost and lonely among the stars, and this may leave puzzles where to place Earthbound human morality in a vast meaningless universe. “The more the universe seems comprehensible, the more it also seems pointless” (Weinberg 1988, p. 154). More recently physics has made dramatic discoveries at astronomical and submicroscopic ranges, such as the formation of elements in the stars involving microphysical process, such that the midrange scales, where the known complexity mostly lies (in ecosystems or human brains), depend on the interacting microscopic and astronomical ranges. This “anthropic principle” endorses and even celebrates human cognitive and moral powers. We humans do not live at the range of the infinitely small, nor at that of the infinitely large, but we may well live at the range of the infinitely complex. That restores human dignity and worth (Barr 2003).

Biological sciences often carry implicit or explicit overtones of who and what humans are, which may not be coherent with the implicit or explicit human self-understandings in classical or contemporary moral education. Human behavior is shaped by selfish genes (Dawkins 1989); we should biologicize ethics as disguised self-interest (Wilson 1975, p. 562). If so, can humans be altruistic? Scratch an “altruist” and watch a “hypocrite” bleed (Ghiselin 1974, p. 247). Ethicists may agree about selfish tendencies in human nature but argue that humans can and ought to be educated toward a common good, or at least more enlightened self-interests. Theologians may find that humans are in need of redemption. Meanwhile, biologists may find more cooperation coded into the human genome than previously thought (Nowak and Highfield 2011).

The sciences may also open up new possibilities (cloning, genetically modified genes; Bruce and Bruce 1998) or threats (climate change, mass extinction; Gardiner 2011) with which inherited moral systems are unfamiliar. Moral education may enlighten and elevate the human nature that has evolved biologically (Campbell 1976).

By prevailing Darwinian accounts, biological natural history results from natural selection, which is thought to be blind, both in the genetic variations bubbling up without regard to the needs of the organism and in selection for survival, without regard to advance. Other biologists hold that such behavior can be more positively interpreted. Organisms defend their lives; their so-called selfishness is really self-actualizing, the defense of vitality. Reproduction is the ongoing sharing of biological value and promise. The genes function to conserve life; they also make possible a creative upflow of life struggling through turnover of species and resulting in more diverse and complex forms of life over millennia.

Such biologists emphasize the continuing vital creative processes over time, the ascent of life from the simple to the complex, a prolific (pro-life) biosphere, the conservation and elaboration of genetic information, and the effective and efficient results of genetic creativity and natural selection. This may lead to a sense of respect for life, made possible by our human singularity, the sole species with moral powers, and with responsibility for caring for other humans and for the Earth.

Reinterpreting natural history more constructively may also have implications for human self-estimates. Humans evolved from prehuman primate ancestors; we may be told that we inherit a monkey's mind. "DNA evidence provides an objective non-anthropocentric view of the place of humans in evolution. We humans appear as only slightly remodeled chimpanzee-like apes" (Wildman et al. 2003, p. 7181). But humans have over three times the brain size of chimps, so that a 3 % difference in protein structures makes 300 % bigger brains. Cognitively, we are not 3 % but 300 % different (Marks 2002, p. 23).

When you compare Einstein with a chimp, it does not appear that Einstein is only slightly remodeled; nor do we wonder whether an atomic bomb built with his theory that $E = mc^2$ is a slightly remodeled ant-fishing stick. An explosion of cognitive powers emerges with the human mind, an event otherwise unknown in natural history. Neurosciences may agree that the human mind is immensely complex and also find openness and mutability (in synaptic connections) that permits humans to be morally responsible (Merzenich 2001). "We are hugely different. … the differences are light years apart" (Gazzaniga 2008, p. 13).

The ecological sciences will add that on Earth humans are (and ought to be) at home, the root idea in ecology. A moral priority is a sustainable biosphere. Ecologists also find that humans are degrading the biosphere. They may be apprehensive about ecosystem services or impending extinctions (Millennium Ecosystem Assessment 2005). They will demand education in conservation biology. No one is rational if he or she is neutral, dispassionate, about one's home. One is immoral if unconcerned about life in jeopardy on one's home planet. Biologists are almost unanimous in their respect for life on an endangered planet. The Earth's impressive and unique biodiversity warrants wonder and care.

In both science and moral education, one seeks enlightenment. Philosophers may push the claim that modern science, after 400 years, still leaves the ultimate value questions urgent and unresolved. Indeed, there is no scientific guidance of life. The value questions remain as acute and painful as ever.

Motivation and the Learning of Science

David Fortus
Weizmann Institute of Science, Rehovot, Israel

Keywords

Achievement goals; Engagement; Lifelong learning; Motivation; Self-determination

Introduction

Why is motivation so important? Learning is typically the result of intellectual, emotional, and physical engagement, and engagement is an outcome of motivation. Without motivation there is little engagement, and without engagement, little learning can occur. This is true in general, not only for the learning of science; one is not likely to become proficient at tennis, carpentry, or any intellectual activity unless one is motivated, for whatever the reason, to become proficient at these activities.

While motivation is a necessary condition for learning to occur, it is also a desired outcome of learning. Knowledge is like a skyscraper, each level built on the foundations provided by the lower levels. However, for the construction to continue beyond a certain level, there needs to be motivation to do so. Thus, for example, one can learn about Rutherford's model of the atom and be content with this knowledge, without any desire to learn more about the atom. Moving on to the next level (perhaps Bohr's model of the atom, in this case) requires the motivation to go further. This motivation can be developed and fed by the process of learning about Rutherford's model. Thus, learning and motivation are intertwined – the first seldom occurs without the second and the second needs to be fostered by the first for learning to continue.

Theories of Motivation

There exist several theories of motivation (Schunk et al. 2008) – expectancy-value theory, attribution theory, self-determination theory, and achievement goal theory. While none of these theories were developed specifically for use in science education, they have all been applied in the context of science education.

Expectancy-value theory in science education addresses the combined effect of the perceived value of learning a science topic and the expectation of succeeding to learn it, so

$$\text{Level of motivation} = \text{perceived value} \times \text{success expectancy}$$

One's success expectancy is directly related to one's perceived self-efficacy in science, while the perceived value of learning a topic is related to the cost involved in learning the topic (time, effort, negative feelings), the interest in the topic and the pleasure involved in learning it, the practical value of understanding the topic, and if the learning of the topic supports the attainment of personal needs (social acceptance, values, identity).

Attribution theory attends to the perceived attributes for success or failure at a task related to learning, such as talent, perseverance, luck, difficulty of task, etc. Each of these attributes has three dimensions:

(a) Locus – Is the attribute perceived by the individual as located "in" or "out of" him/her (such as skill and self-efficacy, attributes that are typically perceived as individual, personal, located "in" the student, versus difficulty of the task, which is typically perceived as an externally imposed condition, and therefore "out" of the learner)?

(b) Controllability – Is the attribute grasped as something one can control and manipulate (such as effort versus luck)? The locus of control is a combination of locus and controllability. For example, while I may accept that I control how much effort I exert, I may feel that I am being forced to exert effort rather than choosing to do so myself. The locus of control has been used in studies on wait time, problem solving, understanding of the nature of science, meaningful learning, and others.

(c) Stability – Is the attribute grasped as something constant or variable (such as fatigue or help from friends)? The more the attributes for success are perceived as internally located, controllable and stable, the greater will be the motivation to engage in a learning task.

Both expectancy-value theory and attribution theory focus on the magnitude of motivation for engaging in a learning task; while self-determination theory and achievement goals theory also attend with the effects of being more or less motivated, they also emphasize the qualitative nature of motivation, distinguishing between different types of motivation.

Self-determination theory emphasizes every person's need to belong, to feel able, and to be autonomous. It distinguishes between intrinsic motivation (doing something for its own sake) and extrinsic motivation (doing something because it leads to certain results). Research shows that highly intrinsically motivated people tend to be more adaptable and have better conceptual understanding than people with lower intrinsic motivation. Intrinsic motivation is supported by providing students with a sense of control and choice, challenges that lie within their zone of proximal development, positive feedback about their abilities, and close personal relations.

Achievement goal theory has been used more often in science education studies than the other motivational theories. It focuses on individuals' goal orientation, which is why individuals engage in learning activities. The theory distinguishes between two main goal orientations: mastery goals orientation and performance goals orientation. Mastery-oriented individuals strive to develop competence in order to achieve a sense of mastery; they learn because they want to understand. Mastery goals orientation is positively associated with a wide range of positive cognitive, emotional, and behavioral outcomes and should therefore be fostered by parents, teachers, and schools. Performance-oriented individuals strive to demonstrate competence and are therefore concerned with others' perceptions of their competence and with their ability relative to others. Performance goals are subdivided into performance-approach and performance-avoidance goals. According to this distinction, when pursuing performance-approach goals, individuals are focused on attaining favorable judgments of competence; they learn because they want others to think they understand. On the other hand, when pursuing performance-avoidance goals, individuals are focused on avoiding unfavorable judgments of competence; they are concerned that others may think that they don't understand. Findings from studies that have adopted this distinction between performance-approach goals and performance-avoidance goals support its prevalence among students and strongly suggest that performance-avoidance goals are associated with maladaptive patterns of engagement. On the other hand, the evidence regarding performance-approach goals is not consistent. People are not either mastery oriented or performance oriented. Mastery orientation and performance orientation are two independent continua characterizing individual learners. One can be both high mastery and performance oriented or be characterized by any two values of goal orientation on both continua.

Aspects of the Significance of Motivation in Learning Science

We have all learned things that we no longer remember; often we don't even remember that we ever learned these things! Knowledge that is not revisited, built on, used, and embellished is doomed to fade away. When we are faced with an issue, such as whether or not to consume genetically modified foods, in order to reach a position that is not just emotionally driven but also supported by reason, we need to be able to recall and draw upon concepts related to genetics, nutrition, and ecosystems that we learned in middle and high school. More likely is that whatever we learned in high school will not suffice to reach a firm understanding of the issues at stake in genetic engineering; so we will need to go beyond our school-based knowledge and learn new ideas. For this learning to occur, we need to be motivated to learn. Thus, the goal of helping people become lifelong learners is contingent on the existence of ongoing motivation to learn (Maehr 2012). The goal of education is not to fill a pail but to light a fire (sometimes attributed to Yeats).

Rather than feed the fire of motivation to learn science, many studies from the late 1960s and onward suggest that schools often do the opposite – they extinguish it. Six-year-old children are typically full of awe and curiosity about the world. Your average 14-year-old child, however, has lost his drive to understand and make sense of the world, he is no longer inquisitive. Research has not only documented students' declining motivation to learn science but has also shown that this waning of motivation to learn science is not an inevitable consequence of adolescence; schools and teachers can support and enhance students' motivation to engage with science or they can diminish it (Nolen 2003; Vedder-Weiss and Fortus 2012). Clearly this has great significance when considering the widespread phenomenon of declining student enrollments in science and how to reverse such trends. Understanding the reasons for this decline in the motivation to learn science and how to best address it should be one of the central goals of the science education community.

Multiculturalism

Felicia Moore Mensah
Science Education, Teachers College, Columbia University, New York, NY, USA

Keywords

Culture; Diversity; Equity; Multicultural; Social justice

Multiculturalism

Multiculturalism has been used by scholars and practitioners from countries all over the world in referring to educational efforts to instruct and infuse more positive values about human pluralism and to improve the learning potential for all students. Multiculturalism is a philosophical position and movement that assumes that the gender, ethnic, racial, and cultural diversity of a pluralistic society should be reflected in all of its institutionalized structures but especially in educational institutions, including the staff, norms and values, curriculum, and student body. It recognizes that equality and equity are not the same thing, meaning that equal access does not necessarily guarantee fairness.

Within the United States, the origin of multiculturalism was more concerned with freedom, liberty, and equality and less with particular subcultures in society. However, over time, multiculturalism has evolved to focus on ethnic and cultural diversity, as well as cultural identity. Cultural identity is based on traits and values learned as part of our ethnic origin, religion, gender, age, socioeconomic level, primary language, geographical region, place of residence (e.g., rural, suburban, or urban), and disabilities or exceptional conditions. Each of these groups (also called microcultures, subsocieties, subcultures, subcommunities) has distinguishable cultural patterns shared with others who identify themselves as members of that particular group. Individuals belonging to the same microcultures or subcultures share traits and values that bind them together as a group. Although numerous microcultures exist within most nations, the United States is exceptionally rich in having very diverse and distinct cultural groups that make up its population and history. Individuals with competencies in several microcultures may be considered bicultural or multicultural or bilingual and multilingual. These individuals may develop a broader view and range of cultural competencies as a member of multiple microcultures (Grant and Ladson-Billings 1997).

Multicultural Education

Multicultural education grew out of two primary movements – the Civil Rights Movement of the 1960s and 1970s and the Ethnic Studies movement, which grew out of the Civil Rights Movement. During these movements, African Americans and many other groups of color demanded equity and equality in the policies and practices of schooling. Consequently, numerous schools developed and taught ethnic studies courses and colleges and universities established ethnic studies departments or programs. Also during the Civil Rights Movement, other groups (women, people with disabilities, the poor, and gays, lesbians, and bisexuals) began to increase their efforts to make schooling equal and equitable for members of their groups. In the 1970s, the multicultural education movement grew. The Civil Rights Movement and the Ethnic Studies movements were energized by scholarship and participation by groups of color, women, and people with disabilities, and soon the influence of these movements began to capture the attention of K-12 and university educators. From that time to the present day, multicultural education has developed to become the educational vision and approach to school and societal change that has been advocated by an increasing number of people, but also objected and challenged by others.

Multicultural education, sometimes referred to as multiethnic education, antiracist education, or multiracial education, has been used by countries around the world and thus widely used in the field of education. It is a philosophical concept and an educational process. Multicultural education as a philosophy and practice continued its early development as different groups (African American, Asian American, Latino, Native American, and European American) began to learn (both formally and informally) about how race, class, and gender influence their presence in society and in educational settings and how their group and other groups contributed to the growth, development, and history of the United States. As an educational process, multicultural education has many approaches that vary widely. Although there are many different approaches, leaders within the field of multiculturalism have reached some level of consensus on the goals, aims, and purpose of multicultural education (Banks 2001).

Goals of Multicultural Education

A major goal of multicultural education is to reform the school and other educational institutions so that students from diverse racial, ethnic, and social-class groups will experience educational equality (Banks 2001). Another important goal of multicultural education is to provide both male and female students an equal chance to experience educational success and mobility. Multicultural education theorists are increasingly interested in how the interaction of race, class, and gender influences education, yet the emphasis that is given to these variables varies greatly. Most multicultural scholars and researchers agree that institutional changes must occur if the goals of multicultural education are realized or implemented successfully. Institutional changes may reside in changes in the school curriculum; teaching materials; teaching and learning styles; the attitudes, perceptions, and behaviors of teachers and administrators; and the goals, norms, and culture of the school (Sleeter and Grant 2009). Therefore, multicultural education confronts social issues involving race, ethnicity, socioeconomic class, gender, sexual orientation, and disability. Multicultural education provides instruction in familiar contexts that are built upon students' diverse ways of thinking. It encourages students to investigate world and national events, as well as how these events affect their lives. It teaches critical thinking skills, as well as democratic decision making, social action, and empowerment skills.

Multicultural education theory, practice, and research are conceptually defined in several different ways, with a number of educators attempting to deal with this differentiation by developing typologies or approaches to multicultural education. These typologies and approaches also aid in defining the goals of multicultural education.

Banks (2001) describes five dimensions of multicultural education as *content integration*, *the knowledge construction process*, *prejudice reduction*, *an equity pedagogy*, and *empowering school and social structures*. Briefly, (a) *content integration* deals with the extent to which teachers use examples, data, and information from a variety of microcultures in illustrating basic educational concepts, principles, generalizations, and theories in their subject area or discipline; (b) *the knowledge construction process* describes the procedures by which social, behavioral, and natural scientists create knowledge and how the implicit cultural assumptions, frames of references, perspectives, and biases within a discipline influence the ways that knowledge is constructed within it; (c) *prejudice reduction* describes the characteristics of children's racial attitudes and strategies that can be used to help students develop more democratic attitudes and values; (d) an *equity pedagogy* exists when teachers use techniques and methods that facilitate the academic achievement of students from diverse racial, ethnic, and social-class backgrounds. Finally, (e) *empowering school and social structures* are designed to help students and teachers cross racial and ethnic boundaries so that students may participate more effectively in school and society. These five dimensions of multicultural education help students to develop positive self-concepts and identities as they learn about the culture, contributions, and history of diverse groups that have contributed to their nation's history.

Nieto frames a definition and goals of multicultural education within a sociopolitical context because multicultural education needs to confront issues of power and privilege in society and not just issues of difference (race, class, gender, etc.). Nieto and Bode (2008) focus on seven characteristics of multicultural education: *antiracist education*, *basic education*, *important for all students*, *pervasive*, *education for social justice*, *a process*, and *critical pedagogy*. First, (a) *antiracist education* makes antidiscrimination explicit in the curriculum and teaches students the skills to combat racism and other forms of oppression; (b) *basic education* advances the idea that all students have a right to engage in core academic subjects as well as the arts and to develop social and intellectual skills and knowledge to be used in a diverse society; (c) multicultural education is *important for all students* because it challenges the commonly held misunderstanding that it is only for students of color, multilingual students, or special interest groups; (d) the *pervasive* nature of multicultural education emphasizes an approach that permeates the entire educational experience, including school climate, physical environment, curriculum, and relationships; (e) *social justice* teachers and students put their learning into action, and students learn that they have the power to make a change in a democratic society; (f) as *a process*, multicultural education is an ongoing developmental process that involves relationship building among individuals and educational institutions; and (g) *critical pedagogy* draws upon experiences of students as well as multiple viewpoints that lead to self-reflection and action.

From a review of the literature, Sleeter and Grant (1985) observed five approaches to multicultural education. They are t*eaching the exceptional and the culturally different*, *human relations*, s*ingle- group studies*, *multicultural education*, and e*ducation that is multicultural and social reconstructionist*. Sleeter and Grant also acknowledged that there is some overlap between the five approaches that they outline. First, (a) *teaching the exceptional and the culturally different* aims to equip students with the academic skills, concepts, and values to function the American society as well as its culture and institutions; (b) *human relations* consists of developing positive relationships among diverse groups and individuals to fight stereotyping and to promote unity; (c) s*ingle-group studies* have a target group that is looked at in depth and information about the group's history, including experiences with oppression and resistance to that oppression, is highlighted; (d) *multicultural education* is used by Sleeter and Grant as an approach to include the previous approaches and to deal with multiple groups at the same time and to reform the total schooling process so that all students benefit from a multicultural education; thus, this approach focuses on issues and concerns across multiple groups (Banks 2001); and (e) e*ducation that is multicultural and social reconstructionist* describes a complete redesign and critical action toward social change. For example, it entails addressing issues and concerns that affect students of diverse groups and encourages students to take an active stance by challenging the status quo, speaking out, and joining with other groups in examining common or related concerns.

Multicultural Education Across Subjects

Multicultural education extends to all subject areas, including science and mathematics as well as social studies, language arts, and art. Multicultural education across different subjects teaches students to apply critical thinking skills to all subject areas. Moreover, multicultural teacher education practice and policy derives from work within subject areas, such as multicultural science teacher education (Atwater and Riley 1993), and prepares teachers to become multiculturalists in their approach to teaching and vision for education.

Scholars and practitioners new to multicultural education as a field may find that the existence of several different approaches to multicultural education may lead to conceptual confusion. This confusion suggests to some that multicultural education is inconsistent, making it the subject of criticism (see Grant and Ladson-Billings 1997 for discussion). The shortcoming of the multicultural approach is that it does not assertively address issues dealing with poverty and unemployment, nor does it necessarily help build the political skills and group solidarity that some ethnic groups need (Grant and Ladson-Billings 1997). However, as more researchers and teachers come to understand multiculturalism and multicultural education, and develop broader views in areas such as **sociocultural perspectives and gender**, the meanings of multiculturalism and multicultural education will become more defined, accepted, and affirmed as well as more refined in its definitions and approaches and its application across different subject areas. Therefore, teachers in each subject area can analyze their teaching style to determine the extent to which they reflect multicultural issues, values, and approaches.

Summary

Multiculturalism is a common feature of many countries in the Twenty-first Century. For some, such as USA, multiculturalism has been a central feature of their society for many years, for others, such as Australia (by many measures today the most multicultural country on the planet) this is a more recent – post World War Two – development. Multicultural education acknowledges and affirms the belief that the strength and richness of such countries is in their human diversity. It demands a school staff that is multiracial, multiculturally literate, and multilingual. It demands a teaching staff that reflects gender and race diversity across subject matter areas. It demands a **curriculum** that organizes concepts and content around the contributions, perspectives, and experiences of all the groups that are a part of US society and the greater world. It confronts current social issues involving race, socioeconomic status (SES), gender, sexuality, and disability. Multicultural education accomplishes this by providing instruction in a social-cultural context that students understand and are familiar with and builds upon students' learning styles and community strengths. It teaches critical thinking skills, as well as democratic decision making, social action, and empowerment skills. Finally, multicultural education is a total process – it cannot be truncated and trivialized. All the components of its definition must be in place for multicultural education to be genuine and viable.

Main Text

Science educators have a long history of incorporating diverse media into classroom experiences. From the advent of educational television (ETV) in the 1950s to microcomputers in the 1980s to the current applications of smartphones and tablets for learning, multimedia videos have been one of the principle means of augmenting the quality of learning in science classrooms. The role that videos play in science instruction has changed dramatically, however, both as a result of changing views of teaching and learning and as a result of the hardware available to teachers.

Initially, educational television was thought of as a means of efficient of delivery of content and equity in school curriculum by ensuring that all children were able to watch high-quality content created by expert teachers (Cuban 1986). These early educational videos were thought of primarily in terms of the ability to transmit factually correct information. While some technology enthusiasts argued that ETV could replace teachers, most educators viewed television as a teaching aid to be used under certain conditions. Television was valued for its ability to depict dynamic scientific processes and remote locations. Most science classrooms have access to TVs, VCRs, and DVD players so that teachers can show videos (or clips of videos) deemed to have some educational value. The use of videocassettes and DVDs reflect the expectation that videos are best used "on demand" (i.e., rather than on scheduled broadcast) and that teachers must have flexibility to integrate them into their curriculum.

The World Wide Web (WWW) has introduced a vital new source of multimedia videos for use in science classrooms. Although the first decade of the public use of the WWW did not have sufficient infrastructure to make video streaming practical in most cases, the increased bandwidth and network service to schools, together with the proliferation of computers, have provided science teachers with a wealth of accessible digital video online. The popular video-sharing site YouTube, founded in early 2005, makes it easy for anyone to upload video clips for public viewing. Not only can science teachers view videos "on demand"; they can dynamically search for relevant video content from home, at school, or during an unplanned moment in class. For example, a science teacher might quickly call up a YouTube video that helps explain a concept in response to an unanticipated question during a classroom discussion. Importantly, students with access to the Internet at home are able to find the videos shown in class or search for additional video content to supplement their learning.

The high volume of multimedia videos, together with the highly accessible searching and viewing environments, can help students take more control over their learning, as ownership and control of video content no longer resides exclusively with teachers. New forms of digital devices, such as smartphones and tablet computers, have make accessing multimedia video content even easier. These devices routinely have built-in video cameras that enable both science teachers and students to create their own multimedia videos for pedagogical purposes.

The twenty-first century has thus seen a shift away from using multimedia videos solely for the purposes of transmission of scientific knowledge; learners can now use relatively inexpensive and common equipment to access, create, and co-construct knowledge about science. Such applications of multimedia videos are consistent with a social constructivist view of learning and fit well within the recent social phenomena of "Web 2.0" (i.e., where many users contribute to collections like YouTube or Wikipedia and all benefit from the aggregated resources). One example of using video to empower students to create knowledge about science is found in the Slowmation project, which challenges students and teachers to create models of scientific concepts (e.g., mitosis) and then take digital photos of their models and edit them into a short stop-motion animation film, complete with voice-over narration (Hoban 2007). In the classroom, a science teacher would facilitate the creation of student-produced Slowmation videos as a way for students to visualize and reflect upon their own ideas as well as to reveal the range of conceptual models that exist within the student community.

Around the same time the YouTube.com emerged, a journalist commenting on the new form of amateur radio on the Internet coined the term "podcasting" (Berry 2006). Podcasting is a portmanteau of the words "iPod" and "broadcast" – the former being the most popular (although by no means only) digital media player over the last decade. A podcast is a syndicated form of media – either audio, video, or textual – that is delivered over the Web. Users can "subscribe" to any podcast using popular software such as iTunes, or via a dedicated website, and listen to or view it using a computer, tablet, smartphone, portable gaming system, or dedicated media player. Podcasts have been called “a converged medium” because they bring together audio and video media, the Internet, and media devices (Berry 2006).

Although there are many professionally produced podcasts available from sites such as Scientific American (e.g., http://www.scientificamerican.com/multimedia.cfm) and the Canadian Broadcasting Corporation (CBC, e.g., http://www.cbc.ca/quirks/), one of the hallmarks of podcasting is the vast array of contributions made by amateurs who simply wish to create and broadcast their own content. Almost any current computer system has the necessary hardware and software to create a podcast, and a variety of free solutions are available for uploading and “hosting” the podcasts. Thus, the barrier to creating and distributing podcasts is low, suggesting possible applications for K12 or higher education. For example, a science teacher might use the Science Talk podcast from Scientific American in the same way that she/he might have used an educational television program in the past – to provide enriched multimedia content to students. Alternatively, a science teacher might challenge students to create their own science podcasts in small groups around a particular topic or theme. Podcasts and digital video clips, because of their ubiquity and ease of creation, editing, and publication, offer exciting new possibilities for science educators to find ways to encourage their students to construct knowledge of science.

Multimodal Representations and Science Learning

Terry Russell
Centre for Lifelong Learning, University of Liverpool, Liverpool, UK

What Is Meant by Multimodal Representations?

The rising science education interest in multimodal representations reflects science educators’ drive to get to the heart of knowledge generation and change, as close to the causal link between students’ not knowing and coming to understand as it is possible to get. “Multimodality” is beginning to define a discrete field of research, though, as it is still in relative infancy, it is in need of being more fully articulated. The general definition of multimodal representations used in this entry is “the depiction or communication of an idea or ideas using more than a single expressive mode, either in synchrony or separately.” Because education has traditionally been so strongly mediated by written and spoken language, an important aspect of this definition is that it is inclusive of all forms of expression, beyond only the linguistic. The definition of “representation” is more ambiguous as the term may be used to refer to both “internal representations” (the existence of which some would contest) and “external representations.” While the use of the one word for both internal and external states is essentially ubiquitous, it is not helpful, but in both instances, the intention is to refer to something “re-presented” or “revealed in another manner,” in a form that differs from that of the referent. Any serious analysis of multimodal representations is drawn into a consideration of its underpinnings in cognitive and brain science as well as philosophy. In those disciplines, the difficulty of dealing with epistemology and consciousness has long been recognized, making an unequivocally clear steer for educationalists' application an unrealistic expectation. However, such a fundamental problem shared across disciplines is helpful in highlighting difficulties to avoid as well as positive ideas to pursue.

Whether in spite of or because of the nonlinguistic comprehensiveness of the definition of multimodal representations, among the frontrunners exploring this new territory are educators specializing in applications to the language arts. The obvious multiple modes to which these educators attend include expressive language (oracy, text) and receptive language (listening, reading), supplemented by the range of modes that add information to the genres of drama, poetry, literature, and language acquisition: gesture, images, nonverbal sounds, facial expressions, and so forth. These modes may arise independently and in combination, sometimes dovetailing complementarily, at other times offering a richness through redundancy of information. "Social semiotics" explicates the multimodal expressions that communicate meanings using such combinations of linguistic and nonlinguistic sign systems. Semioticians will claim, entirely plausibly, that it is only when the full complexity of the multimodal signs and processes being used are analyzed that the nuances of communicated information may be fully comprehended. Semiotic deconstruction of this nature has been applied to the analysis of science teachers' classroom communications. Arguably, such communicative performances are but one step away from rhetoric, in the sense of being shaped by an intent to present information to persuade, or at least, with a clarity that conveys conviction and optimizes accessibility for the recipient.

The commercial and academic interest of the advertising, marketing, and entertainment industries in multimodality is also easy to understand, with "multimedia" and "multimodality" sharing common ground in the potential to exploit a range of communicative possibilities to inform and persuade. Indeed, Marshall McLuhan's still widely quoted declaration that "The medium is the message" can be seen as a herald of current interest. Computer scientists are also significant stakeholders, in both modeling the cognitive processes and exploiting the multimedia potential.

Science educators and learners have access to an extensive array of information communication modes, far beyond language enriched by gesture. Science education can exploit the full range of human sensory systems and use instrumentation to extend the detection of the entire electromagnetic spectrum. In addition, various formats and systems have been invented for quantifying data. A huge selection of possible multimodal representations is used habitually in science: text; images; cross-sectional and labeled diagrams; 3D models and specimens; mathematical, graphical, pictorial images and photographs; chemical symbols and equations; video and audio recordings; magnified images; waveforms; and many more formats. All can be described at a simple level in terms of the basic sensory channels by which they are accessed, with layers of complexity added when used symbolically. What evidence is available to support an informed analysis and management of multimodality, such that claims that it can help to make a difference to teaching and learning processes and outcomes might be tested? Does the modality of a representation make a difference to an individual's performance as a learner addressing a problem or faced with acquiring a new understanding through engaging in some form of conceptual change process? Or from the instructional side of the process, what difference might views about multimodality make that will be of benefit to teaching? An encouraging illustration of representational modes making a difference to performance is found in U-shaped growth, the interpretation of which has a bearing on this discussion.

U-Shaped Behavioral Growth

U-shaped behavioral growth is a phenomenon that has been debated in child development literature for decades and which continues to be reported in various manifestations. This form of growth has usually been described in cross-sectional samples by age, where the correct solution to a problem is achieved by a younger age group, drops out in a middle group by age, and reappears in the behavior of older subjects in the sample. The domains in which this developmental pattern of correct-incorrect-correct outcome is recorded are varied; the age ranges typically span something like 4–12 years. The theoretical relevance to a discussion of multimodality resides in the interpretation of the subjects' underlying reasoning. The favored interpretation is that two representational formats are being used, with the attempted deployment but incomplete mastery of a more advanced format resulting in a temporary decline in performance. This can be illustrated by reference to the understanding of transformations associated with intensive physical properties.

An intensive property does not change with changes in its extensive property. Temperature is an example: volumes of water at a given temperature may be mixed (changed in extent) but the resulting temperature remains the same. Strength or "sweetness" of solution is another intensive property. When volumes of liquid of the same concentration are added together, the ratio of solute to solvent remains constant even as the extensive property is increased.

When presented with the combination of two volumes at the same temperature or of identical sweetness, younger children (around 4 years) predict correctly no change in the resultant sweetness or temperature, as do older subjects (around 12). However, those approximately in the middle of the 4–12 age range tend to predict an increase in temperature or sweetness. It is the interpretation of this kind of error that illuminates the potential impact of multimodal representations. The inference, based on qualitative interview responses, is that two separate representational systems are being deployed. While the younger respondents are referring to an intuitive representation of temperature and sweetness, those in the mid range, with the correct intention, are attempting to use a mathematical or quantitative representation of the problem. However, they are failing to deal with what is a ratio problem, perhaps because they focus on the numerator rather than the proportion. Their prediction is incorrect until such time as the two representations – the temperature/sweetness and the ratio – are consolidated to generate a consistent outcome. An important aspect of the theoretical perspective on this interpretation is that the correct-incorrect-correct behavioral sequence can be thought of as a positive incremental conceptual progress, though it is masked by a behavioral setback. The generalization drawn is that it helps to have some interpretation of what representations are guiding thinking inside students' heads if we wish to manage multimodal representations positively.

The Structure of the Brain and the Structures of Thinking

Knowledge of the structure and organization of the human brain has increased rapidly in recent years but remains one of the outstanding major frontiers of science. Historically, there was a belief that bumps and irregularities discernible on the skull's outer surface might provide clues about the differentiated activity driven from within the carapace. When hypothesized correlations between externally measured features of the cranium and subjects' behavioral and emotional life failed to convince, interest in such approaches withered. However this left some interesting legacies, one such being the idea of human psychology being differentiated and structurally localized, as assumed in faculty psychology. Localized damage may result in specific impairments of psychological functioning, as brain trauma incurred in combat, strokes, and accidents confirms. For example, damage to the right cortex is associated with motor impairment, to the left with language degradation, yet healing often involves compensatory effects, suggestive of an interconnected or holistic brain functioning. The specific and the general view of brain functioning must both be acknowledged and accommodated in explorations of multimodality.

Is Intellectual Functioning Domain Specific or Domain General?

A view of the brain as a general-purpose problem-solving organ, fully interconnected for internal communication of data, might lead to a different view of multimodal representations as compared with an assumption of modularity. Is intellectual behavior better thought of as domain general (interconnected and homogeneous) or domain specific (modular, dealing in an array of restricted, relatively narrow classes of object and properties)? In the latter part of the twentieth century, it was suggested that some structural predisposition was needed to explain the enormously complex language development achieved so rapidly by very young children and the notion of the functioning of the brain as modular gained prominence. Modules for face recognition (another precociously developed human skill) and for the "theory of mind" (the attribution of mental states of knowing to others) have also been suggested as modules. Such domain-specific capabilities at the starting point of development are assumed by some to be distinct and discrete rather than generalizable to all learning.

Ideas About Modularity of Mind

Jerry Fodor, a prominent philosopher and cognitive scientist, suggested in the 1980s that some psychological processes occur as modules, discretely packaged entities. He proposes a three-tier organization: (i) a transducer process that transforms environmental signals into a form usable by "the system," (ii) an input process that recognizes and organizes those transformed signals in different formats or "modes," and (iii) higher-level cognitive functions performed on those inputs. Modules are defined by several particular characteristics, including automaticity and being encapsulated: they are separate from one another and from the third level. Conscious operations across modules are defined as possible only at the third level, where "the system" makes decisions and acts on the basis of all the domains of information from the input structures to which it has access. Only at the third level is there conscious management and the possibility of modules "interfacing" or "talking to one another."

Fodor's formulation offers one way of making sense of the U-shaped growth curves described earlier. Consider again the temperature and sweetness examples used above. The system may have a representation of the taste of sweetness and the feeling of temperature, as well as spatial representations of volume and a mathematical representation of ratio. These must be consciously coordinated to generate a correct prediction to an intensivity problem.

There are other complexities around the notion of modularity. Firstly, Fodor's expression of modularity is known as "modest," in contrast to more recent suggestions by evolutionary psychologists of "massive" modularity, with the proposal that all modules, including higher-level conscious operations, are function specific. This "massive modularity" hypothesis will not be discussed further here. More important is the recognition that those who argue for Fodor-style modules are adopting a nativist position that assumes developmentally predetermined modules. The nativist views of modularity described above are radically and fundamentally challenged by a developmental perspective that insists on a greater attention to the role of epigenesis in cognition.

Modularization as an Epigenetic Process

Epigenetics is a growing field of study, stimulated by recent knowledge about the human genome. Exploration of the environmental variables associated with the expression of very specific genetic factors is made possible, genes being assumed to offer a potential that is realized in a dynamic union with environmental experiences. These kinds of enquiry challenge the paradigm of genetic determinism. They have their counterpart in neurodevelopmental studies that explore the cognitive correlates of genetically linked conditions having an impact on intellectual development (e.g., Williams syndrome and autism). The conclusion, as expounded by Karmiloff-Smith, is that modularization is a progressive process that can only be fully understood from a perspective that assumes very significant developmental plasticity. Neuroconstructivists point to evidence that some forms of environmental interaction over the time of a learner's development give rise to specializations in processing in particular domains.

Developmental and Micro-Developmental Change

Karmiloff-Smith's position is to expect uneven cognitive profiles, consistent with modularity and domain specificity rather than the nativist assumptions of unitary capacity. Environmental interaction over the time of a learner's development gives rise to specializations in processing; genes offer a potential, realized in dynamic conjunction with experiences during ontogenesis, resulting in modularization. Micro-developmental conceptual change follows a pattern involving three recurrent phases. In the first phase, the system's focus is on data arising from interaction with the environment and this phase persists until behavioral mastery. The second phase describes the internal dynamics of the system. In the third phase, with internal mental computations more stable, what Karmiloff describes as a process of "representational redescription" (RR) occurs. That is, the system reflects on what it knows as a new representation emerges.

An interesting contribution from brain imaging technology adds an empirical perspective to the narrative. Functional magnetic resonance imaging (fMRI), combined with a computational model, has been used to link neural activity (blood oxygen flow) to subjects' thinking about word-image instances of concrete nouns. The resulting "brain pictures" manifest characteristic patterns linked to specific word-images, distributed across three to five locations in the brain. Factor analysis of the outputs gave rise to three main semantic factors for physical objects that were reified as "shelter," "manipulation," "eating," and a fourth factor, "word length." Furthermore, similarities in the patterns for the same words generated by different subjects were identified as similar "brain pictures" across the sample. There may thus be some support for a form of localization of function in this work.

Review and Reflection

Figure 1 suggests a summary of the discussion above.

J.J. Gibson used the term "affordances" to describe action possibilities latent in the environment, constrained by the limits of an agent's repertoire of possible activities: this formulation applies equally to humans, to other animals, and to computers as intelligent machines. Affordances are regarded as latent in the environment and measurable; brain-body-environment permutations afford and limit possibilities for activity. An adaptive and evolutionary perspective suggests that the sense organs must be integral with perceptual systems to allow sense making, whereby values, possibilities, and meaning (e.g., "looks good to eat") are directly perceived. Gibson's formulation seems not inconsistent with the notion of modularity.

There are challenges to understanding in the processes indicated in Fig. 1, particularly between categories 3 and 4, the step across from neural physical correlates to mental events. Computer scientists might describe the process as analogous to binary code being translated to ASCII format. Neuroscientists point to basic neural processes including the growth of protrusions in the dendrites that carry the estimated one hundred thousand billion synapses and the transfer of proteins that, it is believed, play a critical mediating role in learning. Roger Penrose offers a quite different speculation that the wave-particle duality of quantum theory could have value in explaining consciousness, challenging the classical physicalism of reductionists and computationalists. The inescapable fact for science educators is that, however much is learned about physical brain processes, there is a chasm

1	2	3	4	5
EXTERNAL	INTERNAL			EXTERNAL
	PRE-CONSCIOUS		CONSCIOUS	
A range of energy forms in the environment is available for transfer from objects and events. Environmental affordances link environment, brain and body.	Energy from external sources impinges on sense receptors in human physical systems.	Brain inputs from receptors are translated into cognitively useable form, with modularisation and pre-conscious processing	Mental activities are involved in meaning creation (‘internal representations’).	Meanings are articulated using a range of formats, communicated externally to the environment as notations (‘external representations’)

Multimodal Representations and Science Learning, Fig. 1 Processes in the formation of representations

in our understanding of the link between the physical and mental events in the brain. The physical and mental descriptions are explanatory categories of two different orders that do not translate one to the other. It is in categories 4 and 5 of Fig. 1 that productive research and development in science education becomes a realistic enterprise.

Implications for Research, Development, and Pedagogy

Cautions: Some theoretical formulations are inconsistent with the arguments as set out above. For example, the theory of multiple but distinct intelligences, suggesting as it does that individual learners have different qualities of mind, is not consistent with the interpretations of multimodal representations discussed here. In its favor, the theory of multiple intelligences redresses the exaggerated weighting that education has traditionally bestowed upon linguistic modes. While the proposition that learners may favor different modalities at different times and in different circumstances is reasonable, to label some students as limited to particular qualities of learning as learning style adherents have advocated could be doing students a great disservice. Multimodality suggests that instruction should sample a rich variety of representational modes to offer all students. To limit individual learners to adopting constrained modes of learning is unacceptable once we accept that all learners with intact nervous systems have access to the same range of multimodality. Individual students might favor particular expressive modes, but these are more likely to be attributable to their sociocultural histories than inherent limitations.

Modularization and culture: Modularization of thinking implies that certain domains are likely to become prevalent in an individual’s thinking, operate faster, and perhaps to some extent become more automatic. Students’ habitual modes of thinking in modern societies are likely to be different from former times when the ubiquity of text, literacy, and quantification of most aspects of our current world and our experience of it were absent. In recent decades, the advent of digital media has been revolutionary for mental life and may account for the ontogenetic emergence of a changed quality in the nature of intelligence. This is one possible interpretation of a fall over a 30-year period in the level of intellectual functioning on a Piagetian task as measured by Michael Shayer and colleagues. Certainly, many twenty-first century students have access and are exposed to a range of multimedia digital representations beyond the imaginations of earlier generations. Such students are likely to be highly motivated by opportunities to express their understanding in ways familiar from the converging media of broadcast television and the Internet. Another perspective on a possible changing quality of mental life is that other activity-initiated representational possibilities might be closed down by increasingly sedentary lifestyles. Some evolutionists suggest that a critical period of motor activity is characteristically essential in mammalian development but is being missed or neglected in favor of digital lifestyle options. On the positive side, science educators are constantly confronted with problems as to how to represent inaccessible concepts that might be rarely occurring, dangerous, or at the extremes of scale. Modern multimedia enriches the range of representational possibilities and needs to be exploited in such circumstances.

Translation and triangulation of multimodal representations: A defining feature of external representations is that any single form can only ever approximate to that which is represented: some features will map propitiously, others less well. Metacognition is acknowledged by educationalists as important in meaningful learning, and the generative meaning-creation behavior required in category 4 requires hard brainwork. The meanings carried by representations cannot be assumed to be self-evident or made sense of by rote. Whether called "representational redescription" or "metarepresentation," the internal generative experience is one of the conscious explicitations, an act of fixing meaning and belief from inchoate to developed form. Cognitive activity fills in the gaps as part of the sense-making process between subliminal and conscious mental operations. Thoughts may need to be articulated externally in diagrams, speech, writing, or some other form in order to be fully realized, but often, the expression does not emerge as intended. While verbal learning is a common shortcut, it may lack the underlying domain-specific firsthand experience of meaning making that is accessed via direct experience.

There are occasions when it is important for science educators to bear in mind that multimodality implies very much more than different wrappings for the identical informational package. Assessment is one such context. Laboratory-based activities in science are highly valued but relatively expensive in management, time, and resources. It would be a cost-effective proposition to dilute laboratory and practical experience with other forms of thoughtful representational activity, both in teaching and in assessment. Such pragmatic management decisions should not be dismissed out of hand on the grounds of nonequivalence. The selected modality makes a difference, and switching modalities, for whatever reason, requires careful empirical consideration of the effects of such changes. For example, there do not seem to be any grounds for categorical assertions on either side that practical work in science can or cannot be assessed by other than practical means.

Drawing on representations from different modalities is intended to facilitate sense making by triangulating, and thus reinforcing, understanding. Students can be encouraged to reflect on the value of different versions or formats, critically scrutinizing the mapping between them. This critical activity is advocated as an explicit, external, and self-aware metacognitive activity. It is recommended as a strategy for accessing the conventional formats used in science teaching, giving students a more nuanced consideration of what is "real." This case-by-case approach to standard representations supports thinking and mediates learning. Since meaning making is such a personal activity, handing over ownership to students, rather than attempting to impose a rigid representational orthodoxy, offers them the opportunity to take creative responsibility for their own learning.

Another pedagogical perspective takes a broader view, from individual cases to the strategic place of representations per se in scientific endeavor. The argument here is that students can be encouraged to consider, from an overarching perspective, the role and value of representational forms and the purpose they serve as used by scientists. This broader perspective, labeled "metarepresentational competence" (MRC), is important in adding a reflexive dimension which helps to bring students' own awareness of their science learning procedurally closer to the way professional scientists operate.

Multiple Intelligences

Rebecca Cooper
Faculty of Education, Monash University,
Clayton, VIC, Australia

Multiple Intelligences

The theory of multiple intelligences is predominantly attributed to the work of noted psychologist Howard Gardner during the late 1970s and early 1980s. Gardner conceived intelligence as having multiple rather than singular forms and developed a set of criteria for identifying unique intelligences, which included:

- It should be seen in relative isolation in prodigies, autistic savants, stroke victims, or other exceptional populations.
- It should have a distinct neural representation, such that its neural structure and functioning should be distinguishable from other human faculties.
- It should have a distinct developmental trajectory; different intelligences should develop at different rates along distinctive paths.
- It should have some basis in evolutionary biology.
- It should be susceptible to capture in symbol systems.
- It should be supported by evidence from psychometric tests of intelligence.
- It should be distinguishable from other intelligences through experimental psychological testing.
- There should be identifiable mental processes that handle information related to each intelligence (Davis et al. 2011).

Gardner initially identified seven intelligences that he developed as a theory of multiple intelligences and later, using the above criteria, Gardner added an eighth intelligence as described in the table below (Table 1).

Given Gardner's understanding of intelligence of being pluralistic, it is not surprising that his theory of multiple intelligences included the notion that each individual has a profile that includes all eight intelligences at various levels of strength and weakness. However it is incorrect to say that an individual would demonstrate no ability in a particular intelligence or that everyone would be classed as gifted in at least one intelligence. In fact Gardner makes only two primary claims:

- All individuals possess the full range of intelligences.
- No two individuals, not even identical twins, exhibit precisely the same profile of intellectual strengths and weaknesses (Davis et al. 2011, p. 492).

Gardner has continued to research his theory of multiple intelligences and believes he has

Multiple Intelligences, Table 1 Description of eight multiple intelligences

Intelligence	Description
Linguistic	An ability to analyze information and create products involving oral and written language such as speeches, books, and memos
Logical-mathematical	An ability to develop equations and proofs, make calculations, and solve abstract problems
Spatial	An ability to recognize and manipulate large-scale and fine-grained spatial images
Musical	An ability to produce, remember, and make meaning of different patterns of sound
Bodily-kinesthetic	An ability to use one's body to create products or solve problems
Interpersonal	An ability to recognize and understand other people's moods, desires, motivations, and intentions
Intrapersonal	An ability to recognize and understand his or her own moods, desires, motivations, and intentions
Naturalistic	An ability to identify and distinguish among different types of plants, animals, and weather formations that are found in the natural world

(Gardner 1993, 2011; Davis et al. 2011)

"suggestive evidence. . . for a possible existential intelligence ("The intelligence of big questions")" (Gardner 2011, p. xiv).

Multiple Intelligences in the Classroom

The educational implications of the theory of multiple intelligences has been summed up by Gardner, "an educator convinced of the relevance of multiple intelligence theory should 'individualize' and 'pluralize.'" By "individualize," Gardner means that an educator should know the intelligence profile of each student in their class so well that they are able to make adjustments to the teaching and assessment that are used. By "pluralize" Gardner means giving consideration to the topics or concepts that are most important and ensuring that they are presented through multiple modes of delivery, while at the same time highlighting the importance of the multiple modes of delivery as a way of considering what it means to understand something well.

Museums

Paulette M. McManus
Institute of Education, London University, Mere, Wiltshire, UK

In science museums you may find iconic artifacts like parts of Watson and Crick's original model of DNA; significant objects like fossils; a series of objects, artifacts, or models illustrating a developmental process or concept; dioramas of all sorts; singular chronological displays; taxonomic interpretations of the natural world; classification displays ranging from minerals to jet engines; explanatory graphics and computer games; and so on. Permanent exhibitions provide well-researched, detailed communications rather than accounts of the latest discoveries which may well be presented in temporary exhibitions. Museums are saturated with objects and the words interpreting them. The eclectic mix is part of their charm.

All museums are, like many scientific activities, expressions of fundamental human cognition patterns and psychological behaviors. Think about curiosity, delight in novelty and the unique, linguistic pleasure in naming and categorizing, love of collecting, delight in observation and measuring, brain and hand-eye coordination allowing the making of incredibly fiddly things, spatial intelligence prompting us to be imaginers of monumental manufacture, appreciation of the natural world, ties to home territories, and respect for the well-made object, or well thought out theory, which leads to aesthetic appreciation. Museums are cultural institutions reflecting varied expressions of natural tendencies.

Communication Research in Museums

Museum exhibitions are a form of 3D media which people walk through in a public, comfortable, and usually publicly funded space. They generally have a long life, maybe up to 30 years or more (recently a 100-year-old exhibition was replaced in a London national museum). Because exhibitions change at such an exceptionally slow pace compared to other forms of modern media, they are seen as an attractive, easy area for research and commentary by academics from emerging or developing fields such as media studies, cultural studies, anthropology, sociology, ethnology, political policy, development studies, and space syntax, along with other computing-based applications. Therefore, much of the critical writing on museums is written from a singular, academic point of view and fails to take account of museum histories, their conservative nature, the time scales to which they work, their restrictive budgets, their concrete communicative style, and their public popularity (McManus 2011).

Critical views have also been expressed by science museum curators who question the impression of the inevitable progress of science inherent in chronologically ordered displays. Within the museum profession there is discussion about communicating the social implications of technological developments, the problematic nature of science as a cultural activity, and how communications can be biased by the social and academic backgrounds of museum people. There is also a vibrant field of museological writing devoted to museum communication, audience studies, evaluation methodologies, and museum management, in which a fashionable tendency to adopt learning theories long after they have been abandoned by formal educationalists is evident. Current relativist interest in learning style theory and constructivism is seen by some as an excuse for inadequate conceptualization and preparation of communications for a general audience.

Museums in Their Historical Contexts

In all cultures, there have probably always been treasuries of objects with religious and kingly significance. Museum institutions are European products of the seventeenth and eighteenth centuries of the Age of Enlightenment. They have spread around the world as a result of colonization, twentieth century globalization, and, recently, as a result of development policies and the rise of mass tourism destinations.

Collections are the foundation of museums and the exhibitions about them may seem timeless. As a result, museum presentations vary according to their institutional histories, so large national science museums often offer a palimpsest of past scientific and technological preoccupations (McManus 1992).

The ancestral form of the museum is the Cabinet of Curiosities created during the Enlightenment in small rooms and galleries in the houses of wealthy men. Here they could show and discuss with their friends interesting rarities, specimens, ethnographic materials, scientific instruments, coins, and antiquities.

Older public museums are derived from subject matter breakdowns of the Cabinet of Curiosities collections. For example, the Ashmolean Museum, Oxford, Britain's first public museum, was founded in 1683 from the collections of John Tradescant, while the British Museum, London, was founded in 1753 from the collections of Hans Sloane. The "consumer characteristics" of such museums were, and sometimes still are, object saturation and authoritatively delivered information. In them, the curators privately researched the collections in tenured academic style, while the public activity of education and interpretation was undertaken by hired guides, educators, or designers. This historic split in status is mirrored in the institutional culture of many museums today.

In the 1960s and 1970s, there was an increasing desire to alter the focus of displays in the older science museums from a taxonomic display of objects to the presentation of explanations of interdisciplinary scientific ideas and concepts such as evolution, ecology, and atomic power. Gradually, a new approach to the visiting public, often based on mainstream educational theory, produced exhibitions with carefully structured information and engaging displays with which people could interact. Under these developments the educational function of museums came to the fore, and new museum professions came to include evaluators and researchers into learning in informal museum environments. The curator became subject matter expert rather than the initiator of exhibitions.

In the early nineteenth century, collections-based museums, discussed above, were slowly joined by science and technology museums concerned with training, the world of work, and scientific advance. Originally these were established to meet the practical needs of industry. For example, the V&A, London, was founded to promote design training. Mid-century, such pragmatic objectives, were rapidly overtaken by influences from a spate of popular trade exhibitions and world fairs. The fusion of the training-orientated, serious technology museum and the popular industrial exhibition with its beam engines and willingness to allow enjoyment gave rise to our familiar science and technology museums.

Around the mid-nineteenth century, there was also a rise in the foundation of provincial public museums which sought to provide sources of liberal education in an age without compulsory schooling. From the mid-nineteenth century up to today, the museum audience in general has become less academic or educated middle class and more general in character. However, it remains the case that an individual's level of education is the strongest indicator of the likelihood of museum attendance.

In recent times, museums devoted to the transmission of scientific ideas and concepts, rather than the building of collections and scholarly research into them, have arisen. Their primary objective is public education and they are often offshoots from educational institutions. Such museums tend to present thematic exhibitions of current contemporary significance and to contain interactive exhibits. Nowadays, themes could include heredity, sustainability, global warming, and so on. Examples of such museums are Palais de la Decouverte, Paris (1937), New York Hall of Science (1964), Lawrence Hall of Science (1968), and the Exploratorium, San Francisco (1969). Science centers could be said to be decontextualized scatterings of interactive devices first pioneered in this range of modern public education museums.

Differences Between Formal and Informal Education

Museums are prime examples of informal educational environments, so it is important for museum people to conceptualize a philosophy of informal education and to avoid mimicry of the attitudes, teaching style, and methods of schools and colleges.

In formal educational situations, where you will learn, who you will learn with, whether you are qualified to learn, who you will learn from, what you will learn, how long you will be given to learn it, and agreement on what you have learned and your level of understanding are matters largely out of control of the individual learner. As a result of these restrictions on the individual, formal institutions are very efficient, admirable means of communicating knowledge throughout societies for the benefit of those societies and the individuals within them. Formal education has developed a pedagogy which, some say, applies to a somewhat restricted range of human learning mechanisms and behaviors. Distinctive forms of evaluation have been developed to assess learning under these enhanced, prescribed conditions.

Most museums have an educational remit built into their trustee documents, but efforts to measure learning in the museum environment using methods from the formal education sector have failed. Here lies a fundamental difference between the two sources of knowledge and understanding. Informal education is entirely free choice in every way and is largely a leisure activity. As far as museums are concerned, people can choose to visit when they feel like it and age or level of experience are not barriers – all are welcome. Museum visitors can attend to exhibits within exhibitions for as long or short a time as they wish, or they can walk straight past them. Since museum visitors arrive with widely different levels of understanding, personal expectations, and differing social contexts (families, friends, or alone), museum professionals must constantly deal with multiple audiences for their communications. Accordingly, useful museum evaluations are concerned with investigations into conditions which would support learning in the motivated enquiries about what sense people make of their experiences, and descriptions of visitor behavior (which can be quite consistent across all museum types). In recent years, public-facing museums have come to understand the differing segments of their increasingly well-educated audiences. Science learning is strongly supported in science museums because most museum evaluation methodologies have been developed in them.

Other sources of informal education include television and radio science programs, science sections in newspapers and magazines, botanical gardens, zoos, nature reserves, archeological sites, and historic houses. The intention to inform during “worthwhile” leisure time unites them all.

Out-of-School Museum Impacts

All types of museum collection can be splendid, rich places for anyone to find out about scientific concepts, processes, and technical applications. However, museums vary and are often very individualistic institutions. Those wishing to use them to teach out of school may have to adopt a lateral thinking approach to tailoring communications and really get to know their local museum. For example, at the Institute of Education, London, beginning mathematics teachers are taken to visit the nearby British Museum to work with Sumerian clay calendar tablets. At another museum, an education section may offer an “off the shelf program” which will just suit curricular needs. Some museums will offer educators Web-based materials, but because the essence of museum use is witness of primary evidence and the sight of “real things”, visits are best, if possible.. A well-planned school visit to any museum will involve a teacher who knows the institution they wish to visit and will not panic about losing control when out of classroom, preparation teaching about the planned experience, quick settling down of excited children in a novel environment, and the allowance of lots of free-choice activity after the planned topic has been dealt with along with follow-up at school afterward. It is important that the informal educational dimensions of museums are catered for.

It is known that children may pester their parents for a return visit to the museum after a school visit. This is especially if they have been taken out of their normal, everyday environment so that they have glimpses of a bigger, more varied social and natural world and have become curious about it. Such visits can leave people with long-lasting visual and episodic memories. Such powerful impacts are reasonable typical outcomes of visits to intentionally educational environments open to the general public (McManus 1994).

National Assessment of Educational Progress (NAEP)

Teresa Neidorf[1] and Michael Sheehan[2]
[1]American Institutes for Research, Washington, DC, USA
[2]Stephen F. Austin State University, Nacogdoches, TX, USA

The National Assessment of Educational Progress (NAEP) is the national measure of what students in the United States know and can do across multiple grades and ages in a variety of academic subjects. The NAEP program includes two components: long-term trend (LTT), an age-based national assessment (ages 9, 13, and 17) that has been conducted since 1969, and main NAEP, a grade-based assessment (grades 4, 8, and 12) begun in the late 1980s that reports trends in student achievement at the national and state level, as well as for select urban districts. Main NAEP assesses students at the national level in reading, mathematics, science, writing, economics, US history, civics, geography, the arts, and most recently in technology and engineering literacy. State- and district-level assessments are conducted in reading, mathematics, writing, and science at grades 4 and 8. Recent state-level assessments also have been conducted at grade 12 in mathematics and reading. Currently, LTT NAEP only assesses students in reading and mathematics, although science and writing were also assessed until the late 1990s.

The National Assessment Governing Board was created by congress in 1988 to set policy for NAEP. The Governing Board is an independent body of diverse members, appointed by the Secretary of Education, with representatives from government and public policy, education, and the general public who reflect a range of perspectives and interests. The Governing Board is responsible for selecting which subjects and grades will be assessed each year, developing the assessment frameworks, setting the Achievement Levels, approving all assessment content, and publicly releasing NAEP reports.

NAEP is administered by the National Center for Education Statistics (NCES), part of the Institute of Education Sciences (IES) in the US Department of Education. NCES oversees the NAEP Alliance, a joint body of contractors who develop, administer, process, score, and prepare reports of the results from the various assessments. For main NAEP, the core subjects (mathematics, reading, writing, and science) are assessed on a regular basis. Since 2001, assessments at grades 4 and 8 in reading and mathematics are given every 2 years. Assessments in science and writing at all three grades and mathematics and reading at grade 12 are conducted approximately every 4 years. Other subjects are assessed periodically, depending on the budget and priorities set by the Governing Board. LTT assessments in reading and mathematics are conducted every 4 years.

Along with providing current information on what students know and can do, a primary

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

purpose of NAEP is to monitor trends, or how student performance has changed over time. The assessments have been designed to allow comparisons of student performance over time and among subgroups of students according to gender, race/ethnicity, socioeconomic status (SES), students with disabilities (SD), English language learners (ELL), and region, as well as other demographics.

For all main NAEP subjects, the Governing Board has developed assessment frameworks, which provide guidance on the content to be assessed, the types of questions, and the administration of the assessment. These frameworks are typically in place for 10–12 years in order to report trends but undergo revision periodically to ensure the assessment stays current with developments in the field and in curricula and assessment. Depending on the extent of framework revisions, a new trend line may be established or a special trend study conducted to compare student performance based on the old and new frameworks. LTT assessments are based on older frameworks that are essentially unchanged since the 1980s.

NAEP assessments also include questionnaires to collect contextual data from students, teachers, and schools, including student characteristics such as race/ethnicity and parental education, classroom practices, teacher characteristics, and school resources and environments. Each student sampled takes a 10–15-min questionnaire as part of the assessment. In addition, questionnaires are administered to the teachers of the sampled students at grades 4 and 8 and to school administrators. NAEP questionnaires are updated periodically and are available to the general public for various subjects, grades, and assessment years (http://nces.ed.gov/nationsreportcard/bgquest.asp).

NAEP assessment development is a multistep process that typically requires about 2–3 years and includes reviews by multiple stakeholders. For each assessment, a large pool of items (test questions) is developed based on the assessment framework. All items undergo content, technical, and editorial reviews for accuracy, framework alignment, and grade-level appropriateness, as well as for potential bias. Reviews are conducted by the test development contractor, a standing committee of subject matter experts and education specialists, NCES, and the Governing Board, which has final approval of all items. In addition, NAEP items in some subjects are reviewed by state and district representatives. All items are pilot tested with a nationally representative sample to evaluate performance before being selected for an operational NAEP assessment used for reporting.

NAEP is a survey of representative samples of students at the national, state, or district level and reports group estimates for populations of students at these levels. NAEP does not provide individual student or school scores, and no single student takes the entire assessment in a given subject (as described in the Assessment Design section of this entry below). Schools are selected from a sampling frame and then students are randomly selected from the appropriate grade at each sampled school. For national-only samples, typically about 8,000–12,000 students are assessed per subject, per grade in roughly 400–650 public and private schools. For state samples, each state has roughly 2,500–3,000 students per subject per grade in about 100 public schools, resulting in more than 150,000 students in the combined national and state sample. Each district sample has about 1,000–2,000 students per subject per grade in roughly 20–100 schools.

Findings based on NAEP data are released to the public through the Nation's Report Card. NAEP reports use two primary methods of reporting student achievement for both current year and trend performance: average scale scores and percentage of students at each NAEP Achievement Level. The NAEP Achievement Levels are Basic (partial mastery), Proficient (solid academic performance), and Advanced (superior performance). For each subject and grade, preliminary Achievement Levels are defined in the framework. After the first operational assessment, the minimum scores corresponding to each Achievement Level are set by the Governing Board. Performance data and questions from the assessment are also used to develop detailed descriptions and examples of the specific knowledge and skills at each Achievement Level.

Results are reported at the national, state, and district level, for different percentiles (10th, 25th, 50th, 75th, and 90th) to show performance at the lower, middle, and higher levels and by key subgroups such as gender, race/ethnicity, SD/ELL status, and eligibility for the National School Lunch Program (as an indicator of SES). Reports may also include results for other demographics and key background variables in the student, teacher, or school questionnaires. All together, the NAEP reports help inform education policy makers and the public.

History of NAEP Science

The first NAEP science assessment was in 1969. From its inception, NAEP was administered to students aged 9, 13, and 17. In the 1980s, NAEP also started including grade-based samples in the grades containing the largest proportion of students in the age-based populations. The current main NAEP assessments at grades 4, 8, and 12 began with the establishment of the Governing Board in 1988 and the transition to national and state-level reporting. The national age-based assessments continued as long-term trend. Both LTT and main NAEP national science assessments were administered and reported separately in the 1990s; the last LTT assessment in science was in 1999.

In addition to the national assessments, in 1990 main NAEP started conducting state-level assessments. The first state-level science report was in 1996. State-level science assessments were administered at grades 4 and 8 in 2000, 2005, and 2009 and at grade 8 in 1996 and 2011. Starting in 2002, NAEP has also conducted a Trial Urban District Assessment (TUDA) in select large urban districts. In science, ten districts participated in 2005 and 17 districts in 2009.

Table 1 below shows the main NAEP science assessments conducted (or planned) at the national, state, and district (TUDA) level, as well as the LTT assessments, from 1969 to 2015.

National Assessment of Educational Progress (NAEP), Table 1 NAEP science assessments 1969–2015

2015	✓	✓ (4 & 8)	✓ (4 & 8)	

✓Check marks indicate an assessment was administered or planned and reported this year at all three grades (4, 8, and 12) for main NAEP or at all ages (9, 13, and 17) for long-term trend (unless otherwise noted). National, state, and Trial Urban District (TUDA) assessments are indicated for main NAEP

†This symbol denotes a special case. There was one science report from 1986, which included both trend results for LTT age-based samples and achievement results for grade-based samples. This was the first combined age/grade sample for science administered at the modal grades (grades 3, 7, and 11) for the LTT populations (ages 9, 13, and 17). LTT populations were redefined starting in 1988 to have modal grades of 4, 8, and 12

[a] This was the first assessment based on a new science framework, developed by the Governing Board, which established the trend line from 1996 to 2005

[b] A new framework was developed for the 2009 assessment, establishing a new trend line

[c] The 2011 science assessment was conducted at grade 8 only to facilitate a comparison between NAEP and the Trends in International Mathematics and Science Study (TIMSS)

Long-term trend reported trends in science achievement from 1969 to 1999. For main NAEP, there were three assessments in the trend line based on the first Governing Board science framework: 1996, 2000, and 2005. A new trend line was established in 2009 with the introduction of a new science framework.

The most recent science framework was used as the basis for the assessments conducted in 2009 and 2011, as well as the development of upcoming assessments. The 2009 framework reflected developments in national science standards and state and international assessments, as well as advances in science and cognitive research since the early 1990s. The 2009 framework is sufficiently different from the previous framework that a new trend line was started.

The 2009 NAEP Science Framework

There are two dimensions in the 2009 science framework that define the science knowledge, skills, and abilities to be measured in the science assessment: science content and science practices. A separate assessment and item specifications document provides more detailed information on the content to be assessed, item types, and other aspects of assessment development and administration.

The science content dimension defines the key science principles as well as facts, concepts, laws, and theories to be assessed. The content dimension is organized into three broad content areas:

- Physical science
- Life science
- Earth and space sciences

Each of the content areas includes a set of major topics and subtopics that further organize the science content to be assessed. The content to be assessed at each grade level is defined by a set of grade-specific content statements for each subtopic. Each subtopic also has an associated set of content boundaries in the assessment specifications document that further clarifies the content included and excluded at each grade. The framework also emphasizes the importance of cross-cutting content (such as energy transformations and biogeochemical cycles), which includes key science principles reflected in the content statements across the content areas.

Table 2 shows the subtopics included in each content area and the target percentage of the assessment across the content areas at each grade level defined in the framework.

National Assessment of Educational Progress (NAEP), Table 2 Distribution of assessment time by grade and subtopics included in the content areas in the NAEP 2009 science framework

Content area	Grade 4	Grade 8	Grade 12	Subtopics
Physical science	33.3 %	30.0 %	37.5 %	Properties of matter
				Changes in matter
				Forms of energy
				Energy transfer and conservation
				Motion at the macroscopic level
				Forces affecting motion
Life science	33.3 %	30.0 %	37.5 %	Organization and development
				Matter and energy transformations
				Interdependence
				Heredity and reproduction
				Evolution and diversity
Earth and space sciences	33.3 %	40.0 %	25.0 %	Objects in the universe
				History of Earth
				Properties of Earth materials
				Tectonics
				Energy in Earth systems
				Climate and weather
				Biogeochemical cycles

The second dimension of the framework is defined by four science practices that describe what students should be able to do with the science content:

- Identifying science principles focuses on students' ability to recognize, recall, define, relate, represent, and reason with basic science principles.
- Using science principles focuses on what makes science knowledge useful in making

National Assessment of Educational Progress (NAEP), Table 3 Distribution of assessment time by grade and general performance expectations included in science practices in the NAEP 2009 science framework

Science practice	Grade 4	Grade 8	Grade 12	General performance expectations
Identifying science principles	30 %	25 %	20 %	Describe, measure, or classify observations
				State or recognize correct science principles
				Demonstrate relationships among closely related science principles
				Demonstrate relationships among different representations of principles
Using science principles	30 %	35 %	40 %	Explain observations of phenomena
				Predict observations of phenomena
				Suggest examples of observations that illustrate a science principle
				Propose, analyze, and/or evaluate alternative explanations or predictions
Using scientific inquiry	30 %	30 %	30 %	Design or critique aspects of scientific investigations
				Conduct scientific investigations using appropriate tools and techniques
				Identify patterns in data and/or relate patterns in data to theoretical models
				Use empirical evidence to validate or criticize conclusions about explanations and predictions
Using technological design	10 %	10 %	10 %	Propose or critique solutions to problems given criteria and scientific constraints
				Identify scientific trade-offs in design and decisions and choose among alternative solutions
				Apply science principles or data to anticipate effects of technological design decisions

sense of the natural world, with an emphasis on explaining and predicting.

- Using scientific inquiry involves applying science principles to answer a question under investigation to extend knowledge and to evaluate evidence, focusing on a few key inquiry practices that are practical to measure.
- Using technological design involves applying science principles to make design decisions.

Table 3 shows the general performance expectations for the four science practices and the target percentage of the assessment at each grade level defined in the framework.

The practices are combined with the content statements to generate specific student performance expectations which are used to develop assessment items.

The framework also describes four cognitive demands that underpin the science practices: declarative knowledge (knowing that), schematic knowledge (knowing why), procedural knowledge (knowing how), and strategic knowledge (knowing when and where to apply knowledge). The cognitive demands provide further elaboration on the skills to be measured by items across the science practices.

There are three components of the science assessment described in the 2009 framework:

- Individual assessments items (administered in paper-and-pencil test booklets)
- Hands-on performance tasks (HOTs)
- Interactive computer tasks (ICTs)

A range of item types is reflected in the framework, including individual items, item clusters that provide a more in-depth measure of particular science concepts, and item sets that require students to predict, observe, and/or explain phenomena. The assessment includes both selected-response (multiple-choice) items and constructed-response items where students are required to generate a written response to the questions. Both short constructed-response items requiring a brief description or quantitative relationship and extended items requiring more complete explanations are included. Constructed-response items have item-specific scoring guides with criteria for complete, partial, and incorrect score levels. Short constructed-response items may have two or three score levels, while extended items may have four or five levels. The framework requires that constructed-response items contribute 50 % of the assessment time.

Both HOTs and ICTs involve investigations and problem-solving scenarios that require students to directly apply their science knowledge and inquiry and problem-solving skills to real-world situations. Hands-on tasks require students to work with physical materials and science tools and have been included in NAEP science since the 1996 assessment. However, the 2009 framework calls for more open-process tasks that allow students to determine procedures and involve more planning, analysis, and synthesis. When performing HOTs, students collect and record data and provide responses to items in a test booklet. Most items in HOTs are constructed response, which are scored to assess both science content knowledge and inquiry skills.

The 2009 science framework was the first NAEP assessment to include interactive computer tasks. The framework defines four basic types of ICTs:

- Information search and analysis
- Empirical investigation
- Simulation of phenomena and models
- Concept mapping

Each task includes elements of one or more of these basic types. The ICTs provide opportunities to use phenomena not easily observed, involve lab situations that would be unsafe or impractical in the HOTs, include simulated internet search environments, and more easily measure the iterative nature of the inquiry and design process. When taking the ICTs, students respond to individual items (selected and constructed response). In addition, student actions as they proceed through the task are also captured and scored.

Assessment Design

The results reported in the Nation's Report Cards from the 2009 and 2011 assessments were based on student performance on the main paper-and-pencil assessment items. NAEP science assessments typically include between 150 and 200 individual items at each grade that cover the content areas and practices in the assessment framework. Assessment items from each content area are assembled into 25-min blocks; these blocks are paired in multiple test booklets that are distributed across the student sample. Each student takes two blocks – about 30–35 total items depending on the number of multiple-choice and constructed-response items in each block – which reflects only a fraction of the total assessment. This design ensures broad content coverage across the large item pool while minimizing the test burden on individual students. Since individual student scores are not reported, NAEP uses scaling methods that produce group estimates for populations at the national, state, or district level based on the subset of item responses obtained from each student in the sample.

The 2009 assessment also included two 40-min hands-on performance tasks and three interactive computer tasks (two 20-min and one 40-min) at each grade. These new components of the assessment were administered as a "probe" to separate, nationally representative samples in 2009 and were not combined with the results from the main paper-and-pencil assessment. The results from the 2009 HOT and ICT probes were reported separately from the main results.

The 2011 assessment was conducted at grade 8 only and was added to the assessment schedule for a special study linking NAEP to the Trends in International Mathematics and Science Study (TIMSS). The 2011 assessment included only the main paper-and-pencil component; the HOTs and ICTs were not administered in 2011. For more information about the NAEP-TIMSS linking study, see http://nces.ed.gov/timss/naeplink.asp.

Reporting and Release

Results from the 2009 assessment were reported at the national level at grades 4, 8, and 12. Results were also reported for grades 4 and 8 at the state level and for the 17 large urban districts that participated in the assessment. In 2011, the assessment was administered at grade 8, and results were reported at the national and state level. The 2011 assessment at grade 8 provided the first trend measure based on the new science framework. Science reports from 2009 and 2011 as well as some previous assessments may be accessed on the Nation's Report Card website (http://nces.ed.gov/pubsearch/getpubcats.asp?sid=031).

The results from the 2009 HOT and ICT probes were published in a separate 2012 report (Science in Action-Hands-On and Interactive Computer Tasks from the 2009 Science Assessment) that provides more in-depth information about students' abilities to conduct investigations, draw conclusions, and explain their results.

NAEP reports average science scores on an overall scale (0–300) based on all items in the assessment at each grade. In addition, subscales are produced for each of the content areas – physical science, life science, and Earth and space sciences. While performance on the subscales is not a focus in the main reports, subscale scores are available on the NCES website.

The 2009 assessment was the first assessment based on the new framework. Using student performance data and items from this first assessment, the Governing Board established the Basic, Proficient, and Advanced Achievement Levels for the science assessment. Descriptions of the science knowledge in each content area as well as the skills in the science practices that characterize each Achievement Level at each grade are provided in the updated 2011 framework (see References below).

The NAEP reports also include item maps and example items to illustrate student performance across grades and content areas. Item maps are visual representations that show the location of the Achievement Levels and place a range of items on the scale based on their difficulty. This provides a method for describing the types of items students at a given score level were likely to be able to do (http://nces.ed.gov/nationsreportcard/itemmaps/?subj=science).

After each assessment, a subset of items is released to give the general public a better understanding of the content of the assessment. New items are developed to replace these released items for the next assessment. The released items, along with performance data and scoring guides, are provided in the NAEP Questions Tool at http://nces.ed.gov/nationsreportcard/itmrlsx/landing.aspx. For science, released items are available from the 2009 and 2011 assessments as well as previous assessments based on the prior framework (2005 and 2000).

All of the ICTs and one of the HOTs at each grade were released after the 2009 assessment. Teachers, students, parents, researchers, and the general public are able to explore the tasks and take the ICTs themselves online (http://nationsreportcard.gov/science_2009/ict_summary.asp). Users can also access the full text of the released HOTs as well as descriptions of the materials and tools used in the tasks at http://nationsreportcard.gov/science_2009/ict_tasks.asp?tab_id=tab2%26subtab_id=Tab_1#tabsContainer.

The NAEP Data Explorer (NDE) permits users to define demographics or contextual variables of interest from the NAEP data and create their own customized tables of results for the nation, state, district, or for different subgroups using either the overall science scale or the content area subscales (http://nces.ed.gov/nationsreportcard/naepdata). Restricted-use data sets are also available to licensed researchers to conduct secondary analyses using NAEP data (http://nces.ed.gov/nationsreportcard/researchcenter/researchsupport.asp).

Future of NAEP

The next NAEP science assessment is currently planned for 2015 and will include the main assessment item blocks, hands-on tasks, and interactive computer tasks in the national assessment. With the release of all of the 2009 ICTs and half of the HOTs, the 2015 assessment will reflect the next generation of tasks currently under development. Following the standard cycle of science assessments every 4 years, the subsequent science assessment is scheduled to be conducted in 2019.

NAEP's move to computer-based assessment started with the ICTs in the 2009 science framework followed by the 2011 writing framework and the 2014 technology and engineering literacy framework. The Governing Board plans to transition each assessment to computer-based administration with each new framework. Although there are no current plans to replace the 2009 science framework, it is anticipated that the science assessment will transition to being fully computer based over the next two administrations.

NCES is exploring a number of other options to move the NAEP program forward. In 2011 and 2012, NCES convened panels of experts in assessment, measurement, and technology as well as state and local stakeholders to provide recommendations on the future of NAEP (10 years ahead and beyond). The paper with recommendations from the panel (NAEP: Looking Ahead – Leading Assessment into the Future) is available on the NAEP website (http://nces.ed.gov/nationsreportcard/pdf/Future_of_NAEP_Panel_White_Paper.pdf).

Conceptualizing the Construct of NOS

Although the current terminology for this construct is "nature of science," it was originally labeled "nature of scientific knowledge" until the mid-1980s. The latter phrase typically refers to characteristics of scientific knowledge as derived from the manner in which it is produced, that is, scientific inquiry (Lederman 2007, McComas 1998). In short, the method of developing scientific knowledge necessarily imbues the knowledge with certain characteristics. When discussing assessment, it must be recognized that NOS has consistently been viewed in the literature as a cognitive outcome. That said, in recent years, some science educators have included some aspects of inquiry (the doing of science) as part of NOS. Traditionally, however, NOS has not been viewed as a skill, attitude, or activity. Additionally, there is a developmentally appropriate level of generality regarding NOS that is accessible to K-12 students and relevant to their daily lives. At this developmental level, little disagreement exists among philosophers, historians, and science educators. It is important to note that the description of NOS that follows is not meant to be a definitive depiction, but rather represents the most common aspects of NOS used in the research literature and taught to K-12 learners.

First, students should be aware of the distinction between observation and inference. In K-12 science classrooms, observations are presented as descriptive statements about natural phenomena that are "directly" accessible to the senses (or extensions of the senses). By contrast, inferences are presented as statements about phenomena that are not "directly" accessible to the senses. The notion of gravity is inferential in the sense that it can only be accessed and/or measured through its manifestations or effects. It is also critically important that students know that both observation and inference are necessarily part of all scientific knowledge.

Second is the distinction between scientific laws and theories. Individuals often hold a simplistic, hierarchical view of the relationship between theories and laws whereby theories become laws when overwhelming supporting evidence is accumulated. For example, biology teachers are often told that evolution is just a theory. This notion is inappropriate. Laws are statements or descriptions of the relationships among observable phenomena. Theories, by contrast, are inferred explanations for observable phenomena. Scientific theories serve important roles, such as guiding investigations and generating new research problems in addition to explaining relatively huge sets of seemingly unrelated observations in several fields of investigation. Although scientific theories and laws are related, it is incorrect to think that theories eventually mature into laws.

Third, even though scientific knowledge is, at least partially, based on and/or derived from observations of the natural world (i.e., empirical), it nevertheless involves human imagination and creativity. Because science is done by humans, it is not a totally lifeless, rational, and orderly activity. Science involves the human invention of explanations and the generation of ideas. This requires a great deal of creativity by scientists. This aspect of science, coupled with its inferential nature, entails that scientific concepts are functional theoretical models rather than faithful copies of reality.

Fourth, scientific knowledge is subjective and theory laden. Scientists' beliefs, previous knowledge, training, experiences, and expectations, in addition to theoretical commitments, influence their work. These background factors form a mind-set that affects what problems scientists investigate, how they conduct their investigations, what they observe, and how they make sense of, or interpret, observations. It is this (sometimes collective) individuality or mind-set that accounts for the role of subjectivity in the production of scientific knowledge; while not intended, it is, nonetheless, unavoidable.

Fifth, science as a human enterprise is practiced in the context of a larger culture and its practitioners (scientists) are the product of that culture. Scientific knowledge affects and is affected by the various elements and intellectual spheres of the culture in which it is embedded. These elements include, but are not limited to, social fabric, power structures, politics, socioeconomic factors, philosophy, and religion.

Sixth, it follows from the previous discussions that scientific knowledge is never absolute or certain. This knowledge, including "facts," theories, and laws, is inherently tentative or subject to change. Scientific claims change as new evidence, made possible through advances in technology, is brought to bear on existing theories or laws, or as old evidence is reinterpreted in the light of new theoretical advances or shifts in the directions of established research programs. Although scientific knowledge is “tentative,” it is also quite durable as knowledge is not accepted without a wealth of supporting evidence.

NOS Assessment Methods and Interpretations

Assessing NOS knowledge has been approached through a variety of instruments (see “▶ NOS, Measurement of”) (Driver et al. 1996). Early instruments were multiple choice and Likert scale measures, such as the Test on Understanding Science (TOUS) from Klopfer and Cooley and Nature of Scientific Knowledge Scale (NSKS) from Rubba (see Lederman 2007, McComas 1998, for a comprehensive listing). These forced-choice instruments were widely used and provided numerical scores that were equated with a level of overall proficiency in respondents’ NOS understanding. The results consistently showed respondents held inadequate conceptions of NOS. The problem, however, is that a single score does not provide sufficient information as to learners’ actual conceptions of various NOS aspects. Based on this score, learners were placed into categories predetermined by the instrument developers (e.g., traditional, nontraditional). In order to inform curriculum development and instruction, more detailed descriptions of conceptual understanding are necessary.

It was not until open-ended survey instruments and interview approaches were introduced that specific misconceptions and areas of difficulty were elucidated. Questionnaires such as the Views of Nature of Science (VNOS) (Lederman et al. 2002) and interview protocols provide opportunities for respondents to articulate their ideas using their own words, examples, context, and rationale. NOS assessments based on open-ended survey and interview measures provide descriptive profiles that include multiple NOS aspects, contexts, and finer nuances of conceptual understanding than is possible with a numerical score from forced-choice items. Interpreting written and verbal responses is based on targeted NOS aspects such as those described above. Interpreting responses leads to a profile of how the respondent describes each aspect and connections among aspects. Profiles can then be compared to desired or accepted descriptions. Profiles include descriptors such as “informed” and “naïve” to indicate the degree to which a learner demonstrates an acceptable or unacceptable view of each targeted aspect. For example, an “informed” view of the tentative NOS would entail consistent reporting that scientific knowledge is inherently subject to revision or change. Such change can result from new information or reinterpretation of existing information. An informed learner would also be able to provide examples and rationale for when and why scientific knowledge would change. A “naïve” view is demonstrated by stating that scientific knowledge represents truth and therefore does not change once developed and accepted. A “naïve” view would describe scientific laws as proven, absolute truths. Assessments have suggested learners can hold transitional or emergent positions with respect to how they understand certain NOS aspects. Evidence for a transitional view is one which the responses are inconsistent, perhaps by context or by aspect. For example, the learner may express understanding that scientific knowledge is inherently subject to change, but still hold the notion that scientific laws, being unchangeable, are the exception.

Representing NOS views on a continuum (naïve – emergent – informed) is useful for tracking changes in views of targeted NOS aspects. NOS assessments and associated interpretation provide researchers and teachers insights into learners’ cognitive understandings of NOS concepts and characteristics. NOS assessments that target conceptual knowledge (e.g., VNOS) have been successful in identifying challenges and misconceptions learners hold and identifying instructional approaches that are effective in addressing these issues.

Despite these successes, there are other assessment approaches that assume a different description of NOS as a construct. Some researchers assume that learners' NOS understandings are assessable through observation of actions during scientific inquiries. This view describes NOS as an epistemic construct demonstrable through behaviors. How someone "does science" is assumed to represent their abilities and NOS understandings. Observing science in practice can provide insights into scientific skills and even reasoning, both important learning outcomes, but not NOS learning outcomes. Research clearly demonstrates inconsistencies between NOS views and teaching approaches as well as scientific abilities. NOS beliefs are not necessarily displayed through behaviors or attitudes. Relying on behavioral measures such as observing students in a laboratory is not enough and, in fact, is insufficient for assessing NOS knowledge.

Assessing NOS Within Instruction

Because NOS-related learning outcomes are cognitive in nature, asking students to articulate their knowledge and understandings about NOS can serve to assess student attainment of these learning outcomes. Equally important, evidence pertaining to the assessment of NOS-related learning outcomes could be generated from asking students to reflect on their actions as they engage with science learning experiences. Students' reflections make the latter approach clearly distinct from attempting to infer student NOS understandings from observing those actions.

Realizing that NOS is a cognitive learning domain serves to demystify the measurement of student learning about NOS. This realization makes available to science teachers a variety of formative and summative assessments that could be used to gauge student progress toward achieving, and achievement of, NOS-related learning outcomes, respectively. Additionally, this perspective allows drawing on a host of science learning experiences as contexts to measure student NOS understandings. These experiences include, among other things, exploring scientific theories and concepts, inquiry-based investigations, discussions of socio-scientific issues, and engagement with science-related texts and narratives. The latter materials include historical case studies, popular science writings and media productions (e.g., popular science books, science-related news reports and press releases, documentaries), and scientific publications. Regardless of the context, instruction and assessment must be purposeful and explicit.

For example, in the context of learning about the geosphere, seventh grade students could be asked, "We seem to know a lot about the structure of the geosphere. How is this knowledge possible given that our deepest explorations have barely scratched the surface of the Earth's crust?" This and similar questions provide opportunities for students to articulate their understanding of the distinction between pertinent observations, such as seismic waves, and an inferred claim or explanation, that is, the model of the geosphere. Similar discussions can be situated in various science topics and serve to gauge whether students have internalized the understanding that observations do not speak for themselves, but always require interpretation on the part of scientists.

Historical case studies provide ample opportunities to measure NOS understandings (see "► History of Science, Assessing Knowledge of"). For instance, after examining a narrative on John Snow and the Broad Street pump, tenth grade students could be asked, "How did Snow identify the source of contamination by observing the scatter dot maps of deaths associated with the 1854 Cholera outbreak in central London?" Student responses could help gauge their understanding of the role of theory in guiding data collection and interpretation. Indeed, Snow's contagion theory served him well in collecting pertinent data, interpreting other evidence, and pinpointing the contamination source. In contrast, the prevailing miasma theory of the time had failed others who attempted to solve the mystery.

Socio-scientific issues and explicit instruction can help students understand the interface between science and society and the resultant issues, such as whether scientists should be permitted to patent genetically engineered organisms. Teachers ask students to articulate the positions, beliefs, and values (economic, aesthetic, cultural, etc.) of the players involved with such issues. In this context, students could be asked, “To what extent did the beliefs and values you attributed to scientists play a role in their position? Defend your answer with evidence generated from examining the published articles about the debate.” Student reflections provide access to their conceptions of the cultural embeddedness of science.

Inquiry activities provide an exemplary context to gauge student understandings of aspects, such as the inferential and theory-laden NO-S. Teachers can ask students to identify observations and inferences in their reports and justify the distinction, or link certain aspects of their investigations to their understanding of the role of theory or prior ideas in choosing what data to collect.

Keywords

Cognitive functions; Cognitive neuroscience; Learning methods; Learning process

Introduction

Education in the twenty-first century is characterized by a number of features that contrast greatly with education of, say, 50 years ago. First, learning is not understood in the way it was earlier. Today considerations of learning are not restricted to a selected type of methodologies but employ a plethora of methods, strategies, and approaches. Secondly, learning contexts today often encompass a diversified group of people, of different age, gender, social and professional backgrounds, and participating in education – schooling or training – for a very wide range of reasons. And a dramatically growing field of education is online learning, offering courses to endlessly diversified audiences located in very distant countries. The field of learning science is nowadays characterized by diversity in terms of learners, learning environments, and learning methods. As a consequence of these multiple diversities, there is a growing demand for interdisciplinary and advanced research on education in order to foster the processes of acquiring knowledge in different settings and for different audiences, as well as to enhance the potential of educational institutions in a world that has no effective geographic boundaries.

In recent years there has been a dramatic advancement in interest in neuroscientific research and in its methods of investigation. This advancement is facilitating our evolving understanding of how to stimulate learning processes and increase one's learning potential, including being better able to take into account individual needs of learners. In general, research on neuroscience in learning encompasses the processes and participants taking part in education, understood in the broadest sense. Thus, the focus in this research is on the various stakeholders taking part in learning and teaching, the place they hold in the educational context, and the activities related to providing and receiving education (all analyzed from the neuroscientific perspective). The growing role of neuroscience in various fields of life has influenced the sphere of education, giving rise to such subdisciplines as neuroeducation or educational neuroscience. There are also such terms as neuropedagogy, neurodidactics, neuroteaching, and neurolearning used to denote the neuroscientific character of educational subbranches.

Neuroscience and learning can also be examined by taking into account a particular domain of study. Thus, such areas as neurolinguistics, neuromanagement, neuroeconomics, etc., can be distinguished, narrowing the scope of investigation to the learning processes taking place in a given domain. In addition, researchers dealing in cognitive neuroscience, cultural neuroscience, social neuroscience, and neuropsychology also address the issue of learning in their studies. Concentrating on the linguistic aspects in learning, neurolinguists study how language is learned and used, by paying attention to the processes taking place in the brain that are caused by education and simultaneously determine learning. On the other hand, neurobiologists are interested in the biological aspect of the nervous system and the biological aspect of learning processes. Taking into account the sphere of neuromanagement, neuroscientists may be interested how managers acquire new organizational knowledge and how the processes of learning influence their corporate performance. In addition, those specializing in neuromarketing pay attention to how customers learn about new products and services as well as how the knowledge they acquire to determine their selection of offered merchandise. In addition, neuroethics and neurostrategy offer additional information on learning in corporate settings, by taking into account corporate social responsibility and organizational goals, respectively (Bielenia-Grajewska 2013).

As yet there has been relatively little neuroscientific research in the specific domain of learning science. Consequently, there is more conjecture about possibilities than analyses of extant research in the remainder of this entry. However, all the above emerging neuroscience specialities have potential to also contribute to our understanding of the learning of science. Neuroscientific investigations of learning science can also be researched through the perspective of tools employed to educate stakeholders in the field of science as well as through the prism of those taking part in learning processes.

Participants in Learning

There are various approaches that can be used in the discussion of neuroscience and learning science, for example, by concentrating on participants/entities or on processes in education. Below I focus on entities, from which perspective the research may focus on learners, on teachers, or on the broadly understood context for the learning or tasks involved in the learning.

Learners and Neuroscience

The concept of a science learner can be viewed in two ways. One is a fixed approach, concentrating on the well-established dichotomy between learner and teacher, often set up in a classroom environment. The second perspective is a dynamic one, stressing the flexibility of roles in learning science. Thus, a teacher will also be a learner in situations aimed at enhancing his or her knowledge (e.g., self-study, professional courses, postgraduate education). No matter which approach is taken, the aspects of learner and neuroscience encompass individual characteristics. Thus, such factors as culture, age, and gender shape one's attitude to learning. For example, one's age may determine the willingness to opt for some learning methods (e.g., games for children or social networking tools for young learners). Another important aspect of learning is the purpose of schooling or training. Thus, one's reason for joining a course determines the selection of materials used in self-study or in formal classes to reach the learning objectives. For example, a scientist preparing his or her speech for a conference may be more willing to practice conversational skills than enhance his or her writing expertise. On the other hand, a researcher writing a scientific report or an article will likely favor developing writing proficiency over speaking skills to enhance the quality of his or her publications. The domain of learners can be enlarged by taking pupil's or student's parents or legal guardians. One of the aspects that can be investigated is the attitude of learners' families towards learning processes and their own preferences regarding schooling and learning science. In that case, those in the direct environment of a learner can be studied by showing how their behavior and own learning selections influence learners' performance.

Teachers and Neuroscience

A teacher is studied by taking into account individual features that determine one's teaching style. Thus, such notions as gender, age, or educational background can be studied in relation to how science teaching is undertaken. In addition, teachers can also be viewed as learners, taking into account their own education and additional training. Thus, teacher's learning abilities can also be investigated, e.g., by paying attention to how teachers comprehend new methods of education, new scientific data, or new tools in schooling. Such studies may include, e.g., the analysis of training devoted to the usage of social online networking tools in teaching or web auditoriums in modern education. As in the case of the abovementioned concept of a learner, teacher can be treated as both a fixed and dynamic notion. The fluid dimension may encompass learners being teachers in some situations since interactions between teachers and learners offer knowledge flows between both sides participating in science exchange. For example, learners' attitude to presented scientific materials or their learning potential offers teachers important feedback how to select new materials for teaching science in an effective way.

Contexts for Learning and Learning Tasks

Research concentrating on neuroscience approaches to understanding more of the processes of learning science may also focus on the characteristics of a given type of education. Learning science can be categorized into conscious and unconscious learning. In this case, learning is researched by taking the notion of active participation into account and distinguishing between implicit and explicit learning. Thus, researchers may investigate how individuals acquire scientific knowledge while concentrating exclusively on learning tasks or while performing other activities simultaneously. Another determinant of learning science is the number of learners taking part. Thus, individual and group instruction can be investigated. In the case of participants' influence on learning, one of the issues that can be studied is how the number of students determines individual cognition and participation in the group. Another option for research is checking the advantages or disadvantages of individual tutoring.

A different classification encompasses formal and informal learning. This distinction provides the opportunity to study the role of formality in learning and how informal and formal settings determine one's cognition and perception. Learning can also be explored by taking into account the place of learning – home, classroom, company, or the Internet. Learning can also be categorized by taking into account both standard and novel methods of learning, with the latter being subdivided into offline and online learning. Analysing the growing role of new technologies, such issues as electronic learning and mobile learning can be distinguished as well. Learning can focus on using one mode of gaining knowledge, or it can be more complex, engaging different activities simultaneously (e.g., walking for exercise and listening to tapes of material one is seeking to learn at the same time). In this case, neuroscience researchers are interested how the interrelation between psychomotor and cognitive functions works in practice. These issues are also important in teaching science in less complex forms for younger ages, e.g., in nurseries and kindergartens.

Issues in Neuroscience and Education

Memory

In the field of neuroscience, researchers are interested in various factors that determine the processes of acquiring and storing knowledge and using it when required. Both short-term and long-term memory are addressed. In addition, different channels of instruction are taken into account. Thus, researchers can study how memory functions when instruction is done through, for example, either auditory or visual channels. It may help teachers select materials for reading and listening comprehension as well as understand the role of speaking and talking in learning new scientific ideas. Another notion studied is the way different factors such as age, gender, or education may potentially determine the processes of encoding, decoding, and storing knowledge, engaging different types of memory. Such knowledge may facilitate the preparation of learning materials that suit the needs of the target audience and their cognitive abilities. Another role of studies on memory is to find out how people with memory problems can be more effectively taught. Neuroscience is interested, among other things, in observing how patients with memory loss or dementia can acquire and store scientific knowledge. Taking into account the notion of memory and durability of information, neuroscientists examine how long certain scientific concepts are stored in memory and what determines for how long they are stored.

Methods and Processes

Learning in the twenty-first century has different expectations, since today teaching and learning often take place in diversified environments. One such an example is teaching and learning foreign languages in a corporate setting. The group of those who want to study language for professional purposes often entails participants coming from different professional backgrounds, representing different age groups and with different levels of desired expertise (Bielenia-Grajewska 2011). Similarly, modern methodologies of learning must encompass diversified methods of investigating learning processes to meet the needs of those having different levels of knowledge in a given scientific domain and various expectations regarding the curriculum. Moreover, neuroscience can potentially provide an answer as to which strategies are better for teaching and learning science. It may enhance the creativity of teachers as far as selection of teaching method is concerned. Applying a processual perspective, neuroscientists study the factors and results connected with learning and teaching procedures as far as knowledge flows are concerned.

Another sphere of interest may be the language of instruction, via the study of the characteristics of bilingual and multilingual education. In this case, language can be investigated as a factor facilitating or diminishing scientific exchanges. In addition, since the multilingual sphere of learning encompasses the role of minority linguistic rights, researchers are also interested in how the attitude to linguistic rights determines learning processes and access to scientific knowledge.

Another approach to learning is through the channels of communication used in different forms of schooling and tutoring. This includes verbal and nonverbal strategies directed at making learning efficient, concentrating on the language as well as pictures used in encoding and decoding information. In addition, attention can be paid to online and offline methods in education. Within the verbal sphere of scientific exchange, neuroscience can facilitate the understanding of the role of figurative and nonfigurative tools of knowledge flows. For example, the use of metaphors in disseminating scientific data can be studied by observing how stakeholders perceive messages and how their reaction to risk is shaped by the symbolic language used in texts, in comparison with, say, more literal tools of communication. Another classification is the division of scientific knowledge into that which is specialized and that which is directed to laymen and how linguistic tools are selected to transfer scientific knowledge to different stakeholders.

Relations

Neuroscience helps to study the role of human relations in the processes of teaching and learning. Thus, teachers' roles in learning communities, distance in teacher-learner interactions, and group characteristics are studied, as well as their influence on the learning processes. Within this domain, the notion of classroom identity, in particular encompassing the relations connected with the sphere of education, can be used. This can also allow for studying education not only from the prism of teachers and learners but also by taking into account the role of both internal and external participants in education. As far as the internal sphere is concerned, administrative staff and the way school life is organized can be taken under scrutiny. The outer dimension may encompass legal, political and cultural factors and their influences on the shape of learning.

Learners with Special Needs

Another sphere of interest as far as learning and neuroscience are concerned is the issue of learning disorders, such as dyslexia, dysgraphia, dyscalculia, and dyspraxia, and the ways these learning difficulties influence the process of understanding and using scientific data. Neuroscience also facilitates understanding the learning processes of the deaf, the mute, the deaf-mute, and the blind; in the case of scientific knowledge, neuroscience may facilitate the research dedicated to finding the effective way of disseminating science to learners with special needs.

Teaching Environment

Learning may also be studied through the prism of teaching and learning environments. This issue may be understood in different ways, by taking into account the immediate and more distant surroundings. For example, the notion of space can be taken into account, studying how fixed and unfixed elements of classroom determine learning processes. Such investigations may involve the way a classroom is built, the distribution of furniture and colors, and the layout of chairs and tables. Learning can also be investigated by taking into account different regulations set up to organize classroom life. Studies may involve teaching times, division into single study units, number of hours per week, or number of students in a class. All these factors can be investigated by the use of neuroscientific tools to show how these determinants are important in learning processes. Another crucial notion in learning environment is how modern technology determines the shape of knowledge acquisition.

Environment can also be studied by taking into account a broader perspective, by looking at the role and the influence of politics, economics, and culture in learning processes. Another macro dimension that can be investigated through neuroscience is the legal sphere of learning; teaching environment can also be perceived through the perspective of norms and regulations determining the way learning is conducted. This dimension may include studying the role of age in starting education or the importance of division into stages in education (e.g., kindergarten, primary, and secondary school). Neuroscientists are interested how children who start schooling at the ages of 5, 6, or 7 cope with different activities. Another issue pertinent especially to the sphere of science is the issue of copyrights, trademarks, and patents.

Neuroscience can also be employed in that case to show the relation between the legal regulation of scientific achievement and their cognition by the wider audience. Learning from the neuroscientific perspective can also be studied by taking into account different levels of investigation. For example, neuroscientific research may concentrate on the micro level, determining how small elements in communication such as morphemes or words determine learning processes. This perspective may focus on both figurative and nonfigurative elements of a language, with metaphors being of particular relevance to science learning. Looking at the meso dimension of neuroeducation, research may focus on the role of texts selected for learning. Analyzing the macro approach, such concepts as learning methods and strategies may be the topic of neuroscientific investigation. It may include, e.g., the analysis of how brain works and how learners respond to questions in experiments conducted by the use of neuroscientific tools.

Tools Used in Educational Neuroscience

Different areas of the brain are responsible for different activities. For example, the hippocampus is studied as far as memory is concerned, whereas the frontal lobe is examined in research on attention or motivation. Since the nucleus accumbens is often taken into account in analyzing emotions, in the case of learning, it can be researched to show pleasure or fear related with schooling or training. The methodologies used in neuroscience can be divided into invasive and noninvasive tools. In the research devoted to learning, neuroscientists rely mainly on noninvasive tools that do not carry any risk for those participating in experiments. Such a technique is functional magnetic resonance imaging (fMRI). It is a neuroimaging technique that uses magnetic resonance to detect brain activities. Conducting fMRI is connected with realizing various stages of investigation involving the subject lying still in an MRI scanner for about 60–90 min. The initial stage lasting about 6–15 min is focused on anatomical/structural scans of the brain. The next stages are devoted to the participant taking active part in the experiment.

A subject may be asked to perform some activities, such as answering questions or selecting pictures. For example, a stimulus is made visible on a screen and a subject is asked to choose a response. When the tasks are performed by the subject, the MMRI records the BOLD signal (blood oxygen level depending) that indicates which areas of the brain are active and which are not. The results are later compared with the control scans performed in the first stage of an experiment (Kenning et al. 2007). Another technique involves studying facial expressions. Facial electromyography (EMG) facilitates the understanding of the face as the mirror of affection (e.g., fear, anger, and surprise), cognition (e.g., concentration and boredom), and personality (e.g., hostility, sociability, and shyness). It offers the measurement of nerve impulses to muscles that determine facial changes and expressions (Helander and Khalid 2012).

Electroencephalography (EEG) may also be used in observing the changes taking place when one studies science. This method is conducted by placing some electrodes on the subject's head in order to investigate differences in neural activities (Lee and Chamberlain 2007). The mentioned neuroscientific tools are used by researchers to investigate how science is perceived by specialists and laymen, how language may facilitate or hinder the processes of learning science, and how to foster the understanding of science among various stakeholders.

Summary

Learning science, due to its complexity in terms of stakeholders and issues involved, is studied in different disciplines. Among them it is neuroscience that offers a broad perspective of researching various participants in learning processes, observing both human and nonhuman elements in the way learning is conducted and perceived. The application of noninvasive tools facilitates the understanding of processes taking place in learning science, involving different types of learners, various learning spaces, and diversified methods of acquiring new knowledge.

Conceptualizing NOS

The phrase “nature of scientific knowledge” (NOS) typically refers to characteristics of scientific knowledge inherently derived from the manner in which it is produced, that is, scientific inquiry (Lederman 2007; McComas 1998). When discussing methods of measurement for NOS knowledge, the conceptualization of NOS must be clear. NOS has been described in various ways. With respect to what is relevant and appropriate for science teaching and learning, the literature strongly supports the view that NOS knowledge is a *cognitive* outcome rather than a skill, attitude, or activity. However, some descriptions include NOS among the realm of scientific epistemic activities represented by skills and reasoning practices. Both of these views describe important learning outcomes but present, and thus measure, NOS in different ways.

NOS as a Cognitive Outcome Versus Epistemic Activity

Despite the debates, there is a developmentally appropriate level of generality regarding NOS that is accessible to K-12 students and relevant to their daily lives. At this developmental level, little disagreement exists among philosophers, historians, and science educators. These general, crosscutting characteristics representing the nature of scientific knowledge as a cognitive outcome are described in the table below. These aspects are not meant to be a definitive listing of NOS, but rather a representation of the most commonly measured aspects in empirical research dating back to the 1960s. Furthermore, these aspects are not to be considered in isolation from each other or from the scientific enterprise. Understanding of NOS includes understanding how these aspects are intricately connected and derived from the scientific enterprise.

NOS aspect	Description
Distinction between observation and inference	Students should be aware of the distinction between observation and inference. In the K-12 science classroom, observations are descriptive statements about natural phenomena that are “directly” accessible to the senses (or extensions of the senses) and about which several observers can reach consensus with relative ease. By contrast, inferences are statements about phenomena that are not “directly” accessible to the senses. The notion of gravity is inferential in the sense that it can only be accessed and/or measured through its manifestations or effects
Distinction between theories and laws	Closely related to the distinction between observation and inference is the distinction between scientific laws and theories. Individuals often hold a simplistic, hierarchical view of the relationship between

(*continued*)

NOS aspect	Description
	theories and laws whereby theories become laws depending on the availability of supporting evidence. This notion is inappropriate. Laws are statements or descriptions of the relationships among observable phenomena. Theories, by contrast, are inferred explanations for observable phenomena. Theories are as legitimate an evidence-based product of science as laws
Empirical basis	Even though scientific knowledge is, at least partially, based on and/or derived from observations of the natural world (i.e., empirical), it nevertheless involves human imagination and creativity. Science, contrary to common belief, is not a totally lifeless, rational, and orderly activity. Science involves the invention of explanations and the generation of ideas. This aspect of science, coupled with its inferential nature, entails that scientific concepts are functional theoretical models rather than faithful copies of reality
Subjective/theory driven	Scientific knowledge is subjective and theory driven. Scientists' beliefs, previous knowledge, training, experiences, and expectations, in addition to theoretical commitments, actually influence their work. These background factors form a mind-set that affects what problems scientists investigate, how they conduct their investigations, what they observe (and do not observe), and how they make sense of or interpret observations. It is this (sometimes collective) individuality or mind-set that accounts for the role of subjectivity in the production of scientific knowledge; while not intended, it is, nonetheless, unavoidable
Socially and culturally embedded	Science as a human enterprise is practiced in the context of a larger culture, and its practitioners (scientists) are the product of that culture. Scientific knowledge affects and is affected by the various elements and intellectual spheres of the culture in which it is embedded. These elements include, but are not limited to, social fabric, power structures, politics, socioeconomic factors, philosophy, and religion
Inherently tentative	It follows from the previous discussions that scientific knowledge is never absolute or certain. This knowledge, including "facts," theories, and laws, is inherently tentative and subject to change. Scientific claims change as new evidence, made possible through advances in theory and technology, is brought to bear on existing theories or laws or as old evidence is reinterpreted in the light of new theoretical advances or shifts in the directions of established research programs

This conceptualization of NOS distinguishes NOS knowledge from scientific practices or inquiry. Some researchers and theorists conflate NOS with science practices. This alternative view describes NOS as epistemic activity and emphasizes elements of scientific practices (Carey and Smith 1993; Sandoval 2005). Scientific practices represent what scientists do (such as asking questions, collecting and analyzing data, generating evidence-based claims through argumentation practices, etc.). Within this view, the practices of reasoning about evidence and critical evaluation of ideas are considered a part of NOS, as are recognizing multiple scientific methods and the use of scientific models and modeling. This view of NOS groups the knowledge and practices together and considers one's views of NOS to be represented through the actions of doing science. While intuitively appealing, this position is not well supported by the research that examines NOS knowledge (as described in the cognitive view) in relation to how one does science. A learner may be able to perform a controlled experiment and produce valid evidence-based claims; however, this same learner may not understand the role of creativity and inference that were involved in that process. Students can design experiments with valid controls, but not understand the necessity of having a control. Nonetheless, various views of what constitutes NOS still exist. Thus, when discussing NOS measurements, the conceptualization of NOS must be clarified.

Measurement of NOS knowledge is approached with the intention of determining learners' understanding of the concept and characteristics. The view that NOS is knowledge (the cognitive position) has been more consistently successful in directing measurement methods for the science learner and teacher. Research has demonstrated that actions and attitudes are not necessarily related to one's conceptual understanding of NOS. While observations can lead to inferences about one's investigative skills and reasoning abilities, relying on behavioral measures such as observing a scientist or a student in a laboratory is not enough and, in fact, is insufficient to infer NOS as knowledge. There is a need for cognitive measures.

Methods of Measurement

Historically, methods of measurement have ranged from Likert scale and forced-choice instruments to open-response surveys and interviews. In the 1950s, early efforts in instrument development included NOS among attitudes about science and scientists. Klopfer and Cooley then developed the *Test on Understanding Science* (TOUS) in 1961. The TOUS is a 60-item multiple choice test targeting understanding of the scientific enterprise, what a scientist is, and the method and purpose of science. The TOUS was widely used yet widely criticized for presenting a narrow depiction of NOS and scientists. These are common criticisms of forced-choice NOS instruments, including the *Nature of Scientific Knowledge Scale* (Rubba), *Nature of Science Scale* (Kimball), *Science Process Inventory* (Welch), among others (see Lederman 2007; McComas 1998, for a comprehensive listing). These earlier measurement approaches were primarily quantitative and quick to administer, thus quick to "grade." Total scores were reported. However, without explanation of what the score meant in relation to respondents' views of NOS, the results were limited. Forced-choice and Likert scale NOS measurements have been highly criticized for lack of validity, biased construction, and limited usefulness to inform researchers and teachers of how learners actually understand NOS and how NOS relates to other scientific knowledge.

In response, measurement efforts shifted to more qualitative and mixed-method approaches that enabled emergent descriptions of learners' NOS understandings. Open-ended surveys and interviews are accepted as more valid because this approach utilizes respondents' words, as opposed to the researchers' words and forced choices. Lederman et al. (2002); Driver et al. (1996); and others have demonstrated the importance of the survey/interview approach to gaining understanding of how learners describe characteristics of NOS, scientists, and scientific investigations. Critics consider this approach to be narrow in how NOS is conceptualized and contextualized. However, unlike the forced-choice instruments, the open-ended nature of surveys and interviews leave opportunity for emergent ideas about NOS. Interviews that follow survey responses enable additional probing for examples and explanation of ideas. There is power in asking questions such as "How do you think scientists use creativity in investigations? Can you provide an example?" and "Why do you think scientists sometime come to different conclusions even when they are looking at the same data, such as with explaining dinosaur extinction? Can you think of another example when this might happen?" Multiple questions that target the same NOS areas result in rich information of how the respondent conceptualizes NOS. The power in this approach is that the words, ideas, and contexts come from the person responding. The interviews increase validity by ensuring the researchers' interpretation is consistent with the respondent's intended meaning. NOS measures such as the *Views of Nature of Science* (VNOS) questionnaire (Lederman et al. 2002), interview approaches (e.g., Carey and Smith 1993; Driver et al. 1996), and other open-response techniques also allow for identifying connections among NOS aspects such as the tentative, creative, sociocultural, empirical, and theory-laden NOS. Moreover, these techniques enable the use of a variety of science contexts and situations.

Measurements of NOS as epistemic activity include observations and interviews (e.g., Carey and Smith 1993; Sandoval 2005). Written instruments have also been used that require respondents to design an investigation or reason through data in the context of a scientific episode or vignette. These approaches are based on the assumption that NOS is represented through epistemic and social acts of doing science. Observations of students and scientists conducting investigations are considered representations of their NOS abilities. Again, this view and measurement approach is in contrast to the afore-described measurements that assume NOS as conceptual knowledge.

Regardless of the approach, measurements of NOS knowledge are framed by how the researcher conceptualizes NOS. NOS conceptualization, measurement methods, and interpretation should be grounded in what is appropriate for the audience. Much of the research in science education that involves the measurement of NOS knowledge focuses on the K-12 population, including teachers and students. However, measures for scientists, preschool children, college students, and adults have also been developed.

Measurement of NOS Within Instruction

Based on the view that NOS-related learning outcomes are cognitive in nature, asking students to articulate their knowledge and understandings about NOS can serve to assess student attainment of these learning outcomes. Equally important, evidence pertaining to the assessment of NOS-related learning outcomes could be generated from asking students to *reflect* on their actions as they engage with science learning experiences. Students' reflections make the latter approach clearly distinct from attempting to infer student NOS understandings from observing those actions.

Realizing that NOS is a cognitive learning domain serves to demystify the measurement of student learning about NOS. This realization makes available to science teachers a variety of formative and summative assessments that could be used to gauge student progress toward achieving and achievement of NOS-related learning outcomes, respectively. Additionally, this perspective allows drawing on a host of science learning experiences as contexts to measure student NOS understandings. These experiences include exploring scientific theories and concepts, inquiry-based investigations, discussions of socio-scientific issues, and engagement with science-related texts and narratives. The latter materials include historical case studies (see, e.g., *The Pendulum Project* by Michael Matthews), popular science writings and media productions (e.g., popular science books, science-related news reports and press releases, documentaries), and scientific publications. Regardless of the context, instruction and embedded NOS measurements must be purposeful and explicit.

For example, students might conduct an investigation of animal behavior using crickets. Teachers can ask students to identify observations and inferences as they generate questions to investigate. They can be required to include distinctions between their observations and inferences in their reports. Likewise, historical case studies are intriguing for students and also opportunities for formative assessment measures. For instance, after examining a narrative on John Snow and the Broad Street pump, tenth-grade students could be asked, "How did Snow identify the source of contamination by observing the scatter dot maps of deaths associated with the 1854 cholera outbreak in central London?" Student responses could help gauge their understanding of the role of theory in guiding data collection and interpretation. Within the context of socio-scientific issues, such as the development and use of genetically modified foods, teachers can ask students to articulate the positions, beliefs, and values (economic, aesthetic, cultural, etc.) of the players involved with such issues. To measure students NOS views with respect to the social and cultural embeddedness of science, students could be asked, “To what extent did the beliefs and values you attributed to scientists play a role in their position? Defend your answer with evidence generated from examining the published articles about the debate.”

The important consideration with in-class measurements of NOS knowledge is to be purposeful and explicitly ask students for their ideas and to explain connections between the science they are doing or learning about and how it represents various features of NOS. In contrast, the alternate view that NOS is exemplified through epistemic and social dynamics of scientific practices infers NOS “abilities” based on observed behaviors. In-class measures from this perspective also include engaging students in scientific investigations, historical and contemporary case studies, and socio-scientific debates. However, rather than explicitly drawing students’ attention to NOS connections and requesting explanations of those connections, the teacher seeks evidence that students can design and conduct appropriate investigations, critically reason through data, and generate as well as evaluate arguments. The expected learning outcomes from this approach must be distinct from those described above for NOS cognitive outcomes, as the research literature clearly demonstrates the ineffectiveness of simply engaging students in doing science for developing conceptions of NOS knowledge (Lederman 2007).

Keywords

Culture, science and religion

Science is essentially a cultural enterprise, one that shapes and is shaped by the broader culture. Conceiving the scientific enterprise as a culture in its own right affirms the role of assumptions and social norms in producing and validating its core knowledge claims and practices. Viewed from this angle, the special aspects that make science what it is are the sets of practices and norms that are inseparable from the knowledge they produce. The boundary that separates science from nonscience is not one of absolute demarcation, but of “family resemblance” (Irzik & Nola, 2014) of knowledge, practices, and social norms, as defined by the community of practitioners working within scientific subfields. In the last three decades, growth in philosophical analyses of various disciplines (chemistry, biology, geology) and in the field of science studies has produced rich accounts about the diversity of epistemic norms and practices that characterize these fields, rendering broad and decontextualized descriptions of scientific methods and practices vacuous.

As a highly specialized sphere of activity, science is not isolated from the rest of the culture in which it is practiced. Oftentimes, it is nourished by the values of that culture. For example, the rise of "Western science" in Europe and the subsequent industrial revolution in the 1700s took place in countries that were open to ideas that did not need to be sanctioned by religious authorities (which varied at the time in their degree of centralization). A certain level of intellectual freedom and state patronage seemed essential for promoting scientific and technological growth. There were religious and political reasons for supporting the rise of science more rapidly in countries that underwent religious reformation, in a way to counter others that were dominated by the Catholic dogma. This was not a case of a Christian versus a non-Christian culture, but that of a Christian culture that allowed a certain degree of openness and freedom of thought that is conducive to innovation. The ensuing age of Enlightenment in the seventeenth century resulted in economic prosperity and power that was instrumental in enhancing military capacity, supporting trade, and expanding colonial interests. Read from our current-day perspective, these developments also resulted in creating a culture of exploitation and an increasing concern about pollution and the impact of rapid development on the human condition. Therefore, a scientific culture cannot occur in vacuum or develop without impacting the material culture as well as the values and worldviews shared by the broader culture in which it exists (Jacob 1997).

From a cultural perspective, therefore, domains of scientific activity can be enabled or constrained by the surrounding cultural forces whether they are ideological, political, or religious. Galileo's work on pendulum motion was not entirely motivated by his personal curiosity but was nurtured by the social and political agenda of improving the accuracy of time measurement and solving the problem of longitude determination (Matthews 2000). Just as scientific research can be enhanced by the societal temperament of the time, it can also be hindered by it. In some cases, areas of research get stalled due to ethical concerns (such as human cloning), other times through restricting funding due to perceived importance and societal prejudice (as in the case of AIDS research in the 1980s). Ideological and political agendas are additional factors that can alter what research is permissible. The former USSR's censoring of genetics research resulted in losing advantage on that front and led to the persecution of scientists working in that field. Similar shifts away from working with scientific ideas seen as threatening or contradicting religious values espoused by the majority population can be found in some countries, but this effect is typically compensated for by a stronger research emphasis on topics perceived to be neutral or compatible with local religious and social values.

There is no question that religious thought infiltrates cultural worldviews and plays a key role in shaping perceptions toward the nature and meaning of scientific knowledge, often defining the relationship between science and religion. In the early days of modern science, the religious worldview motivated scientific activity as a way to understand the "mind of God." As Western science matured and refined its methodologies to rely on purely naturalistic explanation, philosophers, scientists, and theologians have engaged in a fervent effort to characterize the relationship between modern science and religion. The characterization of this relationship has often reflected a continuum of beliefs even by adherents to the same religion. For this reason, the relationship between science and religion cannot be reduced to broad generalizations, as it typically reflects the interpreters' views of the nature of religious texts relative to their elucidation of the nature of scientific knowledge. In other words, there is no monolithic interpretation that represents the views of one religious group regarding the relationship between science and religion. Furthermore, the relationship between science and religion is always contextualized in that at every stage in history, it has been explored from the perspective of the goals and methods of the science practiced at the time and extant religious worldviews.

In theistic religions, especially in Christianity and Islam, positions can be found on all sides of the spectrum. Distinctions between science and religion are usually argued on the basis of the methods of exploration used and nature of evidence used in both domains. Scholars from various Christian and Islamic traditions (traditions whose adherents have contributed in one way or another to the history of modern science) have used strands of arguments that result in three different types of conclusions. Science and religion are seen as (1) separate fields that do not overlap in terms of goals and methods, (2) reconciliatory, or (3) antagonistic. There is no united view that represents all Christian or Islamic sects. Taking key paradigmatic changes in scientific theories (Copernican revolution, Darwinian revolution) as examples, it can be seen that even the official views of one church, Roman Catholic, change over time in significant ways (e.g., position regarding the Galileo affair or Darwinian evolution) though not always in a timely fashion.

It has been argued, however, that there are basic differences between Christianity and Islam in their views of the relationship between science and religion. In Islam, the Quran as a holy text cannot be changed and all evidence is in service of this text. Studying nature is a means to help humans discover God and is not an end by itself. Western thought, however, presumes a direct relationship between mind and nature. God helps humans discover nature or does not play a role in this process. In Islam, nature is the bridge between humans and God, while in Western thought God may be the bridge between humans and nature (though not from the perspective of agnostics or atheists) (Dagher and BouJaoude 1997).

To illustrate the diversity of views regarding the relationship between religion and science, the next few paragraphs describe the positions of Islamic scholars, some of whom are practicing scientists themselves. As is the case in other religions, the scholars' immersion into scientific practice does not necessarily lead them to similar conclusions regarding the nature of the relationship between science and religion.

One view holds that the Quran as the only source of all scientific knowledge. It is promoted by Maurice Bucaille (1979) who advocated the theory of the "miraculous scientific content" of the Quran known as I'jaz. The basic principle of Bucaillism is that the Quran is the source of all scientific knowledge, which can be discovered through the interpretation of Quranic verses. Similarly, the theory of the miraculous scientific content postulates that all scientific knowledge could be acquired from passages in the Quran and that verses from the Quran can be predictions of specific scientific theories. Both views, however, are criticized because the so-called predictions are "retrospective" discoveries in that they go backward from the actual discovery to finding one or more Quranic verses that could be used to support the actual discovery. More importantly, these views, if taken seriously, would open up the Quran to falsification. It is well known that science is an ever-changing body of knowledge. Consequently, a scientific theory that is falsified based on new scientific evidence but has been supported by a verse from the Quran could lead to serious conflict.

A different view of the relationship between science and Islam is presented by Seyyed Hossein Nasr, an Iranian scholar, who rejects the attributes of modern secular science and suggests that these attributes have led to the collapse of the scared view of the universe and to environmental and nuclear disasters. As such, Nasr is considered by many to be the founding father' of Islamic environmentalism. According to Nasr, Islam has the important role of reintroducing the sense of the sacred in modern Western science and integrating religion and ethics with science rather than relegating these to policy decisions, ideas that are shared by Ziauddin Sardar, another Islamic scholar. These ideas, however, are criticized by many on the basis that they are Islamic but cannot claim to characterize modern science.

A third view of the relationship between science and religion from an Islamic perspective is attributed to Mohammad Abdus Salam, a devout Muslim, who won the Nobel Prize for physics with others in 1979. Abdul Salam's ideas focus on the complementarity of science and religion and the total separation between the spiritual and the physical world. According to him, science helps us to understand the physical world, while religion helps us understand the spiritual world. Abdus Salam is also known for advocating self-governance and total independence of science, ideas that have received much criticism because they portray science as an independent sphere of knowledge that should not be scrutinized by society and scientists as moral beings who hold the interest of society to heart.

What constitutes science according to Islam is not easy to discern because of the variety of views about scientific knowledge. What is important to highlight in relation to the broader culture is that religiosity and not religious affiliation seems to drive thinking about the relationships between science and religion. Evolution is a case in point. Evolution is part of the science curriculum in Egypt, in which the majority of the population is Sunni Muslim, and in Iran, in which the majority are Shiite Muslims. However, evolution is not part of the curriculum in Saudi Arabia whose population is almost totally Sunni Muslims and in Lebanon in which the population is divided almost equally into Christians, Sunni Muslims, and Shiites. The situation described above is not restricted to Islamic countries in the Middle East. Social controversy centered on Islamic creationism is increasing in Europe. Likewise, social controversy over evolution in the USA continues to be prevalent in certain Christian circles, causing evolution education to become a significant political issue.

In cultures that adhere mainly to nontheistic religions, such as Hindu or Buddhist traditions, the relationship between religion and science is more fluid. This is attributed to the pluralism that characterizes Hindu spirituality: "It is a holistic tradition that does not distinguish entirely between apparently conflicting principles, such as the one and the many" (Dorman 2011, p. 598). The Hindu tradition sees in science a legitimate but incomplete way of knowing. In the broader Hinduism cultural worldview "science, philosophy, and religion all blend together" (Dorman 2011). While this did not interfere with the pragmatic endorsement of Western science by the Hindu culture, the adoption of science has not entailed a whole-hearted acceptance of the scientific spirit or the metaphysical commitments and duality underlying Western science.

According to Raman (2012), Hindu, Islamic, and other postcolonial scholars sometimes point to Western science as an instrument that destroys local cultures and warn about the "hegenomic and all-devouring nature of the change ushered in by science, technology, and the globalization of English and Western lifestyles" (p. 568). These challenges, faced by many developed and developing countries, are considered to be "significant and non-trivial. Indeed, they are among the difficult challenges facing all peoples" (Raman 2012, p. 568). Concerns about these issues have fueled much discussion in the science education community. Implications to science curriculum and instruction have mostly focused on different proposals for bridging rather than replacing students' folk knowledge or traditional ways of knowing by attending to the ethnic, cultural, and linguistic aspects involved in science learning.

This discussion about cultural perspectives pertaining to nature of science highlighted some of the social, political, and religious factors that shape how science is perceived. It presents a survey, albeit incomplete, of ideas written about this topic. More attention was dedicated to the role of religion, given that in some regions of the world, perceived conflict between scientific theories and religious views has resulted in altering the content of the science curriculum. Details were provided on how scholars interpret the relationship between Islam and science to demonstrate the diversity of views that exist on this topic. Similar diversity can be expected to be found in other religions/religious frameworks as well.

The ways in which science influences culture and is influenced by it continue to frame many of the discussions in science education. Indeed, aspects of scientific knowledge and technology that conflict with traditional ways of knowing or political agendas, threaten existing ideologies, challenge religious or cultural worldviews, or pose new ethical dilemmas are bound to influence what and how science is taught. The ways in which such conflicts are addressed by a nation's science education policies and practices will inevitably have broad and far-reaching consequences on the scientific literacy of its citizens' and their ability to compete in a global economy.

Induction; Scientific method; Theory; Theory-driven; Theory-laden

Careful and systematic observation has long been recognized as an essential part of scientific investigation and a key element in scientific theory building, although views about the nature and status of scientific observation have undergone substantial change in recent years.

The traditional image of science asserts that observation provides a secure base of facts from which knowledge can be derived. It further asserts that the scientific endeavor begins with observation. Both these assertions are suspect. The supposed security of scientific observations rests on the assumption that human observers have direct access to the properties of the external world, that is, nothing enters the mind except by way of the senses and that the mind is a tabula rasa on which our senses inscribe a true and faithful record of the world. In other words, observations are independent of the opinions and expectations of the observer and can be confirmed by direct use of the senses by any other observer. When Friedrich Nietzsche (1906/1968) states that "everything of which we become conscious is arranged, simplified, schematized, interpreted through and through" (para.477, p. 463), he is making the key point that we interpret the sense data that enters our consciousness in terms of previous experiences (and the sense we have made and continue to make of them), prior knowledge, beliefs, and expectations. Because it is dependent on the observer's existing knowledge and understanding, observation cannot be taken as necessarily indicative of the true state of affairs. Rather, it is a view of the world through a particular lens, that is, a particular way of looking at the world. When we acquire new knowledge and understanding, we open up new ways of seeing and explaining the world.

The key to scientific observation, as distinct from simple everyday "looking at things," is a sound theoretical frame of reference on which scientists agree. In consequence, scientific observers have to learn how to make sense of what they see in terms of accepted theory, especially when deploying one of the many observational instruments used by scientists. Michael Polanyi (1958) makes this point superbly in his graphic description of a medical student struggling to make sense of X-ray photographs:

> He watches in a darkened room shadowy traces on a fluorescent screen placed against a patient's chest, and hears the radiologist commenting to his assistants, in technical language, on the significant features of these shadows. At first the student is completely puzzled. For he can see in the X-ray

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

> picture of a chest only the shadows of the heart and the ribs, with a few spidery blotches between them. The experts seem to be romancing about figments of their imagination; he can see nothing that they are talking about. Then, as he goes on listening for a few weeks, looking carefully at ever new pictures of different cases, a tentative understanding will dawn on him; he will gradually forget about the ribs and begin to see the lungs. And eventually, if he perseveres intelligently, a rich panorama of significant details will be revealed to him: of physiological variations and pathological changes, of scars, of chronic infections and signs of acute disease. He has entered a new world. He still sees only a fraction of what the experts can see, but the pictures are definitely making sense now and so do most of the comments made on them. (p. 101)

Of course, the X-ray pictures have not changed at all. What has changed is the observer (in this case, the medical student) and the observer's ability to interpret observations using particular theoretical knowledge. It is knowledge (concepts and theories) that enable us to make meaningful, significant, scientific observations. As N.R. Hanson (1958) puts it, "there is more to seeing than meets the eyeball."

The inductive process outlined in the traditional view of scientific method requires the assembly of all relevant observations and information, from which a generalization will eventually emerge through logical analysis. How, one might ask, does an innocent and unbiased observer know what is relevant and, therefore, what to observe? Observation, especially scientific observation, is a selective process and so requires a focus of attention and a purpose. An observer needs an incentive to make one observation, rather than another. As Peter Medawar (1969) puts it, "We cannot browse over the field of nature like cows at pasture" (p. 29). Making a scientific observation presupposes a view of the world that suggests particular observations *can* be made and are *worth making* – i.e., they are of scientific significance. In other words, scientific observation is neither innocent nor unbiased. It is not "objective" in the sense that some school science curricula imply. Rather, it is purposeful, theory dependent, and theory driven. In practice, some view of the world (some theoretical perspective) *precedes* observation and guides it. It is simply not possible to observe things for which you are conceptually unprepared. As Hanson (1958) points out, until Paul Dirac postulated the existence of positrons, the tracks they leave in cloud chambers were not seen at all or were dismissed as mere experimental noise. When armed with the new knowledge Dirac gave them, physicists found clear evidence in those same cloud chamber experiments of the existence of positrons. Likewise, sunspots went unrecorded in Europe until Galileo's work overthrew belief in the perfection of the heavens, whereas Chinese astronomers (with no such overriding beliefs) had been recording them for centuries. It seems to follow that there cannot be a piece of absolutely indisputable observational knowledge whose meaning is not impregnated in some way by prior belief about the world. This is not to deny that science can sometimes proceed inductively, as in situations where data are obtained first and then interesting issues and problems are identified by "data mining," but it is to say that induction is also theory driven to the extent that scientists make theory-driven decisions about what counts as data, deploy theory-impregnated instruments to collect that data, and express their findings and conclusions in language that is rich in theoretical assumptions.

All observation statements employ theoretical language. Seemingly simple observation terms such as *dissolving* and *melting* are heavily impregnated with theory; observational expressions like "craters on the moon" or "solar eclipse" even more so. The quality and usefulness of observation statements depend on the level of sophistication of the theoretical language available to the observer. Without such a language, perceptions cannot be given meaning and observations cannot be recorded and subjected to critical scrutiny. What is described in scientific observations is never "pure phenomena" (whatever that might mean) but phenomena seen through the lens of particular theories. Theoretical knowledge opens up possibilities that otherwise would not exist, and as a science develops and builds new theoretical knowledge, scientists are able to generate knowledge by making new and different observations. Thus, we learn about nature, and we also learn *how* to learn about it by learning (i) what constitutes significant information, (ii) how to collect it, and (iii) how to interpret it and communicate it to others.

To summarize, scientists work within a theoretical framework that guides their actions and invests observational data with *particular* meaning. Recognizing that scientific observation is theory laden and that students may sometimes have a different framework of reference from the teacher has an important consequence for science teachers: that the skills of scientific observation have to be taught and, moreover, taught and learned within particular theoretical contexts. Two points can be made. First, it is just not possible to teach someone to observe in a way that is independent of the context in which the observation is to be made. Second, unless teachers provide extensive guidance, there can be no guarantee that students in school science lessons will observe even the readily observable. Thus, it is the science teacher's job to ensure that students perceive the world in the appropriate way – that is, the way in which currently accepted science (or the school version of it) deems appropriate. In science lessons, we are not teaching students to observe per se. They can already do that; they have been making observations for many years, since long before they came to science classes. Our responsibility is to teach them to make *scientific* observations, and for that they need appropriate conceptual understanding.

Online learning environments; Technology and science education research; Web-based science inquiry environments

Introduction

Online science inquiry environments are designed around the unique affordances of the Internet as a medium to facilitate inquiry. The design of such environments acknowledges the multifaceted aspects of science as a cognitive, social, and cultural endeavor through which humans seek to systematically examine and understand the natural world around them. Online inquiry refers to the use of online resources to engage in the practices of and gain knowledge about science. The main distinguishing characteristics of online science inquiry, as compared to other forms of inquiry, include the reduction of spatiotemporal limitations (i.e., fixed locations or set time limits) that might otherwise constrain access to information and communication, access to expert databases and public resources, and increased opportunities for personalizing and customizing learning experiences. These affordances are further enhanced when coupled with recent technological improvements such as mobile computing and advanced data-mining techniques.

Such environments may be employed in any combination of face-to-face, online only, or blended learning, with interactions occurring synchronously and/or asynchronously within the environment. Finally, despite the mediation of technology, the teacher remains an important learning partner in these environments, with the challenging role of orchestrating activities and interactions, monitoring student ideas, and intervening strategically (i.e., with mini lectures or small group discussions) to ensure effective learning.

While the Internet offers many unique affordances for learning, the underlying goal of online science inquiry environments is fundamentally aligned with other powerful learning environments developed by science educators. Research has shown that successful learning environments promote deep understanding, knowledge integration, and critical thinking, embed assessment and feedback mechanisms, and create communities where learning can be fostered (Bransford et al. 1999). Thus the term "online science inquiry environments" does not refer to any digital resource on the Internet, but is reserved for those environments that offer a carefully scaffolded virtual space where learners meet to pursue common learning goals. As online inquiry may require greater levels of self-regulation than other forms of instruction (particularly if students are working from home), metacognitive supports, included to help learners understand the task, monitor and reflect on their progress, is a common characteristic of online science inquiry environments (Quintana et al. 2005).

Online science inquiry environments are rooted in an understanding of science learning as a multidimensional, constructivist, and profoundly social endeavor. Like other forms of science inquiry, they seek to help learners pose meaningful questions; formulate hypotheses; collect, interpret, and explain data; and engage in epistemic practices that will help them gain an appreciation of the nature of science. Like other powerful inquiry methods, online environments are guided by the importance of sense making, providing multiple representations of scientific concepts, scaffolding student learning, making thinking visible, articulation, reflection, and self-regulation (Slotta and Linn 2009). To help explain what makes online inquiry environments distinct from other forms of science inquiry learning, the following sections will discuss their characteristics, using two online science inquiry environments – WISE and STOCHASMOS – as examples.

Increased Authenticity

Online science inquiry environments can take advantage of the wealth of Internet resources to make learning more authentic, using real-world problems to engage learners in complex scientific reasoning, promote active learning, and increase motivation. For example, the Web-Based Inquiry Science Environment (WISE), one of the earliest online inquiry platforms (Slotta and Linn 2009), engaged students in the Deformed Frogs controversy, where they inquire about a real problem of frog malformations using current Web materials and a variety of inquiry tools. Deformed Frogs was a science inquiry curriculum unit written in partnership with scientists who were actively investigating that issue. Research by the WISE team has shown that such environments foster a grounded and evidence-based understanding of scientific concepts and support argumentation and reflection.

Guided yet Flexible Learning

Online inquiry science environments can provide technology-based scaffolds for learning activities while still allowing learners to explore rich, Web-based resources. One example of the application of such a capability can be seen in the support of evidence-based reasoning. As students use the Internet to locate data in support of their arguments, they can also benefit from technology scaffolds that guide them through a particular task structure. For example, the STOCHASMOS platform (Kyza et al. 2011) scaffolds students in reflecting and making grounded connections between data and interpretations using a data capture tool which automatizes the documentation and transfer of evidence from any webpage or other software to an online reflective workspace. This allows students to focus on the conceptual aspects of the task and allows freedom in exploring Web resources while at the same time anchoring these actions back to a process of reflective inquiry. Online science inquiry environments differ in how they support flexible learning. WISE uses a guided inquiry approach, providing an "inquiry map" that students follow, launching a succession of inquiry tools and activities. STOCHASMOS depends on the learners' adoption of a problem-based scenario with concurrent use of the reflective workspace to guide their reasoning with data. Other technologies are designed to serve as a metacognitive layer intended to guide online activity, such as the Artemis tool, which supports the organization of online information; Symphony, which guides learners through an inquiry cycle; and the Digital Idea Keeper which supports the organization and planning of online inquiry (Quintana et al. 2005).

Enhanced Social Interaction

Another characteristic of online inquiry environments is their capability of promoting and enriching social interactions. Environments such as WISE and STOCHASMOS aim to support collaboration in the classroom, emphasizing learning from and with peers. However, such environments also make use of synchronous and asynchronous tools that allow communication with students from home or disparate geographical locations. For example, STOCHASMOS includes tools to share ongoing work between groups of students who, in turn, can provide synchronous and asynchronous context-based feedback to their peers. Such work can help focus and structure students' online interactions, providing unobtrusive guidance while students still remain in control of their learning process. The use of such prompts can also support metacognitive awareness and reflective thinking in such collaborative exchanges.

Embedded Assessment and Educational Data Mining

The opportunities for data-driven assessment and adaptive feedback are important capabilities of online science inquiry environments, which typically collect automatic data logs of learners' activities that allow for the construction of numerous forms of feedback and assessment. For example, WISE can provide immediate feedback on some assessment items but also provides well-organized reports to teachers and supports their evaluation and feedback to students. Other systems employ on-demand reports that provide enhanced and ongoing assessment information to teachers and to students. Research is currently exploring the use of artificial intelligence techniques to support the personalization of learning based on user modeling, providing customized materials, adaptive support, or notifications to the teacher to take action.

Teacher Adaptation of Learning Environments

One of the advantages of engaging with Web-based science learning is the ease with which teachers can engage in designing or adapting such environments. Web-based authoring tools have reduced the need for sophisticated technological skills to create scaffolded learning environments in science through the use of such tools as content-management systems and wiki technologies. For example, both the WISE and STOCHASMOS authoring platforms allow teachers to author online learning environments. While it remains a challenging process for teachers to become Web-based learning designers, existing systems provide authoring supports that help scaffold epistemologically appropriate designs, as well as the ability for teachers to customize existing designs from the library of projects (Slotta and Linn 2009). Additionally, the process of engaging teachers as designers can create opportunities for professional development.

Challenges and Opportunities

To take full advantage of the affordances of the online science inquiry environments, teachers need to invest time and effort in developing the relevant technological pedagogical content knowledge. Even though the online nature of such technologies may make it somewhat easy to get set up and going in the classroom, a considerable investment is required to understand how to use such technologies most effectively and especially how to balance computer-based and human scaffolding (Slotta and Linn 2009). As new forms of mobile and ubiquitous computing gain acceptance and technologies become interoperable, online science inquiry environments will likely converge with other technologies to create more seamless learning environments that cater to the needs of the learners. Such environments could serve to transcend the traditional boundaries between formal and informal or online and offline learning by supporting learning and communication across space and time. Finally, to help researchers take full advantage of every new step forward, open-source initiatives can help create synergies and promote exchange and co-development (Slotta 2010).

Introducing Online Media for Informal and Formal Science Learning

The past 35 years have seen an unprecedented period of growth in the development and use of online media for informal and formal science learning (Holliman and Scanlon 2004). These are educational media where the computational power of computers and the interconnectedness of communications technology converge. As such, these are media that are networked, e.g., via the Internet, intranets, or Short Message Service (SMS). In simple technical terms, networking requires interconnectedness and interoperability between computing devices that can be located in multiple locations and different time zones. This involves digital information that can be efficiently stored, searched for, and then retrieved and shared.

Developments with online media have profound implications for the accessibility of all areas of knowledge, not least for informal and formal science learning. Online digital information, such as school intranet pages, can now be "retrieved" from a number of geographically distributed locations via a uniform resource identifier (URI; a codified address that points to a resource on the World Wide Web). This information is sent to the user, such as a teacher, parent or guardian, school-age pupil, university student, or informal learner, via a network. Applications (such as a web browser) hosted on compatible devices (including personal computers, personal digital assistants (PDAs), and mobile phones) then "read" and "reformat" this digital content (e.g., the title of the school intranet page always goes in the middle at the top; the accessibility options directly underneath, left aligned; and so on).

This entry provides an initial definition of online media for informal and formal science learning. Three key trends in the current (2012) digital landscape will then be outlined: media convergence, accessibility, and collaboration and participation. The entry will draw on examples to illustrate some of the concepts being used to analyze and describe educational media and their uses in formal and informal science learning.

There is one note of caution. Educational media can be sold as commercial products that are developed and promoted within a competitive marketplace. It follows that, as a prospective consumer, citizen, and learner, the reader needs to retain a critical attitude when assessing the relative merits of educational media.

Finally, for this introduction at least, the examples discussed in this entry are necessarily small in number, and they are only briefly described. What follows is an attempt to map what is a rapidly developing landscape, technologically, socially, economically, politically, legally, and culturally. No entry that discusses online media could ever claim to be future proof. It will be up to the reader to apply these ideas, seek out new ones, locate additional examples, and critically engage with relevant academic literature.

Media Convergence and the Pervasive and Ubiquitous Nature of Digital Technologies

Convergence is a significant trend that has considerable relevance for how online media and educational resources are accessed and used by formal and informal science learners. In a technological sense, media convergence is all about integration and interoperability, the coming together of computing networks, information and communication technologies, and digital forms of information that are inherently adaptable, delivered via "intelligent" platforms, applications, and devices. From an end user's perspective (e.g., those seeking to learn new skills, competencies, and scientific knowledge with the aim of applying this learning through online conversations, participation, and collaborative contributions), media convergence involves digital technologies that encode and decode multiple streams of, in this case, science content. This can involve linked and aggregated text, galleries of still images with the opportunity to upload and tag further images, moving pictures (such as a virtual field trip), digital simulations, self-pacing interactive tutorials (that can be structured to provide automated feedback, advice, or comments), sounds, music, science-based computer games, access to remote experiments or equipment, opportunities to input and analyze data "on the move," or any combination thereof. This content is mediated through one or more devices and platforms of the end user's choosing, such as a mobile phone, tablet, laptop, desktop computer, or personal digital assistant (PDA). These media can then be customized and consumed “automatically” via feeds that match the user’s personalized profile on the device(s) of their choice.

As a result of the convergence of computers with communications technologies, teachers, parents or guardians, and informal and formal learners with network access have opportunities to teach and learn about scientific information that is relevant and useful to them, wherever and whenever they are, and on an increasing range of computing devices. To illustrate the point, imagine an idealized (and simplified) scenario where a university student (let us call him Fred) is on his way to an astronomy lecture on a Monday morning. Fred travels on the bus from his home to the campus watching (and listening through headphones) to an archived television show about astronomy on his smartphone. He checks the website associated with the television series and texts an answer to a competition announced during the episode as entries close at lunchtime that day. On the same journey Fred responds to a text message from a fellow student asking him to send them details of where the lecture will be archived as they are unwell and cannot attend. Fred gets to the lecture hall and checks his emails before the lecture starts. As the lecture finishes he tweets details of an open access repository where one of the academic papers that the lecturer recommends is hosted. After the lecture, he goes to the university library where he checks the discussion forums of a citizen science astronomy project that he has been contributing to. This is all achieved through a networked “post-desktop” computing device called a smartphone, but without what we used to think of as a phone call being made. This is pervasive, ubiquitous, personalized, and mobile computing where the distinction between formal and informal learning is blurred and where the student – Fred – is both learning about and contributing to astronomy within the course of a couple of hours, all of which is mixed in with leisure activities.

Of course, to become a pervasive and ubiquitous digital hardware, tools and technologies have to be flexible, adaptable, intuitive, and useful. Fred provides us with just one example of this. The widespread adoption of these technologies emphasizes the point. These technologies are profoundly social and have been designed with a good range of uses and users in mind.

It should come as no surprise, given the example described above, that the processes that facilitate media convergence are shaped by social practices and cultural values, and vice versa. The success of online media is reflected in the changes in how people access and use information, and by the blurring, in places, of the distinction between some aspects of formal and informal learning. We use digital technologies to learn about the sciences, politics, sport, and so on while also contributing, through the use of these technologies, to the public discourse about these subjects. Where once people had opportunities to collate and filter scientific information via various “traditional” communication channels, such as textbooks, printed encyclopedias, and science documentaries on television, now digital technologies are also playing an important role. In effect, well-designed educational media enable different routes to learning that can combine in powerful ways, e.g., through narrative, interactive, adaptive, communicative, and productive forms (Laurillard 2002). Indeed, the reader is contributing to this trend by reading this entry in an online encyclopedia and accessing other related content through hyperlinks. Furthermore, if there is a wish to extend, revise, or delete this entry, some media forms (e.g., Wikipedia) would allow the reader to do this, thus extending the learning experience.

Accessibility: Open and Easy Access to Educational Resources and Scientific Information

The second theme that we consider in this entry is accessibility. This broad theme can be subdivided into at least two important subthemes:

- Open and easy access to scientific information

- Accessibility of educational resources to ensure that they are designed for end users with different needs

Open and Easy Access to Scientific Information

Routine and continued access to reliable and credible scientific knowledge (in conjunction with the skills and competencies to filter, analyze, and respond to it) is crucial for informal and formal science learning. Concepts such as the “digital divide” illustrate that a lack of routine access to information, scientific, or otherwise can reinforce preexisting structural inequalities and hamper science learning.

Access to scientific information can be influenced by a number of factors, particularly financial constraints, which can be compounded by the fact that one piece of hardware is rarely considered to be sufficient in the digital age. Furthermore, hardware, software, and network infrastructure need to be upgraded over time, adding to the overall financial cost of accessing scientific information. In addition to financial considerations, the ability to connect through secure, networked infrastructure is vital to ensure that users can access educational resources with confidence and share data and information quickly and effectively.

However, financial constraints are only one hurdle, and the proliferation of digital forms of knowledge requires skills (and continued training) in order to effectively navigate through the digital ecosystem. In other words, formal and informal learners need to develop systematic information literacy skills that enable them to sort the “wheat from the chaff” and to be able to assess and respond to information and resources that are considered credible and reliable (Weiner 2010) . This can be a particular challenge for informal science learners if they have little or no formal training in how to systematically source credible scientific information, while formal learners need support and study time to develop, practice, and demonstrate these skills.

Another important issue that has been the subject of much attention is the denial of access to resources that can be used for educational purposes because the content is not generally available for public consumption, e.g., because it is behind a subscription paywall. Developments with open educational resources, open access to research papers, and open datasets provide alternative routes to content that can be used for educational purposes. Typically, open educational resources are made available free of charge to the user under licenses that promote reuse, and sometimes reversioning, but with certain conditions attached, e.g., a requirement that the resources are not resold for commercial purposes.

Open educational resources have become hugely popular. Open Learn – Learning Space, for example, a repository of open educational resources developed by the UK’s Open University, has been used by over 21 million unique visitors from 2006 to 2012, while the Open University resources on iTunes U have generated over 58 million downloads from 2008 to 2012. This wider trend in making educational content freely available is illustrated by the emergence of Massive Open Online Courses (MOOCs). MOOCs provide informal learners with access to educational content, but without having to formally register for a course. These developments have led to discussions about the role and purposes of higher education institutions. This is illustrated by a disaggregation of the functions that universities and lecturers provide for students: content in the form of open educational resources; support, which can be provided by lecturers and/or by peer learners; and assessment and accreditation, two functions which may be relevant only for registered learners (McAndrew et al. 2010).

Accessibility of Educational Media and Resources

Open and easy access to scientific information takes on another dimension when we consider users with special educational needs. Ensuring that users with different needs can access and use forms of online media, either directly or through the use of enabling technologies, requires a more inclusive and participatory design process.

"Design for all" encapsulates this approach. This approach has benefits for all users because the resulting hardware, tools, technologies, and resources will be more adaptable and flexible, thus facilitating user customization. All learners can benefit from well-designed educational resources, and a user-centered approach to design greatly improves the chances that end users will be able to access the same or equivalent information. In practice, accessibility issues need to be considered at each stage of the design process: initial design and planning, asset creation, asset compilation, and media output. A combination of formative and summative evaluation, involving users with different needs, should inform each stage of the design process. The information gleaned through this user-focused design process can then inform the advice and guidance that is provided to prospective learners before they begin their study, e.g., in identifying core versus optional content, requirements, activities, and assessments.

Developments with digital technologies have helped to automate some aspects of production processes, particularly around text-based resources. For example, digital information can now be provided in multiple forms. The same text can be printed, rendered as a series of linked web pages, and "screen read" as a spoken word. Resources should also be designed to allow users to decide which font size and text/background contrast they find easiest to read. These developments provide technological solutions that make the same content available in multiple forms.

Resources should also be checked to ensure that they connect effectively with different enabling technologies (e.g., screen magnifiers, screen readers, and speech synthesizers). And there are other routine procedures that producers of educational media should make available, including the production of screen-readable transcripts for audio and audiovisual resources, keyboard-accessible navigation of web pages (including keystroke alternatives to using a mouse), and the routine provision of alternative text explanations for images.

Collaboration and Participation: The Contribution of Online Citizen Science Initiatives

The third and final theme to be considered in this entry is collaboration and participation. After a brief introduction to ideas about citizen science projects that are at least partly conducted online, a typology of activities is offered for these increasingly popular activities to demonstrate the different levels of collaboration and participation that informal and formal science learners experience.

What Is (Online) Citizen Science?

Citizen science is a form of research collaboration involving both scientists and members of the public. Participants engage with scientific research projects to address authentic scientific research questions. Citizen science projects have a history that dates back at least a century, e.g., to the Christmas Bird Count, which was first organized in 1900 by the Audubon Society in the United States. Participants who engage with citizen science projects are given opportunities to learn about aspects of scientific research while also contributing and collaborating in various ways.

Online media have enabled the development of citizen science projects where data can be collected, collated, assessed, and analyzed using digital tools and technologies (Hand 2010). These projects make it possible for interested citizens (who may also consider themselves to be informal and formal learners) to participate in scientific research that is mediated by technology. They can participate within the comfort of their own home, on a field trip, and/or in a school classroom; over the summer holidays, as part of an extracurricular science club; or within scheduled science lessons.

Participants can conduct a range of tasks, e.g., collecting and submitting data and/or analyzing data that has been collected by others. A number of online citizen science projects have also developed resources for learning. Zooniverse, for example, has developed a number of educational resources that support activities within informal and formal science learning environments.

Online citizen science projects can be classified into at least three types: distributed computing projects, distributed thinking projects, and scientific discovery games.

Distributed Computing Projects

Distributed computing projects represent the earliest form of online citizen science. These projects were developed in response to the large amounts of data produced by projects, such as SETI (Search for Extraterrestrial Intelligence). In this type of activity, project organizers invite networked users to volunteer part of their computer's processing capacity for the analysis of data. Initially potential participants (e.g., citizens with a general interest in the search for extraterrestrial life) access information about the distributed computing project and the related science from the project website. Should they want to become more involved, participants download the project software usually to a desktop computer or games console. That networked computing device will automatically download and analyze small packages of data using the project software and then returning the completed work units to the original project server.

The level of interaction and participation on the part of the citizen scientists is relatively limited. However, participants in distributed computing projects have opportunities to learn about the project and its methodology and to offer resources in support on this venture. But, due to the automated nature of the analytical procedures, the levels of interaction and collaboration beyond this are limited. Participants can interact in other ways though, e.g., through online forums where they are provided with opportunities to discuss topics of interest with other citizen scientists and/or the project scientists.

Distributed Thinking Projects

Distributed thinking projects typically involve classification tasks and observational skills that cannot easily be undertaken by computers, such as pattern recognition tasks. Participant contribution is likely to begin in the same way as distributed computing projects, e.g., by learning about the research questions and methodology from the project websites. Those who go on to register on distributed thinking projects will be required to contribute on a more active, cognitive level than for distributed computing projects.

For distributed thinking projects, participants are likely to need some level of training in the required analytical tasks, e.g., engaging in learning through online tutorials. And, as with any scientific research project, due consideration must be paid to the potential for error in the analysis conducted by all participants. In some distributed thinking projects, this is minimized by giving numerous citizen scientists the same task. It is worth noting, therefore, that the results obtained by citizen scientists in these types of projects are generally comparable to those obtained by professional scientists.

One of the most popular examples of a distributed thinking project is Galaxy Zoo, where hundreds of thousands of images of galaxies have been classified by online citizen scientists. Galaxy Zoo participants have been instrumental in several important discoveries, for example, the discovery of a new type of galaxy, and have also appeared as coauthors on academic papers.

As with other types of citizen science initiatives, distributed thinking projects can lead to the emergence of online communities and collective identities, e.g., Galaxy Zoo participants refer to themselves as "Zooites." These communities often emerge entirely through online interaction where participants share information concerning the scientific aims of the project, information relating to the background science, and technical questions relating to data analysis or the downloading of software.

Distributed thinking projects have developed to the point where this conceptual idea has developed beyond single projects. For example, the success of Galaxy Zoo has inspired the development of a number of distributed thinking projects within the umbrella project known as "the Zooniverse," including (among others) Whale

FM, where participants help to track whale populations by identifying distinct whale songs; Planet Hunters, in which participants look for extrasolar planets; and Seafloor Explorer, where the participant helps to record ground cover and the number and types of animal species present on the ocean floor.

Scientific Discovery Games

Scientific discovery games are the third of the three types of online citizen science discussed in this entry. These are online games that are based on an authentic scientific problem. Participants contribute through their puzzle-solving abilities and/or spatial awareness skills. Players do not necessarily need any special scientific knowledge or gaming skills before they start to play. This knowledge can be learned through online tutorials or from other players.

One of the best known examples of scientific discovery games is Foldit, an interactive puzzle game where players attempt to elucidate the three-dimensional structure of protein molecules. Players can play individually, or within a team, and compete against one another within a points system. Protein structures that come closer to their "natural" configuration (i.e., one that requires the least amount of energy) are awarded a greater number of points.

Since its launch, a number of significant scientific breakthroughs have been made by Foldit players. For example, two teams of Foldit players were instrumental in "solving" the three-dimensional structure of an enzyme relevant to HIV infection – a problem that had confounded biochemists for the best part of decade. Players also use online forums to discuss issues related to the game and the science associated with it.

Scientific discovery games can also offer a novel form of collaboration not only between professional scientists, games designers, and interested citizens but also between citizen science players. For example, Foldit players share puzzle strategies and scripting code and help to guide new players through the rules of the game. In effect, Foldit is not just an online scientific discovery game. It is also a community of skilled games players who are willing to collaborate and share their expertise in the furtherance of cutting-edge scientific research.

Foldit provides an example of the potential of online media for formal and informal learning. The most successful Foldit players have developed expertise and gained skills and competencies in particular areas, forming communities of practice in relation to particular areas of the game. They have gained the requisite knowledge and skills to participate in this scientific endeavor through different routes, in all likelihood combining their experiences of formal and informal science learning to the point where they can share this learning and collaborate with others. If the pioneers of networked infrastructure and the early developers of digital hardware, tools, and technologies are reading this entry, they can be proud of what others can achieve individually and collectively through the power of online media.

Opportunity to Learn

Joan Herman
National Center for Research on Evaluation,
Standards, and Student Testing, UCLA,
Graduate School of Education and Information
Studies, Los Angeles, CA, USA

Keywords

Academic engagement; Curriculum exposure

Opportunity to learn (*OTL*), a term introduced by John Carroll in the early 1960s, conveys the idea that students' school learning is a result of the time they spend engaged in learning and thus that students cannot be expected to learn if they do not have adequate time to do so (see Carroll 1963). Since its introduction, OTL has played key roles in international assessments, accountability policies, and practices and is standards-based reform. These themes are expanded below, including OTL's role in policy and practice and measurement methods.

The What and Why of Opportunity to Learn

John Carroll's model of learning offers a base definition for OTL by establishing that learning, as measured by achievement tests, is a function of the time students are engaged in learning the specific topics on which they are assessed relative to the time they need to learn those topics. The model also sets out a general set of categories that influence how much time is needed – for example, student ability and availability and effectiveness of instructional resources. OTL thus can encompass both student engagement in relevant curriculum and the sufficiency and effectiveness of such engagement (see McDonnell 1995). The concept, defined by one or both dimensions, has been used to understand and explain student performance, as a policy lever to promote equity and fairness in education, and as a tool for improving teaching and learning.

IEA's Second International Mathematics Study (SIMS) in the 1980s provides the first large-scale application of OTL to examine the extent to which differences in curriculum and instructional exposure to particular topics, rather than the ability to master those topics, might explain differences in achievement. SIMS defined OTL as instructional exposure, as gauged through curriculum analysis and surveys of teachers, and was followed by the Third International Mathematics and Science Study (TIMSS), which added video analysis of classroom practice to delve more deeply into OTL differences that could explain cross-national differences in performance.

Concurrently, policy makers, notably the United States, looked to accountability as a means for improving student outcomes. Minimum competency exams in many states in the United States, for example, required that students pass a test to receive a high school diploma, and state and federal legislation moved toward holding schools and students accountable for achieving high standards of learning. Public discussion of OTL standards soon followed. Motivated largely by fairness concerns that students not be held accountable for content and skills they had not had the opportunity to acquire, OTL standards also were intended to signal what needed to be in place to enable students to achieve higher learning standards and potentially to create a framework for monitoring and improving OTL and hence educational effectiveness. Among the proposed standards were those involving:

- Curricula and materials
- Teacher capability
- Continuous professional development
- Alignment of curriculum, instructional practices, and assessments with content standards
- Safety and security of the learning environment
- Nondiscriminatory policies, curricula and practice
- School financing

These standards expanded existing definitions of OTL to clearly reflect concerns for equality of opportunity. OTL is thought to be central in explaining and remedying the achievement gap for economically disadvantaged and minority students. Their case is supported by research documenting both the relationship between OTL and student performance and disparities in OTL associated with race, ethnicity, language, gender, and disability status, for example, in teacher qualifications, available curriculum materials, course access content, and school finances.

Finally, at the core of the OTL concept is the need for effective curriculum, instruction, and teaching to enable students to achieve rigorous learning goals. This same sentiment permeates standards-based reform, where systems establish standards for student learning and assess how well students are achieving them. Educators are charged with designing and delivering curriculum and instruction – effective OTL – that will enable students to achieve the goals and with using assessment data to improve their efforts. Analysis of OTL goes part and parcel with improvement. If students do not do well, is it because they lacked OTL and/or what aspects of curriculum and instruction were insufficient to enable students to develop the scientific understanding they were expected to achieve?

Methods for Assessing Opportunity to Learn

A variety of methods have been used to assess opportunity to learn, including teacher and student surveys, teacher logs, analysis of curriculum and instructional artifacts, observations of teaching and learning, and archival data. Most methods primarily focus on content analysis and emphasize the alignment between content that is taught and that which is assessed. For example, surveys, observations, and analysis of curriculum artifacts (e.g., lessons, text books, assignments) have been variously designed to examine whether or not specific topics have been taught (content coverage), how much instruction time each topic has received (content exposure), or the extent to which a topic is or has been a major, minor, or no priority in classroom instruction. Quality of instructional delivery, as measured by the nature of the activity in which teachers and students are engaged, and level of cognitive demand also are typical foci for OTL instruments.

For example, Andrew Porter's (see Porter 2002) content alignment methodology has been used extensively in teacher surveys describing the content of classroom instruction, content analyses of instructional materials and assessments, and indices of alignment between standards, instructional content, instructional materials, and/or assessment. The methodology uses a two-dimensional matrix composed of the topics of instruction and categories of performance expectations – or cognitive demand. Topics can vary by course, grade level, and locale and can be specified at various levels of detail, for example, force and motion, chemical reactions, kinetics, and equilibrium – or major concepts and subtopics within each. Cognitive demand categories are consistent across grades and subjects in science and include the following categories: memorize, perform procedures, communicate understanding, analyze information, and apply concepts. Instruction and the standards and/or assessments are charted relative to the matrix to indicate the amount of time spent on each topic and, for each topic, the relative emphasis given to each category of cognitive demand.

Norman Webb's (see Webb 2007) methodology, as another example, has been used to examine the alignment between tests and the standards and objectives the tests are intended to measure, but it also could be used to examine the alignment between instruction and assessment. Qualified raters work from an established set of standards and objectives and identify the standard and/or objective measured by each item or task on a given test. They also use a 1–4 scale, the depth of knowledge elicited by each item and evident in each standard or objective. Both the Porter and Webb methodologies provide summary indicators of the breadth and depth of alignment and gaps in coverage.

Other methodologies have not been directly used in science education but are potentially applicable to it. For example, the CRESST assignment analysis methodology has been used to examine the quality of OTL by evaluating the nature of the assignment's learning goals, alignment between those goals, instructional activity, assessment, and the intellectual rigor of the expected work (See Clare-Matsumura & Pascal 2003).

Use of OTL Data

Analysis of OTL can be conducted at the individual student, classroom, school, district, regional, or national levels. For example, a teacher might diagnose an individual student's learning needs by considering the student's OTL relative to his/her performance. Similarly, that same teacher may evaluate the strengths and weaknesses of her curriculum by considering the class's assessment results in light of the content and cognitive demands of the OTL students have been provided. A school, district, or state might consider equity in the OTL it provides by examining OTL by subgroup, and courts in the United States, in fact, have used such data to inform decisions on equality of opportunity. All users might consider what inferences might be drawn from the data to improve OTL and thus to support improvements in learning.

Out-of-School Science

Justin Dillon
Department of Education and Professional
Studies, King's College London, London, UK

Keywords

Ecological studies; Environmental education; Field trip; Fieldwork; Science beyond the classroom

Out-of-school science refers to the diverse range of activities that take place beyond the classroom. Such activities include those which take place in the school grounds, in local open spaces and parks, and further afield, often at residential centers. One major category of out-of-school science is fieldwork, a term that usually refers to the collection of data, including observations, as part of an ecological study. Indeed, traditionally, out-of-school science is often regarded as being predominantly biological in nature. However, there is a strong tradition of earth science education taking place outdoors and the physical sciences can also be taught beyond the classroom.

There is substantial evidence that under the right conditions – properly conceived, adequately planned, well taught, and effectively followed up – out-of-school science provides opportunities to develop knowledge and skills in ways that add value to students' everyday experiences in the classroom (Rickinson et al. 2004). A key issue here is the need to integrate science learning in the classroom with what takes place outdoors, a process that involves effective pre- and post-activities. Although the novelty of the outdoors may lead to memorable experiences, novelty can also significantly reduce learning as students can be distracted by new and sometimes challenging situations. The preparation, therefore, has to take account of the learner's prior experiences and needs in terms of feeling secure and safe.

Seeing scientific phenomena out of school can strengthen understanding as well as develop new knowledge. As well as experiencing phenomena in real-life contexts, students are able to develop a sense of place, that is, an appreciation of their locality and the environmental features found there. Other benefits of out-of-school science include increased appreciation of how science works and improved teacher-student relationships.

The evidence suggests that longer programs are more effective than shorter ones. At their best, residential centers may offer highly trained staff with expert local knowledge and adequate equipment for a wide range of scientific activities, such as water quality monitoring using physical, chemical, and biological techniques. An issue here is the relationship between the normal classroom teacher and the fieldwork tutor. While it is common to find teachers handing over responsibility for teaching to the tutor, collaborative teaching can have a positive impact on the learning that takes before, during, and after a visit.

A number of barriers are often cited as reasons why some teachers do not take their students outdoors including the cost, health and safety concerns, and student misbehavior. However, the fact that so many teachers do take their students beyond the classroom suggests that these barriers are not the real problems. Challenging teachers' views of what counts as science and developing their confidence in adopting new pedagogies are more likely to be the real challenge for advocates of out-of-school science.

Pacific Island Ancestry

Donald H. Rubinstein
University of Guam, Mangilao, GU, USA

Keywords

Cultural diversity

Pacific Islanders number approximately 13 million people residing in more than 25 island nations and territories, dispersed across the largest geographic feature on Earth – the Pacific Ocean – with growing communities of recent migrants settled mainly in the Pacific Rim nations. In many ways this population is unique among world cultural groups. The Pacific Islands were the last major area on earth to be settled by humans, the last region to be colonized by metropolitan powers, and among the last territories to undergo decolonization – with several islands remaining as non-self-governing territories (e.g., New Caledonia, Guam, and American Samoa). The Pacific Islands are also unique in terms of their degree of indigeneity and cultural continuity, having the largest proportion of indigenous people and lands held through customary land tenure, of any region of the world (Regenvanu 2009).

The Pacific Islands include enormous geographic, linguistic, and cultural diversity. Humans first moved into the region from Southeast Asia roughly 40,000 years ago, during the late Pleistocene epoch when lowered sea levels exposed land bridges across much of present-day Indonesia, joining the islands of SE Asia to the Asian mainland and joining New Guinea to the Australian continent. New Guinea islanders can claim the greatest antiquity among Pacific Islands populations, and recent archaeological research has revealed that New Guinea may be one of the oldest sites in the world for plant domestication and the development of agriculture (Denham et al. 2004).

Around 4,000 years ago, new technologies of long-distance seafaring enabled groups of people on and around Taiwan to expand southward and then eastward across the island archipelagoes of present-day Philippines and Indonesia and to settle along the coastal areas of the already-inhabited islands. Speaking Austronesian (or "Malayo-Polynesian") languages, this human expansion reached the eastern limits of the earlier settlements by about 3,000 years ago (Kirch 2010). Subsequently, Austronesian-speaking seafarers sailed into the remote Pacific, eventually settling islands throughout the vast areas of the "Polynesian Triangle" (with apices at Hawaii, Easter Island, and New Zealand) and "Micronesia" (the small islands of the Marianas, Carolines, and Marshalls north of the equator). The settlement of the vast Pacific Ocean, using indigenous knowledge of navigation and

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

seafaring, must rank among the greatest achievements in human exploration and migration. Austronesian speakers, embodying some 1,200 languages distributed from Easter Island to Madagascar, were the most widely dispersed language family in the world, prior to the colonial expansion of English.

Since the Pacific War, islanders have migrated increasingly to metropolitan destinations, largely following the former colonial spheres of control, with the commonwealth-affiliated South Pacific Islanders moving to New Zealand and Australia and US-affiliated North Pacific Islanders moving to the United States. Auckland holds the distinction of being the largest Polynesian city in the world, while Hawaii and the US west coast are home to growing communities of Samoans, Chamorros (from Guam), and other Micronesian islanders. The Pacific Islander diaspora is creating vibrant new communities abroad while maintaining a sense of cultural identity and continuity through dance and other performance arts, tattoo, family celebrations, language maintenance, and social and economic exchanges with their home communities in the Pacific Islands.

Paradigm

Hanne Andersen
Department of Physics and Astronomy – Centre for Science Studies, Aarhus University,
Aarhus C, Denmark

Keywords

Exemplars; Incommensurability; Problem solving; Scientific revolutions

Thomas S. Kuhn introduced the notion of “paradigm” into the philosophy of science to describe the consensus within a given scientific community based on past achievements that members of the community held as exemplary and thus on how to model future research on these achievements. In his monograph The Structure of Scientific Revolutions from 1962 (2nd edition with a postscript from 1970; for detailed accounts of Kuhn’s philosophy, see, e.g., Hoyningen-Huene 1993 or Andersen 2001), Kuhn described the development of science as successive periods of cumulative normal science separated by noncumulative revolutions.

According to this account, normal science is dependent on a paradigm in the form of a set of received beliefs that marks out what the acceptable research problems are and what acceptable solutions to these problems must look like. Yet some of the scientific problems defined by a paradigm may eventually turn out to be unsolvable within the framework of the paradigm, what Kuhn calls anomalies. If these anomalies cannot be resolved, they may cause a crisis in the scientific community, and in some cases this crisis eventually leads to a scientific revolution, also called a paradigm shift. The paradigms separated by such a revolutionary divide will in some areas be so different that the relation between the new paradigm and the old cannot be seen simply as one of extension or refinement. Instead, the concepts involved in a paradigm shift may change in important ways, such as the concept "mass" that is independent of the object's velocity in Newtonian mechanics but dependent of the object's velocity in the theory of relativity. Proponents of different paradigms may therefore have difficulties communicating, because they use some concepts in different ways. Kuhn termed this relation between the paradigms separated by a revolution or paradigm shift "incommensurability," a term that comes from mathematics where it means "no common measure."

According to Kuhn, the phased development of science – paradigm, crisis, revolution, new paradigm, etc.–, presupposes that a paradigm has been established so that there is consensus within the scientific community on various fundamentals. A distinction can therefore be made between the pre-paradigmatic stages of science while it is still characterized by a plurality of competing schools of thought and its mature stages when a shared paradigm has been developed.

The term paradigm has been used in several different ways. Sometimes it is used to denote concrete exemplary problems and problem solutions, sometimes it is used to refer to classical texts from the history of a discipline, and sometimes it is used to denote the entire global set of commitments shared by the members of a given scientific community. It has therefore been criticized for its ambiguity, and in response to this criticism, Kuhn tried to disentangle the various uses by introducing the idea of a disciplinary matrix containing four different elements: (1) the symbolic generalizations that are used within a given discipline, that is, the scientific laws in their most fundamental forms (e.g., Newton's second law of motion, $F = ma$); (2) beliefs about which objects and phenomena exist in the world (e.g., that forces exist); (3) values by which the quality of research can be evaluated (such as accuracy or consistency); and (4) so-called exemplars which are the exemplary problems and problem solutions that scientists from a given discipline work on and recognize.

Paradigms in the form of exemplary problems and problem solutions play a special role in science education. Kuhn argued that textbooks do not describe the problems which a discipline addresses in the abstract; instead they exhibit concrete problem solutions and ask the students to solve additional problems that are closely related to those that have been displayed in the textbook. In this setting, the term paradigm denotes standard examples, similar to how the term is used within language teaching.

Participation, Gender-Related

Megan Grunert
The Mallinson Institute for Science Education,
Department of Chemistry, Western Michigan
University, Kalamazoo, MI, USA

Participation and achievement in the sciences have varied over time, and currently, there are substantial differences by country and within cultural groups. The United States and the United Kingdom have similar patterns of participation and underachievement for girls and women in the sciences. Many other industrialized countries have higher participation rates and achievement for girls and women compared to the United States and United Kingdom. Many developing nations have low participation rates due to access, societal and religious norms, and other factors. Across and within countries, cultural attitudes and expectations play a significant role in the participation of women and girls in science.

In the United States, adolescence typically corresponds to a decline in girls' interest, participation, and achievement in science. This is attributed partly to peer influences and a desire to be popular and well liked. Students start to identify science careers and scientists as isolated, hard, and masculine. As evidenced by research such as the Draw-a-Scientist Test, where students are asked to draw someone who is a scientist, it is clear that children and adolescents have clear expectations of who does science. This activity has repeatedly resulted in students drawing older white men in lab coats with unruly hair and glasses, reminiscent of Albert Einstein. The perception that scientists should look like that can be problematic for individuals who do not identify with this image, such as girls and underrepresented minorities.

Self-concept and identity are believed to play a substantial role in the differential participation rates in science. Science is often characterized as masculine, leading students with a more feminine gender identity to see a scientific career as incompatible with their conception of self. Additionally, research has shown that students who possess a scientific self-concept are more likely to be interested in pursuing a science major or career. Some of the challenges with the narrow perceptions of scientists and science careers stem from a lack of positive role models. This is a circular problem, as the lack of diversity in science perpetuates scientist stereotypes, thereby limiting students' interest in pursuing science when they cannot identify with scientists and do not develop a scientific self-concept.

Perceptions of science and scientists are not isolated to students; they are also present in teachers. These inherent beliefs about who is capable of doing science can unconsciously be passed on to students through teachers' classroom behaviors. If boys are encouraged to enter science fairs, participate in science outreach activities, or engage in scientific inquiry when girls are not, it can generate a cultivated lack of interest in girls and sense that they should not be doing science. Likewise, research has shown that teachers often expect boys to excel in math and science, making them more likely to call on boys for answers during class and less likely to call on girls. These messages send clear signals to girls about their abilities and social expectations about scientists, even if the messages are unintentional. Sexism, overt or otherwise, can be a barrier to girls' participation in science.

Mathematics achievement, self-efficacy beliefs, and course enrollment have also been related to science participation. Girls tend to take fewer math and science courses in junior high school and high school, which is disadvantageous to pursuing a science major or career. Taking more math and science courses predicts later academic success in STEM and is correlated to higher confidence and a higher likelihood of choosing a STEM major in college. Research has shown there is a difference in the confidence and self-efficacy beliefs of boys and girls, which has also been attributed to the lower participation by girls in science. Some of the differences seen in confidence levels can be attributed to perceived preparation, with girls and women feeling behind compared to boys and men. Additionally, when making peer comparisons, girls tend to underestimate their abilities, while boys overestimate their abilities even when they are equally prepared and qualified.

Pedagogical Content Knowledge

Andoni Garritz
Facultad de Quimica, Universidad Nacional Autonoma de Mexico, Mexico DF, Mexico

Keywords

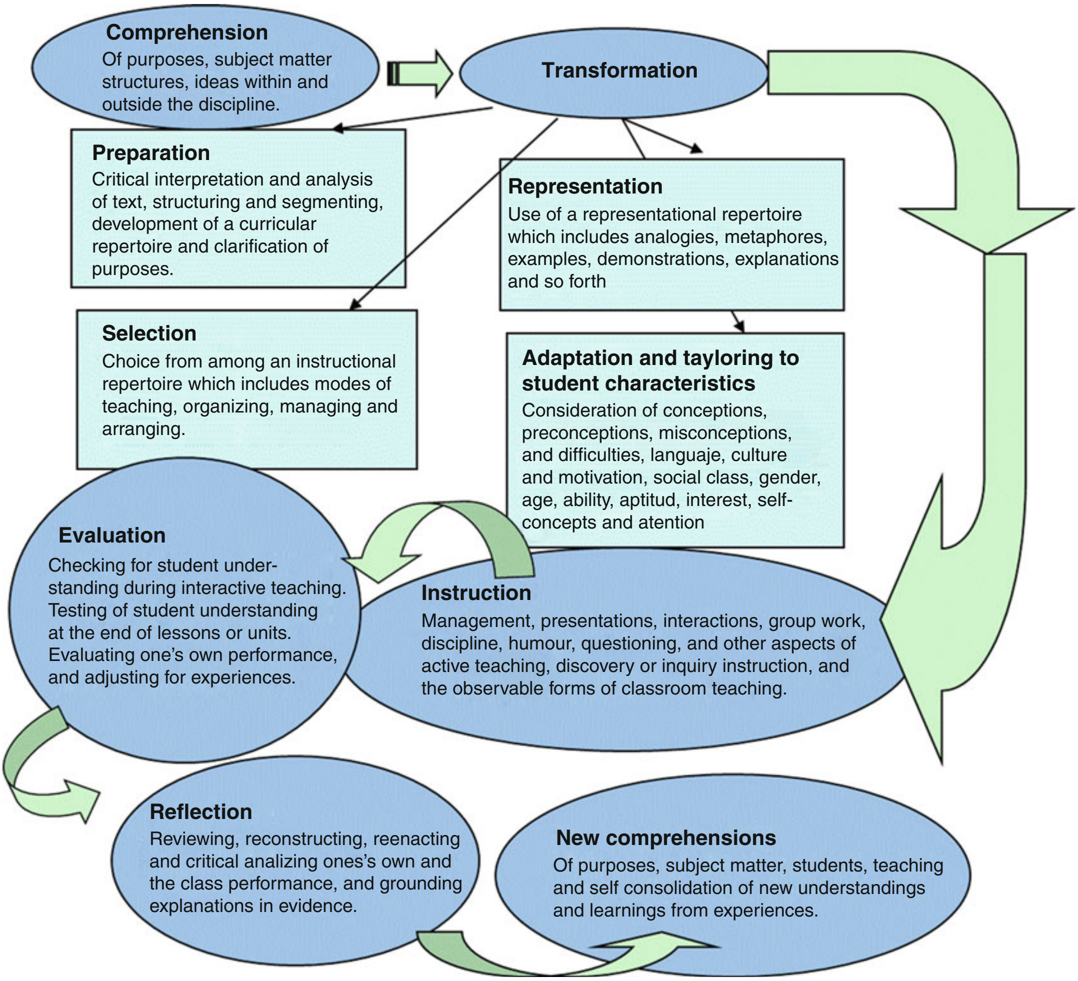
Content knowledge; Filters; Subject knowledge; Teacher beliefs; Teacher knowledge

At the October 2012 PCK Summit in Colorado Springs, USA, a group of international scholars met to share definitions, applications, and interpretations of the construct of pedagogical content knowledge (PCK). The following description was proposed by one of the discussion groups and adopted by consensus: PCK is "defined as a personal attribute of a teacher and is considered both a knowledge base and an action . . . [It is the] knowledge of, reasoning behind, planning for, and enactment of teaching a particular topic in a particular way for a particular reason to particular students for enhanced student outcomes" (Gess-Newsome and Carlson 2013). The four times that the word "particular" appears in this definition is a double-edged sword. On one hand, it means that PCK must be reconstructed specifically each time a given teacher, within set objectives, has to present a certain topic to a specific set of students with a distinctive background and learning characteristics. On the other hand, it represents a superb challenge, being that PCK is an academic construct that represents an intriguing idea, rooted in the belief that teaching requires much more than delivering content knowledge to students, involving designed purposes and the best ways to represent and evaluate that knowledge.

PCK has been a field within which much science education research has been conducted. The array of publications range from Gess-Newsome and Lederman's (1999) book that combined several visions of PCK, looking at ways of assessing and measuring the construct and its impact on science teacher education programs, to the Kind (2009) extended paper where an analysis of PCK models was conducted alongside an examination of methods of elucidating PCK in experienced and novice teachers.

The idea of PCK is enticing because it seems to be such a clever way of imagining what the specialist knowledge of teaching might involve. PCK is complex and usually so deeply a part of a teacher's intrinsic practice that it is tacit and, more often than not, largely inaccessible. The difficulties allied to making more use of PCK lie in its elusive nature. PCK conjures up an image of cutting-edge knowledge of practice, something special and important, something that could define expertise, something that could illustrate, in a meaningful way, why teaching needed to be better understood and more highly valued. PCK is the knowledge and beliefs that teachers develop, over time and through experience, about how to teach particular content in particular ways in order to enhance student understanding.

The term PCK was first coined by Lee Shulman three decades ago. Reflecting on his original lecture entitled "The Missing Paradigm in Research on Teaching" (presented at the University of Texas at Austin, summer 1983), he commented that "most [people] were shocked when I declared that the missing paradigm was the study of subject-matter content and its interaction with pedagogy" (Gess-Newsome and Lederman 1999, forward). In an elaboration of his original concept, Shulman (1987) proposed seven categories of a teacher's knowledge base: orientations, general pedagogical knowledge, content knowledge, curricular knowledge, knowledge of learners, contextual knowledge, and pedagogical content knowledge. We can see that this list includes pedagogical content knowledge as part of the knowledge base that a teacher should possess and enact while teaching.

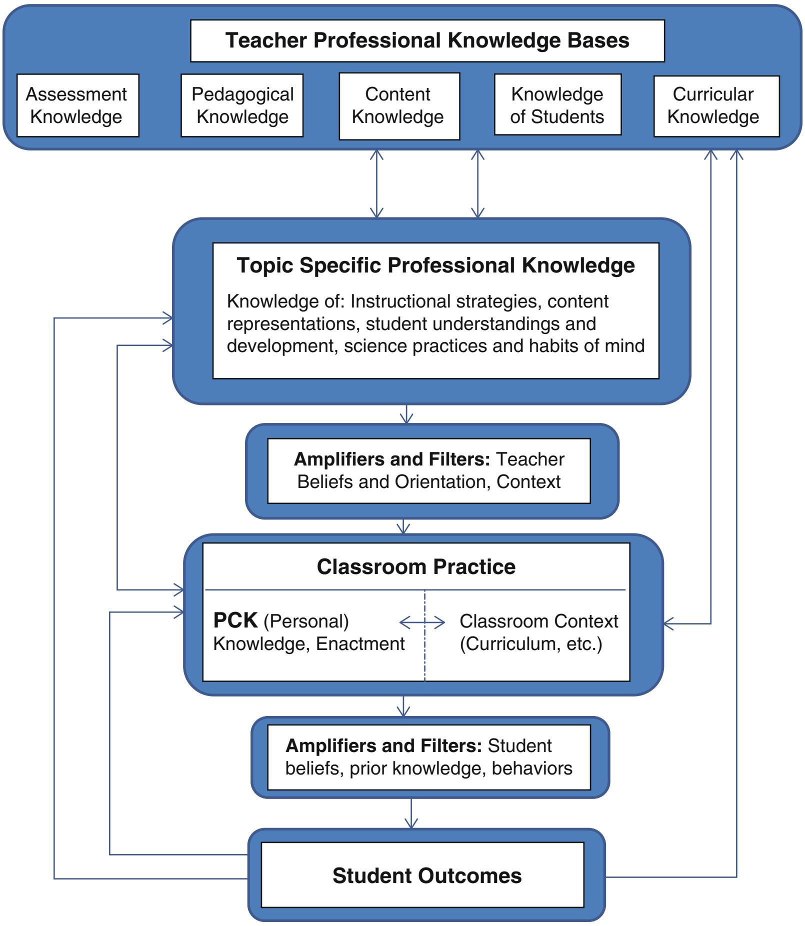


Pedagogical Content Knowledge, Fig. 1 A model of pedagogical reasoning and action (Diagram reproduced with permission from Salazar (2005), based on information first presented by Shulman (1987))

In the last part of his 1987 article, Shulman developed a "model for pedagogical reasoning and action," a diagram of which is presented in Fig. 1. This diagram shows the sequence of considerations made by teachers each time they go through an instructional activity on a specific topic; starting from comprehending the content, they transform it in intelligent representations, selecting them from their repertoire and adapting the representations to the actual student characteristics. The second stage of the process is a cycle in which the instruction is followed by its evaluation, a reflection of the class's performance and a new set of comprehensions in a spiral trajectory that overlays the preparatory stages for subsequent activities.

It has to be emphasized that beliefs and knowledge permeate all of the components of PCK. In the PCK Summit, Marissa Rollnick mentioned that she conceives that beliefs act as a filter that the teacher, unwittingly, places between the knowledge base and his/her action in the classroom or laboratory. Gess-Newsome and Carlson (2013) included the filtration idea in their most recent PCK model, illustrated in Fig. 2. Assessment, content knowledge, pedagogical knowledge, knowledge of students, and context knowledge compose the knowledge base of the teacher, but all that is filtered by the teacher's beliefs, orientation to, and context

Pedagogical Content Knowledge, Fig. 2 Situating PCK within teacher professional knowledge and influences on classroom practice and student outcomes (Reproduced here with permission)



of, the practice of teaching where classroom context also acts. The final purpose of teaching is to increase student learning outcomes, but that is mediated (or filtered) by a set of factors that enact in each one of the students in different ways, because of their individual motivations, behaviors, alternative conceptions, learning styles, and knowledge constructions.

In summary, ensuring that teachers have good content (subject matter) knowledge is only part of the story for a science teacher: possession of effective teaching skills, paying close attention to a teacher's "amplifiers and filters," is also needed. As a closing remark, we copy two questions that Sandra Abell (2008) posed to PCK researchers as future challenges: "What is the relation of PCK (in terms of quality and quantity) to teacher practice?" and "What is the relation of PCK to student learning?" (p. 1412).

Pedagogical Content Knowledge in Teacher Education

Jan Van Driel

Keywords

Science teacher education; Subject matter knowledge for teaching; Teacher knowledge; Teacher learning

Introduction

The term pedagogical content knowledge was introduced by Lee Shulman in his presidential address to the American Educational Research Association (Shulman 1986). Shulman argued that for a long time, research on teaching and teacher education had undeservedly ignored questions dealing with the content of the lessons taught. Shulman presented a strong case for pedagogical content knowledge (PCK) as a specific form of knowledge for teaching which refers to the transformation of subject matter knowledge in the context of facilitating student understanding. Fundamental in the definition of PCK is the notion that teachers' knowledge of strategies to teach a certain topic is related to, if not based on, their knowledge of how students learn that topic and their understanding that students' learning may vary according to the learning abilities of the student, the context, and so on. Shulman suggested that the more teaching strategies teachers have at their disposal within a certain subject domain, and the better they understand their students' learning processes in the same domain, the more effectively they can teach in that domain.

Teacher Education

In the past 20 years, a plethora of publications studying and integrating PCK into teacher education have been published in the research literature. Publications have addressed various subject areas, including English, mathematics, science, physical education, and social studies. In the domain of science education, various studies have been conducted into ways of structuring and organizing preservice science teacher education programs to promote the development of PCK (for overviews, see, for instance, Gess-Newsome and Lederman 1999; Abell 2007). However, the reported impact of such programs on the development of preservice science teachers' PCK is varied. The most successful programs address both preservice teachers' subject matter knowledge and their educational beliefs in the context of learning to teach certain topics. Such programs combine various elements, including the use of relevant research literature (i.e., on student learning of subject matter), the design of lesson series, opportunities to teach these lessons, and reflective activities – such as writing reports and sharing teaching experiences in collective meetings (see Van Driel and Berry 2010). Studies in this context concluded that the development of PCK is a complex process which is connected with deepening of subject matter knowledge and improved awareness of pedagogical issues. It would appear, however, that preservice teachers often experience difficulties merging subject matter courses and education courses that are not integrated by design. In the context of such nonintegrated programs, it has been demonstrated that knowledge development appears most strongly influenced by individual and contextual factors, resulting, among other outcomes, in the adoption by preservice teachers of "conventional" instructional strategies, stressing facts and procedures instead of student understanding.

Science Teachers

In studies on experienced science teachers, it was also found that PCK is quite sensitive to personal characteristics of teachers and their working contexts. Several studies have reported substantial differences between the PCK of experienced teachers around the same topic area, even when their subject matter knowledge is similar, and when they teach the same curriculum. These differences appear to stem from a range of factors including different orientations towards teaching science that teachers may hold; different purposes of teaching science, often related to local curricula; and other contextual factors. The development of PCK is perhaps then best viewed as a complex interplay between knowledge of subject matter, teaching and learning, and context and the way teachers combine and use this knowledge to express their expertise.

Conclusion

Concluding this brief review, PCK should be considered as dynamic, that is, for a certain topic, it develops over time, based on teachers' experiences teaching that topic more often. Specific interventions, in teacher education or professional development programs, can contribute to enhancing science teachers' PCK. In addition, PCK needs to be flexible, so that teachers are able to adapt their approaches to accommodate for differences between individual learners and specific classroom situations: An effective way to teach a certain science topic on Monday morning in a certain class may not work very well in a different class on Wednesday afternoon.

Notwithstanding the complexity of PCK, and its sensitivity to personal and contextual factors, it seems possible, and worthwhile, to capture and portray PCK in such a way that key notions of teaching and learning a specific science topic are made explicit. Also, discussing and sharing such key notions among science teachers may contribute to the establishment of a "collective" PCK, that is, a shared or common form of teachers' professional practical knowledge about teaching certain subject matter. At the same time, there should, of course, be room for individual teachers to adapt or complement this shared knowledge to their own situations.

Keywords

Pedagogical content knowledge; Teacher knowledge; Teacher Learning

Pedagogical knowledge (PK) is a term used for knowledge of how to teach that is applicable across a range of teaching areas. The term general pedagogical knowledge (GPK) is sometimes used as a synonym so that a distinction can be made between knowledge of how to teach generally and knowledge of how to teach a particular subject area which is usually referred to as pedagogical content knowledge (PCK). Shulman (1987) described seven types of teacher knowledge: content knowledge, general pedagogical knowledge, curriculum knowledge, pedagogical content knowledge, knowledge of learners, knowledge of educational contexts, and knowledge of educational aims, purposes, and values. General pedagogical knowledge (GPK) is described as "those broad principals and strategies of classroom management and organisation that appear to transcend subject matter" (Shulman 1987, p. 8). Some writers have used each of the knowledge types described by Shulman separately in describing teachers' work, while others have used different amalgams of the types so that teachers' work can be seen more holistically. The relationship of GPK to other knowledge types is of interest.

Gess-Newsome (1999) suggests that a model of teacher knowledge in which teachers draw on separately developed knowledge types in a flexible manner, to suit particular teaching needs, is an Integrative Model. In contrast, a Transformative Model is one in which a new knowledge form is synthesized from other forms of knowledge into a different way of knowing, more powerful than the separate parts that go into its development. For example, PCK is commonly seen as a transformation of content knowledge or subject matter knowledge, pedagogical knowledge, and knowledge of context into a new knowledge that is of use during the complex act of teaching. Thus PK or GPK is part of, or a contributor to, knowledge for teaching particular subjects so that students understand them. Researchers have found that strongly developed GPK can support the development of PCK where other contributing knowledge types are still growing (Sanders et al. 1993). Similarly, underdeveloped GPK appears to slow the development of PCK particularly in beginning teachers (Mulholland and Wallace 2005).

Clayton, VIC, Australia

Keywords

Self-study

Background

Pedagogy of teacher education is a term that is used to describe the knowledge and practice of teaching and learning about teaching. It is a construct that emerged in the literature based on the notion that teachers of teachers require specialist knowledge and skills about teaching that are particular to the teaching of teaching. Following on from studies in the 1970s and early 1980s aimed at defining expertise in teaching, that which teacher educators need to know and be able to do to prepare the next generation of teachers started to attract serious attention from teacher educators themselves. As a consequence, teacher education programs came under scrutiny and questions about how best to prepare teachers created a need to better understand how learning about teaching was influenced by student teachers' experiences in their teacher education programs.

A Starting Point

Heaton and Lampert (1993) argued that a pedagogy of teacher education offered ways of challenging traditional teacher preparation programs and, if genuinely grasped by teacher educators, could create innovative opportunities through which the problems of practice could become pivotal in learning to teach. A strong example of how this focus on teaching and learning about teaching moved toward the center of teacher educators' efforts was captured in *Teachers Who Teach Teachers* (Russell and Korthagen 1995). Russell and Korthagen's collection illustrated how the hopes, expectations, and knowledge of teaching about teaching began to be more rigorously researched by teacher educators and marked a shift in who did the research that counts in teacher education (i.e., external researchers who observed teacher education or those involved in the work of teaching about teaching). Teacher educators started to break new ground through a focus on, and methodologies for, researching their own and their students' learning of practice that mirrored that of the teacher research movement in schools. As teacher educators began to question and coalesce around the value of researching their own teaching, self-study of teaching and teacher education practices (Hamilton et al. 1998) began to take hold and gain traction in the research community.

Self-Study and a Pedagogy of Teacher Education

The self-study movement was very attractive to teacher educators as it raised the profile, not only of their work but the knowledge and practice crucial to making that work more highly valued. As the literature in self-study grew throughout the 1990s and the first decade of the 2000s, the notion of a pedagogy of teacher education became more prominent; perhaps because it was one way of conceptualizing and articulating knowledge of teaching and learning about teaching in more meaningful ways for teacher educators. As a consequence, the concentration of research on the teaching of teaching, teacher education program structure, and organization came under scrutiny and was often perceived as defining teacher education, not always in positive ways. Hence, a pedagogy of teacher education offered ways of breaking free from the constraints derived from program structures.

Principles of Practice

Korthagen's concerns about the structure of teacher education and how it shaped the nature of learning led him to focus attention on the importance of a pedagogy of teacher education as described in the book *Linking practice and theory: The pedagogy of realistic teacher education* (Korthagen et al. 2001). In that book he proposed three central principles that shaped his notion of a pedagogy of teacher education; they were that the teacher educator should help the student teacher (1) to become aware of his or her own learning, (2) to find useful [learning] experiences, and (3) to reflect on those experiences in detail. The essence of Korthagen's approach to a pedagogy of teacher education then was for teacher educators to explicitly implement teaching of teaching strategies constructed through, and responsive to, his three principles. In so doing, a shared knowledge of practice could become a tangible outcome in student teachers' learning to teach and also help teacher educators build their knowledge of practice in constructive ways.

Refining a Pedagogy of Teacher Education

The notion of a pedagogy of teacher education placed the knowledge and practice of teaching and learning about teaching at the heart of teacher education in new ways and became more prominent in the literature throughout the later part of the first decade of the 2000s. What a pedagogy of teacher education is and how it might be better understood and developed was conceptualized in an explicit way through *Developing a Pedagogy of Teacher Education* (Loughran 2006) which highlighted the distinction between the *teaching* of teaching and the *learning* of teaching. In so doing, a pedagogy of teacher education was conceptualized around the specific aim of building deeper understandings of the knowledge and practice of teaching *and* learning about teaching.

From the teaching about teaching perspective, there are important aspects of being a teacher educator that are seen as influencing knowledge of practice. For example, making the shift from being a (science) teacher to being a (science) teacher educator has implications for how the role of teacher educator is constructed and performed. Underpinning this shift is the recognition that simply "doing teaching" is not sufficient for framing the work of being a teacher educator. Becoming a teacher educator is much more than a change in title or a change in the place in which teaching occurs. Being a teacher educator involves understanding pedagogy in ways that involve the explicit development of a shared language of teaching and learning, of approaching practice as being problematic, and of recognizing and responding to principles of practice such that a major effort is made to better align "thoughts and deeds" in teaching about teaching.

From a learning about teaching perspective, recognizing and responding to what it feels like to be a student teacher matters. The ways in which learners are encouraged to, and supported in, reflecting on their learning about teaching are crucial. One way of doing that through a pedagogy of teacher education is to adopt a student teacher as researcher stance, "students of teaching live a different reality in learning to teach than do their professors who observe their students' situations, and so, students of teaching are rightly the experts in relation to understanding *their* context, *their* position and the expectations *they* feel, face and create for themselves . . ." (Loughran 2006, p. 139). When teacher educators create conditions for learning and trust their students to capitalize on their learning about teaching experiences, that learning becomes more important, more meaningful, and more highly valued.

Science Teacher Education

Berry (2007), in her examination of what she described as tensions in teaching about Biology teaching, was an early leader in articulating a pedagogy of (science) teacher education. It could well be argued that her notion of tensions illustrated ways for others to frame their learning about the teaching of science teaching. In fact, in *Self-Studies of Science Teacher Education Practices* (Bullock and Russell 2012), a collection of studies based around a pedagogy of teacher education was articulated and portrayed within the specific context of the teaching of science teaching. The book highlighted a number of recurrent themes central to the issue of teaching and learning about science teaching, but one in particular was that of tensions, embodied in the tension between transmission and interpretation. This tension draws on common ground evident in archetypes of science teaching and teacher education that encouraged science teacher educators to look more deeply into their teaching and their students' learning. In attempting to engage student teachers in learning through inquiry, by attempting to create curious and puzzling pedagogical situations, and in supporting the notion of risk taking and experimentation in learning to teach, science teacher educators actively pursue a pedagogy of teacher education that makes their purposes and actions explicit, clear, and meaningful in their science teacher preparation programs. Their pedagogy of teacher education is strongly associated with the desire to dispel transmissive approaches to teaching and passive behaviors in learning. Bullock and Russell's book illustrates well how the use of pedagogical practices can help not only teacher educators but also student teachers, to develop their pedagogical reasoning and thus become better informed about the nature of science teaching and learning.

Overview

At its core, a pedagogy of teacher education considers teaching as much more than the delivery of information about how to teach. A pedagogy of teacher education places great value on the knowledge and practice of pedagogy as evident in the scholarship and expertise of expert teacher educators. The juxtaposition of similar underlying concerns about the nature of science teaching and teacher education makes the pedagogy of (science) teacher education a particularly powerful vehicle for supporting the development and articulation of (science) teaching *and* learning about teaching.

Physics Teacher Education

Pamela Mulhall
Monash University, Clayton, VIC, Australia

Keywords

Learning to teach; Pedagogy; Physics; Teacher education

Physics teacher education shares similar concerns to programs for preparing teachers of other science disciplines through its fundamental focus on student-centered teaching. However, there are important differences between physics and the other science disciplines, and these strongly influence the pedagogy of physics teacher education (Tiberghien et al. 1997, 1998).

How Physics Differs from Other Sciences

Physics is regarded as the most fundamental science. It has a reputation as being abstruse, difficult, and highly mathematical. It differs from the other science disciplines in a range of ways. For example, although common in biology, teleological explanations are unacceptable in physics because of their anthropomorphic connotations. Physics has relatively few theories and their predictive power is strong; by contrast biology has many theories but their predictive capacity is often lacking. Logic and parsimony are highly valued in formulating physics explanations but play a less significant role in other sciences such as biology and chemistry which deal with more complex systems and behaviors.

What Preservice Teachers Typically Learn in Physics Courses

Typically, preservice teachers develop their physics knowledge in courses taught by university physics departments (or, frequently, engineering departments) where the treatment of physical laws is very mathematical, and lectures and laboratory work comprise the standard approach to teaching. The nature of physics explanations and other philosophical issues are rarely explicitly addressed.

There is considerable research to suggest preservice teachers' experiences as learners in such courses often profoundly influence their approach to teaching physics. That is, in learning physics, they also learn about a pedagogy of physics teaching whereby the teaching of a topic often begins with definitions of concepts and developing relevant physics equations which are confirmed by laboratory activities. Conceptual understanding is assumed to develop through solving quantitative problems. However, a large body of research has found this approach to teaching often fails to develop deep conceptual understanding of even otherwise successful learners. Consequently, preservice teachers often emerge from such courses with inadequate understandings of the subject they intend to teach and a view of teaching and learning physics which is at odds with that presented in physics teacher education courses (Mulhall and Gunstone 2012).

What Preservice Teachers Typically Learn in Physics Teacher Education Courses

Physics teacher education courses promote the importance of developing students' understanding of physics concepts using qualitative approaches. They challenge the traditional view, noted above, that a proficiency in problem solving guarantees adequacy in conceptual understanding. They explicitly consider the inherent difficulty of many physics concepts. Using a constructivist view of learning, preservice teachers are taught to begin their teaching of a topic by finding out what the physics learner already knows and believes and to develop understandings by providing experiences in which learners engage qualitatively with physics concepts *before* being introduced to mathematical representations. Ways of using laboratory work to promote effective learning are also considered, given research indicates that the forms of laboratory work typically used in schools and universities often fail to promote learning.

Promoting the importance of qualitative approaches that encourage students' intellectual engagement with physics concepts requires attending to assessment practices, as it is well recognized that learners focus on that which is going to be assessed. The traditional approach to assessment in physics promotes the capacity to solve standard textbook problems but does little to support the development of conceptual understanding. For this reason, physics teacher education addresses qualitative ways of assessing conceptual understanding in addition to the quantitative approaches that are familiar to preservice teachers through their prior experience as physics learners.

Approaches to Developing Preservice Teachers' Practice

Constructivism informs the approach taken to teaching physics preservice teachers to teach. As noted above, they tend to have preconceived views about teaching physics that were developed during their previous experiences of learning physics so they expect physics teacher education courses to merely teach them tips and tricks that can be employed in the classroom. Challenging and developing their views is often achieved through placing them in the role of learners of physics in which they discuss ideas about the physics of a situation presented to them in, for example, a demonstration, qualitative physics problem, or POE ("predict-observe-explain") activity. This typically reveals a range of understandings and misconceptions about the phenomenon under discussion. These discussions serve a number of purposes and help to reframe preservice teachers' thinking about teaching physics in ways that develop their practice. Firstly, they help advance the conceptual understanding of the preservice teachers and thereby model a teaching approach that they can use successfully with their own learners. Secondly, these discussions also facilitate preservice teachers' recognition of the importance of paying attention to developing qualitative as well as quantitative understandings in the physics classroom. In so doing, the preservice teachers develop rudimentary forms of pedagogical content knowledge, which may be further advanced using CoRes (Content Representations) and PaP-eRs (Pedagogical and Professional-experience Repertoires) in specific topics (Loughran et al. 2012).

Inevitably such discussions also involve epistemological and ontological issues (e.g., How we know what we know? What do we think exists?). Thinking about such questions, which are rarely addressed in physics courses, helps promote reflection by preservice teachers about their students' intended learning and the importance of teaching physics as "a way of knowing." Extending these discussions to include a consideration of the role of peer review and notions of uncertainty in physics knowledge claims is increasingly seen as being important in the education of physics teachers, given the current trend of curricula in various science disciplines to include the theme of science as human endeavor.

Introduction

It is ironic that Jean Piaget is widely known as a child psychologist, yet he himself did not identify with this label. Rather, he used the term *genetic epistemology* to describe his work. In this context, *genetic* does not refer to genes but to the origin and development of knowledge. Usually, *epistemology* refers to the study of the nature, sources, scope, and validity of knowledge, and it is considered to be a branch of philosophy. Piaget, however, did not believe that epistemological issues fall under the sole jurisdiction of philosophy. Instead, Piaget argued that empirical methods can contribute to the solution of epistemological problems, particularly because knowledge itself is in constant flux and always remains incomplete. Thus, rather than an end in itself, the study of cognitive development in children was for Piaget only one means to address epistemological issues. This also explains why Piaget was not at all interested in determining the cognitive level of an individual child; rather, he was interested in what is common to all children at a specific level of thinking – what Piaget referred to as the *epistemic subject*.

The central questions that Piaget's genetic epistemology aims to address are concerned with the creativity and rigor of knowledge. Creativity manifests itself as novelty that emerges at every level, from the biological to the highest cognitive level of functioning. At the same time, human knowledge, particularly logical and mathematical knowledge, is rigorous and logically necessary ($2 + 2 = 4$ could not be otherwise and must universally hold to be true for all rational persons, provided we are operating in a base 10 numerical system). Piaget's answer to these questions is a particular brand of constructivism that has a biological foundation. Ultimately, his answer is grounded in the nature of life: "the very nature of life is constantly to overtake itself, and if we seek the explanation of rational organization within the living organization *including its overtakings*, we are attempting to interpret knowledge in terms of its own construction, which is no longer an absurd method since knowledge is *essentially construction*" (Piaget 1971, p. 362, emphasis in original).

In this essay, we first describe the key concepts of self-organization, assimilation, accommodation, scheme, operative and figurative aspects of intelligence, equilibration, and constructivism. Then we provide a brief review of the main characteristics of Piaget's four developmental stages. Finally, we examine the roles of consciousness, semiotic function, affectivity, and social interactions in Piaget's theory. Because of the scope of Piaget's work, our essay necessarily is selective. We refer the reader to the monographs by Chapman (1988) and Smith (1993) and the edited volume by Müller et al. (2009) for a more detailed coverage of the topics presented here.

Self-Organization

It is generally accepted that psychological development has a biological basis. The question is how the relation between biology and psychological development should be conceptualized. Currently, a popular approach is to reduce development to the unfolding of hereditary programs or to the maturation of particular areas of the brain. Piaget considered such reductionist approaches inadequate because they fail to capture essential characteristics of psychological functioning: the consciousness of meaning and the irreducibility of implication to causality (see below).

Piaget used the concept of self-organization to characterize the relation between biology and psychological development (see Piaget 1971). At the biological level, *self-organization* is the process by which a system perpetually reconstitutes its processes (e.g., metabolic cycles) and elements (e.g., cells) in order to preserve its continuous functioning. Living systems are self-organizing systems; in exchange processes with their environment, they spontaneously reproduce their organization. Machines, by contrast, are not self-organizing systems; their functioning does not result in their reconstitution, and their reproduction is controlled by an external agent.

In its evolution, the continuously self-organizing process leads to the emergence of higher-order self-regulatory processes, which, on the level of cognitive functioning, reflects the basic mechanisms (i.e., the logic or reason) of self-organization and, at the same time, constitute the most complex instruments for regulating the exchange with the environment (Piaget 1971). Cognitive functioning reflects reason in a double sense: it is the product of reason that is intrinsic to nature (i.e., in the logic of self-organization) and through cognitive functioning reason in nature becomes conscious of itself.

Piaget thus argues that cognitive processes are the outcome of and extend the processes of organic self-organization by using and adapting to new circumstances the different systems of organic self-regulation that can be found on the genetic, morphogenetic, physiological, and nervous levels. In support of this claim, Piaget describes many functional and structural analogies between cognitive and organic functioning. Central among these analogies is the triad of assimilation, accommodation, and scheme.

Assimilation, Accommodation, and Scheme

The complementary functions of assimilation and accommodation describe the general characteristics of the exchange between organism and environment. Assimilation is the aspect of an organism's activity wherein elements of the environment are integrated into the organism's preexisting organizational structures (i.e., the relations between elements). Accommodation, on the other hand, provides the material for the structuring activity of assimilation. Accommodation is the aspect of the activity wherein an organism's existing schemes are differentiated and modified in response to the environment. For example, a preexisting metabolic cycle assimilates particular nutrients by breaking them down into the elements that contribute to the continued functioning of the living system. The assimilatory cycle needs to be modified when the organism encounters a new nutrient (accommodation) (Piaget 1963). Assimilation and accommodation maintain the equilibrium between an organism and its environment.

Assimilation and accommodation at the psychological level extend the physiological interactions between the organism and the environment because their functioning no longer depends on the incorporation of material elements but now incorporates informational content. At the psychological level, schemes are structures composed of affect, sensation, motor movement, and perception. Assimilation refers to the incorporation of new information into already existing schemes, a process giving meaning to the content (Piaget 1963, 1985). For example, when a baby grasps a rattle, the rattle is assimilated to his or her grasping scheme and thereby attains the functional meaning of being "graspable." Assimilation always uses the existing psychological scheme; its functioning carries the history of the subject's interaction with the world into each particular act. For example, an infant who has differentiated various ways of interacting with the rattle will have different action potentialities available compared to an infant who has not.

Accommodation refers to the modification of existing schemes to account for particular features of the object or situation. Because schemes are structures with varying degrees of generality, applying them to particular situations always requires an adjustment or accommodation. Accommodation thus particularizes the general schemes, supplies them with specific content, and modifies them in doing so (e.g., the preexisting grasping scheme needs to be modified, becoming more specific to take into account the particular spatial position of the rattle).

Assimilation, accommodation, and scheme are inseparable. Assimilation is always a structuring activity because it involves integrating content into existing schemes; thus, structures do not exist independently of structuring activity: "Assimilation is hence the very functioning of the system of which organization is the structural aspect" (Piaget 1963, p. 410). At the same time, the incorporation of new elements leads to the modification of the scheme and thus to accommodation. Accommodation brings about adaptation to the environment, but this adaptation is always a function of the structuring activity of assimilation.

Operative and Figurative Aspects of Intelligence

Closely related to the concepts of assimilation and accommodation are Piaget's notions of *figurative* and *operative* aspects of intelligence. The figurative aspect of intelligence includes the functions of perception, imitation, imagery, and (in part) language that are supplied by the accommodatory aspect of activity. The figurative aspect provides signifiers, which, in turn, provide the data on which the structuring activity of assimilation acts. For example, an infant may perceive a rattle, and, assimilating it to an action scheme, she recognizes rattle as something that can be shaken (i.e., the sight of the rattle serves as a signifier of what can be done with it).

In contrast, the operative aspect of intelligence, common to both sensorimotor actions and higher-order cognitive functions, refers to the transforming and form-giving, or structuring, aspect of knowledge. The operative aspect of intelligence transforms subject–object relation by inserting the data provided by the figurative functions into increasingly complex structures. In other words, the operative activity of the human mind results in the construction of more and more complex relations (spatial, causal, logical, etc.) between person and world, and the figurative aspect is subordinated to the operative aspect. The operative aspect of intelligence, then, is central to understanding the kinds of qualitative changes that occur in Piaget's account of cognitive development.

Equilibration

At each point in development, children are in a state of equilibrium with the environment, characterized by a particular balance of assimilation and accommodation. Development is a process that leads to increasingly more stable (complete and consistent) forms of equilibrium. Piaget termed this process *equilibration* (see Piaget 1985). The theory of equilibration takes central place in Piaget's later work (see Müller et al. 2009), in which he focused in more detail on the specific processes involved in equilibration. Although Piaget identified several processes as playing an important role in the equilibration processes, such as dialectics, contradiction, affirmation, and negation, the generation of possibilities, and the process of becoming aware, his theory of equilibration remains unfinished. Here we focus on the role of reflecting abstraction in equilibration, as reflecting abstraction is central to the construction of more powerful knowledge structures (Piaget 1971, 1985).

Reflecting abstraction is an elaborative process by which children discover the structural aspects of their cognitive activity. For instance, putting marbles, one after the other, in a receptacle is an action with several structural aspects, one of which is based on the creation of a serial order and another on the creation of a set with a growing number of elements. By becoming aware of the relations between and coordination of their actions, children abstract structure (the coordinatory or operative aspect of actions) from content and, in turn, project this structure to a higher cognitive level.

The mechanism of reflecting abstraction then ensures that development has an intrinsic logic and proceeds by way of successively conceptualizing the structures or forms of knowledge underlying previous knowing levels. Thus, the forms of stage n become the contents of stage $n + 1$. With each new and higher stage, the forms become increasingly abstract.

Constructivism

Piaget described his epistemic position as constructivism, and he saw this position as an alternative to empiricism and nativism. According to Piaget, the central ideas of empiricism are that the function of cognitive processes is to copy reality as closely as possible and that the mind is largely passive in this process. Piaget argued that these empiricist assumptions are conceptually flawed and are not consistent with empirical findings (see Piaget 1972). The idea that knowledge consists of a copy of reality is flawed because there would be no way to evaluate the accuracy of such copies as they cannot be directly compared to reality itself. In contrast to empiricism, nativism does not argue that knowledge comes from the outside but is innately prepared and lies dormant to be triggered by environmental stimulation. Piaget argued that nativism was contradicted by empirical findings that showed knowledge develops gradually and goes through a number of stages (see below).

As an alternative these interpretations of knowledge, Piaget (1970, p. 104) proposed that “in order to know objects, the subject must act upon them, and therefore transform them.” Piaget’s constructivist view implies that knowledge does not preexist in the world to be imposed on the children, nor is it already innately preprepared in the child. Knowledge develops through the subject’s interactions with the world; it is in the course of these interactions that the child comes to better understand the world by coordinating her own actions (Piaget 1954).

In contrast to empiricism and nativism, Piaget conceives of the subject as always active, interacting with the world. Without an active subject, there would be no novelty. Furthermore, the activity of the subject is always bound to a structure. For this reason, reality cannot be copied but only assimilated to the subject’s particular structural framework.

Developmental Stages

In standard psychology textbooks, Piaget is typically portrayed as a stage theorist who claimed that stages are general structures that define a child’s behavior in each area of cognitive functioning and that age is a criterion for stage. Consequently, it is argued that Piaget’s theory is flawed because empirical evidence shows that at any point in development, children’s behavior is heterogeneous and not homogeneous (e.g., they may reason at a preoperational level in one conservation task and at a concrete operational level in another) and that particular stages emerge earlier than Piaget would predict.

This portrayal of Piaget’s stage theory is utterly incorrect (Chapman 1988; Smith 1993). Piaget did not claim that stages are characterized by homogeneity, and, in fact, Piaget often made the opposite point that variability should be expected (Chapman 1988). Furthermore, variability in children’s performance on structurally similar tasks is entirely consistent with the basis of Piaget’s grounding assumption that thought originates in action. Based on this assumption, cognitive structures should, at first, be context- and content-specific. That is, cognitive structures cannot be separated from their content, and although structures involving different content (e.g., number and volume) may be of the same logical form, they develop independently in a functional sense through the child’s activity with these different areas of content.

Some of the extensive previous learning research in science education that is derived from Piaget’s views has these same fundamental flaws of assumptions of stages being characterized by homogeneity. This is particularly the case for at least some of those studies that have generated data from simple paper and pencil tests that claim to locate students at some constant point in a sequence of stages of development.

Stages are also not defined in terms of age. Rather, they are defined in terms of the performance on particular tasks that Piaget analyzed in terms of the operations and structure they require. He acknowledged that the age of acquisition of operations is highly variable and influenced by the amount of cognitive stimulation. Furthermore, central to Piaget was not the age at which the stages emerge but the mechanisms involved in stage transitions. Each stage is a temporary equilibrium in the process of equilibration. Because the stages build on each other, they constitute an invariant sequence. We next briefly describe the main characteristics of each stage (see Chapman 1988; Müller et al. 2009).

Sensorimotor Stage. Piaget (1963) termed the developmental period during approximately the first 18 months of life sensorimotor intelligence. It plays a key role in bridging the gulf between the biological level of functioning and rational thought. Sensorimotor intelligence is a practical, embodied intelligence on the basis of which infants interact with the world through perception–action cycles. At the sensorimotor stage, meaning is originally embedded in unreflective activities; objects have a functional, practical meaning, they are things at hand, utensils for practical use or manipulation. Infants employ action schemes like sucking, pushing, hitting, and grasping to explore and manipulate the world. At the outset, the newborn has no self-consciousness and no clear awareness of what effects she herself produces through actions on the world and what effects occur independently of her actions. By coordinating her actions and applying them in the social domain (imitation), the infant gradually learns to distinguish between self, other persons, and world. Piaget traced the process of differentiation and coordination of action schemes through several sensorimotor substages. For example, toward the end of the first year of life, infants construct hierarchical relations between actions by subordinating one action as a means (e.g., removing an obstacle) to another action as an end (e.g., grasping the rattle). The coordination and differentiation between actions results in the construction of increasingly complex relations between objects as reflected in the development of such basic categories as space, time, causality, and object (Piaget 1954). For example, in order to remove a cushion that is placed in front of an object, the child must realize for herself that the cushion, in fact, is placed in front of the object (space), that she must remove it before grasping the object (temporal series), that the object behind the cushion still exists (object-permanence), and that in order to remove the cushion, she must grasp it (spatialized and objectified causality).

The sensorimotor period ends with the emergence of symbol representations, which allow infants to transcend the immediate here-and-now. At the completion of the sensorimotor stage, for the infant, his own action is no longer the whole of reality and instead now becomes "one object among others in a space containing them all; and actions are related together through being coordinated by a subject who begins to be aware of himself as the source of actions" (Piaget 1972, pp. 21–22).

Preoperational Stage. The emergence of the symbolic or, as Piaget also termed it, semiotic function marks the onset of the preoperational stage, which extends from about 2 to about 7 years. The semiotic function underlies children's abilities to engage in a number of different activities, such as deferred imitation (i.e., imitation in the absence of the model), pretend play, drawing, psychological functions based on mental images (e.g., recall memory), and language. These activities are practiced and refined during the first substage of this stage, the level of preconceptual thought (approximately 2–4 years of age). At the same time, preoperational thought is characterized by profound cognitive limitations. For example, although preconceptual thought is no longer tied to particular objects or events (the here-and-now), it fails to distinguish between individual members of a concept and the generality of a concept. To illustrate, when Piaget's daughter Jacqueline was 31 months old, she cried upon seeing a slug, "There it is!" When she saw another slug a few yards further she said, "There's the slug again." Concepts thus remain midway between the generality of the concept and the individuality of elements composing it. On the one hand, there is no concept of a general class; on the other hand, particular objects have less individuality and easily lose their identity.

At the second substage of preoperational thought – termed *intuitive thought* – symbolic representational schemes become increasingly coordinated, and children become capable of relating two such schemes to each other by means of unidirectional logical relation. For example, in comparing the liquid in two differently shaped containers, children may use height in order to infer the amount of liquid, but ignore the width of the container. Intuitive thought thus remains centered on one dimension (e.g., height) and fails to establish bidirectional relations between dimensions.

Concrete Operational Stage. During the concrete operational stage, which emerges around 6–7 years, operations (i.e., internalized actions such as putting like objects together, putting objects in one-to-one correspondence) become coordinated and integrated into logical systems. As a result, children no longer center on one aspect of a situation, and they can mentally reverse transformations that have occurred in reality. The coordination of operations into systems also leads to the emergence of logical necessity.

Piaget devised a variety of conservation tasks to assess concrete operational thought. Conservation refers to the understanding that a whole exists as a *quantitative* invariant and therefore remains intact despite the rearrangement of its parts. For example, the number of objects in a set does not change by rearranging them (e.g., spreading them out). To understand that the quantity has not changed, children need to coordinate transformations in two dimensions (density of objects, length of row of objects). An operative understanding of conservation is logical in nature; it is not given by empirical observation of transformations.

Another concept that children understand at the concrete operational level is class inclusion. A typical class inclusion task requires children to compare the number of objects in the including or superordinate class with the number of objects in the most numerous of two of its subclasses. For example, given 12 daisies and 4 roses, children are asked, “Are there more daisies or more flowers?” A correct answer requires that children conserve the including class (B) while making the quantitative comparison between it and the included class (A). Although this may sound simple enough, such a comparison actually involves a multistep process in which children must not only be able to construct the including class, but also be able to reverse this operation by properly decomposing it. The first step involves being able to combine two subclasses to form a superordinate class, or A (daisies) + A’ (roses) = B (flowers). The second step involves performing the inverse (negative) operation associated with this combination of subclasses. This entails subtracting each subclass from the superordinate class such that A = B − A’ and A’ = B − A. The inverse operation, thus, implies that children construct each subclass through negation under the including class. Piaget termed this type of negation *partial* because it is applied to a part of a larger whole. Through partial negation children realize that the subclass A is an autonomous whole, which enables them to recognize that there are some B’s that are not A’s (e.g., there are some flowers that are not daisies) and that, therefore, there are more B’s than A’s.

Formal Operational Stage. The last stage of cognitive development described by Piaget emerges during adolescence. Piaget and his collaborator Bärbel Inhelder studied formal operations by presenting children and adolescents with concrete material (e.g., different weights, strings of different length) to be manipulated in order to discover scientific laws or the cause of a result from several possible factors (e.g., which factor – weight, length of string, height of dropping point, force of push – determines the frequency of the pendulum’s oscillation). These studies revealed that children approached scientific problems in a qualitatively different way than adolescents. Although children were capable of classifying and cross-classifying the independent variables, of properly ordering magnitudes of the independent variable along one dimension, and of putting these seriations into correspondence with their effects on the dependent variable, they failed to separate the involved variables by varying only one variable and holding all others constant. As a result, these children did not supply adequate proof for their statements. By contrast, from the outset, adolescents formulated hypotheses and derived conclusions from these hypotheses. They then proceeded to test these hypotheses by systematically controlling all variables except the one under investigation. Thanks to their systematic experimental approach, adolescents excluded hypotheses that were contradicted by observations and converged on the hypothesis that was actually true.

For Piaget, the difference between children's and adolescents' approaches to these problems suggested the reversal of the direction between reality and possibility: whereas in the concrete operational stage, possibility remains an extension of reality; in the formal operational stage, reality is subordinated to possibility. Adolescents are capable of thinking hypothetico-deductively by drawing necessary conclusions from truths that are considered merely possible.

Consciousness

The notions of assimilation, meaning, and consciousness are closely interrelated in Piaget's theory. At the psychological level, the structuring activity of assimilation comprises a need and is directed toward specific goals. It refers to particular elements or objects toward which human activity is directed and confers meaning on these elements. Assimilation thus captures the intentional nature of human consciousness that has been highlighted by continental European philosophers (Brentano, Husserl).

Consciousness is a system of meanings that are related to each other by implication. For example, the action of pulling a blanket upon which a rattle is placed in order to grasp the rattle shows that the infant understands that the spatial relation "placed upon" implies that the rattle is drawn along, especially if the infant does not pull on the blanket when the rattle is placed next to it. Logical necessity ("if $2 + 4 = 6$, then $6 - 2$ must be 4") and moral obligation ("I ought to") present other, more advanced cases of meaning implication. Meaning implications cannot be reduced to cause-effect relations (the truth of $2 + 4 = 6$ is not the cause of the truth of $4 - 2 = 2$ in the same way that hitting the patella is the cause of the knee jerk reflex).

Piaget's way of conceptualizing consciousness has two important consequences. First, the notion of causality does not apply to states of consciousness, not even at the level of sensorimotor intelligence, because causality is based on an external (independent) relation between cause and effect. Accordingly, neurophysiological approaches to sensorimotor intelligence remain incomplete because they fail to capture the intrinsic connection and the meaning-conferring, implicatory function of the structuring activity of assimilation. Second, it is easier to see how logical necessity can develop out of implications than how it can possibly emerge out of cause–effect (e.g., stimulus–response) relations.

How did Piaget conceive of the relation between consciousness and physiological processes? Piaget proposed that every psychological phenomenon has a physiological concomitant and that there is no causal connection between psychological and physiological phenomena (psycho-physiological parallelism). States of consciousness cannot provide a causal explanation of physiological processes and vice versa. Rather, Piaget thought that the structures of consciousness and physiological processes are isomorphic to each other, which amounts to an isomorphism between a system of implication and a causal system. At the same time, consciousness is not just an epiphenomenon because it adds value and understanding to organic and physiological processes.

Semiotic Function

Piaget held that consciousness is always based on signs or better signifiers. Signifiers are items that convey meaning. At the sensorimotor level, signifiers are not yet differentiated from their referent (signifieds). Signifiers at this level are termed *indications*. An indication is an "objective aspect of external reality" (Piaget 1963, p. 193), "a perceptible fact which announces the presence of an object or the imminence of an event (the door which opens and announces a person)" (Piaget 1963, pp. 191–192). Signifiers at this level are sensorimotor schemes that confer meaning on the elements interacted with.

At the end of the sensorimotor stage, the coordination and differentiation of schemes culminates in the emergence of signifiers that are differentiated from their signifieds. Piaget termed a system of such signifiers the *semiotic function*.

The semiotic function subsumes both symbols and signs. Piaget defined symbols such as mental images as signifiers that resemble the things signified, and signs, such as words, as arbitrary and conventional signifiers. The semiotic function makes it possible for children to form mental representations and to think about absent objects as well as past, future, and even fictitious events. It also increases the speed of processing because it makes it possible to imagine at the same time the successive phases of an action. Finally, it opens up the possibility of reflecting on and understanding the reasons why some actions are successful and others not (Piaget 1954).

During the preoperational period, children use symbols, among others, in symbolic play (e.g., a toy cup stands for a real cup), deferred imitation (e.g., imitating an action of an absent model), and drawing. Piaget believed that particularly young children need to rely on the use of individualized and personal systems of symbols. This is because personal symbols make fewer processing demands than language which is based on collective and arbitrary signs. Piaget recognized that language is essential to socialization, which, in turn, modifies action and behavior. Verbal exchange between individuals allows children to share ideas, and the resulting "collective concepts" reinforce individual thinking (Piaget 1995). Being more mobile than symbols, language also makes a unique contribution to the mobility of thought.

At the same time, neither language nor symbols are the source of the forms of thought found at the concrete and formal operational stages. According to Piaget, these forms of thought are grounded in the practical coordination of actions (e.g., grouping objects, seriating objects) at the sensorimotor stage. The semiotic function, and particularly language, is necessary for the interiorization of actions (i.e., without the semiotic function, operations would have to be executed as successive actions and could not be condensed into a simultaneous whole), but it is not sufficient to explain logical thought. In sum, Piaget considered the semiotic function only a tool used by and dependent on the operative aspect of intelligence.

Affectivity

Piaget believed that all behaviors involve an affective aspect and a cognitive aspect. The affective aspect is responsible for motivating the organism's interaction with the environment by assigning a value or goal to the behavior. However, achieving a particular end can involve a number of different paths. It is the cognitive aspect of behavior that structures such paths and thus the relation between the individual and the environment. In other words, affect provides the values and ends for actions, whereas cognitive functions are the means for achieving the ends.

To illustrate that any intelligent act contains both affective and cognitive contributions, take the following sensorimotor action: a child reaches for a toy by pulling on the blanket under the toy. This act has an affective component. In fact, two types of affectivity are involved in this act: synchronic affectivity (in the moment) and diachronic affectivity (over time). First, the child evaluates his current actions with feelings of success and failure (synchronic affectivity), and second, the child's evaluations of the situation involve a system of values that he has developed over time, engaging his interest in obtaining the toy (diachronic affectivity). These affective components regulate the cognitive component of the act that facilitated obtaining the object by pulling on the blanket. Thus, affect provides direction for intelligence, first by regulating interest and effort and second by assigning value to solutions sought. As such, for Piaget, affect and intelligence are inseparable, and Piaget often underscored the role of affectivity in intellectual growth.

Social Interaction

Piaget is often accused of failing to address the role of social interaction in development. This, however, is not the case (see Piaget 1995). Piaget was by no means oblivious to the role of the social in development, as attested by, for example, his statement that "human intelligence is subject to the action of social life at all levels of development from the first to the last day of life"

(Piaget 1995, p. 278). In his work Piaget struggled with the fundamental epistemological question: "Is it the individual as such or is it the social group that constitutes the motor or, if you prefer, the 'context' of intellectual evolution?" (Piaget 1995, p. 215). Piaget contrasts his own solution to this question with theoretical positions which suggest that rationality is derived either from the individual or the collective. By reducing the social to the aggregation of ready-made individual consciousnesses, individualism provides an atomistic explanation of the social and rationality. Collectivism, on the other hand, considers the social as a whole that cannot be derived from an additive composition of individuals. Rather, the collective whole is characterized by emergent novel properties and structures, and it modifies its members (i.e., individual persons, see Piaget 1995).

Piaget criticized both individualism and collectivism and proposed an interactive relational position as an alternative explanation of the role of social interaction in intellectual development. According to the interactive relational position, "there are neither individuals as such nor society as such. There are just interindividual relations" (Piaget 1995, p. 210). These relations between individuals are primary and "constantly modify individual consciousnesses themselves" (Piaget 1995, p. 136). The interactive relational point of view leads to a more fine-grained analysis of specific social relationships and their implications for development. Piaget describes two extreme types of social interaction: constraint and cooperation. Constraint involves the imposition of authority and group traditions on the individual; constraint does not promote cognitive and moral development. In cooperative interactions, relations are based on reciprocity and equality; cooperation promotes cognitive and moral development.

The upshot of the interactive relational view is that because the individuals must coordinate their actions vis-a-vis the world, "[i]ndividual operations and cooperations form one inseparable whole in such a way that the laws of the general coordination actions are, in their functional nucleus, common to inter- and intraindividual actions and operations" (Piaget 1971, p. 98). Individual operations and cooperations are subject to the same kind of combinations and transformations as actions and operations, thus the question of whether rationality is essentially social or individual becomes mute: "To wonder whether it is intrapersonal operations that engender interpersonal co-operations or vice versa is analogous to wondering what came first, the chicken or the egg . . . The internal operations of the individual and the interpersonal coordination of points of view constitute a single and the same reality, at once intellectual and social" (Piaget 1995, pp. 294, 307).

Conclusion

Piaget's theory is an astounding one in terms of both scope and depth. Piaget's theory addresses several fundamental epistemological questions such as the relations between biology and cognition, cognition and affect, the social and the individual, and nature and nurture. Piaget presents a systematic theory of the process of signification, the structure of consciousness, the role of action, and the experience in development. In these respects, Piaget's theory is still unparalleled.

Planetaria

Anthony Lelliott
Marang Centre for Maths and Science Education,
University of the Witwatersrand, Johannesburg,
South Africa

A planetarium (or planetaria in the plural form) is a form of purpose-built auditorium for displaying a presentation about the night sky and astronomy. The term was formerly used for devices that demonstrated the movements of the planets and Moon and, in pre-Copernican times, the Sun. Today, these devices would be referred to as orreries, after the Earl of Orrery who had one built for him in the eighteenth century. Modern planetaria date from the development of projectors, whereby the stars and planets are projected on to the inside of a domed roof. Developments throughout the twentieth century resulted in progressively sophisticated devices, most of which were projectors situated in the center of the auditorium, displaying stars and planets on the domed roof. By the 1980s, computerized projectors were being developed, and the current generation of digital projectors (including 3D) is able to handle not only astronomy visualizations as seen from Earth but also other contents such as flybys to other stars and the cosmology of black holes, as well as phenomena at the micro- and nanoscales. According to the World Planetaria database (www.aplf-planetariums.org), there are over 2,200 planetaria in use worldwide, of which 138 have sizable domes of 20 m or more. In 2012 it was estimated that nearly 115,000 people visit planetaria annually worldwide.

Learning in Planetaria

There is a long history of learning in planetaria, as they were developed for both educational and entertainment purposes. The main advantage of the planetarium is its dome, which represents the night sky in a three-dimensional manner together with an omnidirectional perspective, neither of which is possible to visualize on two-dimensional textbooks, chalk boards, or screens. Sky phenomena can be observed either in real time or, more commonly, by compressing time such that cycles are evident as being periodic (e.g., the phases of the Moon). Further advantages include the absence of light pollution and the addition of various audiovisual effects which enhance the realism and enjoyment of the show. Planetarium software is also available for computers as well as applications for mobile devices so that they can be pointed at the sky to identify visible objects.

The educational value of planetaria, which became very popular during the 1960s space race, has long been espoused, but there is relatively little research which shows their value. Smith (1974) found that although the majority of early research studies into the use of planetaria were of a descriptive nature and were not rigorous, it was useful for the development of the field due to its novelty. Later studies of an experimental, comparative nature had conflicting results, with some finding that planetaria enhanced learning and others refuting this. Other research was more focused on the curriculum, assisting schools to develop their earth science and astronomy curricula more effectively. Nearly 20 years later Riordan (1991) suggested that there was still no consensus that the educational use of planetaria was effective. However, a recent paper by Brazell and Espinoza (2009) describes a meta-analysis of 19 experimental, comparative studies carried out between 1966 and 2007 which provided sufficient statistics to calculate effect sizes. Their conclusion is that "the planetarium has been an effective astronomical teaching tool," which is good news for planetarium educators. An area which appears not to have been studied to any great extent is the effect of planetaria on people's attitudes towards science or astronomy. This is important, as people's affective domain is thought to be influenced by visits to other informal learning sites such as aquaria, zoos, and science centers.

In summary, planetaria have had a substantial history over the past century as entertainment and educational institutions that can effectively communicate science content about astronomy. As the technological devices they have access to become more sophisticated, their appeal is likely to become greater, allowing them to branch out into areas of scientific phenomena which can be visualized by such digital media.

Pluralism

Cathy Loving[1] and Mychelle Smith[2]
[1]Department of Teaching, Learning and Culture, Texas A&M University, Texas, USA
[2]Texas A&M University, Texas, USA

Two distinct types of pluralism exist in science education: methodological and philosophical. Methodological pluralism involves the premise that multiple methods of scientific research exist due to the fact that choices must be made depending on the nature of the research and the phenomena being studied. In this belief, there is no one method for all of science; therefore, a plurality of methodologies can exist. The different fields of study under the science umbrella allow for easier understanding of the existence of multiple methods for studying science. Philosophical pluralism, however, takes the idea of plurality to an abstract level in which humans' understanding of reality and truth creates multiple explanations of the phenomena of life. These explanations are influenced by cultural and historical context. In philosophical pluralism, subjectivity can never be fully removed; therefore, multiple truths, realities, and ideas coexist. Early pluralism debates were focused on the unity of science thesis, which included uniting all the sciences under one label to describe a general *science*. Pluralists view science as having distinct separations with multiple methodologies, investigations, and theories. Current pluralism discussions involve debates within particular sciences to debates about metascience concepts to discussion about how philosophy, history, and sociological accounts of science relate to one another. In the current educational climate, there is an appreciation and need for interdisciplinary approaches in science. When using the term *pluralism*, the distinction must be made between plurality in science and pluralism about the sciences. Plurality is a "feature of the present state of inquiry in a number of areas of scientific research," whereas pluralism is "a view about the state of affairs" (Kellert et al. 2006, p. ix). Understanding must also be established between monism and pluralism. Monism is the aim of science to discover one single explanation for the natural world and all principles and methods of inquiry can relate back to that one single explanation. Pluralism holds the belief that there is no one right explanation to fully explain the natural world.

Not all pluralists fit into the same category. The plurality spectrum ranges from modest to radical pluralists. Modest pluralists "tolerate a plurality of theories because it is difficult to predict which research program (or preliminary theory) will lead to a theory that provides a complete account of the phenomena" (Kellert et al. 2006, p. xii). Radical pluralists, more specifically constructivists, believe in an indefinite number of theories, which are only limited by human resourcefulness (Kellert et al. 2006, p. xiii). An additional division within pluralism is the battling ideas of competitive and compatible pluralism. In competitive pluralism, scientists test hypotheses in order to find the one correct theory. Competitive pluralists acknowledge the existence of multiple hypotheses, yet in this view, there is one theory that will represent the best answer and all other theories will be considered erroneous. In compatible pluralism, the scientific theories can coexist, meaning that multiple explanations could exist for one phenomenon. Compatible pluralists understand that hypotheses are not mutually exclusive.

Many opponents of pluralism wonder, if we are explaining *one* world, why are there multiple models, theories, and hypotheses? Some scientists may view the existence of multiple hypotheses as a sign of error. "The diversity of views found in contemporary science is not an embarrassment or sign of failure, but rather the product of scientists doing what they must do to produce effective science" (Mitchell 2002, p. 55). Science by nature is experimental. The idea of pluralism represents multiple ways in which scientists conduct, learn, teach, and understand science.

Scientific pluralism can be seen in curriculum debates, teaching methodologies, and teacher beliefs about the subject matter. Understanding the possibilities of multiple methods, beliefs, and ideas about science can aid teachers in preparing students for success in a pluralistic world. Just as bears do not exist in one environmental scene in the wild, students do not learn only in the engineered and standardized classrooms. Learning takes place in a plurality of locations and environments. "The landscapes of pluralism should be the main focus of a science education centered on preparing students to make informed choices and fully participate in society in ways that are reflective, reliant, and reciprocal of Earth's many natural environments that sustain life itself" (Mueller and Bentley 2007, p. 332). Science education must not only come from one source – the textbook – but also be studied in relation to students' lives. Pluralism represents so much more than ideas and methodologies; pluralism involves cultures and diversified ways in which humans live and experience their lives through multiple realities. These multiple realities lead to multiple understandings.

Colonialism; Neocolonialism

Postcolonialism

Postcolonialism is a term that is used to help describe how institutions of the dominant cultures of the world in the global north work to devalue and ignore the self-knowledge of cultures of the global south. This self-perpetuating pattern of inequality and privilege is challenged in postcolonial frameworks where it is understood that “Knowledge is inherently questionable, and when the institutions of . . . science are working well, it is persistently questioned. It is the foreclosing of questions, and thus the end of the learning process, that defines the moment when science turns into ideology and its ideas become state, corporate or institutional dogmas” (Connell 2007, p. 228). Postcolonialism is about being prepared to engage in the unlearning of privilege.

Being privileged concerns how the institutions of the global north (the minority world) claim the right to name the world on behalf of the global south (the majority world), to build theories using economic and political power and control “on the experience of the most privileged 600 million people, then assume it accounts for the whole 6,000 million who are actually in the world” (Connell 2007, p. 212). To name the world in your own language is to understand and describe it a particular way and thus have control over it.

Postcolonialism is a perspective from which to question and critique, challenge, and transform the processes of colonialism and neo-colonialism. The issues addressed include who is permitted to speak, under what conditions and for what political purpose, and how knowledge is constructed and translated within and between various cultures existing within asymmetrical relations of power. Postcolonial theory, in its many varieties, seeks to create strategies for other ways of describing the nature of the world and to rethink what counts as knowledge in a context of respect for all intellectual traditions.

The Processes of Inscribing Privilege on the World

A postcolonial perspective involves a study of the historical processes by which power is disseminated and maintained. This perspective allows us to examine the grand narratives of colonialism/imperialism with their agendas of expansion, progress, and enlightenment: colonizing nations deliberately and systematically renamed, devalued, ignored, and silenced knowledge systems of the cultures they colonized.

For the black peoples, there is only one destiny, and this destiny is to be white (Fanon 1952). Fanon argued that white colonial cultures equated blackness with inferiority and impurity which then shaped the self-view of those who were subject to imperial authority: the black person’s soul is a white person’s artifact – to be black is to be the creation of patterns of fundamentally racist European thought.

There are two indivisible foundations of imperial authority – knowledge and power (Said 1978). The most formidable ally of economic and political control, Said argues, has long been the business of “knowing” other people because this “knowing” (in the sense of constructing them) underpinned imperial dominance and became the mode by which they were increasingly persuaded to know themselves – as subordinate to Europe. In a recent edition of *Orientalism*, Said points out that imperial narratives have had little trouble reinventing themselves in the political and economic context of globalization with its transnational corporate organizations embedded in an ideology of neo-colonialism (Said 2003).

Promoting corporate capitalism, this ideology supports economically devastating, culturally homogenizing, and ecologically destructive activities in vulnerable communities. Implementing planned policy imperatives of industrial nations of the north to maintain their influence in countries of the south, neo-colonialism is a continuation of the past practices. Supported by digital communication technologies purporting to be politically and ideologically neutral, neoliberal globalization policies spread via the Internet are examples of unequal exchanges that rely upon assumptions of cultural equity.

Education, like other commodities, is imported from the north to the south in the market-driven global economy, and this involves the imposition of northern administrative models and curriculum and assessment patterns for schools, foreign “experts” to ensure correct implementation, and a reliance on expatriate teachers, particularly at secondary and tertiary level. Indigenous education patterns are destroyed as “institutions like schools, universities and governments, through their assimilation regimes of standardisation and power laden rituals of credential granting, have proven remarkably good at epistemological homogenisation and the creation of a global monoculture” (Gruenewald and Smith 2008, p. 140).

The “Northernness” of Science: Describing Privilege

In her critique of northern science from a postcolonial standpoint, Sandra Harding argues that the term “science” is embedded in a positivist epistemological framework and is usually understood to refer only to the production of knowledge in the global north. This understanding promotes a belief of supposed objective methods used to construct supposed value neutral knowledge. Northern science is promoted as being culture free, and repeated claims are made regarding privileged notions of universal relevance. That is, northern science considers itself to represent universal knowledge and a coherent and unified representation of nature’s order (Harding 2006).

From a postcolonial perspective, universality is about epistemological disenfranchisement involving a process of selection and erasure, dispossession, and exclusion. This cultural hegemony is based on a myth that nature is knowable in the same way and from the same point of view, ignoring powerful connections between politics, economics, culture, and pedagogy. What is at issue is that it does not seem to occur to the north to doubt the universality of its own science, based on an assumption that cultural and epistemological hegemony does not matter (Harding 2006).

Writing from an African experience, Paulin Hountondji (Connell 2007) describes how, since colonial times, while scientific data is gathered and applied in the colonies, the theorizing happens in the global north. The resultant theory is distributed through a global network of institutions from the World Bank down, including universities, scientific organizations, journals, and the juggernaut of international foreign aid.

From a self-appointed position of privilege, the north argues that other knowledge systems do not deserve the name “science” because of their cultural elements, and they cannot be integrated into a harmonious or unified relation with northern science (Harding 2006). It is not unusual to find indigenous knowledge systems described as being nothing more than irrational, anthropocentric, and primitive thought of the other that is “intellectually discredited, dropped from curricula of schools and universities, or ripped off by corporations pursuing intellectual property rights” (Connell 2007, p. xi).

Questioning Northern Privilege

When the north does acknowledge indigenous knowledge systems, it is on the north’s terms. Paulin Hountondji insists that ethnoscience (the academic discipline that tries to reconstruct non-western cultures’ views about the natural world) represents a European gaze on indigenous knowledge. He argues that it is necessary to be concerned with the relevance, value, and local meaning of indigenous knowledge and the reasons why it is bound up with the so-called myth and magic (Connell 2007).

It can be argued that knowledge is not a matter of correctly representing the world (Rorty 1979). Rorty suggests that knowledge is not so much a way of mirroring nature as a matter of conversation and social practice. When we decide what counts as knowledge, our judgment rests not on how strongly a “fact” correlates to the world so much as whether it is something that society “lets us say.” What we can and cannot count as knowledge is therefore limited by the social contexts that we live in, by our histories, and by what those around us will allow us to claim.

Similarly Sandra Harding argues that the distinctive social and political history of the development of modern sciences is not external to the content of these sciences – “the very best supported scientific claims and practices, no less than false beliefs, are caused by social relations as well as by nature's regularities and the exercise of human reason. . . permeated by historically and culturally local values, interests, discourses and choices about how to organise the production of scientific knowledge. . . which aspects of nature modern sciences describe and explain, and how they are described and explained have been selected by conscious purpose and unconscious interests. . ." (Harding 2006, p. 43). Therefore, there is no sense of absolute rightness or wrongness to be discovered. The sciences we have are not inevitable; they are currently agreed upon fictions that are open to transformation. Transformations that will help us take into account the cultural elements that limit our understanding of the world.

Liminal Spaces and Unlearning Privilege

The notion of a liminal space, a space of possibility, comes from the word *limen* meaning the threshold, any place or point of entering or beginning. Liminal spaces are rich in reflexive potential. Reflexivity, like epistemology, does not address what we know but how we think we know. It is a process of arousing our self-awareness and, from a postcolonial perspective, we must inevitably confront our own processes of interpretation. It can be a space of risk as we engage with new possibilities in relationship with others.

Liminal spaces are not about bringing together or reinscribing the old hegemonies, rather they are about an opening up between and around each other. Working at the very frontiers of our intellectual selves and our understandings, we make visible our most cherished values, not to find a common meaning but to find a means of communication where the greatest differences can be expressed simultaneously.

At an epistemological level, we embrace empathetic practices of entering the imagination of others and learn to hear different voices. We must relinquish our privilege and dominant ways of knowing and learn to understand what it might be like to experience and see the world as others see it. It requires a language for describing frailty, humility, uncertainty, paradox, and contradiction.

Postcolonial Places in Science Education

Educators must interrogate how centers of power and privilege are implicated in their own politics and articulate the situated nature of their own personal beliefs, based on an understanding of the limits, partiality, and particularity of their own politics, values, and pedagogy (Giroux 1993). Educators must possess a theoretical understanding, beyond the positivist approaches to teaching supported by current neoliberal curriculum, to identify the ways in which difference is constructed through various representations and practices that name, legitimate, marginalize, and exclude the voices of subordinate groups.

A postcolonial pedagogy of place is an attempt to create something new from the liminal spaces of between. Our relationship to place is constituted in alternative stories as the primary unit of knowledge, and these stories shape our relationship with different places (Somerville et al. 2009). Pedagogies of place are local and embodied, challenging the objectifying strategies of "science" that separate us from our connections and relationships with the natural world. They critique decontextualized content approaches that fail to interrogate the conceptual frameworks and practices of Eurocentric philosophies and how these sciences have guided and made them appear not only reasonable but also the only such reasonable kinds of science (Harding 2006).

Pedagogies of place make explicit the philosophical, sociological, and historical assumptions that form part of scientific understanding about nature. Learning occurs where subjugated knowledges and northern science knowledge make contact. Every time we make a representation in our places, it is understood to exist besides a proliferation of other representations. Postcolonial "place making comes to be understood in terms of creating the conditions of meeting rather than the provision of a theoretical backdrop to prescribed social activity" (Carter 2009, p. 25).

Postmodernism in Science Education

Wolff-Michael Roth
Applied Cognitive Science, University of Victoria, Victoria, BC, Canada

Keywords

Postmodernity

Postmodernism possibly is the most misunderstood and most widely abused term that exists in our language. There are likely to be as many definitions of and opinions about postmodernism as there are people in a gathering. Given this wide variation, it is not surprising to see the concept itself being identified with confusion, fuzziness, and anything goes. Most fundamentally, as the name suggests, it is a reaction against modernism, itself associated with a set of ideas often denoted by the term metaphysics. The "post" in postmodernism is meant to mark the attempt to overcome modernism without retaining any of its forms of thought, which would be the case if postmodernism were merely a negation of modernism. At its heart, postmodernism is the attempt to think the flux of life, though this point gets often lost in the debate.

History of Modernism

In pre-Platonic Greek thought, the idea of life as a pervasive, never-ending (Heraclitean) flux was actively discussed. Thinking flux requires concepts that are very different from those that denote ideas, which have a thinglike character. With Plato, who shaped the dominant stream of Western philosophical thinking, the world accessible to human experience was but a shadow of another, non- and therefore metaphysical world. These ideas were said to determine human speech and behavior, which were merely an expression of underlying intentions. This form of thinking came to be formalized to its limit by the philosopher Immanuel Kant, who suggested that cause–effect thinking as a fundamental category of thought.

Cause–effect thinking underlies all technology and modern sciences; it also underlies almost all theories of human cognition. Given that postmodernist forms of thought question the very existence and usefulness of cause–effect thinking, it may not come as a surprise that there is actually very little work being done in science education related to postmodernism, which may be in part due to the antithetical nature of postmodernism, on the one hand, and science education practice and major theoretical approaches used in research, on the other hand. Karl Marx was one of the first to oppose such ideas, suggesting that the metaphysicians had everything confused, because it is not consciousness (and mind) that determines life but it is practical life that gives rise to human consciousness. It may not surprise either that scientists and engineers are vehemently opposed to postmodernism, even though they do not tend to understand very well what the term stands for.

Critique of Modernism

Friedrich Nietzsche was the first to launch a major attack on modernist thinking, providing detailed analysis of why cause–effect thinking is inherently false because, in the flux of life, causes cannot be determined until the effects are known. But because effects are not known until after the event has been finalized, causes can be determined only after the event and never before or during. He also showed that as soon as cause–effect thinking is abandoned, common notions of the agential subject have to fall, as well as common notion of objects as stable entities. Other ideas crumble, including those pertaining to the body/mind and mind/matter distinctions. What is gained are the continually unfolding life, language, and learning, that is, everything that is in process.

Seed of Postmodernism

Martin Heidegger pursues this kind of thought in his texts that are critical of technology, a fact often misunderstood to be an animosity toward the latter when in fact Heidegger's concern was with the underlying form of thinking merely epitomized in technology. He proposed difference in itself as a way of thinking being, which is inherently in flux. It is precisely these ideas about difference in itself that became to core of the philosophical developments that now are clustered together under the banner of postmodernism. Thus, for example, Gilles Deleuze takes up Nietzsche's agenda to theorize the flux of life in terms of repetition, which is never the same because that which is repeated already is different within itself. Jacques Derrida introduces concepts such as that of *writing*, which is based on the idea of writing on a magic pad, where new writing both erases what had been written on it before and keeps it simultaneously as a trace. As a result, as Jean-Luc Nancy suggests, no two persons are the same; there is only one aspect that everyone in a culture shares, which is that she/he is different from everyone else. The Russian (language) philosopher Mikhail Bakhtin, who has had some impact on science education, fundamentally takes the same position – even though precisely those ideas are yet to be taken up in science education.

Postmodernism in Science Education

If such ideas were taken up in science education, this would mean the abandonment of the agential subject, who constructs knowledge and identity; it would mean giving up the cherished notions of knowledge and knowledge structures that somehow can be accessed and assessed; and it would mean giving up issues such as the attribution of responsibility for what happens in the classroom to the sole person of the teacher. It would also mean giving up the belief that learning could be planned ahead of time and it would give up attributing agency to the teachers (or students) in the acquisition or construction of knowledge. To date, there possibly is only one real attempt to articulate the implications of such forms of thought in science education (Roth 2008). It shows that other cherished theories – e.g., agency/structure, border crossing, and third cultural space – are antithetical to this form of thought that has abandoned the centrality of cause–effect thinking. Taking up postmodernism also requires (re) thinking such issues as ethics, pertaining to the teaching–learning relations and to the relation between the products of science and technology and society.

Poststructuralism and Science Education

David Blades
University of Victoria, Victoria, BC, Canada

Keywords

Deconstruction; Poststructuralism; Signifiers; Structuralism

Poststructuralism is part of a larger cultural movement called "postmodernism," although poststructuralism is not synonymous with postmodernism. Structuralism first arose in cultural anthropology and quickly was adopted in other fields as researchers attempted to chart a middle ground approach to understanding human activity between the reductionism of natural science and the seeming subjectivity of phenomenology, existentialism, and psychoanalysis. Anthropologist Levi-Strauss and other structuralists, such as those in linguistics (Saussure), cognitive psychology (Piaget), and education (Bloom), approach all social systems as sets of regularities that an objective, ideologically neutral approach can discover and articulate. Structuralism further maintains that understanding these practices is possible if one assumes that the meaning of these practices exists entirely within the social structures under study and thus can only be approached as part of the patterns and relationships that form the systems. Within each pattern, structuralists argue, exist abstract "rules" of behavior that can be discovered and articulated, called "codes" and categories, or "signs" that form the constitutive elements of the system.

Structuralist approaches pervade modern educational systems in such areas as curriculum development, cognitive psychology, and planning lessons using taxonomies of educational objectives (Cherryholmes 1988). Teachers and students are assumed to exist as signs of relationships; for example, teachers "implement" the curriculum and students learn what is taught. Certain forms of knowledge, such as science, are considered to be legitimate "subjects" of the school curriculum and are standardized and constructed as a series of steps all children, more or less, can take to achieve a supposed understanding of concepts, whether in science or in any school subject. The meaning of this system exists within itself; for example, "doing an experiment" in science education holds meaning for the students, teachers, and the designers of the experiment, and structuralist approaches to science education assume that this meaning can be used to make revisions to the experiment as a learning activity. What is assumed is that all signifiers such as "teacher" or "student" or "experiment" embody standard meanings.

A central tenant of structuralism is that the truth about systems can only be discovered from within the system itself. Poststructuralism began as some philosophers argued that this claim is paradoxical since anyone approaching a system outside that system must, from a structuralist perspective, be part of their system and thus invariably bound up in the meanings they bring to their analyses. The structuralist assumption is thus self-defeating since one can never discover an "objective" meaning within any system other than one's own, and even this assumption is suspect since the structures we see may not be the structures seen by others; constructivist research in science education demonstrates this point very well. Individual variability in the experience of reality is further compounded by the lack of reliable representation of the signs in a system. Rather than a direct relationship between a sign and what it signifies, poststructuralism observes that the signs are defined through reference to other signs, creating what philosopher Jacques Derrida described as an endless chain of deferred meaning. From this point of view, there is never any clear, unequivocal meaning in any system, and the structures that exist to make up the system – even the idea of the system itself – are historically and politically constituted, mobile, and therefore not part of any particularly objective reality. What passes then as "knowledge" or "truth" operates to maintain and provide impetus for particular relationships that in themselves are not true or even knowledge in any transcendent, universal sense (Foucault 1980). For example, structuralists might point to the signifier "science student" and then, assuming that this category exists, talk about types of science students, even proposing a categorization of these students. Poststructuralists are deeply suspicious of such categorization because it first depends on assuming a transcendent, objective meaning to the signifier "science student." But what is assumed here in this combination? Does being a science student assume a concomitant relationship with a teacher? Is someone exploring the algae in a local pond by dipping a stick into the water "doing science" or is science only learned in the context of students/teachers/schools? We might assume the signifier "science education" is school-based, but why do we move to this assumption? Is the meaning of science education ever fixed? If not, and poststructuralists argue this position, poststructuralism presents a series of challenges to what operates under the sign of "school science education."

Three Poststructural Challenges to Science Education

Poststructuralism is skeptical of any approach that considers school science a system that can be articulated and analyzed for curriculum development and change (Blades 1997). There is, from a poststructural perspective, no "truth" about science education, or anything for that matter, that might direct change. Second, poststructuralism challenges and undermines notions of progress and positive growth in knowledge, even though this assumption underpins the entire history of science as presented in school science education. For example, why does school science education assume the development of atomic theory was a type of "progress"? We might counter by suggesting that such knowledge has assisted in the development of chemistry, medicine, etc., which in fact defers the response to another set of signifiers (such as "medicine") but does not really answer the question. From a structuralist view, the question seems absurd; of course it is "better" to have more information about the natural world. The poststructuralist challenge is to define "better" and even to challenge the fundamental notion of knowledge itself. This third challenge strikes at the very raison d'etre of science education since poststructuralism also deconstructs the very notion of science as an objective study of nature (Weaver et al. 2001). Poststructuralism advanced the now common argument that observation is never a culturally neutral act but instead situated in the flow of historical and political antecedents and current discourses, a point well established by historian of science Thomas Kuhn. In this way, poststructuralism challenges that what is produced by "modern science" as "knowledge of the world" – instead, poststructuralists note that other ways of seeing and understanding the world exist. For example, a wolf might be *Canis lupus* from the perspective of modern scientific taxonomy, but what is categorized as a "wolf" in this schema might in some Aboriginal cultures instead be considered a reincarnated ancestor. Science might argue that this moves knowledge into superstition, but poststructuralist thought challenges such simple dichotomies as "science" and "superstition." Poststructuralism does not play favorites: the knowledge produced, shared, and passed along in Aboriginal cultures is also subject to poststructural critique – all signs presented as "knowledge" falls under the gaze of poststructural deconstruction, including acknowledging the irony of its own sign as "post"structuralism.

The End of Poststructuralism

Poststructuralism undermines through relentless questioning the fundamental assumptions that support and maintain what we call "science education" by denying any transcendent meaning of this term for all and any participants in the discourses indicated by this signifier. This presents a serious challenge to all approaches to institutionalized schooling and curriculum change in science education. Even more difficult is the deconstruction of knowledge claims of modern science as truth about how the world was, is, and could be, presenting questions about the very foundational premise of science education.

While this relentless questioning can be useful as a kind of cultural mirror, we are left with a serious and urgent challenge: How can we establish a sense of ethics and understanding, albeit always tentative, of ourselves with/in the universe? Poststructuralism has no response to this essential and important question, suggesting only a somewhat nihilistic elusiveness to all meaning. While poststructuralism may thus contribute to an increased humility and a return to admissions of tentativeness in science theorizing, humankind will need to turn from the relentless yet barren critiques of poststructuralism to discover possibilities for a hopeful science education.

Practical Work

John Wallace
OISE, University of Toronto, Toronto,
ON, Canada

Keywords

Apparatus; Equipment; Experiment; Hands-on; Laboratory; Manipulatives; Minds-on

While practical work is a ubiquitous feature of science classrooms, the term is used in a variety of ways. Sometimes referred to as "prac" or "pracs," the expression is typically describes hands-on activities or investigations involving scientific equipment or apparatus. In secondary settings, practical work can range from formal procedural "experiments" taking place in a school science laboratory to more student-centered, inquiry-based activities. In primary or elementary classrooms, practical work often involves students working with more concrete everyday materials. In this context, teachers may refer to students' use of "manipulatives" to explore scientific phenomena. In recent years, educators have offered a number of critiques of practical work (see "▶ Laboratories, Teaching in"), emphasizing the importance of balancing hands-on activities and minds-on engagement with the underlying principles behind the activities.

Practicum/School Experience/Fieldwork

Xavier Fazio and Louis Volante
Department of Teacher Education, Faculty of Education, Brock University, ON, Canada

Keywords

Fieldwork; Practicum; Science teacher education

Practicum and Teacher Education

Practicum experiences are widely recognized by prospective teachers and teacher educators as one of the most valued and integral elements of any teacher education program. Regardless of context, this perspective is ever-present and central to learning to teach science (Russell and Martin 2007). It is during the practicum when many teacher candidates self-assess their own suitability for teaching and their place in the profession. Practicum can be considered an all encompassing term used to describe field and clinical experiences in schools. Typically these practicum experiences are organized by a teacher education institution and involve a stand-alone field experience course or are an academic requirement for a science methods course.

Depending on the program, these school-based field experiences can occur throughout a program of study, and traditionally a science teacher education program culminates with a prolonged practicum experience during the teacher candidate's professional or preservice year. These experiences primarily involve (i) student teaching and (ii) internships. In the former, teacher candidates are given significant responsibility in a classroom, under the supervision of a certified teacher, for science planning and instruction and are expected to develop and demonstrate professional competence in an authentic context involving elementary and secondary science students. For the latter, teacher candidates are expected to be engaged observers of professional practice while assisting and co-teaching with an experienced mentor science teacher. While practicum experiences can vary in terms of activities and duration, ultimately, these experiences consist of a period of observation, modeling, teaching, reflection, and critique with the supervision of an experienced science teacher – typically referred to as an associate or cooperating teacher. The key to the success of these orientations is the multiple roles played by associate teachers. They play an integral role in supporting a novice science teacher's initiation into the teaching profession.

Many teacher education programs use practica for multiple goals depending on the overall mission of the teacher education program. In some jurisdictions there are accrediting organizations, for example, the Council for the Accreditation of Educator Preparation (CAEP) in the United States, which identifies professional standards for accreditation of teacher preparation programs and stipulates that institutes provide practicum experiences for all science teacher candidates. Clark (2002) identified four major purposes of practicum for teacher education programs: (a) experimental component for the teacher education program, (b) long performance evaluation, (c) apprenticeship in teaching, and (d) opportunity to practice inquiry-oriented teaching. While not mutually exclusive, each of these purposes has its own conceptual and philosophical backdrop.

Learning During Practicum

During a practicum, science teacher candidates are expected to integrate academic and practical knowledge of science teaching by observing an experienced teacher and also demonstrate their capabilities as a teacher by student teaching in a school context. During these experiences important outcomes are learned which are crucial to their development as science teachers. One of the fundamental outcomes for prospective science teachers is the managing of materials and students in a science classroom or laboratory. This includes organizing students in small groups or a large-group format and also managing science equipment, information and communication technology, and other materials for students in a safe and effective manner while they learn biology, chemistry, physics, and earth sciences.

Another integral experience is based on student-teacher interactions. Here, teacher candidates typically learn about assessment techniques for student feedback (e.g., questioning) and how to use effective discourse with students in a laboratory and classroom setting. Teacher candidates integrate both pedagogical and disciplinary knowledge in order to effectively plan lessons for science students. In order to effectively construct pedagogical and practical knowledge, science teacher candidates need opportunities to self-reflect on their teaching goals and science students' learning outcomes. Associate teachers are vital to this as they can contextualize and support teacher candidates during this often tumultuous time. Academic faculty advisors also play an essential role to facilitate learning from these practicum experiences.

Challenges

One of the challenges facing teacher education is the lack of coherence or alignment between practicum and science teacher education courses (Korthagen and Kessels 1999). That is, the relationship between academic and applied learning during practicum is not fully conceptualized or enacted. When courses (e.g., science methods courses) are aligned with practica, an opportunity exists to support prospective science teachers in meaningful learning and implementing innovative practices learned from an academic setting. For instance, when science teacher candidates have an opportunity to explore a 5E instructional model for teaching science concepts, ideally they should have an opportunity to see it modeled by their associate teacher and practice implementing this instructional strategy in a science classroom. However, many logistical challenges (e.g., academic course timing) and mitigating factors (e.g., associate teacher support) deter many institutions from providing seamless experiences for teacher candidates from course work to practica. General efforts to narrow this gap include having multiple practicum experiences and by establishing a -school-university partnership. However, many innovations in science teacher education have focused on short-term impacts on teacher candidates, either implemented during their time at the university or in a single practicum session in schools.

Linking Academic and Practical Learning

Another attempt to better bridge academic learning and practicum-based experiences is by changing the actual model for teacher preparation. Indeed, there have been a number of reform proposals over the last few decades that have focused on altering structural design features in teacher education programs. Not surprisingly, these reforms have resulted in important impacts on science teacher candidates. One example is by organizing science teacher education programs using a professional development or partner school model, where there is a formal articulation between a practicum school and university regarding the components of a teacher education program (Schoon and Sandoval 1997). This has produced important impacts for both novice and practicing science teachers in school settings. In this model, teacher education faculty and associate teachers share roles and responsibilities for the entire science teacher education program and mutually benefit from the program.

Another model involves science teacher candidates and university faculty advisors themselves co-participating with the science teacher candidates and associate teachers in the teaching of science in schools (Tobin et al. 2001). This model blends the traditional theory-practice dichotomy found in many teacher education programs. Some institutions have extended practicum experiences to augment learning to teach science by organizing internships in informal science education settings. Museums, aquariums, and after-school or science camps are all settings that contrast with formal school science contexts, yet offer enhanced learning opportunities for science teacher candidates.

What all these models emphasize is a recognition that learning from practicum experiences needs to be central to learning how to teach science. Importantly, academic faculty must be involved to support science teacher candidates to effectively explore and understand their field experiences in schools and find new perspectives that are theoretically informed. With this said, all aspects of teacher education must operate in concert to equip science teachers not only with a rich repertoire of instructional techniques but also the skills and general disposition needed to engage in effective science teaching. The practicum component plays a pivotal role in this process – but it must be properly designed to do so and implemented within settings appropriate to achieving these objectives.

Conclusion

Regardless of its importance to science teacher candidates, the research on practicum experiences and teacher learning is still limited. Future study examining the impact of practica on novice science teachers' views and practices is required. This research should seek to investigate practica across a variety of school settings, including different science subject areas, and explore the effectiveness of different practicum models.

"Curriculum" is a word used with different meanings: some referring to a written document which sets out what is to be taught and/or what is to be learned and some to the full range of experiences that affect what students learn. This entry adopts the first of these and is concerned with the content of documents that set out intended learning experiences and expected learning outcomes across the years of schooling, in this case the first 6 (in some cases 7) years of formal education. Using this approach means that the pedagogy through which the learning goals are to be achieved is something for teachers, curriculum projects, and program developers to decide. Examples of these two components of curricula form the main sections of this entry, following a brief review of the background and rationale for teaching science from the start of formal education.

Background: The Roots of Primary Science

Before the major changes beginning in the 1950s and 1960s, science was included in some elementary schools in Western countries largely as a result of the actions of a few inspiring scientists and educators in the nineteenth century. For example, in the UK, H E Armstrong, T H Huxley, and other members of what was then the British Association for the Advancement of Science campaigned to broaden the range of topics and methods of teaching beyond the only form of teaching about the natural environment that was then practiced – the “object lesson.” In these lessons teachers followed a dull routine of showing an object (which might be a piece of coal) and asked questions about it that often called for memory rather than observation. Armstrong promoted the heuristic method of learning through discovery, based on a view of scientific knowledge as being developed inductively from sensory experience. Although helping to promote a more active role for the children in their learning, both the philosophical underpinning of heurism and its practicability made it difficult to defend.

At the beginning of the twentieth century, support for change in the whole ethos of primary education was being promoted in many developed countries through the writings of educators such as Dewey, Montessori, and Homer Lane, building on the earlier ideas of Froebel and Pestalozzi. The ideas they advanced came to be described as “progressive” education. However, in practice little changed for several decades due to the impact of the First World War, the depression in the early 1930s, and then the Second World War and its aftermath. Indeed in England it was not until 1994 that the change from all-through “elementary” education to separate primary and secondary for all children, advocated in the late 1920s, was finally enacted.

Rationale

Teaching science in the primary and elementary schools has been justified in different ways. In the 1920s and 1930s, science was advocated as part of the progressive movement and a response to children’s curiosity and interest in finding out about the world around, although with little effect in the vast majority of schools. The postwar period saw a groundswell of support for active learning and the inclusion of science in the primary curriculum. More practical reasons were also being voiced, stemming from the widespread concern about the poor state of science education and its failure to keep up with the scientific and technological developments during and after the war. In response to this concern, attention was first given to renewing secondary school science, but it was soon realized that such science as there was in the primary school was failing both in developing pupils’ understanding of the scientific aspects of the world and in preparing them for secondary science education.

There was some resistance to regarding primary science as a preparation for secondary science and the most strongly supported arguments were concerned with the benefit to the children during their primary school years. The predominance of such views can be seen later in the report of an international meeting of primary science educators held by UNESCO in 1980 which listed the main reasons for primary school science. These included:

- The development of an enquiring mind; promoting children’s intellectual development, including thinking in a logical way and problem solving
- Improving the quality of children’s lives
- Assisting in other subject areas, especially language and mathematics
- Equipping children for living in an increasingly scientific and technological world
- Learning science can be “real fun”

Most of these claims were based on little more than wishful thinking or the response of enthusiasts to the novel activities in the early science projects. Even though there was hardly any research evidence for them, such arguments were used in support of giving science a place in the primary curriculum. Interestingly primary science was embraced sooner in less developed countries than in developed countries where there was more skepticism about unsubstantiated claims. Thus in the early 1970s, alongside and often drawing upon projects in Western countries, there were projects sponsored by ministries of education and often with the help of organizations such as the British Council, UNICEF, and UNESCO and in Sri Lanka, Israel, Brazil, Indonesia, Singapore, Lebanon, Sudan, Saudi Arabia, Bulgaria, India, and many African countries.

The Impact of Research

Such research in primary science as there was in the 1970s was mostly concerned with the impact of the new curriculum materials on teachers and teaching, revealing far lower levels of uptake than expected. With regard to impact on pupils, studies which compared different curriculum projects with each other or with traditional teaching from textbooks found no significant differences in pupils' scientific achievement, although some US studies reported an increase in questioning and process skills as a result of using new materials.

Stronger reasons for beginning science at the primary level have emerged from research into students' conceptual development. Studies of the ideas that students hold about the scientific aspects of the world became a major focus of research in science education in the 1980s. Many of these ideas – at first called "misconceptions" and later described as "alternative frameworks" or "children's ideas" – were in conflict with accepted scientific views. Research in many countries revealed remarkably consistent patterns in secondary students' ideas, which were the initial focus of attention. The ideas of primary and middle school students were studied, particularly by researchers in New Zealand, Greece, the USA, and England. These studies revealed a range of ideas about the scientific aspects of their surroundings that children had developed from their limited experience and ways of thinking. For example, children commonly describe the process of seeing as if it is their eyes that produce the light that enables them to see. When asked to show how they see an object, they draw and describe a ray of light directed out of the eye to the object along the line of sight. This is an understandable interpretation of the subjective experience of "looking" and a persistent and widespread conception, which can interfere with later learning.

How children come to form these ideas has been suggested by the research into very young children of preschool age and babies, revealing intense mental activity in the preschool years. So it is not surprising that children enter school with some ideas already formed about how things in the physical and biological world "work." Their ideas about the natural world are developing from birth and throughout the primary years whether or not they are taught science. Without intervention to introduce a scientific approach in their exploration, many of the ideas they develop are nonscientific and if these persist they may obstruct later learning.

As well as helping students to a better understanding of aspects of the world around them, it was argued that starting science in the primary school had benefits to society. These follow from young people developing understanding of key ideas that enable them to make informed choices about, for instance, their diet, exercise, use of energy, and care of the environment. Equally the development of scientific skills and attitudes can support a growing appreciation of the role of science in daily life.

Towards National Curricula

In the absence of national, regional, or district curricula, that is, before the 1980s, what was taught at the primary level was largely guided by the materials produced by projects. The early primary science projects promulgated different views of science and what was to be achieved in learning science. Some gave priority to the development of an inquiring mind, to problem-solving capability, and to logical thinking, promoting a view of science as a process of inquiry, while others prioritized the development of major science ideas. The rather extreme positions of these early projects soon gave way to more balanced views, acknowledging the interdependence of the use of scientific processes and thinking and the development of understanding of science concepts (Harlen 2008).

The diversity of content and to some extent of approaches was curtailed once national, regional, or district requirements were established. In many countries the trigger for setting out agreed aims was the desire to assess what students were learning, assessment practices being poorly developed at that time. National and international projects of assessment in science, such as NAEP in the USA, the APU in England, and the IEA program of surveys, required frameworks for what should be learned and assessed.

A curriculum document describes at a general level the intended learning across the relevant age range. There are generally two kinds of statement:

- Inputs, or what is to be taught – giving a broad overview of progression, set out year by year or in for "stages" of schooling
- Outcomes, or what is to be learned – specifying outcomes for the purpose of assessment, described in various ways, such as "learning outcomes," "performance expectations," "standards" (as in the USA), "attainment targets" (in the English curriculum), or "achievement standards" (in the Australian Curriculum).

In some curricula, statements of what is to be taught are combined with learning outcome statements in one document; in others these are quite separate and often created by different agencies, concerned variously with the content and with assessing learning. There is also a considerable difference in what is included, according to whether or not the implementation of curriculum is required by law or has only the status of "guidelines." Non-statutory documents can contain guidance and exemplars of teaching methods, without infringing the role of the schools to decide matters relating to pedagogy.

These curriculum statements cover the whole age range of compulsory schooling, primary and secondary. The next two sections focus on what is included about the intended input and outcomes in the primary/elementary school years.

What Is to Be Taught

Statements of what is to be taught invariably include reference both to inquiry, or process, skills and to content or "knowledge and understanding" to be mastered. In most cases these are listed separately. The National Curriculum for England (DfE 2013) for the primary school is a typical example. It specifies under the heading "Working Scientifically" skills and processes such as planning investigations and obtaining and evaluating evidence. The rest of the program of study lists various content topics relating to the disciplines of biology, chemistry and physics. For the skills there are statements of what "pupils should be taught" during years 1-2, 3-4, and 5-6 and for the content areas what is taught in specified for each year. Thus some threads of progression can be discerned, but there is no overall discussion of progression in these areas, as there is, for instance, in the USA *Framework for L-12 Science Education* (NRC 2012). This has three dimensions:

- Scientific and engineering practices (e.g., planning, carrying out investigations)
- Crosscutting concepts (e.g., patterns, systems, energy flows, and cycles)
- Disciplinary core ideas (physical, life, Earth and Space sciences, and applications of science)

For the first two of these, the framework identifies particular practices and crosscutting concepts and describes the course of development. This leads to a summary of what students should know by the end of grade 12 rather than a more detailed description for grades along the way. For the core ideas, however, intended achievement at the end of grades 2, 5, 8, and 12 are identified, as in the example in Box 1.

The Australian science curriculum (ACARA 2012) also has Science Inquiry Skills and Science Understanding as two separate strands, with Science as a Human Endeavor as a third. Science Understanding is divided into four sub-strands – biological, chemical, earth and space, and physical sciences with the content in each being specified year by year.

Box 1: Grade Band Endpoints Relating to "Structure and Function in Organisms" from A Framework for K-12 Science Education (NRC 2012)

By the end of grade 2. All organisms have external parts. Different animals use their body parts in different ways to see, hear, grasp objects, protect themselves, move from place to place, and seek, find, and take in food, water, and air. Plants also have different parts (roots, stem, leaves, flowers, fruits) that help them survive, grow, and produce more plants.

By the end of grade 5. Plants and animals have both internal and external structures that serve various functions in growth, survival, behavior, and reproduction.

By the end of grade 8. All living things are made up of cells, which is the smallest unit that can be said to be alive. An organism may consist of one single cell (unicellular) or many different numbers and types of cells. . . .

Identifying Progress

The years of primary education, from age 5 to age 11 or 12, span a period of considerable cognitive change. During this time students gradually move from being characteristically egocentric to being able to take another's point of view, from thinking that is closely related to action towards the mental manipulation of ideas and the formal thinking that most will achieve later in the middle or high school years.

Science curricula endeavor to promote progression in learning by setting out learning outcomes at various stages. Ideally these should be based on evidence of how learning typically proceeds. The assumption that this is a step-by-step progression underpins the proposed sequences developed by the 2001 AAAS Atlas of Science Literacy and some of the research into "learning progressions." How justifiable it is to try to specify for all students what is to be learned before the next step can be taken depends on how closely the outcomes are specified. In some cases what is to be learned is set out year by year and in others only in terms of achievement at the end of longer periods of 2 or 3 years. The closer the specification, the more problematic the decisions about the exact sequence and the greater the risk of the detail obscuring sight of the overall aims – the overarching powerful ideas and the skills of scientific inquiry. The statements of the specific ideas and skills that students are expected to learn ought to be justifiable in terms of progression towards these overall aims. Such a structure provides for consistency across the primary-secondary boundary since at all times the overall aim is to progress towards the same overarching ideas. When this structure is not made explicit, the content of a curriculum can appear to be no more than an arbitrary selection of what is to be taught, based on tradition or what is easily assessed.

Specifying Learning Outcomes

Given the widespread view that inquiry skills and concepts should be taught in an integrated way, their separate specification in curriculum documents seems unhelpful. Yet expressing the interdependence of process and content in setting out what is to be learned is a continuing challenge for curriculum designers. In most science curriculum documents, the separate specification of skills and content in the overall framework is carried through in the separate specification of learning outcomes.

The English National Curriculum identifies the statements in the program of study, of what pupils are expected to know, apply and understand, as the attainment targets to be achieved during years 1 and 2, 3 and 4, and 5 and 6. Box 2 gives these statements for "working scientifically".

In the Australian curriculum achievement standards are specified for each year. The outcomes for Science Understanding are brought together with those for Science as a Human Endeavor in a single paragraph but remain separated from outcomes for Science Inquiry Skills. Box 3 gives examples for Years, 2, 3, and 4.

The Scottish *Curriculum for Excellence* departs from this separate specification by expressing goals at different points, roughly 3 years apart, as a combination of process and content, described as "experiences and outcomes" (see Box 4).

A similar combination of different dimensions is proposed in the draft Next Generation Science Standards (NGSS 2012) based on the K-12 Science Education framework in the USA. Although the framework, as mentioned earlier, does not specify year-by-year outcomes for the three dimensions (scientific practices, cross-cutting concepts, and disciplinary core ideas), the NGSS are specified for each year within topics, as in Box 5. The topics are related to the core disciplinary ideas in the framework.

As these examples show, the primary school science curriculum is still developing, as practice and research reveal more about progression towards key science ideas and about the role and nature of inquiry skills.

Box 2: Attainment Targets for "Working Scientifically" in the National Curriculum for England (DfE 2013)

During years 1 and 2:

- Ask simple questions and recognize that they can be answered in different ways.
- Observe closely, using simple equipment.
- Perform simple tests.
- Identify and classify.
- Use their observations and ideas to suggest answers to questions.
- Gather and record data to help in answering questions.

During years 3 and 4:

- Ask relevant questions and use different types of science enquiries to answer them.
- Set up simple practical enquiries and comparative and fair tests.
- Make systematic and careful observations.
- Gather, record, classify, and present data in a variety of ways to help in answering questions.
- Record findings using simple scientific languages, drawings, labeled diagrams, etc.
- Use results to draw simple conclusions, make predictions, etc.
- Identify differences, similarities, or changes related to simple scientific ideas and processes.

During years 5 and 6 (end of primary school):

- Plan different types of scientific enquiries to answer questions, including recognizing and controlling variables where necessary.

Box 3: Achievement Standards of the Australian Science Curriculum for Science

By the end of Year 2, students describe changes to objects, materials, and living things. They identify that certain materials and resources have different uses and describe examples of where science is used in people's daily lives.

Students pose questions about their experiences and predict outcomes of investigations. They use informal measurements to make and compare observations. They follow instructions to record and represent their observations and communicate their ideas to others.

By the end of Year 3, students use their understanding of the movement of the Earth, materials and the behavior of heat to suggest explanations for everyday observations. . . . They describe how they can use science investigations to respond to questions and identify where people use science knowledge in their lives.

Students use their experiences to pose questions and predict the outcomes of investigations. They make formal measurements and follow procedures to collect and present observations in a way that helps to answer the investigation questions. Students suggest possible reasons for their findings. . ..

By the end of Year 4, students apply the observable properties of materials to explain how objects and materials can be used.... They describe relationships that assist the survival of living things and sequence key stages in the life cycle of a plant or animal. They identify when science is used to ask questions and make predictions. They describe situations where science understanding can influence their own and others' actions.

Students follow instructions to identify investigable questions about familiar contexts and predict likely outcomes from investigations. . .. They suggest explanations for observations and compare their findings with their predictions. They suggest reasons why their methods were fair or not. They complete simple reports to communicate their methods and findings.

Box 4: Experiences and Outcomes for "Biodiversity and Interdependence" in the Scottish Curriculum for Excellence (2010)

Early stage (end of first primary year) I have observed living things in the environment over time and am becoming aware of how they depend on each other. I have helped to grow plants and can name their basic parts. I can talk about how they grow and what I need to do to look after them.

First stage (end of fourth primary year) I can distinguish between living and non-living things. I can sort living things into groups and explain my decision. I can help to design experiments to find out what plants need in order to grow and develop. I can observe and record my findings and from what I have learned I can grow healthy plants in the school.

Second stage (end of primary school) I can identify and classify examples of living things past and present, to help me appreciate their diversity. I can relate physical characteristics to their survival or extinction. I have collaborated in the design of an investigation into the effects of fertilizers on the growth of plants. I can express an informed view of the risks and benefits of their use.

Box 5: Examples of the Draft USA Next Generation Science Standards

Grade 2 Standards for structure, properties, and interactions of matter

Students who demonstrate understanding can:

a. Evaluate natural or designed objects to explain how the properties of the materials suit different purposes.
b. Collaborate with others to design an object built from a small set of pieces to solve a technological problem.
c. Provide evidence that some changes caused by heating or cooling can be reversed and some cannot.
d. Measure and compare the physical properties of objects.

Grade 3 Standards for interactions of forces

Students who demonstrate understanding can:

a. Investigate the motion of objects to determine observable and measurable patterns to predict future motions.
b. Investigate the motion of objects by comparing the relative sizes and direction of forces on an object at rest to the forces on an object whose motion is changing.
c. Use models to explain the effects of balanced and unbalanced forces on a system.
d. Investigate the forces between two or more magnets to identify patterns.
e. Investigate the push-and-pull forces between objects not in contact with one another.
f. Design and refine solutions to a problem by using magnets to move objects not in contact with one another.

Primary/Elementary School Science Curriculum Projects

Wynne Harlen
Graduate School of Education, University of Bristol, Bristol, UK

The first projects to publish materials to support science education in the primary school (students aged 5–12) began in the 1960s. Since that time many hundreds of curriculum projects in primary school science have been developed in countries across the world. The ideas and materials produced in many of these projects can be traced to certain influential projects, which are the focus of discussion here. These key projects occurred in two main waves, the first ones beginning in the 1960s and the second about 25 years later.

Projects of the 1960s

In the USA three science projects for primary school students began working at the same time in the early 1960s. They differed in structure and were based on contrasting views of science and learning. The *Elementary Science Study* (ESS 1966) provided a range of activities that enabled students to work scientifically, based on the argument that children are by nature questioning and enjoy solving problems. The activities they described emphasized the development of scientific processes, such as observation, planning and conducting investigations, and interpreting data. Although the content was related to science concepts, the program was unstructured in relation to concept development. There was an emphasis on using simple, everyday materials, but where special materials were required, they were provided in a class kit.

The approach of *Science – A process Approach* (SAPA 1967), as its title suggests, was also process based but, in contrast with

ESS, was highly structured. It identified the processes in two groups. Those appropriate for young students were as follows: observing, using space-time relationships, using numbers, measuring, classifying, communicating, and predicting. Once students had developed these, other processes were added: interpreting data, formulating hypotheses, controlling variables, defining operationally, and experimenting. The materials for teachers – there were no student texts – took the form of booklets each focusing on a specific process, sequenced by grade.

The *Science Curriculum Improvement Study* (SCIS 1967) aimed to develop students' understanding of the nature and structure of science. The intention behind the classroom materials was to give the students sufficient knowledge and experience "so that they will be able to have some understanding of scientific work being carried out by others, even though they themselves do not become scientists. This quality we have called scientific literacy" (Karplus and Thier 1967, p. 30).

To this end the material was organized around several major scientific ideas, such as systems, material objects, interaction, relativity, and organisms. The material for teachers took the form of units relating to these major ideas. Units set out objectives and explicit instructions for teaching, including what to tell students. Equipment kits were developed for the units and there were booklets for students.

In the UK two projects began in the early 1960s. These differed in focus on process or content as did the projects in the USA. One was a research and development project in primary science, the *Oxford Primary Science Research Project*, funded by the UK Department of Education and Science and set up 1963. It produced a book for teachers on how to develop students' ideas relating to four major overarching concepts – energy, chance, structure, and life. This project had little impact and is only noteworthy on account of its focus on concepts, in considerable contrast to the second project. The Nuffield Junior Science (NJS) project, set up as part of the Nuffield Science Teaching Program, began in January 1964 with the rather different aims of "producing children who are keenly observant, questioning, able to devise means of getting answers to their questions, scientifically rigorous and can communicate." To achieve these aims the project gave the teacher maximum flexibility and no student materials or kits of equipment were produced. One of the books for teachers described a range of activities for students presented in the form of case studies. The material was unstructured and there was no attention given to a coherent development of science concepts.

A project which followed NJS, although based on a similar child-centered view of primary education, provided greater structure. This was *Science 5/13* which, during its 8 year life, provided a statement of "objectives for children learning science" to help teachers work purposefully, 26 units for teachers giving ideas for children's activities related to children at three stages of development, and information about the background science for the unit topics.

Beyond the USA and the UK, other countries were establishing their own science projects. The program of development in Africa, the Science Education Program for Africa, included the *African Primary Science Project* which produced 52 short topic-based units for teachers, a handbook for teachers and a sourcebook for teacher trainers. The approach taken had much in common with *ESS* and *Science 5/13*, providing ideas for classroom activities around topics but leaving decisions about the choice and sequence of students' activities to the teacher. Some African countries developed their own program with more structure, seen as necessary in view of the low level of many primary teachers' own education. The northern states of Nigeria based their primary program on a modified list of SAPA processes, organized into a 6-year course.

Revision of existing projects and development of new ones continued throughout the 1970s. At the same time it became evident that changing practice, towards more active learning, was a difficult and long-drawn out process. Problems were exacerbated by most primary teachers' poor knowledge of and attitudes towards science.

Studies of implementation in both developed and developing countries found that the curriculum projects were having little impact beyond a few enthusiasts. Moreover, economic downturn in the late 1970s delayed the efforts that further development required.

Projects of the 1980s and 1990s

In the 1980s, in both the UK and the USA, reports on the state of education exposed a cause for concern. In England the 1978 report of a survey by HM Inspectors of Schools, *Primary Education in England*, noted that few classes visited "had effective programmes for the teaching of science." The UK government firmly endorsed the place of science in its policy document *Science 5-16*: *A statement of Policy* of 1985. In the same year a project of research was begun, funded by the Nuffield Foundation, into the science concepts of primary students, the *Science Processes and Concepts Exploration* (SPACE) project. After the National Curriculum was introduced in England and Wales in 1989, requiring the teaching of science in primary schools, the research was extended to cover the range of concepts included at the primary level and became the basis for the major science curriculum project of the 1990s, *Nuffield Primary Science* (NPS). The NPS materials comprised a set of teachers' guides, short booklets for students, and guides for coordinators and in-service leaders, linked to the National Curriculum. Based on a constructivist approach to teaching and learning, students' activities start with exploration of materials or events during which teachers elicit the ideas the students have about phenomena related to the topic. The guides give examples of students' ideas derived from the SPACE research and suggestions for taking these ideas as starting points and helping the development of more scientific understanding.

In the USA the 1983 report *A Nation at Risk* revealed that less than 1 % of school districts had effective science education programs. One response to this was the creation in 1985 by the Smithsonian Institution and the National Academies of the National Science Resources Center (NSRC). A key aim of the NSRC was to produce programs and support for science teaching based on research into how to bring about change in schools as well as how to develop students' conceptual understanding. NSRC produced the project *Science and Technology Concepts* (STC) for elementary and secondary schools, with supporting classroom and professional development materials and kits of equipment. Meanwhile the Lawrence Hall of Science produced *Full Option Science System* (FOSS). Its third edition was published in 2012 to reflect the National Research Council's Framework for K-12 Science Education. FOSS materials include teacher guides, equipment kits, science stories for students, videos for teachers, and an assessment system. A further project, *Insights*, was produced by the Education Development Center. This modular program for elementary science is organized around six major themes similar to the themes of SCIS. The hands-on experiences are carefully sequenced in the 21 modules, providing a structured approach for teachers to follow.

The projects in the USA, particularly *STC* and *Insights*, influenced developments in the 1990s in other countries. In France, a trial in 1996 of some *Insights* modules led to the development of the project *La main à la pâte* (*LAMAP*), *supported by the French Academy of Sciences*. The project has been in constant development since that time, producing a wide range of materials, a support network and a website that provides over 300 classroom activities, documents on science teaching, and online access to scientists to answer teachers' questions. The teaching approach is based on a sequence of stages within a lesson designed to develop science concepts and inquiry skills. It is expected that science occupies a minimum of 2 h per week and that each student will keep a notebook describing their work in their own words.

LAMAP has set up pilot centers in many countries in Europe, Latin America, and Southeast Asia. The project's resources are made freely available and have been adapted, for example, in China, in creating the Learning by Doing project, and in Brazil, Colombia, Serbia, Cambodia, and Senegal. In Europe, the inquiry-based approach to science education and some materials of LAMAP have been spread through the Pollen and Fibonacci projects, involving 24 countries of the European Union.

The STC project has also been disseminated to Mexico, Chile, and Sweden and used in developing these countries' own elementary science programs. The Swedish project, Natural Science and Technology for All (NTA), was begun in 1997 as a project of the Swedish Royal Academy of Science. It has been expanded and developed and since 2003 is managed by a cooperative of schools and municipalities, each having an NTA coordinator. This arrangement ensures that the kit of materials required for each unit is provided when needed and when a unit is completed the kit is returned to a center for refurbishment ready for another class.

Many of the post-1990 projects combine science with technology and engineering. By contrast, in England, the National Curriculum treats science and technology as separate subjects, and this has led to different projects being created for science and technology.

Most recent projects pay attention to the use and development of students' language skills both as means to cognitive development and ends in themselves. In Australia, the Primary Connections project makes this a major focus, aiming at developing students' knowledge, skills, understanding, and capacities in both science and literacy. It promotes an inquiry approach through a five-phase lesson structure, 5Es: engage, explore, explain, elaborate, and evaluate. Thirty-one units provide activities for students in each year from kindergarten to year 6 in physical, chemical biological, and Earth and space sciences. An associated professional learning program helps teachers to understand the program and adapt and extend the units.

What Is Primary Science?

It is universally accepted that learning science is important for the future lives of all citizens. Therefore, science as a required part of primary and secondary education has become commonplace in most countries. As children have a natural inclination and creativity for science and the world surrounding them, one expectation of teachers is the need to develop the skills for catching students' ideas and stimulating their questioning and their (scientific) reasoning. However, research illustrates that there has been a common concern about primary teachers' lack of scientific knowledge which has been seen as a major barrier to developing quality science teaching and learning in primary schools. Today, primary teachers' scientific knowledge is widely recognized as having improved, but there is still world-ranging debate about the level and nature of scientific knowledge needed by a primary teacher in order to teach science effectively.

There is a lot of international research that indicates that students' interest in science declines in the early postprimary years, while other studies suggest students' positive attitudes towards science increase within primary level. There is global recognition of the problem of decreasing interest in school science. Reasons for the situation include such things as the content-driven nature of the science curriculum, the perceived difficulty of school science, students' difficulties in seeing the relevance of science, and the role science plays in society and children's everyday world as well as home-related and social-related factors. Other reasons suggested for this decline in interest include a lack of practical work in science, nonspecialist teaching, and overemphasis on practice assessments for national tests.

It has been suggested that teachers in general and perhaps primary teachers in particular need knowledge and skills to stimulate students' enthusiasm in science and also that the lack of continuity and progression between primary and postprimary science should be addressed by bringing primary and postprimary schools together to devise "bridging units" between primary, postprimary, and secondary school. Hence, arguments about rethinking science in primary schools and across the primary-secondary school transition in forming students' attitudes towards science are well supported.

Over the last decade, several countries have experienced government interventions leading to reforms of teacher education programs and national school curricula for all levels. As a consequence, new curricula for primary science have raised discussions of primary teachers' scientific knowledge and attitudes towards, and confidence in, teaching science. Primary teachers are faced with the need to teach several subjects, and coping with their shifting roles in different subject matters suggests a need to have content knowledge in all these different subject areas. However, as science in primary schools is often taught in an integrated setting, estimating the amount of science taught in terms of hours per week is difficult. Science in primary school is often described as a broad subject made up of many domains. As such, the question as to what counts as science in primary schools is important in shaping the way activities are planned and organized in the primary classroom. Further, the evidence and arguments that support the role of science in the primary curriculum must be recognized in order to ensure that *what* and *why* science is taught also matches the learning intentions.

One strong argument for science in the primary curriculum is that children's ideas about the world develop throughout their primary years whether or not they are taught science. Without any intervention, many of the ideas they develop are nonscientific and may in fact confuse their learning of science phenomena in future education (Harlen and Qualter 2009). Further, students' interest in sciences, in most cases, is formed early, often in primary school, yet that interest tends to drop quickly in physics, chemistry, and technology in the early secondary school years. Therefore, another argument for introducing science in the early primary years is to stimulate students' interest, engagement, and attitude towards science.

At a primary level, activities generally begin from objects and events connected to the students' everyday experiences. In describing "big ideas" in science, Harlen referred to progression towards key ideas which together enable understanding of events and phenomena of relevance to children's lives during and beyond their school years. Harlen argues that science big ideas should have explanatory power in relation to a large number of phenomena that are encountered by students in their lives. They should provide a basis for understanding issues involved in making decisions that affect their own and others' health and well-being, the environment, and their use of energy. They should also provide enjoyment and satisfaction in being able to answer or find answers to the kinds of questions that people ask about themselves and the natural world. Finally, these science big ideas should have cultural significance – for instance, in affecting views of the human condition – reflecting achievements in the history of science, the inspiration from the study of nature, and the impacts of human activity on the environment. These big ideas have a strong relevance for primary education, the beginning point for studying science in the formal classroom setting.

It is well argued that important features of provision for learning science in primary years are the development of inquiry skills; the opportunity to observe and investigate familiar objects, materials, and events; and the opportunity for students to talk to each other or to the teacher and to express their existing ideas and develop them in the light of new information gathered either from their practical investigations or observations. However, sometimes the focus of activities in the (primary) classroom might put emphasis on what the students will be *doing* to the detriment of that which they are intended to *learn*. Therefore, a crucial role of primary science is "to build a foundation of small ideas that help children to understand things in their immediate environment but, most importantly, at the same time to begin to make links between different experiences, and ideas to build bigger ideas" (Harlen and Qualter 2009, p. 39). To do so, teachers need to gather information about children's inquiry skills and ideas of science and use it to help them achieve their goals and move on.

Developing Student's Ideas of Science

Children, even when very young, have ideas about the world around them, and these ideas play an important role in their learning experiences. They come to school with different ideas about certain phenomena and concepts even though they have never had any formal instruction on these concepts. Children form their conceptions on the basis of their everyday life and experiences (Driver et al. 1985) and build up their scientific knowledge from a range of sources outside the school environment. One way of developing, engaging, and challenging students' ideas of science is through the notion of scientific literacy.

Scientifically literate people are interested in and understand the world around them; engaged in the discourses of and about science; able to identify questions, collect data, and draw evidence-based conclusions; skeptical and questioning of claims made by others about scientific matters; and able to make informed decisions about the environment and their own health and well-being. A shift in the emphasis of primary science education towards scientific literacy requires careful consideration on behalf of teachers and as such dedicated time and structures for reflection and spaces to experiment and play with ideas. If teachers in primary school work with these skills to develop students' ideas of science, they may well form a basis for future citizens who will engage with science at a personal and a societal level and therefore offer a springboard for understanding science so often sought in the educational community.

Many primary teachers indicate that science is the subject they least enjoy teaching, in part because they are afraid their teaching will uncover ideas they do not understand and cannot explain to students. The challenge of addressing students' ideas shows that even though primary teachers believe that knowing about and addressing students' ideas is important, these beliefs are not always confirmed in their instruction. Teachers' ability to respond to ideas depends on different factors such as teaching experience, content knowledge, and access to materials. When teachers do not understand the concept, it is avoided, or not addressed, during instruction. On the other hand, research also indicates that teachers often feel challenged to acquire the resources needed to create science learning environments that stimulate students' scientific reasoning.

Helping students to change and develop their ideas of science is based on the assumption that students are willing to express their ideas. If they do not feel that their ideas are valued, they are less likely to share them publicly. One way of probing students' understanding about science concepts has been through the use of "Concept Cartoons." A Concept Cartoon shows different characters arguing about the answer to a question or debating alternative explanations of scientific phenomena using many of the well-documented misunderstandings, as well as correct understandings. As such Concept Cartoons can be used to stimulate discussion before, during, or at the conclusion of an investigation. In a primary school context, students can use these Concept Cartoons to develop their ideas of science, to structure debates, and to articulate reasons for selecting one explanation over another.

Harlen and Qualter (2009) suggested that learning in science is generally viewed as a process of developing and changing children's ideas as opposed to *giving* them the ideas. Before a teacher can gain access to children's ideas, it is necessary to establish a classroom climate in which children feel that it is safe to express their ideas and in which their ideas are valued and taken seriously.

One way of creating such a safe learning environment and probing students' ideas and inquiries used in an Australian primary school context is called the "wonder wall" (Nilsson 2011). The "wonder wall" is a wall on which students place different questions about scientific concepts and phenomena. These questions could be "what is a shadow?," "how does medicine work?," and "what happens when we get ill?" Even though the wonder wall is used as a way of uncovering students' ideas, it is well worth noting that not only the students but also teachers can put their questions on the wall. The reason for this is explained by a primary teacher when he stated that he wanted his ". . . students to understand that as a teacher [he] also ha[d] inquiries and as a teacher [he] do not always know all the important facts or bits of information" (Nilsson 2011, p. 136).

As mentioned above, an important aim of primary science is to stimulate students' curiosity about the world around them, to develop their ideas of science, and to encourage critical and creative thinking. To fulfill this aim, students need to acquire both factual knowledge and the skills of identifying questions that can be addressed scientifically. Young children need to experience the world around them. However, students may appear to be enjoying an activity but really be more entertained than engaged in learning. Seeing beyond a fun activity can therefore be a catalyst for more sophisticated thinking about science teaching and learning in primary schools. This requires activities that go beyond simple sensations to students developing their ideas, raising questions, planning how to obtain evidence, predicting what might happen, and thinking about how to capture and share their findings. In order to develop this complex set of skills, students need to go beyond being told about science but instead explore their ideas through interactions and practical inquiry. For these learning experiences to occur, primary school teachers' knowledge and skills are crucial.

Teaching Primary Science: Teacher Knowledge and Self-Confidence

Research into teachers' knowledge and beliefs of teaching and learning has been shown to have a great impact on classroom practice. Several studies have shown the connection between teachers' science knowledge and confidence in teaching science. Even though there has been some progress in developing teacher confidence in primary science over the last 10 years, the situation has not dramatically changed.

While a small minority of primary teachers have undertaken science studies, significantly, few have specialized in studying science. Further, many primary teachers have had little or no success in their own study of science, which influences their attitudes towards, and self-confidence in, teaching science. Another challenge for primary teachers has proven to be the lack of previous experiences with hands-on science or inquiry activities in their classrooms. Other reasons as to why primary teachers lack confidence in science teaching have been insufficient subject knowledge, lack of experience in science practical investigations, and lack of access to equipment or support for organizing equipment. There is also the possibility that primary teachers do not have a view of the nature of science knowledge that would provide insight into how science can stimulate productive learning experiences for students.

The low confidence of primary teachers often results in teaching that is limited to “science activities that work” that involve only science content with which the teachers feel familiar. Further to this, a commonly noted problem in preservice primary science education arises from the situation that the majority of preservice teachers do not have a genuine interest in science. Olson and Appleton (2006) highlighted that method courses that provide science inquiry activities and stimulate student teachers to discuss how science content could be explained to students have a great influence on student teachers’ attitudes and skills in successfully beginning teaching primary science.

Although the findings of a number of studies have indicated that science method courses can be successful in developing positive attitudes towards teaching science, increased science knowledge by itself will not consistently result in improved self-confidence. As new teachers often feel anxious about conducting science experiments with students, there is a need for student teachers not only to develop their subject matter knowledge but also to see how the knowledge is meaningful in a primary school context.

Students’ attitudes towards science are influenced by teachers’ behavior in the classroom such as asking challenging questions, portraying the essence of a scientific approach to students, and stimulating their enthusiasm and interest. But this is difficult when the teachers themselves are uncertain of the subject content. Hence, an important issue for both preservice and in-service teacher education is to consider how to increase primary teachers’ interest for, and engagement with, teaching and learning science.

Many studies into subject matter knowledge (SMK) emphasize that teachers cannot explain the principles underlying physical phenomena to their students if they do not explicitly understand them. Teachers need to understand the structure and nature of their discipline, have skills in selecting and translating essential content into learning activities, and recognize and highlight the applications of the field to the lives of their students. For successful primary teaching, teachers need the capacity to transform the content knowledge they possess into forms that are pedagogically powerful. For developing such capacity, it is important to create conditions for practical experiences in primary science teaching that are reasoned and reflected upon.

Primary science, for example, through a scientific literacy approach, can work to help students develop different skills, to engage in discourses of and about science, and to understand the world around them. Through science activities, students can develop the necessary skills to drive their inquiries of a science topic in meaningful ways. They can reflect on and respond to ideas and find evidence to describe science knowledge, facts, and information. In such a way, science activities can provide a purpose for learning through drawing, singing, reading, writing, questioning, and reasoning.

In order to promote such learning processes, teachers need to be aware of strategies for helping students to understand the language of science. Children’s questions and ideas in science can further be used as tools to influence primary teachers to confront their own thinking about science content in order to improve their own knowledge. An important aspect of primary teaching is not to “tell” the right answer but to help students see the purpose in why they learn things and the way they can use that knowledge in their everyday lives. Therefore, revising the role of the primary teacher from being the supplier of all the right answers to a facilitator or lead learner is crucial for beginning to move towards developing good science teaching and learning in primary schools. That is the challenge that confronts Primary School Science teaching today.

In this entry, "Print Media" will refer to agents of various means of mass communication that use print as the primary form of interaction. "Communication" will mean those science communications directed towards the general public, towards science students at particular grade levels, scientists in a particular field, and members of the public with keen interests in science. "Print" will refer to the written word and to other forms of literate communication, such as graphs, charts, tables, and diagrams that can be combined with the written word in science communications. The technology for displaying the print – paper, film, computer screens, smart phones – is not relevant to this discussion. Specifically, the entry will not be about science communications in which the spoken word plays a primary or large role, such as conference presentations or workshops. Although conference presentations and workshops often are accompanied by print, the print usually is not independent of the oral presentations. In the print media that is the focus of this entry, the science communications are self-contained and, at least in principle, can be understood without aural input.

Print media communicate science in a variety of forms. This entry will address the following: primary scientific literature, journalistic literature (newspapers, science magazines, the Internet), and educational literature (textbooks, trade books, adapted primary literature). The Internet is a special case because it contains all of the forms in which science communication occurs. We group it with journalistic literature, and when we speak of the Internet, we mean only those communications that fit with the journalistic category, although we recognize that the Internet contains print designed for educational purposes. Also, e-book forms of textbooks and trade books are considered equivalent to the paper forms for discussing the characteristics that are examined in this entry.

Primary Scientific Literature

Primary scientific literature is written by scientists, for scientists, and appears in specialized scientific journals – scientific periodicals – and books. Primary scientific literature appears in a wide array of forms to match the large number of types of scientific research. Many pieces of primary scientific literature report studies in which data were collected and used as evidence to draw conclusions. Some primary literature does not present new data but draws upon data reported in other studies in order to support a new conclusion. Primary scientific literature need not present data at all but can report theoretical research – sometimes using mathematics – that proposes a view of how some aspect of the world works. The theory might then be used to predict that under certain conditions certain events would be observed to occur, or might be used to explain known events that have gone unexplained for some time. Sometimes data reported by primary literature derives from experiments, other times from surveys or from observational studies. Always, primary scientific literature is technical, requiring specialized knowledge to fully understand (Myers 1991). Always, primary literature is argumentative, making a case for a conclusion either on the basis of evidence or on the basis of reasons drawn from theory or logic. Primary literature describes scientists' best efforts to communicate their reasoning. As such, primary literature is incomprehensible or only marginally meaningful to those without specialized education in the field.

Journalistic Literature

Under the heading of journalistic literature are included newspapers, science magazines, and the Internet (with the restrictions described above). Journalistic literature typically has some basis in primary scientific literature, by relying on the primary literature as an authoritative source, and adapts the information for a purpose different from that of the primary literature (Jiménez-Aleixandre & Federico-Agraso 2009). One frequently occurring type of adaption is to present the results of primary scientific literature without the evidence and reasons for those results. A second type of adaptation is to speak to the practical implications of the research findings and to tie why the research was done to these practicalities, a topic that might not have appeared at all in the primary literature. A third sort of modification often included is a human interest angle to the research, often some anecdote from the lives of the scientists who conducted the research or some connection between possible implications of the research and particular persons whom the results might affect.

The results of these adaptations are texts that are primarily expository in structure – attempting to relate events and situations as they are – compared to primary literature, which is mostly argumentative in nature, attempting to defend conclusions. However, studies have shown that argumentation occupies on average about one-fifth of the space in individual newspaper and magazine science articles and can occupy as much as nearly one-half the space. It also has been found that the statements in journalistic literature generally are presented as true (on average about two-thirds of the time) with little hedging. However, up to one-fourth of the statements in individual pieces of journalistic literature are presented as uncertain. In primary scientific literature, hedging is the norm. Comparable figures for the Internet are not available, but the Internet's enormous diversity would suggest that the reader of science communications there could expect to find at least the range of characteristics found in newspapers and magazines.

The result for the reader is that a wide range of interpretive skills and strategies are needed for accurate understanding of science communications found in journalistic literature. First, we need to recognize the characteristics of most science students. Interpreting narrative is their greatest strength. Interpreting exposition and description is less fully developed, but is strong in some people. Interpreting argumentation is the least developed of all. Many readers think of reading simply as word identification and information location. Science educators need to recognize the misinterpretations students are likely to make and the remedial action that can be taken to help them. Hedges are likely to be missed, so students need to be taught to look explicitly for them. Causes are likely to be confused with correlations, and descriptions of phenomena and proffered explanations of them are likely to be treated in the same way; so students require practice in distinguishing these different aspects of meaning. Also, students need to be made aware of their bias towards certainty, and to be taught strategies to help them recognize the uncertainty and tentativeness built into all genuine accounts of science. Finally, students need to be taught to take care with structure. They must be taught to keep separate the story line from the scientific description and from the argument. If necessary, these might need to be physically pulled apart into separate documents or separate parts of the one document. If there is argumentation, students should be shown how to make its structure paradigmatic – reason and conclusion juxtaposed – with indicator words: "because," "consequently," "therefore," and "however" supplied where they are missing from the original journalistic literature.

Educational Literature

Under educational literature designed to communicate science, we include textbooks, science trade books, and adapted primary literature, regardless of the technology used to present them.

Science Textbooks

Science textbooks are ubiquitous and have been studied extensively. From the earliest to the most advanced levels of science education, they tend to have the same general characteristics. Science textbook authors introduce various organizational features to help readers to comprehend tables of contents and indexes, learning objectives and overviews at the beginning of chapters, vocabulary lists with meanings, review questions at the end of chapters or sections, and visualizations. Science textbooks also introduce reading difficulties by presenting enormous quantities of information, frequently at a superficial level, which makes sense-making difficult, and accompanied by large amounts of new technical vocabulary, which places additional demands on comprehension.

Compared to journalistic literature, textbooks tend to contain an even greater proportion of expository text, virtually no argumentative text, and a small proportion (~10 %) of narration. Also compared to journalistic literature, textbooks generally state hardly anything as other than truth: there is little hedging and, to all intents and purposes, no tentativeness. This style of communication creates in students an expectation for truth and thus biases their interpretation strategies such that they tend to miss tentativeness and uncertainty when it is expressed. Textbooks concentrate on the facts and conclusions of science and not on how those facts were derived and conclusions reached. This concentration does not prepare students well for interpreting journalistic literature, which also devotes most of its space to facts and conclusions, but also spends significant time speaking about research methods and what motivated the research in the first place.

The number of visualizations in most science textbooks is very large. These visualizations range from photographs of people, places, and things to charts, graphs, and tables containing technical information and, to diagrams and figures designed to portray processes and objects not directly observable. Visualizations are intended as an aid to interpretation. However, research has shown that visualizations often are designed in such a way as to impede understanding. Furthermore, whereas the target audience for visualizations is often those students having difficulty learning science, it is those students with a firm grasp of science who learn the most from visualizations. Thus, science teachers are well advised to provide frequent and structured assistance to students to help interpret visualizations in science textbooks.

Science Trade Books

In the primary and elementary grades, trade books are often the preferred print media support for science instruction. Science trade books are literary books containing science content and are designed for a general readership rather than for the purposes of formal education (Ford 2005). Trade books provide both interesting possibilities and challenges for teaching science in school. The vast majority of reading instruction in schools takes place using narrative texts, and the reading strategies taught in that context are simply assumed to be applicable to expository and argumentative texts. To an extent, the strategies are generalizable, but also to an extent learning to read is genre specific. Science trade books are primarily expository in nature and thus fall into a type of text on which students have received less specific reading instruction (Norris et al. 2008). Thus, any difficulties in reading science trade books that arise from the genre of the books risk being associated in students' minds with science itself.

Other significant issues arise in the use of science trade books to teach science in schools. First, research has documented a bias among teachers to select life science topics almost to the exclusion of the earth and physical sciences. Second, given that science trade books typically were not designed as instructional resources, they provide little or no support for teachers in designing lessons. Third, in a manner similar to science textbooks, science trade books tend to concentrate on scientific content knowledge and mostly to ignore concepts of evidence, procedural knowledge, and the nature of science and scientific inquiry. Fourth, when the books focus on evidence, it tends to be upon direct observation, which runs the risk of intensifying a bias students are known to possess in taking as scientific evidence only that which is directly observable. Fifth, the development of scientific vocabulary is addressed in science trade books, and considerable new vocabulary is provided in them. Nevertheless, trade books rarely build upon the best and latest research on language acquisition, such as the need for repeated opportunities to use new words in context.

Science trade books can be useful sources of scientific information and vocabulary for use in educational settings. However, like science textbooks, they can portray a distorted image of the nature of science. Therefore, as with all educational resources for teaching science, they function best in the hands of teachers knowledgeable of the content and procedures of science, and of the pitfalls in learning this subject and how to navigate around them.

Adapted Primary Literature

Adapted primary literature is designed to overcome the problems faced by textbooks and trade books in the teaching of science. Adapted primary literature is an adaptation of primary scientific literature for use by science students that attempts to maintain much of the canonical form of the primary literature while making allowances for the level of scientific knowledge possessed by the students. In maintaining the canonical form of primary literature, adapted primary literature contains much more discussion of methods, fuller presentation of data, more extensive argumentation, and more widespread expressions of tentativeness than any form of print media other than primary literature itself. Adapted primary literature has much of the look and feel of primary literature. There are titles and authors listed at the beginning. There are discussions of findings including mentions both of the strengths and of the weaknesses of the studies. Often, there are arguments directed to impugn interpretations of the results alternative to the one presented.

Research into the use of adapted primary literature with elementary school and high school students shows that, as might be expected, the genre presents specific challenges. Students are not used to facing text in this form. Encouragingly, what the research does show is that students think more critically about adapted primary literature than they do about textbooks and journalistic literature (Yarden 2009). One conjecture for why this might be so is that adapted primary literature actually invites critique, much as science does, by its hedged and tentative mode of expression. This is a good result, because it demonstrates that when students are asked to read texts that resemble primary scientific literature, they start to read more like scientists. The risk is that tentativeness is seen as a shortcoming of science, so teachers cannot end instruction with just a naïve view of the fallibility of science. Students need to grasp how science can be uncertain and, at the same time, the most reliable source of knowledge available.

Conclusion

The ability effectively to use print media is crucial to the communication of science, whether for the one sending or the one receiving the communication. There are many forms of print media used in the communication of science, and each brings its own communicative strengths and its own interpretive demands.

Prior Knowledge

Keith S. Taber
Faculty of Education, University of Cambridge,
Cambridge, UK

Keywords

Diagnostic assessment; Prerequisite knowledge; Prior learning

The term "prior knowledge" is used in relation to teaching and learning and refers to the knowledge that a learner or group of learners has prior to a specific learning episode or course/program of study. The notion of prior learning is important from at least two perspectives. From the perspective of educational purposes, educational provision should be designed such that each stage or phase of educational experience allows learners to make progress beyond what they have already achieved in earlier stages or phases. So, for example, teaching about any science topic in secondary education should represent progression over what is taught in primary school. Similarly, an undergraduate program will be designed so that the curriculum for the final year students is more advanced than that met by freshers. The design of a curriculum therefore involves making decisions about appropriate target knowledge at each stage or level informed by assumptions about the prior knowledge of students studying at that stage or level.

A second, but related, perspective is that of the nature of the processes of learning. It is widely considered that academic learning is an iterative process, where learners use previous learning and experience as interpretive resources to make sense of new teaching and over time develop their existing understanding and knowledge through the process of relating existing knowledge to new ideas, examples, or contexts they meet in their studies. This is a basic assumption of constructivist models of learning. Analysis of science concepts, and research exploring students' ideas and possible learning progressions, suggests which prior knowledge is needed to meaningfully learn key concepts set out in the science curriculum (Alonzo and Gotwals 2012). That prior learning which is considered essential for making sense of a new concept is referred to as prerequisite knowledge.

Diagnostic assessment techniques, and sometimes published diagnostic instruments, may be employed by teachers to check whether student prior knowledge matches the identified prerequisite knowledge at the start of a topic or course of study and to check whether students have already learned material in the teaching scheme

(Treagust 2006). Where learners already show reasonable grasp of target knowledge, adjustments to teaching may be made to avoid repetition and to ensure progression in learning is possible. Where diagnostic assessment suggests prerequisite knowledge is absent, then either remedial tuition can be provided, or adjustments to teaching programs may be made to omit or defer concepts that students are not yet well prepared to learn. The importance of students' prior knowledge to the success of classroom learning is now widely acknowledged and is reflected in a much-quoted aphorism due to the educational psychologist David Ausubel (1968: vi): "The most important single factor influencing learning is what the learner already knows. Ascertain this and teach him [or her] accordingly."

A great many studies into student knowledge and understanding in science education have found that learners' prior knowledge about science topics cannot be considered simply in terms of the presence or absence of the prerequisite knowledge needed for learning the target knowledge set out in the curriculum. Research suggests rather that students commonly hold alternative ideas in many science topics that may overlap only partially or may even be completely at odds with prerequisite and/or target knowledge. These alternative ideas have commonly been labeled with various descriptors such as intuitive theories, misconceptions, alternative conceptions, and alternative conceptual frameworks. Research suggests that these alternative ideas are often significant for learning of target knowledge – frequently although not always in ways that interfere with intended teaching – and that they may at least sometimes may be tenacious and continue to dominate the learner's thinking about a topic after teaching of the canonical scientific ideas. Diagnostic assessment of prior knowledge is therefore an important part of science teaching with at least three important functions:

- To check that students do not already hold the target knowledge to be taught
- To test for the presence of essential prerequisite knowledge
- To identify alternative conceptions that may impede learning of canonical target knowledge

Problem Solving in Science Learning

Edit Yerushalmi[1] and Bat-Sheva Eylon[2]
[1]The Weizmann Institute of Science,
Rehovot, Israel
[2]The Science Teaching Department, The
Weizmann Institute of Science, Rehovot, Israel

Introduction: Problem Solving in the Science Classroom

Problem solving plays a central role in school science, serving both as a learning goal and as an instructional tool. As a learning goal, problem-solving expertise is considered as a means of promoting both proficiency in solving practice problems and competency in tackling novel problems, a hallmark of successful scientists and engineers. As an instructional tool, problem solving attempts to situate the learning of scientific ideas and practices in an applicative context, thus providing an opportunity to transform science learning into an active, relevant, and motivating experience. Problem solving is also frequently a central strategy in the assessment of students' performance on various measures (e.g., mastery of procedural skills, conceptual understanding, as well as scientific and learning practices).

A *problem* is often defined as an unfamiliar task that requires one to make judicious decisions when searching through a *problem space* with the intent of devising a sequence of actions to reach a certain goal. *Problem space* is defined as "an individual's representation of the objects in the problem situation, the goal of the problem, and the actions that can be performed in working on the problem" (Greeno and Simon 1984, pp. 591). This exploratory nature of problem solving mandates an innovative, iterative, and adaptive process. In contrast, in an *exercise* the solvers apply a preset procedure, with which they are acquainted, to reach the problem's goal, and therefore the solvers' choices are limited (Reif 2008). Whether a task serves as a problem or an exercise for a particular solver depends on the prior knowledge of the solver.

School science problems share common traits that stem from their being grounded in a scientific knowledge domain: prediction is derived from well-specified premises and requires precision; real-world phenomena are simplified and their description is reduced to a few variables. Where appropriate, school science problems require the use of formal, explicit rules that are part of a scientific theory. These rules must be interpreted unambiguously, as compared with the plausible, implicit knowledge structures that serve in everyday reasoning. However, the problems typically used in science classrooms vary greatly along dimensions such as authenticity (i.e., abstract vs. real-world context), specifications of known and target variables (i.e., well vs. ill structured), duration (a few minutes to several months), complexity (i.e., the amount of intermediate variables), and ownership (i.e., the problem defined by the teacher or by the student). At one end of the problem spectrum, one can find the abstract, well-structured, short, and simple problems that are commonly found in traditional textbooks. At the other end, one can find design or inquiry projects that introduce a real-world context, are ill structured and complex, and involve the students themselves who define the project goals and who engage in extended investigations that they have roles in determining.

Domain-Specific Knowledge and Problem Solving

The relevance of research on problem solving to science instruction increased in the 1970s, when researchers began studying problems anchored in specific knowledge domains (e.g., chess, physics, and medicine). Some of this research focused on short and well-structured problems encountered in science classrooms, all of which require well-defined problem-solving procedures. This research originally took an information processing perspective. It involved two central methodologies: the analysis of "think aloud" protocols of both more and less experienced subjects (described in this research as "experts vs. novices") in a specific domain to determine how each group approached problem solving and the construction of computer programs to simulate and validate theories of human behavior in solving problems. Research on experts and novices has underscored the importance of domain-specific knowledge in problem solving, as well as the role of problem solving in developing domain-specific knowledge and general problem-solving methods.

Experts' and Novices' Approaches to Problem Solving

One aspect in which experts and novices in a certain domain differ is their prior knowledge structures and how they use these. When approaching problems, both experts and novices rely on specific cues (e.g., keywords, idealized objects, and previously encountered contexts) in the problem situation to automatically retrieve domain-relevant information. However, experts store in their memory hierarchical structures (schemas) of domain-specific knowledge (declarative and procedural) that allow them to use cues in problems to quickly encode information (chunking) and to reliably retrieve schemas. Experts' schemas revolve around in-depth features (e.g., underlying physics principles), in comparison with novices' problem schemas, which rely on surface features (e.g., "pulleys") and are fragmented. However, other researchers (Smith et al. 1993) who have taken a constructivist, "knowledge-in-pieces" view of learning argue that novices abstract deep structures of intuitive ideas rather than representations organized around concrete surface features.

When solving problems, both experts and novices were found to use heuristics – general but weak methods to enhance their search process, such as a means-ends analysis, starting from the problem's goal and working backward to the given problem situation, recursively identifying the gap between the problem or goal and the current state and by taking actions to bridge this gap. However, unlike novices, in describing a problem, experts devote considerable time to qualitative analysis of the problem situation before turning to a quantitative representation (Reif 2008). More specifically, experts often make simplifying assumptions, construct a pictorial or diagrammatic representation, and map the problem situation to appropriate theoretical models by retrieving effective representations that derive from the experts' larger and better organized knowledge base. In addition, experts differ from novices in their approach towards constructing the solution: while novices approach problems in a haphazard manner (e.g., plugging numbers into formulae), experts devote sufficient time to effectively plan a strategy for constructing a solution by devising useful subproblems. Experts also have better metacognitive skills and spend more time than do novices in monitoring their progress: they evaluate their solutions in light of task constraints, reflect on their former analysis and decisions, and revise their choices accordingly as necessary.

Problem Solving as a Learning Process

Problem solving may trigger a process of conceptual change, leading learners to develop scientifically acceptable *domain-specific declarative knowledge*. Namely, learners can refine and elaborate their conceptual understanding by engaging in problem solving in a deliberate manner: articulating how they apply domain concepts and principles, acknowledging conflicts between their ideas and counterevidence, and searching for mechanisms to resolve these conflicts.

Similarly, successful learners were found also to work in a deliberate manner when learning from worked-out examples. Worked-out examples in standard textbooks frequently omit information justifying the solution steps. Research (Chi 2000) indicates that learners tend to generate content-relevant articulations (self-explanations) to make sense of solution steps. Successful problem solvers generate more self-explanations and, in particular, principle-based ones. More specifically, they tend to relate the solution steps to the domain principles or elaborate on these principles. Self-explanations serve learning by either bridging the gaps that correspond to the omissions in the solution or by a self-repair process in which solvers attempt to resolve a conflict between the scientific models conveyed by a worked-out example and the possibly flawed mental model held by the solver.

Acquiring *domain-specific procedural knowledge* takes place when the problem solver, applying general but weak search methods, identifies successful domain-specific procedures that are stored for future use. These acquisition processes play an important role in designing e-tutors for problem solving. Another mechanism for acquiring domain-specific knowledge is the use of analogical reasoning in solving analogous problems that may be similar in one of two ways:

1. They may be similar in the material properties shared by the two problem scenarios (e.g., the heart and a pump). Devising an analogous scenario to an original problem scenario can help the solver to focus on relevant variables and identify a strategy to solve the original problem. Instructors have used intermediate scenarios, termed bridging analogies, to support the process.
2. Another type of similarity between two problems refers to the scientific concepts and principles that the solver employs to solve the problems. Solvers often rely on the procedure used in solving a previous problem (i.e., a source problem) and map it to construct a solution to a target problem (e.g., resolving the forces in a static equilibrium problem, where various force agents are considered).

Identifying clearly the similarities as well as the differences between analogous problems can help students to acquire domain-specific procedural and declarative knowledge.

Research underscores several factors affecting learning through problem solving:

- *Metacognition* relates to the extent to which within a problem-solving process the purposeful pursuit of learning, accompanied by an awareness of one's beliefs and goals, takes place.
- *Epistemological beliefs*, such as one's expectation to engage in a deliberate search process or merely to retrieve an algorithm to solve a problem, affect what learners notice and think about when they act.
- *The sociocultural nature of learning* highlights the contribution of cooperative learning that engages students in discussing and arguing their ideas when solving problems together.
- *Cognitive load* (Paas et al. 2010) results from the limitations of working memory, impeding meaningful learning when the solver has to process simultaneously vast amounts of information.

Instructional Methods for Fostering Problem Solving and Conceptual Change

The traditional teaching of science problem solving involves a considerable amount of drill and practice. Research suggests that these practices do not lead to the development of expert-like problem-solving strategies and that there is little correlation between the number of problems solved (exceeding 1,000 problems in one specific study) and the development of a conceptual understanding.

Cognitive apprenticeship underlies many instructional strategies that have been found to promote expert-like problem solving. During problem solving, learners interact with their peers and with their instructor and reflect on the connections between their existing ideas and practices and those that more closely characterize experts' culture of practice and decision-making. The roles of the teacher are (a) *modeling*, explicating the tacit problem-solving processes of the expert, (b) *coaching* learners as they engage in scaffolded problem-solving, and (c) *fading*, gradually decreasing this support until the learners can work independently.

Two complementary mechanisms of scaffolding problem-solving have been suggested (Reiser 2004): *structuring* and *problematizing*. *Structuring* a task refers to reducing its complexity and limiting the choices of the problem solver. *Problematizing* directs one's attention to aspects that one might otherwise overlook. Instruction should be balanced between structuring and problematizing so that tasks will be manageable to learners yet remain challenging and engaging. These mechanisms can be carried out for the range of problems described in the introduction.

The following are some examples of structuring methods that have been shown to be effective:

1. *Worked-out examples* can be used to "model" the tacit goals and reasoning underlying the problem-solving strategies of experts, which later can be used in students'

solutions. To narrow the problem space and minimize the cognitive load, researchers use methods such as labeling solution steps in terms of "subgoals." This approach has also been implemented in e-tutors that follow a *reciprocal teaching* approach, where computers and students alternately coach each other.

2. Tools that assist learners in applying heuristics when seeking solutions. For example, inquiry or design maps recommended for guiding a particular design or an inquiry project serve as visual aids that may help learners to decompose open-ended problems and track what steps they have taken in a problem solution.
3. Explicit verbal reminders (prompts) can induce problem solvers to formulate self-explanations and to self-repair their understanding.

Like structuring, problematizing also takes different forms along the problem spectrum previously mentioned. For example, researchers have pointed out the instructional value of problem situations that elicit intuitive ideas and result in confusion (e.g., qualitative conceptual problems) to trigger argumentative discussion. Problematizing in this context refers to techniques used to stimulate argumentation, such as asking students to express their ideas, encouraging them to identify gaps in their understanding and by providing the requisite time and social atmosphere so that they can work to resolve any disagreements. Incorrect examples (e.g., the teacher providing solutions she/he knows to be erroneous) were found efficient in triggering reflection and in highlighting critical features that distinguish between scientific and lay interpretations of the scientific concepts and principles involved.

Programs such as "systematic inventive thinking" (SIT), based on analyzing many patents, illustrate the interplay between structuring and problematizing in promoting creativity when solving ill-defined problems such as design projects. In such programs learners study methods for functional analysis of systems and systematic problem-solving strategies for carrying out divergent and convergent thinking.

Part and parcel in the design of instruction is the careful choice of assessment tasks and methods of scoring that align with the learning goals. These choices have a strong impact on the problem-solving practices that will take place in the classroom.

Assessment for Problem Solving

Problem solving is positioned as a central objective within the curricula of many countries where it is seen as providing a basis for future learning, for active participation in society, and for undertaking activities of personal interest (NRC 2010). Problem solving was introduced as an additional assessment domain in PISA 2003 because participating countries were interested to know if and how students' capacities in reading mathematics and science were matched with an overall capacity to solve problems in real-life situations. The OCED framing (OECD 2012) for problem solving links it with transfer/translation – the ability to apply what has been learned in one context to new situations. Assessment of problem solving therefore is linked to monitoring student understanding of science ideas and practices in and through tasks that have meaning and applicability beyond school-based academic success, a goal that is evident in science curricula worldwide. This contribution scopes out the nature of and challenges inherent in assessment of problem solving for formative, summative, and monitoring purposes.

Scoping the Foci for Assessment of Problem Solving

A task becomes a problem for an individual or group when they do not immediately have the knowledge and skills needed to address it. Non-routine problems require both student knowledge generation and sustained attention. A problem has meaning within science curriculum, instruction, and assessment when it provides a frame for and demands the use or development of scientific concepts, scientific disciplinary practices, and science evidentiary bases and when it is compelling and consequential for students. The PISA 2012 generic definition of problem-solving competency overviews this generally accepted meaning for "problem" and "problem solving" as follows:

> Problem-solving competency is an individual's capacity to engage in cognitive processing to understand and resolve problem situations where a method of solution is not immediately obvious. It includes the willingness to engage with such situations in order to achieve one's potential as a constructive and reflective citizen. (OECD 2010)

Assessment of student problem-solving capacity therefore needs to present students with a specific practical, real, or hypothetical problem or set of problems to solve, and it needs to take account of the breadth of conceptual, practice, motivational, and affective aspects needed to solve a problem.

While there is considerable variation in the specification of the exact capacities required in problem solving, there is general agreement that it involves, in one form or another, the following aspects:

- Recognizing that a problem situation exists and establishing an understanding of the nature of the situation
- Planning/devising and carrying out activities targeted to reaching a solution
- Monitoring and evaluating/reflecting on progress throughout the activity
- Communicating the problem solution

Students can develop and exercise these capacities through a range of pedagogical approaches, including inquiry- and project-based learning. Nonetheless, how to assess the full ensemble of the interdependent and often contingent and emergent knowledge, skills, and dispositions that students need to deploy over the course of solving an authentic problem is challenging, with this challenge present irrespective of whether the purpose for the assessment is formative or summative for students or for school, national, or international monitoring (Harlen 1999).

Challenges, Imperatives, and Opportunities in Assessment Problem Solving

The Influence of the Problem Context

Student demonstration of problem-solving capacity and inclination is strongly influenced by the context, content, and format of an assessment task. Context can relate to the everyday setting in which a problem is embedded. For instance, one subgroup of students might bring strongly held cultural values and knowledge to questions about environmental protection and sustainability, while another subgroup might bring an influential set of experiences about force and motion grounded in, say, skateboarding or basketball. The context for an assessment also includes where students undertake the task since a classroom and laboratory setting may signal different kinds of thinking that are required. It also offers different materials and resources for data generation and hypothesis testing, particularly for primary-aged students in countries where science is taught by a generalist rather than a specialist science teacher. Context can also link to students' proficiency in the language of the task and the language of science associated with the task and underpinning concepts. It can relate to the social arrangements for a task. This said, the extent to which the assessment context, rather than conceptual demand, dominates as opposed to having a modifying effect is a matter of contention, with the debate broadly linked to the extent that scholars conceive of learning as situated. Nonetheless, there is general agreement it is not valid to assess problem-solving skills via tasks that require conceptual understandings beyond those that can reasonably be expected of student respondents. While this cannot ever be completely assured, approaches for dealing with this problem depend on whether the assessment purpose is predominately diagnostic, formative, or summative or for school and system monitoring.

The context of an assessment has equity and social implications for each of these purposes and associated stakeholders. The literature indicates that an individual's degree of expertise in a given problem-solving domain has a greater influence on their approaches to problem solving within that domain than the individual's age or general developmental level. Students who perform well in one assessment item will not necessarily do so in another assessment task that targets the same skills but in a different context. On the whole, students demonstrate more advanced levels of problem solving if they have some degree of expertise or concrete prior knowledge about the task in question. Relevant, student prior knowledge and expertise can come from home or community experiences as well as from prior schooling which shape opportunity to learn and to demonstrate what one knows/has learned. It is noteworthy that the tasks in the PISA science assessment aim to take the influence of context into account through the use of topics that most students would have informal experience of in their homes and communities, irrespective of their countries. Within the problem-solving strand, the goal is that, as much as possible, tasks avoid the need for expert prior knowledge.

Assessment of Individual or Collaborative Problem-Solving Capacity

An Individual's problem-solving actions are thought to provide insight into their capabilities and inclinations to engage in and employ "higher-order" or "complex" thinking and other general cognitive approaches to challenges they might confront in life. This is especially the case when computer-/web-based assessments are used to track the resources students access and the conjectures they explore. However, the capacity to solve problems as a member of a group is recognized as essential in successful future employment and participation in twenty-first-century society. It is also central to the way most scientists work. Collaboration and communication are central the skills and competencies in current curriculum statements worldwide, including those aspects that focus on student science learning. The type of ill-defined and authentic science inquiries and projects most likely to engage students in learning and using science concepts and scientific practices and ways of communicating and consequently to demonstrate their capacity to learn, learn about and use science, generally relys on a breadth of expertise that can only be marshaled and deployed by a team.

There are significant challenges associated with assessing student collaborative problem-solving skills. These challenges are both conceptual and practical, with these two factors often intersecting such as in, for example, the issue of how do we/do we gauge individual contributions to the whole. Group final products are sometimes used as a basis for assessment, but these are not able to reflect individual or group actions, knowledge, or strategy use and development nor communication processes. Other approaches include the use of portfolios, especially e-portfolios with students encouraged to document and reflect on their actions, thinking, and decisions through the use of a range of modes and media such as digital video, audio and photographs of investigations, data collection, and so on.

The Role of Computer-/Web-Based Assessments

A number of research groups, mainly within the United States, are exploring the merits of web-based units that incorporate opportunities for self, peer, and teacher formative assessment interactions as well as the ongoing generation and collection of data that can be used to make a summative/cumulating judgment about student learning (Behrens et al. 2010). For instance, the Technology-Enhanced Learning in Science (TELS) Center has developed interactive lessons that guide students in research-based knowledge integration practices using an online map and embedded assessments. Inquiry maps guide students to articulate their ideas, test their predictions, critique each other's views, and distinguish new and elicited ideas. TELS assessments comprise multiple-choice and explanation items which ask students to connect ideas into arguments. Another example comes from the Interactive Multi-Media Exercises (IMMEX). This program tracks students' actions and data-mining strategies to arrive at a solution, grouping the strategies into types and identifying pathways into specific strategy types. In addition, it offers the possibility for students to collaborate to solve a problem and so has the potential to be used to elicit students' communication skills along with the capacity to consider other view points and self-management (Cooper et al. 2008).

PISA 2015 (OECD 2013) plans to use computer-based assessment of student collaborative problem solving. The PISA 2015 Draft Collaborative Problem Solving Framework proposes three core collaborative problem-solving competencies: establishing and maintaining shared understandings, taking appropriate action to solve problems, and establishing and maintaining team organization. The assessments will be computer based as a way of controlling the input and influence of a student's "collaborator" and to allow for the tracing of student decisions and actions. This will be the first time that "interactive problems" have been included in a large-scale international survey, and developments have implications for national and more local systems of dynamic/performance assessment.

Formative Assessment During Problem Solving

- The focus of the earlier sections has been towards the summative and monitoring aspects of assessment. Teacher and student ongoing assessment of student achievements, progress, and needs is central to teaching and learning problem solving. In order to present students with problem-based tasks, teachers need to know what might constitute a problem for their students. Units of work need to begin with an assessment of this with problems and lessons planned using this information. Subsequently, teacher and student formative assessment (Black and Wiliam 1998) is crucial for students to progress towards the successful and efficient resolution of a problem.

- Teachers need to engage in formative assessment to know where students are in their thinking and development and to assist them in deciding on next steps. Teachers can use of variety of sources of in situ information to build up a picture of student development and progress towards a potential problem solution including noting in what contexts students can perform particular tasks, what resources they access and use and how, and so on. Teachers can use resources in the setting to provide feedback to students on their progress and next steps. There is ample evidence, from a range of research programs and countries, that this is the most challenging aspect of formative assessment for teachers. This is all the more so as teachers aim to guide student problem solving when different students might pose and pursue different questions and pathways towards the resolution of the same problem. Active engagement in assessment can help in this. Student formative self-assessment is essential if students are to monitor and make informed decisions about the direction of their inquiry and in deciding on productive next actions. While collaborative problem solving distributes the load and increases access to ideas the assessment demands are increased: students need to monitor the extent to which understanding of a problem and productive solution processes is shared around the group and any actions contribute to the whole. These aspects need to be a focus for teaching and assessment.

Conclusions

Student capacity in problem solving of science-based/science-related tasks, including their capacity for collaborative problem solving, is central to their ability to participate as citizens. Student problem solving is embedded in a number of recommended instructional practices such as inquiry- and project-based learning. Assessment validates and makes visible what is deemed worthwhile, and so it is important that this capacity is assessed, both formatively and summatively. An increasing number of tools are available for teachers, schools, and other organizations to undertake this assessment, but this area remains a key focus for theoretical, practical, and policy development.

Problem-Based Learning (PBL)

Coral Pepper
School of Education, Edith Cowan University,
Perth, WA, Australia

Keywords

Deep learning; Group work; Solving problems

Problem-based learning (PBL) represented a major and widespread change in educational practice within higher education when introduced into McMaster University and Case Western Reserve Medical Schools during the 1960s (Barrows 2007). The teaching and learning strategy spread during the 1970s into medical schools in Newcastle (Australia), Maastricht (Netherlands), and New Mexico Universities. Since then problem-based learning has spread across the world and is currently practiced intermittently across the United States, Canada, Europe, Singapore, and Australia. From beginnings in medical schools, problem-based learning has been introduced into all of the health sciences, engineering, business, science, and education. Increasing uptake of problem-based learning (which differs from problem solving) occurred because it was considered a means to engage students in deep rather than surface learning and was viewed as a successful strategy to align university courses with the real-life professional work students were expected to undertake on graduation.

Problem-based learning is considered "problem-first learning" because it is the problem which defines the learning. Instructors design problems to represent authentic, real-world situations or issues likely to be addressed in the work place on graduation. Typically, students in small groups work through the problem to decide on the information and skills they will need to investigate the issues identified and strive to resolve the situation. Often the problem involves collaboration between disciplines so that students are required to build on current knowledge to synthesize then integrate new information. Instructors monitor group processes and facilitate student learning.

However, students themselves are responsible for the learning that occurs within the group. Generally standard problems developed in education programs are well constructed so that all elements of the problem are clear from the outset and there is a preferred process to arrive at the correct conclusion. In a shift from this format, problems crafted for problem-based learning are ill structured and vague, where students define the elements of the problem and there are often alternative pathways to alternative solutions. Throughout this student-centered and self-directed process, students collaborate to share their knowledge and reflect on their learning and assessment (Azer 2008). Contemporary examples of ill-constructed problems suitable for problem-based learning include those centered on policy (fixing a price on carbon emissions), engineering design (processing gas onshore or offshore), and ethical dilemmas (levels of support to refugees).

On beginning a problem-based learning task, students work in small groups of four to eight, which may be self-selected or allocated by the facilitator. Students often underestimate the importance of negotiating group protocols so this is the initial priority before identifying the learning outcomes and sharing their prior knowledge. They are then able to determine gaps in their collective knowledge and plan strategies to obtain further information they perceive as required. Regular group conversations occur, and during the process students commonly reassess the requirements of the task as their collective knowledge increases so that their learning focus may alter. Throughout problem-based learning, facilitators participate to support student learning without directing or providing all of the information for the students. On completion of the task, students provide a summary of their learning for assessment. This may take the form of oral presentations, formal reports, or executive summaries. It is appropriate also to include an element of peer assessment.

Modern insights on learning emphasize four elements of learning: that learning should be constructive, self-directed, collaborative, and contextual. The problem-based learning strategy meets each of these criteria. Researchers supporting problem-based learning describe many benefits gained by engaging in the strategy. The first of these is to increase students' own engagement in learning with them experiencing deep learning rather than surface learning. This is due to the alignment of teaching and learning activities and between curricular objectives and the assessment tasks. Students are also perceived as taking greater responsibility for their own learning by deciding on the information and skills they require to investigate problems and then synthesizing new information to provide solutions to those problems. While high-achieving students are often hesitant to welcome group work, many warm to problem-based learning after experiencing the student-centered focus and the opportunities to pursue group interests. Small group work also contributes to reducing student dropout because it encourages them to share and elaborate their prior knowledge, share responsibility for group goals, and engage in learning in a social context.

As a teaching and learning strategy characterized by flexibility and diversity, it is implemented in a variety of ways in different disciplines in diverse contexts. (Savin-Baden 2003; Savin-Baden and Howell Major 2004) Typically medical courses use problem-based learning case studies where a multifaceted problem is posed in place of a series of traditional lectures on sequential topics throughout a learning program. Clinical courses are often restructured and the entire curriculum remapped for the problem-based learning approach. (Barrows 2007) Engineering students are frequently exposed to problem-based learning in the form of project work during their final years of study, and science students are regularly introduced to problem-based learning to complete assessment tasks within their studies. In addition a simplified version of problem-based learning has been introduced into primary and secondary school settings in recent years, although in these contexts a fundamental aspect of much tertiary PBL is changed. In school contexts there are no forms of professional/work contexts that have the same shared immediacy for students as is the case in most tertiary contexts.

Process Science

Robin Millar
Department of Education, University of York,
Heslington, York, UK

"Process science" (or a "process approach") refers to science courses or programs that emphasize the development of students' "science process skills," that is, their ability to use the "processes of science" in carrying out tasks. These are considered to be the processes which scientists follow when exploring the natural world and developing scientific explanations. There is not complete agreement among science educators on what the specific processes of science are. Most lists of processes however include observing, measuring, classifying, inferring, predicting, hypothesizing, and finding patterns, and some also add: experimenting, planning investigations, controlling variables, communicating, and others. A "process approach" to science contrasts with the more usual "content approach," in which the development of students' practical and inquiry skills is seen as secondary to, or a by-product of, the development of their scientific knowledge and understanding.

Perhaps the best-known course of this kind, and one of the earliest, is *Science – A Process Approach* (*SAPA*), developed by the American Association for the Advancement of Science in the 1960s for use in primary (or elementary) schools (Livermore 1964). The teaching activities are grouped according to the science process involved, and the course is given coherence by these rather than the science content. *Warwick Process Science*, developed for use in secondary schools in the UK in the 1980s (Screen 1986), consisted of a series of units, each designed to develop a specific process skill through activities linked only by the process involved and drawing on a range of science content.

The process approach emphasizes science as a form of inquiry, rather than as a body of knowledge. Advocates of a process approach argue that learning of process skills is more durable than learning of content and that these skills are transferrable to everyday situations and hence are a more valuable outcome of school science. A process approach is also said to enable students of a wide range of abilities to experience success in learning science. Another argument for a process approach in primary school science is that it is claimed to develop abilities that enable students to learn science content more easily and effectively in later years.

Process science courses have not, in general, achieved the impact, or levels of adoption, that their developers had hoped. The process approach has, however, influenced science curriculum design and teachers' thinking, especially at primary school level where an emphasis on inquiry rather than on content can seem more attractive and appropriate. A process approach offers a relatively flexible way of teaching scientific inquiry, avoiding a more algorithmic view of science method.

The process approach has however been quite severely criticized, on several grounds (see, e.g., Millar and Driver 1987). Its critics argue that it presents a view of scientific inquiry which undervalues the role of ideas and theories and does not distinguish science from other forms of systematic inquiry. It is also argued that children develop competence in many of the "process skills" without any specific instruction and that increasing expertise in the exercise of these skills cannot be clearly described in domain-general terms.

Proficiency Levels

Gabriela Noveanu
Curriculum, Institute for Educational Sciences,
Bucharest, Romania

Keywords

PISA; Proficiency levels

Proficiency levels represent performance levels encapsulating typical students' proficiency in a definite interval of the scale delineated by cut points; they are characterized by ranges of values on the continuous scale grouped together into bands. These levels make possible the comparisons of performances across subgroups and of average performances among groups of students. Being at a level means that students placed at a particular level based on ability estimate would be more likely to accomplish tasks at that level. By implication, they would most likely be able to successfully complete tasks at or below that location, but would be less likely to be able to complete tasks above that point, on the scale.

For example, for print reading in Programme for International Student Assessment 2000, student scores were transformed to the PISA scale. The continuum of increasing print reading literacy is divided into five bands – level 1, level 2, level 3, level 4, and level 5 – each of equal width having two unbounded regions, one at each end of the continuum. The information about the items in each band – difficulty estimates, framework classifications in terms of text, aspect and situation, and brief qualitative descriptions capturing the most important cognitive demands – is used to develop summary descriptions of the kinds of literacy associated with different levels of proficiency. The students' locations on those scales are estimated, and the location estimates are then aggregated to generate and report useful information about the literacy levels of the respondents.

Keywords

Plans for learning science; Science activities

Program, as used in science education, can be used to simultaneously define plans for learning science and activities that are ancillary to, and supportive of, that learning. This concurrent meaning is seen in documents such as the National Science Education Standards (National Research Council 1996). This document sets out parameters for the goals, design, development, selection, and adaptation of opportunities for learning science and establishes standards for the content, teaching, and assessment of those opportunities, taking into account the context and policies of the jurisdiction. Drawing from this document, a comprehensive science program should:

- Be developed within and across grade levels to meet a clearly stated set of goals
- Be developmentally appropriate, interesting, and relevant to students' lives, emphasize student understanding through inquiry, and be connected with other school subjects
- Be coordinated with mathematics teaching and learning to enhance student use and understanding of mathematics in the study of science and to improve student understanding of mathematics
- Give students access to appropriate and sufficient resources, including quality teachers, time, materials and equipment, adequate and safe space, and the community
- Ensure that all students have equitable access to opportunities to achieve their potential
- Empower schools to work as communities that encourage, support, and sustain teachers as they implement effective science teaching and learning

Programme for International Student Assessment (PISA)

Peter Fensham
Mathematics and Science Education Centre,
Queensland University of Technology, Brisbane,
Australia
Monash University, VIC, Australia

The assessment of the science component of the OECD's PISA project introduced a radically new intention for the assessment of science learning and operationalized this with a novel instrument that included item types that had not previously been used in such large-scale testing, either nationally or internationally.

The OECD's commission for the PISA project in 1998 was to provide information to participating countries about how well prepared their 15-year-old students were for twentieth-first-century life in the domains of reading, mathematics, and science – an unusually prospective brief for the assessment of learning. Fifteen-year-old students were chosen because, in a number of countries, it is the age when compulsory study of science and mathematics can cease.

This commission required PISA Science to be not another retrospective assessment of students' science learning, as is customary at the levels of classroom, school, regional, national, and international assessments (like those used by the IEA in its ongoing TIMSS project). Such testing is closely tied to the intended curriculum for science and can be used to indicate a student's readiness to progress to the next level of schooling or to further study of the sciences beyond schooling in universities or other tertiary institutions.

Future preparedness for life in society as an assessment intention was quite unknown in 1998 among the OECD countries. There were, thus, no existing models for such testing, and one had to be developed that would lead to measures of the students' capability to apply their science knowledge to twenty-first-century contexts involving science and technology (S&T).

This innovative intention to measure preparedness was applauded and endorsed by the member countries of the OECD, but there was widespread skepticism about what would be found by such a study, since the application of science knowledge in unfamiliar contexts was not something that existing science education in schools was emphasizing. It was encouraging that the students in many countries performed well on the tests although there was clear scope for improvement in all cases.

Future Preparedness as a Goal for Science Learning

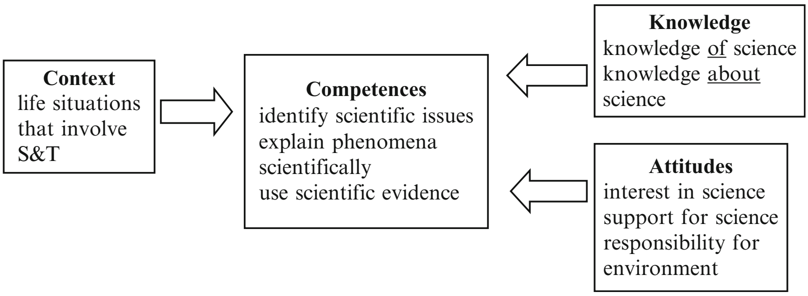
It is quite common to find the science content knowledge for teaching and learning listed in a curriculum's statement under a dual heading of "Knowledge and Understanding." It is as if these two words are synonymous, since there is usually no explanation that they may be intended to refer to different learning of the same content from shallow recall to deeper application.

This difference was made explicit in PISA Science. It would primarily measure how well students can apply the science knowledge they have learnt to novel S&T real world contexts. Hence, the PISA testing would go beyond the simple recall and application of science as it is taught and presented in textbooks.

The organization of PISA meant that science was a minor domain in PISA 2000 and 2003, so that the Science Expert Group had the opportunity to explore several approaches to its task before settling on a framework that would deliver a defined goal for student achievement in 2006 when science was the major domain. The framework is presented in Fig. 1.

The goal was a measure of students' scientific literacy defined as an individual's:

Programme for International Student Assessment (PISA), Fig. 1 Framework for PISA Science 2006 (From OECD 2007)



- Scientific knowledge and use of that knowledge to identify questions, to acquire new knowledge, to explain scientific phenomena, and to draw evidence-based conclusions about science-related issues
- Understanding of the characteristic features of science as a form of human knowledge and inquiry
- Awareness of how technology shapes our material, intellectual, and cultural environments
- Willingness to engage in science-related issues and with science as a reflective citizen (OECD 2006)

With this definition, PISA Science was firmly committed to what Roberts (2007) was to describe as a Vision II approach to science knowledge, which is one that looks outward to science and technology (S&T) in the everyday real world rather than inward to the sciences as specialized disciplines (Vision I).

The scientific literacy definition was differentiated as three cognitive and three affective scientific competences – *identifying scientific issues*, *explaining phenomena scientifically*, *and using scientific evidence* and *interest in science*, *support for science*, *and responsibility toward resources and environments*. The more specifically described competences were then the guides for the design of test units consisting of an S&T context about which several items could be asked relating to these competences. A fuller description of this use of science contexts in assessment and some of its shortcomings are discussed in Bybee et al. (2009).

The Mode of Assessment

The use by PISA Science of a paper-and-pencil mode of assessment has both positive and negative outcomes for science education. This mode made the testings, in general, a familiar activity to many (but not all) of the countries' students. Since PISA Science was not bound by a curriculum sense of science, PISA could use fewer simple multiple choice items and hence more valid types of item, complex multiple choice, and free response. The inclusion of the range of item, types in the projects should encourage countries and their schools to also use a wider range of assessment items since the more precise and open ones can then offer diagnostic as well as formative indications of student learning.

The development of the achievement tests for PISA Science (and for TIMSS) has involved procedures to ensure validity and reliability that go beyond those used in most countries. They include extensive face validity of the items among panels of experts, linguistic and cultural analyses for bias, and statistical analysis of extensive trials with student samples in several countries to establish each item's discriminating power, etc. (for PISA see McCrae 2009). These thorough approaches to test development now stand as exemplary models for the development of similarly intended assessment instruments at a national, regional, or local level of education, where extra-school tests and even fewer of the intra-school tests set by science teachers have such good item design.

Difficulty Level of Items

Retrospectively, the very large number of responses to its items enabled six levels of difficulty to be identified. The cognitive demand in the items of each of these levels was then described leading to quite new understanding of this feature of science learning that provides an indication of these depth dimensions for science learning, which can have diagnostic usefulness for teachers when teaching an associated topic (OECD 2007).

Assessment of Affect About Science

In the years since PISA has begun, there has been an accelerating stream of reports from international and national studies that indicate a decline in student interest in science and in science careers, particularly across the more developed countries. As in its approach to cognitive science learning, PISA Science broke new ground in associating interest in science, support for science, and responsibility for the environment, to the specifics of the science content and context as well as with a more generic measure of the first two. Thus, affective items were embedded in the contextual units as well as being asked in the student questionnaire.

The embedding of affective along with cognitive items in the main assessment test was a major innovation and contribution to science education in two ways. Firstly, it signaled very clearly that both types of learning were natural expectations from compulsory school science. Secondly, the embedding meant that students could respond positively to the specific science in one contextual unit and negatively to what underlay another contextual unit. A much richer portrayal of their affect resulted. This approach to affective responses to science is discussed in more detail by Olsen et al. (2011).

A negative aspect of PISA Science lay in its use of the paper-and-pencil mode, since there are now a number of commonly agreed curriculum goals for school science education that are not amenable to this mode of testing. The classic and abiding example of these is the assessment of practical performance in science, but now decision making about socio-scientific issues, context-based science, and science project work in and outside school can be added as not amenable to this mode of testing (see Fensham and Rennie 2013). The silence of the OECD and PISA Science on this point may unfortunately be interpreted as suggesting these other science learnings are not of worth.

Another unfortunate practice in these large-scale projects is that they release only a small fraction of the items from any one testing so that their elegance as scales is never publicly evident. By now however, enough items have been released for them to be used as reliable "item banks" for the types of science learning that PISA Science intends.

Project for Enhancing Effective Learning (PEEL)

Ian Mitchell
Faculty of Education, Monash University,
Melbourne, VIC, Australia

Keywords

Action research; Metacognition; Pedagogical knowledge; Teacher knowledge; Teacher research; Teacher Thinking; Teachers as Researchers

Background and Overview

The Project for Enhancing Effective Learning (PEEL) is a grassroots, Australian, collaborative action-research project involving teachers and academic colleagues researching ways of stimulating and supporting metacognitive student learning. It was co-founded in 1985 by John Baird (University of Melbourne) and Ian Mitchell (Monash University). It has continued for over 25 years, involving thousands of teachers, in hundreds of schools, in several countries because it addresses issues important to many teachers.

How and Why Did It Start?

PEEL synthesized two lines of research; Mitchell had been researching, in his science classrooms, ways of getting students to retrieve and where necessary restructure their existing and often alternative conceptions and had found that real and very positive classroom change was possible. These aspects of thinking involve one type of metacognition – Mitchell's students had learned to purposefully reflect on their ideas in the light of classroom activities and discussion. Baird had been researching metacognition more broadly and his work (Baird 1986) included other aspects of thinking; he had found, for example, that students commonly did not link different lessons such as theory and practical lessons, did not seek to identify the key points in something they read, and did not reflect on the purpose of an activity – or even recognize that there would be one.

Why Were Teachers Needed as Researchers?

Baird had described metacognitive thinking, but how to achieve this was largely unknown. Further progress required a group of teachers researching and developing new practices in an action-research spiral, where what was being done evolved in the light of classroom events. Baird and Mitchell agreed to collaborate with a group of 10 teachers from the school where Mitchell taught half time. The project centered around weekly meetings where the teachers developed and reflected on changes to their classroom practice that were driven by the project's goals. Unusually for the time, the teachers and their academic colleagues shared control over all aspects of the project, including research questions and design.

Goals

The overriding goal was to develop learning that was more informed, intellectually active, and independent through enhanced metacognition – the knowledge, awareness, and control of learning; however, the group knew little about what this could look like in practice. They also expected to be researching the processes of student and teacher change. As it happened, the first 3 months were extremely difficult for hitherto unsuspected reasons associated with the complexities of student change – the group had not anticipated the existence and importance of tackling what were very narrow and strongly held student views about the roles of students and teachers in classrooms.

What Caused PEEL to Spread?

PEEL was unfunded and planned as a 2-year initiative at one school. However, at the end of that time, the teachers refused to let it end, firstly because they found the process of collaborative action research stimulating and secondly because they were valuing the changes to their classrooms. More teachers wanted to join from the original school and, from 1988, from other schools. PEEL spread to other schools in a process that was unanticipated and driven by the desire of teachers to develop ways of improving how their students approached learning. A network of schools, initially secondary, but later including primary schools, developed in the state of Victoria and later among catholic schools in NSW (states of Australia). Mitchell convened this network and, to maintain coherence, established a newsletter, PEEL SEEDS, that became the journal of the project and a database, *PEEL in Practice*.[1] that at the time of writing has over 1,500 largely teacher-authored articles that can be searched by any combination of over 300 search fields relating to learning, teaching, and classroom change. In the 1990s, PEEL spread to large numbers of schools in Denmark and Sweden; from 2005, PEEL played an important role in the founding and sustaining of a network of school-based teacher research groups in China. This shows that ideas from PEEL have been seen as relevant and important in a wide range of educational contexts.

Some Outcomes

Hundreds of Cases Describing Different Aspects of Quality Learning

PEEL teachers have provided multiple and rich descriptions of what metacognition can look in a very wide range of contexts, in virtually all subjects at all levels of schooling. In doing this they have extended our vision of what is possible in terms of quality learning. When the project began, for example, the group was not sure whether students in year 7 would be old enough to be able to discuss and reflect on their learning; it is now clear that students all the way down to grade 1 can do this and take significant responsibility for their learning. These cases and the PEEL database have been used in multiple ways in teacher education at several universities; they connect theory to practice, provide credibility to theory, allow beginning teachers to share the thinking, doubts and uncertainties of experienced teachers, and provide rich stimuli for discussion.

Classrooms Became More Enjoyable

PEEL is a teacher-driven project; it began in a low socioeconomic school that presented classroom challenges to teachers. A key reason it has continued was because teachers valued their classrooms becoming warmer, more collaborative, and less stressful. The classroom looks and sounds different; there were significant changes in classroom discourse and communication (Mitchell 2010). Students, for example, ask questions that reflect monitoring of understanding – they are more explicit about what they do and do not understand and what they need or would like to know. They frame what PEEL teachers have called thinking questions that extend what is being done and allow teachers one route to building a sense of shared intellectual control by making use of these questions to drive what is being done. A growing sense of shared intellectual control means the classroom becomes a learning community with students working more collaboratively with each other and the teacher and being more willing to take risks such as sharing and defending their views, challenging something the teacher or another student says, and tackling tasks in new, creative ways.

Learning Became More Purposeful and Effective

One important outcome of metacognition is changes in roles of and relationships between students and teachers; students make a wider range of decisions and accept that they need to take more responsibility for their learning. The students build understandings that the teacher has a learning agenda and why this is important.

Metacognition promotes deep processing with students monitoring their understanding and

---

[1] (See www.peelweb.org for further details on PEEL)

thinking about what they are doing and how well they understand it. Students actively seek links between different activities and ideas, between their school and home lives, and reflect on the purposes of classroom activities and how these connect to the key ideas and skills of the topic. These debriefing discussions on why we did what we did today are important; PEEL teachers found early that their students had no experience of thinking about the purpose(s) of an activity and, consequently, what they were intended to have learned from it. This meant that many classroom activities, where students had apparently successfully done what was required, were revealed as being far less effective that had been presumed.

Teachers Substantially Expanded Their Pedagogical Repertoire

Another outcome of PEEL that has been very attractive to many is a huge increase in the teachers' knowledge of pedagogy and how to achieve classroom change. PEEL has generated both shorter-term tactical and longer-term strategic knowledge of teaching. Tactical knowledge includes the development (or adaption) of over 200 generic teaching procedures that stimulate and support different aspects of quality learning such as different forms of linking. This resource has been very useful in teacher education in several universities, exposing beginning teachers to a rich tool bag of pedagogical options. Many also provide the basis for hands on workshop activities. Tactical knowledge also includes explicating what are subtle and often tacit teacher behaviors such as those associated with initiating and sustaining a fluid discussion.

The many mutually reinforcing ways of building a sense of shared intellectual control is one form of strategic knowledge in that it is not enacted in a single lesson like a teaching procedure, but over many lessons and in multiple ways. Providing students with opportunities for different types of choices and decisions, framing a small number of big ideas for any unit, and making these a focus of reflection are other strategic aspects of practice. More generally, teachers develop a learning curriculum that runs parallel with their content curriculum. As mentioned above, one of the very early lessons in PEEL was that changing how students approached learning was a complex and challenging task that needs to be done by evolution, not revolution; this becomes part of teachers' learning agendas.

Teacher Researchers Generate Different Kinds of Knowledge that Are Needed in the Knowledge Base of Education

PEEL has shown the value of teachers acting as researchers and of teacher-academic collaboration. Important aspects of the kinds of teacher knowledge briefly summarized above are not common in the academic literature because they need teachers with long-term research agendas and structures that scaffold the articulation of what is often very tacit knowledge. The benefits flow both ways; apart from the classroom benefits just listed, PEEL continued because teachers found the process of collaborative action research to be rewarding and a highly most effective vehicle for ongoing professional learning.

Concluding Comments

Much system rhetoric about education in the twenty-first century talks about the need for students to learn how to learn and to be able to learn new ideas and skills in a rapidly changing world. PEEL provides important answers as to how this might be done; it also provides ways of addressing problems of student alienation from school classrooms. The project also raises challenges to how many systems position teachers as consumers of top-down knowledge who are expected to have little independent control of what they are trying to achieve in the classroom, but rather to be responding to system level goals and initiatives.

Public Communication of Science and Technology

Sook-kyoung Cho
Korea Foundation for the Advancement of
Science & Creativity, Seoul, South Korea

The great developments of science and technology have given us enormous and even frightening power. Owing to the discovery of electricity, medicine, and ICT, we can live a longer life with more conveniences. At the same time, however, the products of science and technology, such as eugenics and the atomic bomb, have caused serious social problems. The issues of climate change, water shortage, disease, adequate nutrition for all, and energy consumption, which we are facing now, are global problems relating to science and technology.

Effective public communication of science and technology is critical in a world thoroughly interwoven with science and technology. On the one hand, most people consider that the public is not sufficiently informed and represented when it comes to decision making about science and technology. On the other hand, scientists worldwide are more and more willing to engage with the public about their research work. Science communication aims to increase public involvement in decisions relating to science and technology by providing more accurate scientific knowledge and information and by expanding opportunities to participate in scientific and technological activities. It also aims to increase the quality of the decision-making process for research and technological applications, which today can have far-reaching effects. In addition, it helps people to understand social and cultural contexts of scientific research and become aware the beauty of science. Science and technology communication, after all, aims to increase the creativity of individuals, communities, and societies, as well as the competence of citizens when they are facing the global issues.

Public Communication of Science and Technology (PCST) started formally in late 1980 in France, slightly after the Public Understanding of Science (PUS) movement in the United Kingdom, at a time when public disbelief in science and scientists was increasing. The PCST is similar to a context model of PUS, because it is based on the consideration that cultural and social values of each stakeholder are important and must be taken into account when science is communicated to the people. Another PUS model is the deficit model where the public, assumed to be homogeneous, is considered as deficient and misguided in its present lack of uptake and understanding of science. In contrast, PCST and the context model of PUS are more concerned about the interaction among the public, the scientists, and others who are involved in communication. PCST has gained its academic support in the appearance of the master's degree courses for science, technology, and medicine communication starting from the United Kingdom and has expanded through the journals of *Science Communication* and *Public Understanding of Science*.

The main issues of PCST are expressed in the following questions: Who is able to be a good science communicator: scientists, science journalists or writers, etc.? What is the role of a science communicator, is it either a translator or a conveyer of science? Among knowledge or information, attitude, and public support, what is the most important in science communication? Which is more effective in science communication, the deficit model or the context model? How can one measure the result and quality of science communication? What are the most suitable strategies for inducing more diverse participation of stakeholders in science communication? And is it possible to have a general theory of science communication applicable not only to developed countries but also to developing countries that have such different traditions and indigenous knowledge?

In order to enhance PCST worldwide, the International Network on Public Communication of Science and Technology (PCST Network) organizes conferences or meetings in different continents. In each conference, nearly 1,000 participants offer hundreds of papers, posters, debates, and plenary lectures. The proceedings are available in the website of the PCST Academy (www.upf.edu/pcstacademy), where documents, courses, books, and events related to PCST are also available. The PCST Network is encouraging the discussion of practices, methods, ethical issues, policies, conceptual frameworks, and economic and social concerns related to PCST, linking practitioners and researchers from different cultures and countries worldwide, in both developed and developing parts of the world, and also providing opportunities for meetings and electronic interactions. And it encompasses all of the explanation and diffusion practices of scientific and technological knowledge that take place outside official and formal education. It includes science journalists, science museum and science center staff, science theater directors, science program producers, academic researchers who study aspects of PCST, scientists who deal with the public, and public information officers for scientific institutions.

Public Engagement in Science

Susan Stocklmayer
The Australian National University,
Canberra, Australia

The term *public engagement* has replaced the earlier *public understanding of science* movement (PUS), mainly in response to a seminal review by the British House of Lords (2000) that examined the relationship between science and society and found it wanting. Following a series of scientific debacles in the 1990s, such as the BSE (“mad cow disease”) scare and the conflict over genetically modified organisms, public trust in science was perceived to be very low. This was a matter for concern, since funding for scientific research and the recruitment of young scientists depend upon positive public attitudes towards science in general. The House of Lords review criticized the public understanding movement for being arrogant and for assuming that a straightforward top-down dissemination of science would achieve positive outcomes.

The review was not the first to comment on the role of PUS: as far back as the early 1990s, the movement had been criticized for its lack of consideration for the public *audience* and lack of respect for public knowledge. This came to be known as the *deficit model* of the public. Nevertheless the guiding principles proposed by the Royal Society in 1985, in which five imperatives for public understanding were stated, were the most influential in driving the PUS movement for the next decade. These five principles constitute arguments for greater public knowledge and understanding. The *economic argument* links a scientifically educated public to innovation and greater prosperity. The *utilitarian argument* is closely allied; the public should be scientifically aware because of the way the community uses science. Science being all around us, we should appreciate and understand how it works. In a sense, the *democratic argument* is a subset of the utilitarian argument. The general public is often asked to make decisions about new technologies and developments that have far reaching effects, locally and globally. It is important, therefore, to have some understanding of these impacts. The *cultural argument* maintains that the best science is to be compared with high art, worth appreciating for its own sake, and educated citizens should have an appreciation of their culture. (This does, however, raise the question of the culture to which science belongs.) Finally, the *social argument* observes that it is the duty of scientists to communicate their research to the public so that the public understands how the money is spent. Reports by Bodmer and Wolfendale in the 1980s and 1990s reiterated these principles and encouraged scientists to communicate their science to a broader public to further these aims. At this time, however, the expectation was that the public would, in consequence, learn and understand more science as a public duty, an assumption that was roundly criticized in the House of Lords Report. A long-term consequence of the PUS movement has, nevertheless, been the regular administration of tests of public knowledge of scientific facts, based upon a survey conducted in 1989 by Durant, Evans, and Thomas. These tests have revealed a remarkably constant level of public knowledge (or ignorance) (Stocklmayer and Bryant 2012).

The House of Lords Report called for a rethink of the science and society relationship and emphasized that the initiative for bridging the gap rested with the world of science and the scientists, not with the public. The arguments above have adjusted accordingly. The term *public engagement* is now commonly used to describe outreach activities worldwide in which the public is invited to participate. Less commonly, the term also encompasses a process of dialogue with public stakeholders, such as consensus conferences and citizen juries, where public knowledge and opinion is both heard and valued. It is now acknowledged that the primary consideration for any successful mode of engagement must be the needs and expectations of the public. Local knowledge and indigenous knowledge are respected for their contributions to the scientific debate.

The idea of public engagement has changed the nature of research into issues and dilemmas at the interface between the public and the world of science. Instead of measurement of science learning, the real complexities of goals and contexts have necessitated cross-disciplinary frameworks and methods. Although such research had its origins well before the millennium, it was not always widely recognized; a broad acknowledgement of the importance of understanding the public is much more recent. Indeed, the notion of scientists' listening to and communicating with the public has led, on occasion, to the proposal that the PUS movement should be replaced by SUP – scientists understanding the public. The emerging discipline of science communication has a strong focus on this aspect of engagement.

Public Science Literacy Measures

Svein Sjøberg
Department of Teacher Education and School Research, University of Oslo, Oslo, Norway

Keywords

Attitudes to science; Civic scientific literacy; Indicators for science; Public understanding of science; Science knowledge; Science surveys; Scientific literacy; Measures

There is a considerable interest in knowing how the public, as consumers, voters and citizens relate to science and technology. There seems to be a broad agreement that *science* (or *scientific*) *literacy* is a good thing (at least as a contrast to science *illiteracy*). In the last decades there has been a proliferation of national and international studies of science literacy, but the concept is foggy and many different dimensions are suggested. There are also many stakeholders who may have competing views about what dimensions such a concept might include. This entry will raise some of the underlying concerns and point to further reading on this very broad topic.

Definitions and Limitations

A treatment of "Public Science Literacy" (PSL) clearly overlaps with other entries like "Science Literacy," "Science for Citizenship," "Citizen Science," "Public Engagement in Science," "Public Communication of Science and Technology," and possibly others. In this entry, the term "Public Scientific Literacy" is considered to be synonymous to "Civic Scientific Literacy" and the frequently used "Public Understanding of Science."

This discussion is limited to the national and international surveys that put numbers on how the adult population relates to science and can be classified as scientifically literate. But even with this limitation, there is an obvious lack of clarity of an accepted operational definition. This has led to a plethora of different instruments and an abundance of claims and findings, often contradicting each other. This is not the place to try to provide precise definitions of the terms, but rather to argue for some care when using the terms and when reading the claims and findings.

The notion of "the public" is the least problematic. In most surveys, this is understood as the entire adult population in a country or territory, often defined as older than 15 years of age, i.e., after the age of compulsory school in most countries.

What is meant by "science literacy" is more problematic. A comprehensive conceptual overview is given by Laugksch (2000). In many languages, the term "science" is a more embracing concept than in English (e.g., Wissenschaft in German). One should therefore note that most measurements of PSL are limited to aspects of the natural sciences and not, for example, the social sciences. But aspects of technology as well as the related engineering are often included in the measures; sometimes also key notions of mathematics and statistics. The report from the National Science Board of the American National Science Foundation is published every second year and is called "Science and Engineering Indicators." Each issue has a full chapter called "Science and Technology: Public Attitudes and Understanding" (NSB 2012). These chapters provide overviews of existing national (US) and international surveys and reviews of main results as well as development over time.

Discussions about what counts as "Public Science Literacy," PSL, have clear parallels to discussions about what counts as science literacy in schools and science education. The influential OECD Programme for International Student Assessment (PISA) of 15-year-old school students has the term "science literacy" as a key concept since testing started in 2000. When science was the core subject of the PISA testing, in 2006, the science education experts made a revised framework that defined "science literacy" (OECD 2006). This framework has a comprehensive discussion of this concept, also rich with references and further reading. While the first two rounds of PISA testing (2000 and 2003) confined science literacy to "competencies" (knowledge and skills) in science, the definition in the 2006 PISA testing was "expanded by explicitly including attitudinal aspects of students' responses to issues of scientific and technological relevance" (OECD 2006, p. 25). It is noteworthy, however, that the resulting PISA score that ranks countries on a scale for science literacy does *not* include the last two dimensions. A main reason is, of course, that there is no clear relationship between the different dimensions that could justify the creation of one single construct.

Stakeholders and Interest Groups

Many groups have an interest in knowing how the public relates to science and technology, both nationally and on a wider comparative level:

The science and technology (**S&T**) **community** is dependent on public trust, confidence, and support for their continued activity for a wide range of reasons: Financial support from public as well as private sources is reliant on how the public perceives scientific research and development. The public image of science and scientists is also of importance for the recruitment of young people to S&T-related studies and careers.

Politicians and their parties have an obvious interest in knowing the attitudes, values, and priorities that the voters have on most issues, and S&T-related issues are key elements in this wider political, social, economic, and cultural context.

Science teachers, **educators**, **and other science communicators** have a professional interest in understanding the knowledge as well as the affective dimensions of how the public relates to their subjects and topics.

Researchers in the social sciences (including science education) have an interest in data that enable them to look for interesting relationships between the different dimensions of PSL (like knowledge vs. attitudes to science). They also try to analyze how different indicators relate to education level, gender, socioeconomic status, etc. They are also interested in comparative data that enable cross-cultural comparisons and data stream that allow analysis of development over time.

The above groups may have different concerns and motives for being interested in how the public relates to science, technology, research, etc., and this is also reflected in what items, constructs, and dimensions they want to include in their surveys. However, educators, the S&T community, as well as industry and national authorities also have a common and obvious concern about national economical competiveness in a high-tech and knowledge-based global market. In this perspective the public preparedness for such a global competition is a concern that is shared among many groups. (Although it is far from clear what kind of knowledge and what kind of attitudes promote such competitiveness!)

Public Science Literacy: Many Dimensions

What is it about science that the public should know? What dimensions should be included in measures of public science literacy? In the following discussion, science is used in the English sense, i.e., not including social sciences, but including aspects of technology and engineering. Mathematics and statistics are not included, although some elements of these are embedded in notions of understanding experiments, fair testing, etc.

Possible (**partly overlapping**) **dimensions to be included**:

1. **Science knowledge**. Important facts, laws and relationships, key ideas, and important theories.
2. **Methods and processes of science**. The role of observations and experiments, ideas about a fair test, controlled experiments, probability, etc.
3. **Science and nonscience**. Demarcation criteria; being able to distinguish science and scientific claims from quasi-science and pseudo-science.
4. **The nature of science and scientific knowledge**. What is scientific knowledge? How reliable and stable is it? Norms and values of science. Science as part of culture. Science and scientists, the institutions of science, and research.
5. **Information sources**, **interest**, **and involvement**. What sources of S&T information does the public use? (e.g., science centers, media, newspapers, journals, Internet) Interest in

S&T versus other fields (arts, politics, sports, etc.). Interest in more specific S&T issues (space, medicine, ICT, gene technology, nanotechnology, etc.). Participation in science-related interest or action groups (environmental, anti-nuclear campaigns, signing petitions, etc.).

6. **Attitudes to science**. Science leads to a better world? Leads to destruction and war? For welfare and progress? Trust and confidence in scientists (relative to other groups). Support for basic science and applied science, R&D? In favor of more public spending on R&D in S&T?
7. **Specific S&T-related issues**: **knowledge and attitudes**. Concrete, contemporary, and potentially controversial issues like environmental challenges, climate change, energy development, stem cell research and human cloning, teaching evolution in the schools, genetically modified food, nanotechnology, animal research, etc.

Many surveys include some or all these dimensions in their instruments, together with background data on gender, age, education level, occupation, as well as political orientation and religious affiliation. Such data, often in time series for several countries and dating back since the mid-1970s, are, of course, interesting data sources for sociological research.

Not all of the abovementioned seven dimensions are, however, usually subsumed under a combined and accepted definition of PSL. The first two dimensions (science knowledge and knowledge of basic features of scientific method) are the elements most frequently included in the definition used by many authors.

It is also an interesting finding that indicators of many of the above dimensions do not correlate, for example, high science knowledge may actually correlate negatively to some attitudes towards science. Hence, combining such dimensions into one meaningful construct does not make sense, neither conceptually nor statistically. There are, however, interesting attempts to combine elements from these dimensions into a meaningful global measure of "Scientific Culture." See Bauer et al. (2012), for an anthology that contains some 26 chapters on "How the Public Relates to Science Across the Globe" from authors from all continents.

Measurement Issues

While there are many studies that claim to measure science literacy of students in schools, for example, TIMSS, but in particular PISA, there are specific challenges when measuring such qualities for the adult population in a non-formal setting. One simply cannot put members of the public to a long and controlled written test of their knowledge and skills, but must prepare surveys where the respondents are willing to participate. The knowledge items in the surveys are most often "disguised" in the form of a quiz game. Data collection may take the form of face-to-face interviews, telephone polls, or written questionnaires distributed by mail. Most items are closed, with fixed answers, but some are also open, free response. (This, of course, complicates coding significantly.) Data collection is often done by one of the many international agencies that are specialists on opinion polls. Sample sizes are usually around 1,000 or more, often drawn by stratified sampling. An overview of such data sources is provided in the abovementioned NSB reports (e.g., NSB 2012).

A challenge for indicators of PSL (as well as for school tests) is to develop items that may be used repeatedly, over long periods of time, in order to monitor trends and changes. This implies that issues that are current, topical, or controversial have to be avoided, since their place on the public and political agenda changes over time. Jon Miller, a veteran in the development of such measurements, notes that the first US attempts to measure PSL in the late 1950s concentrated on issues like radioactive fallout, polio vaccination, fluoridation of drinking water, etc. Later, the depletion of the ozone in the atmosphere received very high attention from the early 1980s. Currently, other topics dominate the political and public agenda, like genetic engineering, embryo-based research, human cloning, GMO food, nanotechnology, etc.

Contemporary surveys, like those of Eurobarometer and similar in other parts of the world, often have a set core of (relatively) stable science and technology items "that stand the test of time" (Miller 2012), plus an extra series of questions related to topical issues on frontier science and emerging technologies, often socio-scientific issues where science knowledge, values, and ethical considerations need to be combined.

The risk when choosing traditional and well-established science knowledge items as core elements in a knowledge test is, of course, that the implicit message about the nature of science is that its results are fixed and eternal and that scientific knowledge is ready-made.

Another challenge for public (and school) surveys of science literacy is the need to have items that are global, that is, of similar relevance to respondents in all countries.

Key examples of frequently used knowledge items for international comparisons in surveys like the Eurobarometer (32 countries), US, Canada, Japan, China, Korea, Malaysia, India, New Zealand follow: (These were used in Eurobarometer 2005, all with a yes/no answer.)

The Sun goes around the Earth.
The center of the Earth is very hot.
The oxygen we breathe comes from plants.
Radioactive milk can be made safe by boiling it.
Electrons are smaller than atoms.
The continents on which we live have been moving for millions of years and will continue to move in the future.
It is the mother's genes that decide whether the baby is a boy or a girl.
The earliest humans lived at the same time as the dinosaurs.
Antibiotics kill viruses as well as bacteria.
Lasers work by focusing sound waves.
All radioactivity is man-made.
Human beings, as we know them today, developed from earlier species of animals.
It takes 1 month for the Earth to go around the Sun.

It is beyond this entry to provide details on results, but it should be noted that there are very large variations in mean scores between countries. Not surprisingly, the knowledge score is also strongly dependent on the level of education of the respondent and of the education level in each country. A general trend is also that the score has been increasing over time in most countries. Further, in most countries it is dependent on age, with the younger respondents being more knowledgeable than older. To a large extent, this is a consequence of the fact that the younger age cohorts spend more time in school than the older generations did.

Public Understanding of Science

▶ Public Engagement in Science

Public Understanding of Science, Assessment of

Jon D. Miller
Institute for Social Research, University of
Michigan, Ann Arbor, MI, USA

The public understanding of science refers to the ability of individuals to read and understand information about basic scientific constructs, including some technological constructs. The concept of public understanding of science reflects a level of knowledge that would allow an individual to read current science journalism, reports from government agencies or nongovernmental sources such as the National Academies, or to watch science television shows like the PBS show Nova. It does not refer to a level of scientific understanding sufficient to obtain employment in a scientific or engineering field.

Unlike school-based measures of student achievement in science, which tend to be curriculum driven, the public understanding of science construct reflects a more functional level of knowledge and use. This construct is often referred to as scientific literacy, and in a seminal piece, Shen (1975) suggested that there are three kinds of scientific literacy. Consumer scientific literacy refers to a level of knowledge necessary to shop for foods, medicines, household chemicals, computer equipment, and modern communication equipment. Cultural scientific literacy refers to understanding science was a way of knowing as compared to other ways of knowing. Civic scientific literacy refers to the knowledge needed by citizens to understand scientific public policy issues and to make sense of competing arguments about these issues.

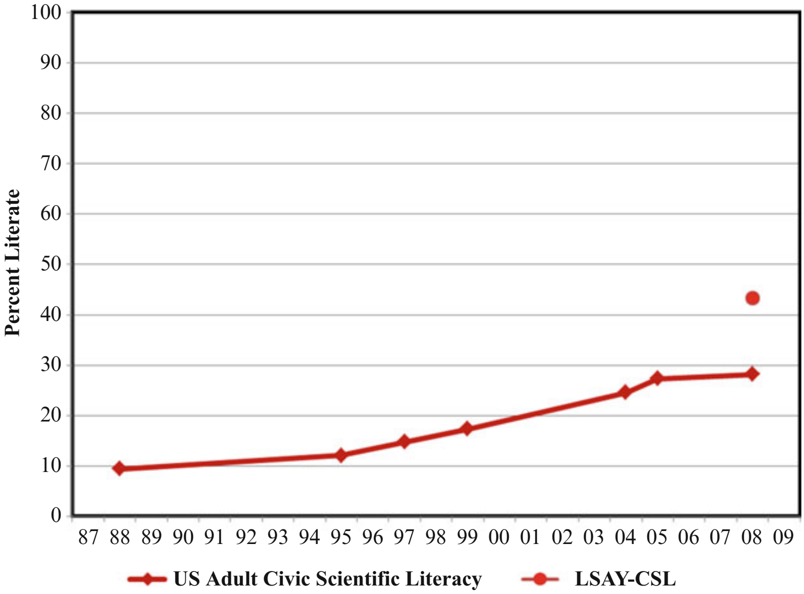
There has been some work on consumer scientific literacy, but the scope of the field is vast and most efforts at measurement and assessment in this area have been narrowed to focus on segments of consumer scientific literacy – computer literacy, health literacy, nutritional literacy, and similar slices of the range of consumer choices.

Miller and others (Miller 1983, 1987, 1995, 1998, 2000, 2001, 2004, 2010a, b, 2012a; Miller and Pardo 2000; Miller et al. 1997) focused on civic scientific literacy because of its importance to the formulation of science and technology policy and the growing importance of science and technology policy issues on public policy agendas. In broad terms, the Miller Index of Civic Scientific Literacy (CSL) reflects the ability of a citizen to read the Tuesday science section of the New York Times or an article in Science et Vie or to understand an episode of Nova. It is a minimal or threshold measure and effective democratic practice would require at least some citizens in a political system to exceed the threshold level.

Using this measure, the level of civic scientific literacy in the United States has increased from 10 % in 1988 to 29 % in 2007–2008 (see Fig. 1). A parallel study of civic scientific literacy in a national sample of young adults aged 37 to 40 – the heart of Generation X – found that 44 % of these young Americans qualified as civic scientifically literate, using the same scale (Miller 2012b). To a large extent, responsibility for this increase in civic scientific literacy rests in the uniquely American requirement that all college students complete a year of college-level science courses as a part of their liberal education. Although this result is encouraging, it is important to note that a majority of all Americans – including Generation X – still fail to meet the minimal requirements included in Miller CSL Index.

A review of comparable measures of CSL in 34 countries found that a substantial majority of adults in all 34 countries failed to qualify as scientifically literate (Miller 2012a). This result is a serious challenge to the basic premises of participatory democracy. Some critics, especially in Europe, dismiss this inability of adult citizens to make sense of important public policy issues that require some understanding of basic scientific constructs as a "deficit model" imposed by an arrogant scientific community (Wynne 1991, 1996; Ziman 1991). The argument is grounded in a belief that all knowledge – including science – is socially constructed and, as such, is politically motivated.

Public Understanding of Science, Assessment of, Fig. 1 Civic scientific literacy in the United States, 1988–2008



If scientific knowledge is socially constructed and politically motivated, then it is not necessary for every individual to know about the nature of matter or life to make judgments about science-based public policy issues. In this view, a correct ideology is sufficient.

To a large extent, this dispute revolves around whether measures of public understanding of science or scientific literacy are diagnostic or prescriptive. Miller has argued that a knowledge-based measure of scientific literacy or public understanding is a diagnostic tool to alert policy makers to a serious problem that threatens the quality of democratic discourse and participation, and there is some evidence that political leaders and policy makers follow national measures of civic scientific literacy and espouse a commitment to broaden the public understanding of science and technology. Wynne and other critics of knowledge-based measures assert that the measurement of literacy means that those adults who are not literate are illiterate and that this is an unacceptable description in a democratic society.

Questioning for Teaching and Learning in Science

Learning Through Questioning

Asking and answering questions about the natural world is clearly the central task of scientific inquiry. In science teaching and learning, asking students questions and encouraging students to answer questions is one of the most highly used and recognized strategies for teaching and learning. In planning science learning experiences, it is worthwhile to consider, to what extent does engaging students with questions facilitate learning about the authentic work of science? And, to what extent do questioning strategies help students learn to ask questions of their own?

In this discussion, three approaches and philosophical positions underlying learning through questioning in science are examined: (1) using questions to assess and test student knowledge, (2) using questions to gain access to student thinking, and (3) helping students learn to ask and answer their own questions in science learning communities.

- *Approach 1: In this approach, the teacher asks students questions.*

  Asking students questions is generally regarded as one of the primary tasks of the teacher. Students often learn through their experiences in formal settings that they will be asked questions about science content orally and through examinations and tests. Asking questions at the start of a lesson can usefully establish basic content information and is important in the evaluation of learning. Presenting questions for students to answer at the end of a unit is generally a key strategy used to create a record of what students know about a topic to facilitate the required creation of grade reports and information on student achievement in learning. It is helpful to consider the difference between close-ended (convergent) and open-ended (divergent) questioning strategies. Close-ended questions may be used to establish a knowledge base or in testing for content knowledge. They are questions that usually have a single correct response and can be answered only by students who know the right answer. An example is: Which planet is closest to the sun? The typical interaction with teacher and student is the following:

  - Teacher asks a question and waits for a student to answer or calls on a student to answer.

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

- Student responds.
- Teacher asks another question and waits for a student to answer or calls on a student to answer.

In this approach to learning through questioning, the locus of authority and the control of the questioning interchange rest solely with the teacher. The teacher holds the correct answer, and what is valued in this exchange is obtaining the correct answer from the students. Only students who hold the correct response may participate successfully in the conversation. Questioning by the teacher is a technique for organizing learning conversations and engagement with science content and assessment. The teacher uses questions to determine whether students possess content knowledge. In this approach, the teacher asks all of the questions, knows the answers, and expects students to provide the correct responses.

- *Approach 2: Using questions to gain access to student thinking*.

Open-ended questions can be answered by any student. Open-ended questions are useful tools for uncovering the ideas students hold about phenomena so that educators may consider how these ideas interact with the content, knowledge, and skills that are designated as curriculum goals for students. Open-ended questions engage students by asking them what they observe, think, and predict or the kinds of action they suggest as useful to engage further in investigation. Some examples are as follows: What do you see happening now that the flame is lit? What do you think will happen when we add vinegar to the solution? Or, how might we investigate this topic to learn more? This approach encourages classroom conversation and discourse to learn content, and during the process of speaking and articulating their understandings, students may gain new insights. Students' correct and incorrect ideas are valued as they reveal learner understandings and help the teacher to design instruction to take into account learners' ideas. Questions are used as tools for uncovering learners' ideas and understandings about a science topic. In this approach, teachers use questions to help students articulate their ideas. Both scientifically correct ideas and incorrect ideas are valued as they give insight into the ways that students are thinking about phenomena.

- *Approach 3: Helping students learn to ask and answer their own questions in science learning communities*.

This approach to learning through questioning is based on a philosophy of learning science that emphasizes creating learning environments to help students formulate, frame, and answer questions of their own and share them in community with others. Guiding students to ask their own questions, then designing strategies to answer them, engages learners in the true discourses of science. To work in this way, teachers create environments where students are able to see that the history of science is driven by asking questions, thinking deeply about them, devising ways to answer them, and sharing the results with others. In such a setting, teachers may model the ways they ask their own questions to learn. Teachers model true science discourse by voicing questions that they do not know the answer to and encourage students to do the same. For example, a teacher may ask, "I wonder what is the best way to find out whether superworms have a preference for light or shaded areas?" The teacher models what it means to be a learner herself and encourages students to join with her to suggest ways to frame and answer questions. She creates an environment that encourages students to observe deeply, to articulate what they see, and to ask questions that emerge from their own observations, sense of wonder, and imagination. This approach makes a central place for and gives high status to learners' questions in the curriculum, and in it we see an altering of the power structure of the learning setting. Students do not wonder, "Do I have the right answer? Am I giving the answer that the teacher is looking for?" Rather, the level of discourse is elevated to conversation and questioning that is at the heart of the discourse of scientific inquiry. In this approach, it is the students who are the primary question askers. The teacher's role is to help students learn how to learn by asking their own questions, designing strategies to learn the answers, and sharing with a community of fellow learners that includes the teacher.

R

Radio

Quentin Cooper
Material World, BBC Radio 4, London, UK

The old adage that many prefer radio to television "because the pictures are better" is one which long had particular relevance to programs covering science. Whatever the topic or field – however infinitely large, infinitesimally small, or intangibly abstract – radio can be intimate, immediate, and inventive. Whereas television coverage in the past was often stymied by the struggle to stage or manufacture appropriate images and graphics, radio at its best has always been able to tap directly into the imagination and get to the heart of stories without gimmicks or distractions.

This balance has changed in recent years with advances in the quality and affordability of computer-generated imagery for TV. If anything, though, this seems to have further stimulated the public appetite for science and helped encourage not only an expansion of science via conventional radio programs but also the use of the Internet to reach audiences with an array of audio podcasts. Although these are highly variable in terms of regularity, reliability, quality, and seriousness, they are all effectively other forms of radio science.

Despite different countries having begun formal science programming at different times, there are two common threads linking much of the early output. First, there was the widely shared belief that the purpose of radio was to "educate, inform and entertain" – a phrase popularized by the BBC's first director-general John Reith in the 1920s but adopted by broadcasters around the world – and that part of that educating and informing included science. The idea that it could also be entertaining came later. Second was the simple fact that the radio itself was such a bewilderingly strange thing to have in someone's home that the first scientific challenge was to explain itself. Bertolt Brecht wrote extensively about the power of radio in the way that some leading intellectuals now write about the Internet and described this introductory phase as "a moment when the technology was advanced enough to produce the radio, and society was not yet advanced enough to accept it."

As with much radio, the format was initially dominated by scripted talks and staged interviews, often with distinct audiences in mind from children to professional organizations. In the USA, one of the first – from the early 1920s – was the *Smithsonian Radio Talks* on RCA, arranged and often given by one of the museum's more confident and clear-spoken curators Austin Hobart Clark. Clark had strong views and unorthodox views on what good science radio required: He believed all on air should be smartly attired as "the speaker who was formally dressed would make a more dignified presentation" and that any science talk "must be wholly

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

accurate, dignified, and without reference to controversial points." Controversial for Clark included evolution, as according to his own theory, zoogenesis, all major life-forms evolved concurrently but separately. He also pioneered the notion of audience participation, arguing that the radio "has significant potential for gathering as well as giving out scientific information" and involving listeners in bird surveys and other data gathering.

In the UK, recordings survive of talks from such distinguished figures as Lord Rutherford in the early 1930s and of a 1942 BBC series *Science Lifts the Veil* presented by another physics Nobel laureate Sir William Henry Bragg. The archives of the Royal Society also have some revealing correspondence from immediately after the end of World War 2, as the BBC attempted to involve some leading scientists of the time (including J. B. S. Haldane, J. D. Bernal, Howard Florey, and Sir Robert Watson-Watt) in developing a new science magazine program. They were told that "the preconceptions of the BBC at this stage are almost entirely confined to broadcasting technique" and much of the discussion centered on who this program should be aimed at, with suggestions ranging from "17- to 30-year-olds of around School Certificate Standard" to "the largest professional group in the country – housewives" to "a decent agricultural labourer who has come back and is having a little rest on a Sunday." Other aspects debated included how much knowledge to assume on the part of the listeners, whether it was only acceptable to deal with areas of absolute scientific certainty (whatever they are!), and the need to show that scientists make mistakes.

All of these, along with discussions about the relative merits of programs presented by scientific experts versus those presented by science communicators, have echoes in science radio (and television) today, and there's evidence of similar issues being wrestled with by early program makers in other parts of the world. Down the decades and across the planet, science has appeared on the radio in almost every imaginable format – including phone-ins, quizzes, your questions answered, documentaries, drama-docs, soaps, and sci-fi where the "sci" bit is for once grounded in genuine science. There are also the countless, but just as important, instances where scientific discoveries, theories, and debates turn up outside of a formal "science" context, in news output, more general discussions, or other programs. In recent years it has become increasingly common to have scientific experts, authors, and presenters as guests on chat shows and elsewhere, often treated no differently from any other "celebrity" interview.

For all these experiments and innovations, the basic formulae for most science programs remain much as they were in the early days of radio: magazines, discussions, and interviews. Among the most successful are CBS radio's 15-min *Adventures in Science* which ran in the USA from 1938 until 1957; NPR's *Science Friday* slot which has now been on the air for over 20 years; BBC World Service's *Science in Action*, which having begun life as *Science & Industry* in 1959 is going strong today; All India Radio's now monthly *Vigyan Bharati*; CBC's *Quirks & Quarks* which has been on air across Canada since 1975 and for the last 20 years has been hosted by Bob McDonald; and the ABC in Australia's 1-h long *Science Show* which also began in 1975 and is still presented by its original host, Robyn Williams.

While most of these long-running series take a broad and broadly topical view of science, there are an increasing number of slots, strands, and single shows which focus on particular areas and issues within science. So on BBC radio in the UK, for instance, the main speech network Radio 4 not only has a new weekly general science magazine programme (replacing the long-running Material World), there are also recurring outlets devoted to the environment, medicine, mathematics, natural history, computing, psychology and scientific biography, as well as many one-offs and short series. In addition to this is the recent proliferation of online science programming and the Internet-enhanced ability to listen to many of these programs and podcasts at a time of the listeners' choosing, and there is now a greater access to a wider range of radio science than ever before.

Introduction

This entry begins with a brief history of trends in learning theories, reading, and science education as a platform for examining science reading. The current state of science reading research is outlined, with an in-depth consideration of contemporary science reading issues emphasizing the last decade (2003–2013) of research and development activities. Then the entry summarizes this decade, including by giving an outline of research and development activities the field needs to explore. These activities are needed to enable the creation of the evidence-based science reading instruction and preparation that is required to meet the demands of the information age. This final section also gives a sketch of some promising science reading programs for elementary, middle, and secondary schools.

Reading about science was the dominant science teaching approach in almost all contexts around the globe in K–12 during the 1950s. Dissatisfaction with this approach and its failure to engage the "best and the brightest" led, at least partially, to the first-generation 1960s science education reforms and to the emphasis on inquiry and discovery approaches. A form of love–hate relationship between science education and reading oscillated between "no science until the students know how to read" and "hands-on science experiences without any reading" – this continues in various forms today.

Over the years, scientists and science educators have slowly realized that the comprehension and construction of text are integral parts of doing and learning science and that without science reading proficiency, a person is not truly scientifically literate (Alberts 2010; Yore 2012). Furthermore, correlations between science literacy and reading literacy in the 2000, 2003, 2006, and 2009 Programme for International Student Assessment (PISA), which emphasized informational text, indicated very high associations (correlations of 0.75–0.88). These are too large to be overlooked and not found for other large-scale examinations of science achievement and reading (e.g., Iowa Tests of Educational Development and the Stanford 9 Test) that stress narrative text. The PISA results suggested shared variance between science achievement and performance on reading *informational* text of 56–77 %; other test results indicated shared variance between science achievement and performance on reading *narrative* text of 10–25 %. Scientists read frequently with distinctive purposes in place prior to entering the textual world before, during, and after experimenting or observing. They read critically with pencil in hand: making notes, drawing diagrams, checking calculations, and connecting in-text ideas to their problem in the margins of the text (Yore et al. 2003). Learners need to do similar reading as they study science in formal and informal environments, but they need to "do first and read later" in order to bring something to the text since science reading is not simply a text-driven endeavor.

A brief history of science reading, and ways it was researched and conceptualized, can be obtained by tracking the patterns among models of learning, reading, and science education over

Reading and Science Learning, Table 1 Patterns in 60+ years of learning theory, reading, and science education

Time period	Learning theory	Reading	Science education	Science reading
1950s and 1960s	Behaviorism	Bottom-up	Teacher-directed dissemination of information	Vocabulary, decoding skills
1970s and 1980s	Cognitive development	Top-down	Student learning through inquiry and discovery	Cognitive strategies, building and accessing prior knowledge
1990s and 2000s	"Cold" cognition	Interactive–constructive	Learning cycles and conceptual change	Interactive comprehension and strategies
2010 and beyond	"Hot" cognition	Interactive–constructive with affective, social, and cultural considerations	Socioscientific issues, project-based learning, informal environments, and e-learning	Synthesis from multiple sources, reader interest and text relevance, integration of verbal and visual information, metacognitive strategies, and disciplinary literacy

the last 60+ years (Table 1). These patterns culminate in the current context of science reading, which suggests potential for future research and gives rise to classroom implications.

Historical Overview

Changes in science reading have been continuous, but the distinctions become obvious if the major influences are considered in 20-year intervals, as can be seen with a brief review of the past six decades. Learning theories typically influence models of reading, contribute to science education reforms, and ultimately inform ideas about science reading. The 1950s interpretations of learning centered on behaviorism – stimulus, response, and reinforcement. Authentic learning tasks were deconstructed into structured conceptual schemes, not unlike learning progressions although usually with less concern (at times even considerably less concern) with the inherent complexity of the whole that was deconstructed, and teaching was based on having learners mastering this sequence of subtasks with the help of extrinsic rewards under the assumption that the sequence would fit together to yield the original complex outcome. The 1950s view of reading was a bottom-up, text-driven process of taking meaning from text that stressed decoding skills with little consideration of the readers' prior knowledge of or interest in the focus topic. The 1950s interpretations of science instruction were teacher-directed dissemination of knowledge with an occasional primary or secondary example of the target concept, and reading about science was often the central strategy to supplement teacher talk. Textbooks were encyclopedias of lower-level science knowledge presented in genres unlike narrative (descriptive, procedural, cause–effect, etc.), with a high concentration of scientific terminology that differed from the vocabulary in developmental reading programs and varied in usage when compared to daily speech. Science reading emphasized vocabulary memorization and drill-and-practice approaches to decoding skills development. These emphases were then very commonly further reinforced by approaches to assessment.

The 1970s interpretations of learning varied worldwide, but in North America and the United Kingdom, they centered on cognitive development and learners' logico-mathematical operations and development stages. A mechanism of assimilation, dissonance, and accommodation was used to explain how people acquired knowledge or adjusted their long-term memories. However, the roles of language were not fully considered, and social transmission was rarely considered. The 1970s view of reading was a top-down, reader-driven act of bringing meaning to text that stressed readers' prior experiences, knowledge about, and intentions for the text. The 1970s interpretations of science teaching embraced hands-on discovery or inquiry approaches where teachers shared or transferred responsibilities for topic and approach to students in teacher–student-shared or student-centered approaches. In this context the reading of science materials was deemphasized or neglected totally. Many reform-based science materials of this era did not contain any supplemental reading materials for student use. Science educators argued that reading was associated with textbooks isolated from experience, and they judged such reading to be bad. Many science educators of the time implicitly shortened "textbook" to "text," leading to the generalized assumption that all texts were bad with science reading having no place in science teaching and learning. Therefore, many of the advances in reading of the 1970s and 1980s were not implemented in science classrooms.

The 1990s interpretations of learning varied somewhat internationally, but again in many countries, they centered on "cold" cognition, an analytical process of constructing understanding in working memory by combining sensory input from short-term memory with stored information and experiences from long-term memory. New understandings were then stored in long-term memory where compatible ideas were added to existing memories (conceptual growth) and incompatible ideas initiated reorganization of the memory network (conceptual change). Approaches to reading centered on an interactive–constructive process where both top-down and bottom-up features were integrated and meaning was made from text and readers' prior experiences, knowledge, and intentions in a cold and analytical fashion. The 1990s interpretations of science teaching were also influenced by cognitive psychology and ideas of conceptual change that emphasized analytical and cognitive features. Approaches to teaching science emphasized experiences with concepts throughout a learning cycle. Science reading was seen as an interactive–constructive process involving texts, contexts, and readers in a top-down/bottom-up process of meaning *making* rather than meaning *taking*. The main purpose of reading in science was to locate and share information and argue about competing interpretations of a concept.

The 2010s interpretations of learning center around "hot" cognition in which affective dimensions (motivations, emotions, beliefs, values, identities, intentions, etc.) were added to "cold" cognition where new ideas embellished preexisting representations or initiated a re-representation of prior understandings within the conceptual network. These affective factors that define humans and social cultural conditions influence people's thinking as they struggle with constraints and adapt to the demands placed on them by the learning, context, and environment. The 2010s interpretations of reading centered on an interactive–constructive framework but reintroduced affective features; they also stressed print, visual, and functional consideration of text in disciplinary contexts for making meaning. Contemporary science teaching approaches emphasize the affective dimensions of learning (e.g., attitudes, motivation, self-concept, identity) and emphasize citizenship and participation in socioscientific debate.

Science Reading Today and Beyond

The views of science reading today involve explicit consideration of current reading comprehension principles applied to scientific text – linguistic knowledge, content knowledge, general and specific reading strategies, and metacognition. When the proliferation of information communication technologies (ICTs) is taken into account and ontological and epistemological aspects of science are acknowledged in disciplinary literacy perspectives, science reading becomes an exciting, challenging, dynamic endeavor. Current trends in science reading include synthesis from multiple sources, reader interest and text relevance, integration of verbal and visual information, metacognitive strategies, and disciplinary literacy. Science reading is seen as a form of critical inquiry during which the reader constructs meaning by synthesizing ideas from multiple information sources that contain an array of different genres and modalities while assessing one's comprehension as well as the trustworthiness of sources. Not all of the information required for successful comprehension is contained in printed text. Science reading requires accessing the concepts portrayed in both verbal and visual components of text and interpreting those concepts according to conceptual, discourse, and domain knowledge.

Metacognition

Reading comprehension is a process of successfully constructing meaning from written text, while deep-level comprehension involves the construction of global meanings by accessing prior knowledge (including stored experiences), reading purposefully, determining importance, and synthesizing information. Successful science reading comprehension depends on a combination of the reader's domain knowledge and proficient use of generic reading skills and discipline-specific strategies. While reading skills are automatic processes (i.e., decoding), reading strategies are clusters of complementary skills and include the metacognitive techniques that successful readers apply in purposeful consideration of the act of reading and understanding. The concept of close reading – careful and analytical consideration of text and the range of word, phrase, and sentence meanings leading to deep understanding – is regaining attention in science. Close reading emphasizes metacognitive processes including accessing prior knowledge, identifying specialized vocabulary, reading purposefully, identifying important information, and monitoring for successful meaning making.

Scientific text, language, and metalanguage (the specialized terms of the science enterprise) do not align with everyday usage. Reading science expository text is not simply a transfer or application of strategies and tactics developed from reading narrative texts; rather, discipline-specific knowledge and strategic resources interact during the negotiations of tentative meanings constructed from the print, visual, structural, and symbolic features of the target text. Metacognition involves readers enacting their knowledge about science reading and regulating the science reading process in real time – thinking about their comprehension, as they are reading, to improve their reading comprehension.

Metacognition has somewhat fuzzy definitions and operational uses, but most definitions include knowledge about the cognitive task and personal control of the task as it is being performed. Some definitions refer to these two components as metacognitive awareness (self-appraisal) and executive control (self-management). Metacognitive awareness considers declarative knowledge (what), procedural knowledge (how), and conditional knowledge (why and when) about the specific task or class of tasks. Executive control considers several real-time functions (sometimes called skills) such as planning action, monitoring progress, and regulating action and effort. Science reading comprehension requires critical thinking, reflection, and metacognitive skills and strategies.

Multiple Sources

Science textbooks have long been the dominant source of science information in classrooms in many countries round the world. In these countries this single source of information is slowly being supplemented or even replaced by a variety of other science texts – trade books, scientific reports, adapted primary sources, news reports, and electronic media. Traditional science textbooks in North America were designed to align with federal/national and state/provincial science curricula in terms of topics and reading levels. Most science textbooks in these jurisdictions underwent reasonably rigorous development and verification procedures; as a result, they were taken as an authoritative source although they tended to promote a traditional (inaccurate) view of the nature of science and the science endeavor and sometimes perpetuated scientific myths and misconceptions.

Trade books are popular sources of information text available in bookstores and libraries that address a single topic or theme in greater depth than textbooks. They typically contain a table of contents, chapters, headings and subheadings, multiple representations, a glossary, and an index. Collections of trade books on science topics have been developed or selected to supplement some inquiry modules in elementary and middle schools by publishers, curriculum committees, and teachers. Trade books frequently use a mixed narrative–expository style that requires readers to apply comprehension strategies beyond those found in the developmental reading programs.

The use of original scientific reports and adapted primary reports has gained traction in secondary school and university science education. These alternatives to the traditional textbook can bring greater currency, depth, and relevance to specific topics; as well, their usage highlights the connections between problem, research question, inquiry, and argument. These varied sources have the potential to more accurately portray modern science as an evaluative body of knowledge arising from attempts to reason, describe, and explain nature and natural phenomena.

Traditional media (e.g., radio, television, newspaper) reports highlight contemporary science and technology research and scholarship. However, news reports (journalistic version reports) have shortcomings: they tend to be brief because of time–space limitations; they sensationalize issues by using provocative titles; they do not provide the data, theoretical backings, and reasoning behind the claims in their argument; and they distort the time between a discovery and its practical application. Specialist science programs and features (in radio, television, print) on the other hand sometimes avoid these shortcomings because of the greater time–space available to them.

Print and electronic reports (e.g., Wikipedia entries, web-based sources, and blogs) have increased the currency of science information but have inherent strengths and weaknesses. Like anything found on the Internet, the quantity and currency are great, but the editorial quality, accuracy, and validity of these sources are questionable and the reports are sometimes aggressively partisan in controversial science areas (e.g., anthropomorphic climate change, vaccination). Frequently, the driving effort is not to inform the reader but rather to market a product, lobby for special interests, or promote specific (and possibly not scientific) viewpoints.

The variety of science texts is also increasing as ICTs become more common in homes, schools, workplaces, and leisure environments. With ICT, rapid text production is commonplace as people text or email one another, add entries to their Facebook pages, and compose blogs, wikis, and tweets. These electronic texts are rich mixtures of words, symbols, videos, pictures, and invented signs unique to the writer and readers.

The expansion of information sources has contributed to the "Net" generation's preferences and approaches to acquiring information from texts. Clearly, the language arts – once conceptualized as reading and writing – need to be considered as a collection of constructive–interpretative pairs: writing–reading, speaking–listening, and representing–viewing.

Verbal and Visual Texts

Science texts, whether electronic or printed, consist of a mixture of words, symbols, and visual representations. Science texts are informational or expository, rather than narrative, and contain a range of specialized genres, features, and structures like layout, logical development, and argumentation. The language in science texts is a collection of everyday language, science concept labels, and the metalanguage of the scientific enterprise. Symbols include common signs, mathematical symbols and formulae, and content-specific notations. Visual representations include graphs, tables, diagrams, and pictures that serve decorational, organizational, representational, and interpretational functions. Well-written texts coordinate and reinforce ideas within the multiple modes of words, symbols, and visuals so that readers can move among these multiple representations to construct, enhance, and transform their understandings.

A shift in emphasis from written information to a combination of verbal and visual elements in conveying science concepts in science textbooks and trade books means that students must be familiar with the forms and functions of both language and images in order to proficiently construct meaning when reading in science. Explicit teaching is required so that readers can learn how to interpret the many visual representations found in science text. Additionally, the meanings conveyed in multiple representations must be synthesized with the information obtained from verbal text while the reader draws on prior knowledge and sociocultural conventions to build domain knowledge.

Disciplinary Literacy

Disciplinary literacy involves using a particular range of representational modes to construct and communicate knowledge. A combination of words and images constructs and represents science as known by scientists and shapes student understanding of science. The written language of science constructs, organizes, and negotiates science experiences; as a result, it has developed unique grammatical and textual features, such as high levels of lexical density (the amount of information contained in a text), abstraction, and technicality (the use of specialized terminology), and the frequent use of visual representations. Scientific discourse, both oral and print, (a) situates genres such as descriptions, procedures, comparisons, cause–effect, and argumentation as distinct forms with specific functions and (b) relies upon the linguistic techniques of noun compounding, nominal groupings, nominalization, and grammatical metaphors to construct, persuade, code, label, extend, and communicate scientific knowledge. Reading in science requires a high degree of disciplinary literacy as a reader negotiates among and between modes, identifies and understands linguistic techniques, and constructs meaning from a range of genres and multiple sources.

Semiotics and Systemic Functional Linguistics

Semiotic theory provides insights into the power of signs and representations found in science text to promote mental activity, helping readers to link abstract ideas and events and leading to understanding without direct or hands-on experience. Scientific texts are rich in signs that indicate objects, ideas, and events by convention and practice. Signs must have particular qualities or characteristics to be considered a sign: a material quality such as substance and shape, some connection with the object that it signifies, and someone to view the sign as a signifier. A sign requires that its producer and its reader share assumptions about the representation; therefore, the meaning of a sign is socially and culturally mediated. Meaning lies in the constructed associations that arise from signs and signified objects.

There is a range of signs relevant to reading and science learning. An *iconic* sign resembles some aspect of reality and shares similar characteristics with its object. A photograph is an iconic sign because it shows many of the features of the original object. An *indexical* sign shows or exhibits the object rather than standing for the object. A weathervane is an indexical sign because it indicates the direction of the wind but does not resemble the wind. A *symbolic* sign represents an object only because of convention or tradition and may share few, if any, of the features of the object. Arrows that indicate force or direction of motion are examples of symbolic signs. Full comprehension of science text requires readers to interpret a range of signs as well as written information.

Language – especially written language – is a powerful tool, likely people's most effective cognitive technology for constructing understandings, that is both necessary to and essential for doing and learning science, not merely a sign system used in the acquisition and communication of scientific knowledge. Systemic functional linguistics (SFL) offers a means to identify the unique features of scientific writing, pinpointing potential sources of reading difficulty and areas for explicit teaching focussed on comprehension. The key characteristics of science information text include text cohesion, authoritativeness, nominalization, lexical density, and technicality.

Text cohesion describes the connection of ideas contained in words, sentences, and paragraphs and is related to the degree of inference required for the reader to construct understanding. Authoritativeness describes the way in which information is presented; science text is typically highly authoritative, with information being presented with no room for doubt. Nominalization is when actions, procedures, conditions, conjunctions, verbs, and adverbs are converted into nouns as a way to expedite explanation, and it occurs frequently in science writing; for example, solidification is a noun that describes the process of turning from a liquid into a solid. The use of nominalization contributes to higher levels of abstraction, making science texts more difficult to comprehend. Lexical density is the ratio of content words compared to overall words. Typical science text has a high lexical density, which makes comprehension more challenging.

Technicality is the use of metalanguage, expressions, and techniques unique to a specialized field. The technicality of science text comes from vocabulary and relational processes. Science vocabulary involves a mixture of high-frequency words and terms with specific science meanings. Science texts often use the same word to indicate two different things: in one place a word might carry meaning as in daily use, and in another it conveys a specific scientific meaning. A common word like “power” might indicate personal or political strength or a specialized physics meaning relating to mechanics or electricity. Science texts also contain specialized terms (e.g., reagent, simple harmonic oscillation, and mitosis) and terms relating to the nature of the scientific enterprise (e.g., theory, model, and hypothesis), all terms with meanings that are unlikely to be encountered in everyday usage.

The relational processes in science text consist of structural patterns such as explanations, comparisons, classifications, and definitions that use conjunctions (e.g., and), disjunctions (e.g., or), implications (e.g., if, then), negation (e.g., not, nor), and equivalencies (e.g., if and only if) in specific ways. These relational processes also contribute to technicality. These require consideration of theme (first element in clause) and rheme (remaining element in clause). Typically, the theme contains an established or known idea, while the rheme is a new idea, thus moving the reader from the familiar to the unfamiliar.

Tippett (2011) proposed an expanded dual-track framework for science reading that included interwoven components of semiotics, SFL, cognitive, and metacognitive networks within the verbal and visual channels. This framework could be used to predict connections and constructive interactions between the verbal and visual channels not fully addressed by earlier frameworks or models of reading or representational comprehension. Additional networks or channels are needed to more fully represent the information sources, strategic resources, and dynamic, recursive cognitive mechanisms enacted in science reading, for example, domain knowledge about the nature of science and scientific enterprise, conceptual knowledge about the target ideas, and discourse knowledge about the traditions, conventions, practices, and functions of scientific language. Currently, it is unclear whether these knowledge resources are best conceptualized as a single central channel in long-term memory that is engaged during science reading and meaning making in working memory or if separate channels for science knowledge (nature of science, scientific enterprise, conceptual knowledge, etc.) and knowledge about scientific discourse (traditions, conventions, practices, functions, etc.) would more accurately predict and explain the processes of making sense of science texts.

Future Research and Developments

The complex nature of science reading is highlighted by the broad range of areas that are ripe for further research. These areas include:

- Expanding the visual/verbal framework of factors seen to affect science reading to include the influence of prior knowledge and domain knowledge
- Clarifying the role of visual information and multiple representations in science reading comprehension

- Examining how metacognition influences *science* reading comprehension
- Investigating the general and task-specific nature of measures of metacognition as it is conceptualized in reading research
- Exploring the mediating roles that metacognitive awareness and executive control appear to play in activating and enacting conceptual and discourse knowledge in science reading comprehension
- Investigating the convergence among metacognition, critical thinking, and reflection on science reading
- Identifying the cognitive factors that influence readers' ability to integrate information that is presented in multiple modes, to identify important information, or to ignore irrelevant information
- Gathering more evidence to validate the use of science reading strategies that are anecdotally reported as improving comprehension to establish "best" practices
- Conducting more research from a "hot" cognition perspective to investigate the impact of the relevancy of science information and the personal interest, intention, or motivation of the reader upon science reading comprehension

Such research will contribute to our understanding of science reading and the many factors that influence making meaning from and with science text.

Closing Remarks

Future research and development in science reading needs to consider both the mainstream (citizenship) and pipeline (career) demands on science literacy. There have been some promising explicit science reading comprehension programs that emphasize reading strategies, vocabulary development, and metacognitive awareness and executive control in elementary and middle schools (cf. Seeds of Science/Roots of Reading, Pearson et al. 2010; University of California Berkeley, Lawrence Hall of Science). However, there have been only limited efforts to understand and develop twenty-first-century science reading knowledge and abilities in high schools and universities (Fang et al. 2011; Fang and Pace 2013; Yore et al. 2003).

Relevance

Edgar Jenkins
Centre for Studies in Science and Mathematics
Education, University of Leeds, Leeds, UK

Questions surrounding the notion of relevance (e.g., relevant to whom, for what, and who decides) are central to the goals of education. However, while the questions have an enduring quality, the answers are socially, historically, and politically contingent and, in some circumstances, are governed by ideological or religious dogma. They are also subject to both internal (e.g., training the mind) and external (e.g., the supply of qualified personnel) referents and to the tensions that arise when different interpretations of relevance require different approaches to what and how science should be taught and assessed.

In the nineteenth century, as science struggled to secure a place within many school systems, relevance was commonly framed with reference to the acquisition of scientific habits of mind ("scientific method") and to the contribution that science could make to a liberal education, the latter being a key outcome commonly associated with the study of the classical languages and mathematics. A contrasting rationale, however, sought to familiarize students with the "science of common things" by emphasizing contextualized knowledge and understanding rather than more abstract scientific thinking (Layton 1973). Each rationale required different content and pedagogy, promoted initially with little or no reference to the psychology of learning. When the latter eventually became more influential in the politics and practice of education, relevance also gradually came to be seen to require matching of what and how science was taught to the maturing mind and shifting interests of the pupils.

Partly in reaction to the role that science had played in the First World War, the emphasis in the interwar years in many Anglophone education systems moved away from an exclusively disciplinary approach to school science to accommodate explicit attention to the human dimensions of scientific activity (Donnelly 2004). Teachers were urged to attend to the biographical and historical aspects of the scientific disciplines and to highlight the personal qualities of outstanding scientists. Relevance thus acquired a strongly moral dimension with scientists presented as dedicated to the pursuit of truth and as sometimes displaying heroic qualities in the face of criticism or personal difficulties. In addition, ideas about how children learn and might thus be taught exerted a greater influence on pedagogy, especially, although not exclusively, in the scientific education of younger children. Such ideas also influenced the selection of some of the scientific topics to be taught and the order in which they should be presented, the latter being determined by the relevance of individual topics to the students' ages and assumed interests. In other education systems, notably Nazi Germany, the former Soviet Union and communist China, relevance was subject to the over-riding political ideology, with school biology being particularly, although not exclusively, affected (Renneberg & Walker 1994).

In many Western education systems, the ending of the Second World War brought a shift in attention away from attempts to widen the goals of school science and led to the focusing of attention on the urgent need to increase the supply of qualified scientific personnel for both civilian and, especially during the period of the Cold War, military purposes (Rudolph 2002). It was a shift that eventually led in the 1960s to a global movement for school science curriculum reform that involved the modernization of content and the promotion of a pedagogy underpinned by the belief that students could best learn science by doing science and, in some cases, supported by Piagetian notions of cognitive development. Relevance thus owed as much to a perception of national needs as to developing the ability to think scientifically by engaging in "authentic science."

Postwar developments, however, also highlighted the social dimensions of the relevance accorded to school science. Differentiation of curricula, either between or within schools, has been a long-standing feature of science, as of most other subjects of the school curriculum in most education systems. Such differentiation reflected widely held assumptions about, for example, the roles of women in society and the intellectual ability or likely future occupations of different groups of school students. In the mid-nineteenth century, elementary and secondary education were strongly associated with different social classes within society, each of which was presumed to require a different type of scientific education and, in some cases, no such education at all worthy of the name. For much of the twentieth century, an introduction to the grammar and syntax of canonical science was judged inappropriate for those who would work in the manual sector of employment, become housewives, or take up occupations for which the knowledge and intellectual training provided by a scientific education was judged irrelevant or of marginal importance. Domestic science and the biological sciences, especially botany and, to a lesser extent, chemistry, were thus commonly judged more relevant to the future needs of girls than physics.

In the latter half of the twentieth century, these historic assumption about relevance associated with school science education were challenged by several developments, although a concern to promote scientific thinking, expressed in a variety of different ways such as "processes" and "skills," was never lost. Newly independent countries sought to give science curricula a rationale that they judged more relevant to their individual circumstances and that was sometimes strongly influenced by narrower nationalistic or religious factors. Attempts to accommodate technology (or design and technology) within school curricula focused attention on the relationship to science, and the rise of information and communication technologies raised important questions about learning and pedagogy. Feminism and other movements concerned to promote equity, the rise of environmental concerns, and the growing interaction of science, technology, and society all contributed to a reassessment of how school science could be made relevant to the needs of pupils growing up in a rapidly changing society. Such challenges were not always readily welcomed by practitioners or policymakers nor were they experienced equally within different education systems. Nonetheless, the period witnessed the introduction of several curriculum initiatives that emphasized "science in context," including the seminal science-technology-society (STS) courses and modules, all of which served to bring the issues surrounding "science for all" to the forefront of professional and political debate.

As the interaction of science, technology, and society became increasingly complex and, in many cases, contentious, the relevance of school science came to be defined with respect to scientific literacy and the public understanding of science: terms that, among much else, related to an ability to engage intelligently with the moral, ethical, economic, or other questions prompted by such interaction. The promotion of such literacy and understanding, however, had to coexist with the need to safeguard the future supply of qualified scientists and technologists, a matter of increasing concern when, during the closing decades of the twentieth century, the popularity of the physical sciences as subjects for advanced study declined in almost all industrial societies.

This decline in popularity of the sciences and the seeming irrelevance of these disciplines to the interests and aspirations of many young people prompted numerous national and international research studies. Among the latter, the Relevance of Science Education project (ROSE) generated a large volume of international data that revealed significant differences between students in the developed and developing worlds in their attitudes to science and technology. In addition, while many students in the developed world had a generally supportive view of science and technology, their attitudes to school science were much less favorable. The ROSE findings contributed to, and confirmed, those of a burgeoning volume of research that explored the "student voice" and established that students' perception of the relevance of their school science education is sensitive to age, to gender, and to cultural and linguistic diversity. The implications of this finding present formidable challenges for the relevance of science education in multicultural societies and for the notion of a science curriculum that seeks to reflect universal scientific findings (Aikenhead & Michell 2011).

A further issue for many legislatures has arisen from the results of international comparisons of student achievement in science, such as TIMSS and PISA, which focused attention on the strengths and weaknesses of different school systems. In many of those systems, the outcomes of such comparisons have led to a revaluation of the relevance of school science education to such goals as problem solving and scientific literacy.

Legitimate interests in the relevance of school science are many and diverse: they range from policy makers, legislators, and teachers to scientists, curriculum developers, and students. Given this, the long-standing and enduring search for such relevance is inevitably a series of compromises that reflects wider changes in society, in politics, and in the professions most closely concerned with science and education.

Religious Education and Science Education

Michael J. Reiss
Institute of Education, University of London,
London, UK

Introduction

Worldwide, religion is of importance to many people. While many people with a religious faith are entirely comfortable with how scientists understand the world, others feel that aspects of science are incompatible with their religious faith. This entry discusses the nature of religion and the nature of science and then examines how religion and science might relate. The aims of religious education and science education are considered and ways of teaching science to take account of religious beliefs are examined.

The Nature of Religion

Religions vary greatly. Nevertheless, the great majority has a number of features in common (Reiss 2008). For a start they have a *practical and ritual dimension* that encompasses such elements as worship, preaching, prayer, yoga, meditation, and other approaches to stilling the self.

Then there is the *experiential and emotional dimension*. This includes the rare visions given to some of the crucial figures in a religion's history, such as that of Arjuna in the *Bhagavad Gita* and the revelation to Moses at the burning bush in *Exodus* and the experiences and emotions of many religious adherents, whether a once-in-a-lifetime discernment of the transcendent or a more frequent feeling of the presence of God either in corporate worship or in the stillness of one's heart.

All religions hand down, whether orally or in writing, vital stories that comprise the *narrative or mythic dimension*, for example, the story of the birth, life, death, resurrection, and ascension of Jesus in the Christian scriptures. For some religious adherents such stories are believed literally, for others they are understood symbolically.

The *doctrinal and philosophical dimension* arises as theologians work to integrate the narrative/mythic dimension into a more general view of the world. Thus, the early Christian church came to its understanding of the doctrine of the Trinity by combining the central claim of the Jewish religion – that there is but one God – with its understanding of the life and teaching of Jesus Christ and the working of the Holy Spirit.

The *ethical and legal dimension* regulates how believers act. So Sunni Islam has its Five Pillars, while Judaism has the Ten Commandments, and other regulations in the Torah and Buddhism its Five Precepts.

The *social and institutional dimension* of a religion relates to its corporate manifestation, for example, the Sangha (the order of monks and nuns founded by the Buddha to carry on the teaching of the Dharma) in Buddhism and the Umma' (the whole Muslim community) in Islam.

Finally, there is the *material dimension* to each religion, namely, such things as places of worship (e.g., synagogues, temples, and churches), religious artifacts (e.g., Eastern Orthodox icons and Hindu statues), and sites of special meaning (e.g., the river Ganges and Mount Fuji).

The Nature of Science

The nature of science is considered in more detail via a wide range of entries in this encyclopedia. Key points to emphasize here are that while the subject matter of science has varied considerably over the centuries, often because of advances in instrumentation, its principal approaches to building up reliable knowledge are fairly consistent. Of central importance is the objectivity of such knowledge – i.e., the knowledge should be independent of the person generating it (unlike, e.g., the work of painters, of composers and novelists, and perhaps of psychoanalysts) – and, relatedly, that such knowledge can be rigorously tested, often by experiment, though such experimentation is less direct for the historical sciences, such as much of geology and evolutionary biology, and for certain other sciences, e.g., astronomy.

How Might Science and Religion Relate?

There is a large and growing literature on how science and religion relate, but the most frequent classification remains that of Barbour (1990) who provides four categories. First, there is conflict. This is the relationship favored by some fundamentalists and by many so-called militant atheists.

Secondly, there is independence. Science and religion are seen as independent either because they use distinctive methods or because they seek to answer different questions. In any event, the result is that each is seen as distinct from the other and as enjoying its own autonomy. The relationship of independence has been favored by many, such as Stephen J. Gould, who holds that both science and religion are worthy of respect but occupy distinct spheres of human enquiry.

Thirdly, there is dialogue. As an example, Barbour points out how our understanding of astronomy has forced us to ask why the initial conditions were present that allowed the universe to evolve. The point is not that the findings of science require a religious faith. Rather, the point is that scientific advances can give rise (no claim is made that they do for all people) to religious questions, so that a dialogue ensues.

Barbour's final grouping is one in which the relationship between science and religion is seen to be one of integration. For example, in natural theology it is held that the existence of God can be deduced from aspects of nature rather than from revelation or religious experience. Natural theology has rather fallen out of favor. Its obverse is that characteristics of God can be deduced from aspects of nature, since the created order is held inevitably to reflect something of its author and sustainer.

The Aims of Religious Education and Science Education

There was a time when the principal aim of religious education was to convert learners to a particular religion or, more often, to keep them within that religion. In some countries this remains the case, but in liberal democracies this is no longer held to be acceptable. Instead, religious education has moved to teaching about religions, showing how people with a religious faith live their lives and understand the world. A frequent claim of those who favor this form of religious education is that, done well, this can also increase tolerance between people of different religions or none.

Science education too has shifted its aims, though in a less clear-cut manner. Unsurprisingly, the main aim of science education is to enable learners to understand how science is undertaken and to know some of the principal contributions to knowledge that it has made – such as the particulate nature of matter, the germ theory of much disease, and the structure of the universe. It remains the case that one aim of school science education is to produce the next generation of scientists, even though science educators have increasingly pointed out that only a minority of school students fall into this category. More recent aims are for school science education to enable citizens to make informed decisions, to promote democracy, to advance social justice, and to lead to socio-political action (Reiss 2007).

Ways of Teaching Science to Take Account of Religious Beliefs

If science teachers deal with religious issues, or science issues that have religious connotations, they should be true to science and respectful of their students and others, irrespective of such people's religious beliefs. Indeed, nothing pedagogically is to be gained by denigrating or ridiculing students (Jones and Reiss 2007). The aim of including religion in science learning is not primarily to teach about religion, but to enable richer and more effective ways to enable students to understand certain ideas within science and to help them understand better certain topics where science and religion interact.

The principle of respect for students has implications for assessment too. Well-designed examination material should be able to test student knowledge of science and its methods without expecting students to have to convert, or pretend that they have converted, to a materialistic set of beliefs. So, for example, while it is appropriate to ask students to explain how the standard neo-Darwinian theory of evolution attempts to account for today's biodiversity, it is inappropriate to ask students to explain how the geological sciences prove that the Earth is billions of years old.

A particular cause célèbre in the science-religion debate arises when teaching about evolution, particularly when some learners come from creationist backgrounds. Part of the purpose of school science lessons is to introduce students to the main conclusions of science – and the theory of evolution is one of science's main conclusions. For this reason, school biology and earth science lessons should present students with the scientific consensus about evolution, and parents should not have the right to withdraw their children from such lessons. At the same time, science teachers should be respectful of any students who do not accept the theory of evolution for religious (or any other) reasons.

Science teachers should not to get into theological discussions, for example, about the interpretation of scripture. They should stick to the science, and if they are fortunate enough to have one or more students who are articulate and able to present any of the various creationist arguments against the scientific evidence for evolution (e.g., that the theory of evolution contradicts the second law of thermodynamics, that radioactive dating techniques make unwarranted assumptions about the constancy of decay rates, that evolution from inorganic precursors is impossible in the same way that modern science disproved theories of spontaneous generation), they should use their contributions to get the rest of the group to think rigorously and critically about such arguments and the standard accounts of the evidence for evolution.

Reporting Results of Large-Scale Assessments

Larry E. Suter
University of Michigan, Ann Arbor, USA

Keywords

Large-scale; NAEP; ; PISA; TIMSS

Large-scale national and international assessments of science for students at elementary and secondary school levels are now conducted regularly in about 70 countries. The purpose of the assessments is to measure trends in each nation’s performance in educating children in the sciences. The statistical studies are repeated at regular intervals to provide important information for policy makers of educational practices on achievement levels for students of different backgrounds such as parent’s education, parental involvement, race, ethnicity, and language spoken. They also provide important measures of the condition of homes, schools, and teachers that affect learning such as student exposure to science content, study practices, and attitudes toward science.

The two international assessments of science that are conducted regularly are the Trends in International Mathematics and Science Study (TIMSS) which is conducted in 63 countries and managed by the International Association for the Evaluation of Education (IEA). The second study is the Program for International Student Assessment (PISA) which is conducted by the Organization for Economic Development (OECD) in about 70 countries.

The assessments contain test items based on a systematic framework of the physical sciences, life sciences, earth, and space sciences, but not of engineering or the social sciences. The test items are made up of specific questions about the content of scientific principles as well as questions that require students to solve problems such as how environmental change occurs. Each of the surveys uses a slightly different framework for defining the content of science intended for elementary and secondary school students. For example, the PISA framework determines whether students are able to solve practical problems faced by working technicians, scientists, and engineers (OECD 2009). The TIMSS assessment stresses students learning of science topics that are specifically presented in the classrooms of most science classes around the world (Mullis et al. 2003). The frameworks are revised occasionally to incorporate the results of research in the sciences and educational practices.

The results of national surveys of student performance in science are reported in publications with statistics that depict the distribution of student population scores (NCES 2011; Martin et al. 2012; OECD 2010). Rather than average the number of correct answers to test items (as would occur in Classical Test Theory), student responses are turned into a scale of science achievement using psychometric models such as Item Response Theory (IRT) that take into account the level of difficulty of each item. This approach improves the ability of the scale to distinguish differences between individual students. The assessment scales are reported within a wide range, such as from 400 to 600 (or any other range arbitrarily chosen by the test constructors) so that the results can be easily summarized into statistical averages or distributions and may be compared with tests administered in previous years to measure change over time (see references to websites). The test scores, however, should not be compared between studies (such as NAEP, TIMSS and PISA) even though they look alike because the underlying test frameworks define science ability somewhat differently.

In order to place the levels of the scale into more meaningful categories, the studies have also created ideal achievement goals called "proficiency levels" that approximate how well students should perform in science. The proficiency levels are reported as the percent of students who perform at, above, or below ideal levels of achievement. In the US national assessment, NAEP, the ideal levels of achievement were established by a national group of experts, the National Assessment Governing Board (NAGB 2008), who were authorized by Congress to standardize the interpretation of the test scores. NAGB sets ideal achievement goal levels from the science assessment score as the percentage of students who scored at or above basic, proficient, and advanced levels. "Proficient" achievement is defined as "solid academic performance exhibiting competency over challenging subject matter." Basic achievement is performance that exhibits "partial mastery over skills fundamental to Proficient performance." Advanced levels of proficiency in science is defined as a student who "demonstrates a solid understanding of the earth, physical, and life sciences as well as the ability to apply their understanding to practical situations at a level appropriate to their Grade" (Loomis and Bourque 2001). The TIMSS study similarly reports the test scores in four levels of "benchmarks" (Advanced, High, Intermediate, and Low; Martin 2012, p. 8). And, the PISA study creates six levels of "proficiencies" that range from low (limited scientific knowledge that it can only be applied to a few, familiar situations) to advanced (students level can use scientific knowledge and develop arguments in support of recommendations and decisions; OECD 2010, p. 149).

Some of the student and school characteristics that are known to affect the level of student achievement are regularly reported in all assessments such as the home environment (parent's level of education, race and ethnicity, number of books in the home, amount of study time, and level of after school activities), the school environment (the amount of resources available to teachers, level of teacher preparation, and the school climate), and the attitude of students toward the subject matter.

Representations and Learning in Science

► Multimodal Representations and Science Learning

Representations in Science

Jens Dolin
University of Copenhagen, Copenhagen, Denmark

Science, perhaps more than any other discipline, is characterized by the use of a huge number of ways to represent its knowledge. When scientists explain and analyze phenomena in the natural world, they make use of graphs, diagrams, tables, equations, definitions, analogies, metaphors, etc., and often new findings are followed by new forms of representations. Physicists at lunch draw sketches at their napkins while orally formulating their points and making gestures with their hands. Magnetic and electrical fields are illustrated with field lines and calculated using vector operators. The quantum understanding of the atom developed the energy diagram. These are examples of why the understanding of and the ability to use different representations are crucial in the understanding of science and why they form some of the basic building blocks in the teaching and learning of science.

Within cognitive science, psychologists have for many decades struggled with how we represent the outer world inside our heads, how the representation is organized as knowledge in our memory, and how we can retrieve it in other situations. This approach to representation can most recently be traced back to Jerome Bruner and his colleagues in the book *Studies in Cognitive Growth* from 1966. They maintained the idea that human beings can represent the world in three ways: by acting, by image formation, and by constructing sign systems. This was inspired by Jean Piaget and, as a parallel with Piaget's stage theory, Bruner and his colleagues also meant that the three approaches to understanding the world formed a developmental sequence. Bruner has later changed his view on learning toward a more sociocultural understanding in which representations are seen as cultural tools, used in concrete situations for a concrete purpose. In a science education context, it is useful to combine the cognitive and sociocultural approaches to representations; representations are both practical tools developed to express the understanding of a phenomenon and at the same time a mental resource. As such representations are notions or signs or symbols that stand for something in the absence of that thing, a thing which typically is a phenomenon or an object in the external world but can be just in our imagination. This external representation is thus learned by ascribing meaning to it, i.e., by giving it an internal, mental representation that links to both the object and its external representation. In semiotic terms, the process of learning a representation becomes understanding it and giving meaning to it as a sign that signifies something about an object.

Given the central place of representations in science, the "big" questions in the context of this encyclopedia are as follows: which representations are particularly useful in science education, and why are these useful? Consider the example of electricity. In a typical lesson, students will discuss the nature of the concepts "current," "resistance," and "voltage"; they will set up an experiment using connecting wires and meters; they will draw the setup; they will log some data; they will systematize the data in columns and graphs; they will hypothesize or verify relationships; they will discuss their findings; they will need to use the proper units.

These situations all involve different forms of representation and it is not possible to give a conclusive list of all possible forms or to put them in logical coherent groups that embrace all forms without overlapping. One way of categorizing the most used representations is in the following groups:

- Phenomenological representation

  An oral or written narrative of the phenomenon you observe or are working with
- Experimental representation

  An experimental setup with material, measuring instruments, software, etc. to investigate the phenomenon
- Mathematical descriptive representation

  Graphs, tables, diagrams, etc. maybe based on logged data or from other sources
- Mathematical symbolic representation

  Functions, equations, formulas, etc. describing and linking and arranging the data
- Conceptual representation

  The definitions, concepts, generalizations, and theories that can clarify and explain the phenomenon
- Figurative representation

  Drawings, metaphors, analogies, and simulations that can visualize and connect to known understanding
- Kinesthetic representation

  Bodily actions expressing the phenomenon at hand

The concept of representation has an inherent duality: On the one hand, it is a *result*, a property, or a characteristic feature or behavior of a scientific phenomenon, and on the other hand, it is also a *practice*, something that is done in science. This duality means there is a need for two different approaches when working with representations in the science classroom. From the perspective of representation as a result, learning science can be seen as a process where students learn the different representations within the specific science domain and where the representations can contribute to a differentiated and multifaceted understanding. When considered in terms of practice, representations can be seen as a more competence-oriented approach where students' abilities to construct representations themselves are seen as a powerful path to learning. Both these approaches acknowledge the importance of having multiple representations for the same phenomenon in order to have a full understanding of that phenomenon. One single representation cannot cover all possible aspects of a topic, and multiple representations using different modes will give a more complete understanding.

It is useful to see a learning process in science as a process where the student appropriates the different representations of the topic/object/phenomenon and is able to shift between them and is able to select an appropriate representation for addressing a particular purpose. Knowledge arises in the transformations between representations, when the student uses one form of representation or the result from one representation in another representation of the same topic. The more the different representations are integrated by the student, i.e., the more transformations and links the student can establish between the representations, the deeper the student's understanding.

Relating different representations can be extremely difficult for students. Research shows that even when students have learned two different forms of representation, they primarily use one of them and only very few students understand how the two forms are connected. For example, high school students have been shown a figure of a ball rolling along a track and then asked to sketch the corresponding graphs of position versus time, velocity versus time, and acceleration versus time. Only 1 out of 118 students was able to do this correctly. At a technical university, little less than half of the undergraduate students passed their calculus-based examinations without being able to understand the fundamental concepts entering into the equations and calculations. This also illustrates the huge learning potential in working with multiple forms of representation to get a full understanding of the problem at hand.

Learning and constructing multiple representations constitutes an efficient path to deeper understanding of a topic – but it is not an easy path to walk. Letting students construct their own representations will normally lead to a better understanding than interpreting a given representation. Learners also need to be confident with one form of representation before another is introduced. The order in which representations are introduced is important. Research indicates that learning qualitative representations should precede quantitative representations. Phenomenological, figurative, and kinesthetic representations will give an organization of the topic that promotes an understanding of a more quantitative representation such as a mathematical symbolic representation. Computer-based animations simultaneously displaying multiple representations of the same simulation can provide a good learning environment for linking between representations.

Retention of Minorities in Science

Jomo W. Mutegi
School of Education, Indiana University,
Indianapolis, IN, USA

Keywords

Higher Education Access

Minority retention in science refers to efforts of educational, government, and corporate agencies to ensure that ethnic and racial minorities as well as women are proportionately represented in the science workforce.

Efforts to improve minority retention in science are driven primarily by the condition of widespread underrepresentation of some minority groups in the science workforce. For example, in USA African Americans, Latinos, and Native Americans typically participate in the science workforce in numbers that are disproportionately smaller than their representation in the larger population. In 2008, these minority groups (frequently referred to as “underrepresented minorities”) comprised 9 % of workers in science and engineering occupations and 26 % of the general population. By contrast, Asian Americans tend to participate in the science workforce in numbers that are disproportionately greater than their representation in the larger population. In 2008, Asian Americans comprised 17 % of workers in science and engineering occupations and just 5 % of the general population (National Science Board 2012). So Asian Americans are not generally considered “underrepresented minorities” and rarely are they targeted for minority retention efforts.

Minority retention efforts are widespread and varied. They involve remediation, enrichment, informal science education experiences, and enhanced or extended formal science education experiences. Minority retention efforts target learners at virtually all age and grade levels, including early elementary-aged students ranging up to advanced graduate students. An example of a common minority retention effort is the summer bridge program. Many university science and engineering departments offer summer bridge programs to incoming freshmen from underrepresented minority groups. Summer bridge programs involve students in accelerated study of science and mathematics coursework that is designed to prepare them for the first year of college. Summer bridge programs may be aimed at either remediating incoming freshmen, giving them a head start on university level work, or some combination of the two. These abbreviated periods of intense study are also intended to help incoming freshmen acclimate to university life.

Although minority retention efforts are widely used by educational, government, and corporate agencies, there is not a strong empirical basis for the effectiveness of these efforts. Consequently, a common practice of successful minority retention efforts is that they employ many interventions simultaneously rather than rely on one or two types of interventions. This practice is sometimes referred to as “overdetermining for success.” One example of a nationally recognized minority retention effort in science that overdetermines for success is the Meyerhoff Scholars Program. This program is an effort of the University of Maryland, Baltimore County (UMBC) that is aimed at increasing the number of underrepresented minorities who pursue advanced degrees in science. Numerous studies have shown that Meyerhoff Scholars earn higher grade point averages, graduate in science at higher rates, and enter graduate school at higher rates than national comparison samples. Rather than focusing solely on one type of intervention, such as financial aid, the Meyerhoff Scholars Program employs up to 14 types of interventions, including financial assistance, enhanced recruitment efforts, a summer bridge program for incoming scholars, formation of study groups, establishment of a culture of success through program values, establishment of a culture of support through program community, personal advising and counseling for scholars, tutoring assistance, opportunities for summer research internships, active and structured faculty involvement, active and structured administrative involvement, organized mentoring relationships, required community service, and family involvement.

In spite of the success of minority retention efforts like the Meyerhoff Scholars Program, the need for minority retention efforts in science persists. One of the more pronounced and resilient problems facing science education is the underrepresentation of certain minority groups in the science workforce. This is a problem that has seen little to no remission in nearly 40 years. So while current minority retention efforts may have impacted local or regional constituencies, they have done little to reverse the national pattern of minority underrepresentation. One possible explanation for this shortcoming is that overdetermining for success is costly and requires a substantial institutional investment. There are relatively few institutions that will commit to minority retention efforts as extensive as that demonstrated by UMBC. Research aimed at identifying more pronounced causal factors will go a long way in helping educational, government, and corporate agencies to commit to more efficient minority retention efforts, thereby serving greater numbers of underrepresented minorities.

Rika

Masakata Ogawa
Department of Mathematics and Science
Education, Tokyo University of Science,
Shinjuku, Tokyo, Japan

In Japan, a subject corresponding to "school science" is called Rika. In elementary and lower-secondary schools (up to 9th grade), the subject name Rika is used extensively. In upper-secondary level, Rika is maintained as the overall subject name but generally divided into several "courses" under the names of Butsuri (physics), Kagaku (chemistry), Seibutsu (biology), and Chigaku (earth sciences).

Elementary schooling modeled on Western education systems started in Japan in 1872. After several revisions within a very short period, the national education system (from elementary to college level) was finally completely established in 1886, and it was at that time when the subject Rika was introduced in elementary school curricula. The origin of the term Rika is still an open question. The overall objective of Rika in elementary school in 1886 was simply a topic list of natural things and phenomena to be taught, but that of the 1891 revised version was quite different and structured: "Rika aims at making pupils; (1) observe (Kansatsu) the usual natural things and phenomena precisely, (2) understand the outline of the interrelation among natural things and phenomena as well as the relation of such natural things to the pupil's lives, and (3) cultivate the love of natural things." From that time the last component, love of natural things (Shizen in Japanese), has been substantially maintained in elementary level for these 120 years (Ogawa 1998). It has been accepted positively by most Japanese as one of the key spirits of the subject Rika and is seen as being in addition to science learning in the sense of Western school science. Thus, Japanese people have been readily confusing science and Rika (especially the spirit of science and that of Rika), even though in the secondary level Rika has never included the component "love of natural things." This is an example of indigenized understanding of science through school science in non-Western cultural contexts.

Role-Plays and Drama in Science Learning

Caroline Smith
University of Tasmania, Hobart/Launceston,
Australia

Keywords

Constructivism; Drama; Role-play

For many the ultimate goal for science learning is to create a learning environment in which students are not only active, deeply engaged participants but also where they have the potential to lead the activity. Role-play and drama have key roles to play in reaching this goal. Role-play tends to be the shorter form of this type of learning and more readily accessed in a classroom. Drama is more considered and formalized and requires more preparation.

However, in the science classrooms of today as in the past, role-play and drama remain far more absent than present. There is a lingering if outdated view that role-play and drama do not belong in the science classroom. Science is viewed as a rigorous, logical, structured, and serious discipline, while role-play and drama are seen as inaccurate, frivolous, and fluffy, belonging more to the arts than the sciences. Such views are at odds with the ways some teachers use role-play and drama to enhance their students' understanding of science. Ødegaard (2003) notes that there is still a dearth of studies on the use and effectiveness of role play and drama in science education.

The use of role-play and drama as science learning strategies in both primary and secondary education originated from a number of different starting points, all of which arose from the recognition and concern that many students were disengaged from science. From the 1970s onwards, research in learning in science turned to what is now generally described as constructivism. This includes alternative conceptions, problem-based learning, cognitive challenge, disengagement, relevance and ownership, gender issues, multiple ways of knowing, and the general complexities of the classroom. Extensive research clearly pointed to the need for less "chalk and talk" and more engaged, active, experiential, student-centered learning, if deep understanding was to be achieved. Role-play and drama provide powerful means for students to engage deeply with the material, including being extended to assessment, where students may choose to demonstrate their understanding through means of role-play and/or drama.

Role-play and drama engage with a fundamental part of human psychology – the desire for creativity and play. By the time children begin learning science at primary school, they are already experienced at play as the means by which they develop their knowledge and intelligence. As Vygotsky noted, children's play is a creative transformation that helps them make sense of their world. Teachers who use role-play and drama as part of their repertoire report that the vast majority of students enjoy participating in them. They enable students to engage emotionally as well as cognitively; something is now known to increase retention and depth of learning. These approaches also assist the learning of those students with high kinesthetic abilities. Developing role-play and drama through group activity enhances students' teamwork and collective decision-making abilities, and being personally engaged supports the construction of and reflection on understanding.

The form and choice of role-play and/or drama depend on the learning context and content. There are two main ways in which role-play and drama can be used to enhance science learning: (1) understanding of scientific concepts that draw on simulation and analogy and (2) human-science relationships that explore the human impacts of science on culture and society, including science history and futures, and ethical and controversial issues.

Scientific Concept Understanding Through Simulation and Analogy

Complex and abstract concepts can be made concrete and hence clearer using role-play as a mode of learning. Students can play the role of an object or element in a scientific system, such as the movement of electrons in an electric current, atoms in a chemical reaction, planets or moons in the solar system, particles in phase changes, and particles in a sound wave.

The level of student ownership depends on the teacher. A good way of developing the role-play is for a group of students to be given a concept, for example, the changes of phase of matter from solid to liquid to gas and back again. Students are challenged to decide how to demonstrate the phase change, then act it out for the class. Extensions can be introduced by both students and teacher, such as relating particle movement to temperature, which readily leads to the extrapolation to no particle movement, i.e., absolute zero. As well, linking the role-play to other learning procedures such as a graphical representation of phase change assists in bedding down conceptual understanding.

Systems can be readily explored using role-play, such as the dynamics of food webs; operation of machines; body systems such as the digestive, circulatory, immune, and urinary systems; or processes such as photosynthesis and DNA replication. Again, students work together to become elements or objects in the system and simulate its functioning through their movements.

Human-Science Relationships

The human impact of science, too often ignored in the quest for conceptual understanding, can be explored using varying forms of role-play and drama. This aspect of role-play and drama assists students to understand that science is complex and ever-changing, the result of human endeavor, rather than a collection of isolated facts and concepts that somehow exist outside of human experience. Students can research and explore different points of view on a topic and present their findings through debates, court cases, hypotheticals, simulated or real meetings, or even public events such as a presentation of an issue of local interest to a local council. Controversial issues in science such as reproductive technologies, genetic engineering, or nuclear energy can be explored through researching and taking on the roles of different stakeholders in the issue. Through role-play and drama, students can discover the history of the development of a scientific theory and the human complexities and conflicts that lie behind what might seem a clear-cut concept. Darwin's theory of evolution and the trial of Galileo are popular issues to examine through role-play and drama.

Taking It Further: Drama, Theater, and Film

Role-play and drama can be taken out of the classroom and elevated to theater and film. In Australia, the Science Teachers' Association of Victoria (STAV) has been holding Science Drama Awards for schools since 1993. The award is designed to foster creativity and integrate science learning with reading, writing, music, art, and the performing arts. Schools submit a script and video of their proposed performance, and finalists are selected to perform in front of a live audience.

Australia's national science agency, the Australian Commonwealth Scientific and Industrial Research Organization (CSIRO), was heavily involved in science drama and theater for all ages through their education arm Double Helix Drama, a youth theater group based in Tasmania and led by science communicator Jeannie-Marie Le Roi which ran from 1990 to 2004. Le Roi (1998, n.d.) has published two useful resources designed to encourage the establishment of similar groups and to assist teachers who wish to explore the use of role-play and drama. The group also acted as mentors to other young people wanting to be involved in science drama and held science drama camps.

Double Helix Drama places all key production roles, both cast and crew, in the hands of the students, with some guidance from teachers and Le Roi's group. These roles include coordinator, scriptwriter, cast members, backstage, costumes, promotion, and administration. The performances include music, songs, dance, and mime and can be serious or comedy. This range of roles and styles of presentation ensures that all students are able to be included in the production according to their capabilities and interests and that science learning takes place for them all. The groups perform theatrical pieces on a range of topics that may illustrate scientific concepts or current controversial and complex issues or moments in science history. Examples include Our Place in Space and Howard Florey – A Tale of Tall Poppies. These and other plays were written and developed by Chris Krishna–Pillay, a prominent science communicator and performer.

Double Helix Drama has extensively performed throughout Australia and also in Korea and New Zealand. Examples of role-play and drama are now readily accessible via YouTube.

Other examples are Scinema which has a students' film section and the Eureka Awards which has a "Sleek Geek" award for science film, established in 1990 to reward outstanding achievements in Australian science and science communication.

In summary, role-play and drama can form an important part of approaches to developing student learning in the science teachers' repertoire. These have the potential to contribute strongly to a student-centered, inclusive, participatory, active, and enjoyable learning environment and are only limited by the creativity and enthusiasm of the teachers and students.

Scaffolding Learning

Elizabeth A. Davis
School of Education, University of Michigan,
Ann Arbor, MI, USA

Argumentation; Calibration; Fading; Learning progressions; Science learning; Zone of proximal development

Definition of Scaffolding

Wood et al. (1976) were the first to use the term *scaffolding*. Within a tutoring context, Wood and colleagues described scaffolding as involving support such as reducing the degrees of freedom available to a learner, emphasizing relevant features of a task, and modeling solutions to a task. They demonstrated how, with this support, children were able to attain higher levels of performance than they could without the scaffolding. In essence, then, scaffolding works as a mediator within a learner's zone of proximal development (Vygotsky 1978). Stone (1998) identified key features of face-to-face scaffolding interactions, including careful determination of the task, accurate diagnosis of the learner's current level of proficiency and calibration of support to match that level, providing a range of types of support, and fading the support over time. Others have argued that scaffolding can be instantiated through physical artifacts or software features that serve as cognitive tools that mediate action. Scaffolding can serve to reduce learners' cognitive load and provide expert guidance. The result of scaffolding in learning environments is that learners become more able not just to accomplish the task with support but also that they learn from the process and improve their future performance.

Scholars have expressed concern, over the last decade or two, that "scaffolding" has been used so broadly and with such limited precision as to have become equivalent in many people's minds with any form of instructional support. These scholars argue that the elements of *calibration* and *fading* are critical in describing a form of instructional support as scaffolding.

Importance of Scaffolding in Science Classrooms

Why is it important to consider scaffolding in science learning environments? In short, it is important because with scaffolding, learners can engage in more sophisticated tasks than they can engage in without support, thus making their learning both more effective and more efficient. Even young children are able to engage in sophisticated scientific practices and learn complex science concepts when provided with strategic

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

scaffolding (Metz 1995). Similarly, while high school students are unlikely to learn complex content or engage in challenging investigative practices on their own, with scaffolding, they can do so. Recognizing these capacities is increasingly important as many nations move toward setting more ambitious science education standards. Scaffolding meaningful learning of science content and practice promotes relevance and integration, thus minimizing the development of inert knowledge.

Scaffolding can promote students' (a) learning of core disciplinary ideas, (b) engagement in scientific practices, (c) understanding and application of crosscutting concepts, (d) involvement in processes and procedures expected in a classroom, (e) collaboration, and (f) metacognition and reflection. Examples of scaffolding – for example, for the scientific practice of argumentation and explanation construction – might include teachers' discourse moves (e.g., regularly asking students for evidence to support their claims until doing so becomes part of the regular classroom discourse), written prompts in print curriculum materials (e.g., hints or prompts for how to write such evidence-based explanations that fade over the course of a unit or a year), or features in software tools (e.g., guides, graphic organizers, or other features that allow students to match evidence with claims and capture in-process thinking). Scaffolding can also be provided via other physical artifacts in a classroom or other learning environment (e.g., posters with inscriptions in a classroom or features provided via handheld devices to be used in museum settings).

While many tend to think of scaffolding as serving a mainly structuring capacity – through reducing the degrees of freedom, for example, or providing additional information or guidance – in fact, effective scaffolding also, in a purposeful manner, increases the complexity of tasks (and then supports learners in accomplishing the new, more complex tasks). One example would be when students are asked to generate artifacts that reflect the disciplinary practices of science (e.g., through supporting claims with evidence and reasoning or through distinguishing observations from interpretations). A second example would be when students are asked at key junctures to reflect on their engagement in a task, rather than proceeding without sufficient mindfulness. In these instances, scaffolding serves to make learning more complex, thus increasing the potential for learning, especially in the long term.

Science Teaching and Learning Implications

One complex area of focus within research on scaffolding is the notion of fading. Fading can refer to changes in the character, amount, or level of support being provided and leads to the learner taking increasing responsibility for the task. Investigating how to fade scaffolding in a science classroom context has been notably challenging. Instructionally, fading might occur in one of at least three ways. The teacher might fade scaffolding for individual students, based on individualized diagnosis and calibration (much as a tutor might fade scaffolding for an individual tutee). Curricular materials might fade scaffolding over a sequence of weeks or months, based on curriculum developers' hypotheses about student learning and progress vis-à-vis instruction; such fading, though, would be at the class level, rather than at the individual level. Finally, software might fade scaffolding over time, based on data collected on individuals or small groups of students. (Progress is being made in the technological capacity to do this effectively.) These different instructional instances reflect differences in how learners' strengths and struggles are diagnosed as well as how support is calibrated and adapted. Studies demonstrate that learners who experience well-faded scaffolding over time can be successful in unsupported variants of the tasks. In fact, some studies have identified positive learning effects of purposefully fading scaffolding within print curriculum materials, providing at least an existence proof that such fading does not necessarily need to be individualized to be effective. Current work on learning progressions may inform with more precision when scaffolding can likely be effectively faded.

Different agents (e.g., teacher, curriculum materials, software tools, peers) can scaffold science learning. The efficacy of supports provided via curriculum materials or software tools is enhanced by support provided by teachers. Teachers, curriculum materials, software tools, and peers can all provide different kinds of scaffolding (e.g., generic and content-specific; process-focused and rationale-oriented) that work synergistically, or they can provide redundant scaffolding that serve to reinforce one another. Student learning is enhanced through such distributed scaffolding.

Science teachers, too, benefit from scaffolding for their learning. For example, educative curriculum materials – curriculum materials aimed at promoting teacher learning as well as student learning – can scaffold teachers' learning about engaging students in scientific practices by providing both guidance about how to do so and rationales for why it would be important to do so. The scaffolds can be faded over time via a coherent set of year-long curriculum materials. Similarly, approximations of practice in which novice teachers rehearse instructional moves with colleagues or teach a science lesson to a small group of children reflect scaffolded learning experiences in teacher education. Thus, while scaffolding is often investigated in the context of student learning, the construct also applies in the context of teacher learning.

In sum, in designing scaffolding to support students' and teachers' learning in and for science classrooms, designers must consider:

- What meaningful task(s) need scaffolding
- How the individual learner's or collective group's strengths and needs can be diagnosed
- How the support can be calibrated, adapted, and faded for the individual learner and on what basis and on what timeline
- In what ways degrees of freedom can and should be reduced to reduce the learner's cognitive load
- Which most salient features of the task should be emphasized
- What expert guidance should be provided (and how)
- How the task can be modeled for the learner
- How the task can productively be made more complex to promote learning
- What various forms of support should be provided (and how)
- What medium should be used for providing the scaffolding and via what agent
- How distributed scaffolding can be used productively
- How the scaffolding can account for the multiple learners in a setting

Scale Scores

Gabriela Noveanu
Curriculum, Institute for Educational Sciences,
Bucharest, Romania

Keywords

NAEP; PISA; Scale scores; TIMSS

Scale scores are derived from responses to assessment items that summarize the overall performance attained by that respondent. The scale scores represent degrees of proficiency in a particular domain. They offer the opportunity to examine the relationships between student performance and various factors measured.

In large-scale surveys such as the Trends in International Mathematics and Science Study (TIMSS), National Assessment of Educational Progress (NAEP), and International Adult Literacy and Life Skills Survey (IALLS), since each respondent responded to just a subset of the assessment items, multiple imputations were used to derive reliable estimates of student performance on the assessment as a whole. Students' proficiencies are generated using as input the students' responses to the items they were given, the item parameters estimated at the calibration stage, and the conditioning variables. The TIMSS eighth-grade reporting metric was established by setting the average of the mean scores of the participated countries to 500 and the standard deviation to 100. For reporting of Programme for International Student Assessment (PISA), results are used scales with an average score of 500 and a standard deviation of 100. NAEP reports the results on a 0–300 scale. The scales arose from the framework being meaningful for feedback and reporting purposes and also defensible with respect to their measurement properties.

School Environments

Stephen Ritchie
School of Education, Murdoch University,
Murdoch, WA, Australia

Keywords

School climate

Schools are easily recognized within communities anywhere in the world. They are housed in familiar buildings and share a common purpose – to provide a place for learning (see Hayes et al. 2006). While they have a sameness that identifies them as schools, each is different. These differences can be subtle, but increasingly researchers document cases where the differences are stark. For example, schools in remote rural communities in Australia have difficulty recruiting and retaining qualified physics and chemistry teachers. Unsurprisingly, for this and other reasons, students from these schools perform below the national mean on international tests that measure scientific literacy. Similarly, students from poor urban schools in large cities in North America often do not demonstrate satisfactory science achievement on high stakes tests. Notwithstanding the importance of appropriate funding models that might ameliorate large differences in school environments, this contribution considers how schools can make a difference by improving science learning for students.

Even though the familiar architecture of schools can lead to a sense of sameness about schools, it is what goes on within the buildings and how the extended school community interacts with school personnel that differentiates schools and promotes or hinders students' learning of science (see Cohen et al. 2009). In other words, school climate matters. *School climate* is a collective phenomenon based on patterns of participants' experiences of school life that gives a school its character (Cohen et al. 2009). Four essential and overlapping dimensions of school climate are safety, teaching and learning, relationships, and environmental-structural. The subcategories of the teaching and learning dimension of school climate, most relevant to science education, include the following: quality of instruction; social, emotional, and ethical learning; professional development; and leadership (Cohen et al. 2009). Innovations related to each of these categories are now overviewed.

Quality of Instruction

Students in science classes are frequently portrayed as disengaged because the content lacks relevance to their lives and is delivered through traditional pedagogies that rely heavily on teacher transmission of information. Yet whole-school innovative projects that focus on improving the quality of students' experiences have been documented.

Conceived in 1985 to enhance science students' metacognition, the Project for Enhancing Effective Learning (PEEL) articulates principles of purposeful teaching for quality learning, which emphasize sharing responsibilities for learning with students and generating new pedagogical knowledge while being supportive and collaborative with colleagues. PEEL has sustained decades of success across schools in Australia and more recently in Canada, Denmark, Sweden, and Malaysia.

A more general approach to improving the quality of whole-school teaching, known as *productive pedagogies*, was implemented across numerous schools, particularly in Queensland, Australia (see Hayes et al. 2006). This large-scale innovative project recognized that classroom practice was at the heart of schooling and quality teaching makes a difference to school experiences of students. The productive pedagogies are clustered around four dimensions, namely, *intellectual quality* (higher-order thinking, deep knowledge, deep understanding, knowledge as problematic, substantive conversation, and metalanguage), *connectedness* (knowledge integration, background knowledge, connectedness to the world, and problem-based curriculum), *supportive classroom environment* (engagement, student self-regulation, student direction of activities, social support, explicit criteria), and *working with and valuing difference* (cultural knowledges, inclusivity, narrative, group identities in a learning community, citizenship).

Shared characteristics between successful projects such as PEEL and productive pedagogies should be expected. For example, the first dimension of intellectual quality from productive pedagogies aligns with several of the 12 principles of teaching for quality learning (e.g., share intellectual control with students, encourage students to learn from other students' questions and comments, use a variety of intellectually challenging teaching procedures). As well, several international innovations in science education have focused on specific dimensions and principles. For example, research conducted on context-based approaches to science shows how teachers and students make connections between real-world contexts and concepts. Other innovative approaches to engage students in learning science feature next.

Social, Emotional, and Ethical Learning

A major focus for science education research has been conceptual change from an exclusively cognitive perspective. Yet recent advances in neuroscience have shown that emotions are equally important in learning because almost all brain regions are affected by emotions. So, science teachers who practice quality teaching might be expected to weave affective experiences intricately through classroom activities.

Recent continuing research has shown how students emotionally engage with activities designed around socioscientific issues (e.g., Tomas and Ritchie 2012) that also aim to develop their conceptual understanding of related phenomena and attitudes to science. Socioscientific issues education aims to develop students' moral, ethical, and epistemological orientations through activities in which the moral implications are embedded in scientific contexts (e.g., biosecurity, coal seam gas, organ transplants, and harvesting). A focus on socioscientific issues in the curriculum could help students not only grapple with some of the most complex social challenges of the century but also develop connectedness with their communities (cf. productive pedagogies). Innovative programs in large US urban schools involving socioscientific issues and other curriculum emphases (e.g., C3 curriculum: choice, control, and change) that afford students' opportunities to consider how these issues (e.g., food) impact on themselves have empowered students to connect students' lives to science in relevant and meaningful ways (see Mallya et al. 2012).

Another way teachers and researchers have improved the social and emotional life of students' in science classes is through the dual process of coteaching and cogenerative dialogue (Tobin and Roth 2005). *Coteaching* requires collaboration between teachers who share responsibility for planning and enacting the curriculum. *Cogenerative dialogue* involves different stakeholders from a class meeting from time to time to discuss how learning can be improved in class and to develop action plans that all members take responsibility for enacting. Used together, coteaching and cogenerative dialogue helps teachers to learn how to build collective decisions with colleagues and collaborate with their students to create and sustain effective classroom learning environments. In other words, they provide a context for on-the-job professional development.

Professional Development

If quality teaching through student-centered pedagogies can make a difference to student learning, then structures (or the social arrangements, relations, and practices that exert power and constraint over what individuals and groups can do) that encourage teachers to collaborate for and with their students should be promoted (e.g., coteaching and cogenerative dialogue). Teacher-led professional communities (e.g., those associated with PEEL) also can be effective sites for improving the quality of teaching and learning. Yet it still may be necessary for schools to invest in creating opportunities for teachers to exchange ideas and discuss professional practice as a normal part of the school day (Hayes et al. 2006). This takes leadership.

Leadership

Even though school principals and heads of science departments are important in transforming and supporting climates conducive to the improvement of teaching and learning, all teachers need to lead. The *collective leadership* in schools necessary to improve teaching for student learning involves the shared responsibility of personnel to generate and enact structures that afford agency (or the power to act) to stakeholders (both individuals and groups). The enactment of collective leadership manifests not only as practices such as cogenerative dialogues but also as solidarity among participants and the generation of positive emotional energy through successful interactions (Ritchie 2012).

School-Community Projects/Programs

Steve Alsop[1] and Sheliza Ibrahim-Khan[2]
[1]Faculty of Education, York University, Toronto, ON, Canada
[2]School of Education, Trent University, Peterborough, ON, Canada

Introduction

In the past few years, science educators, researchers, and policy makers have been increasingly drawn to the educational potential of school-community projects and programs. "Community-referenced education," "community-based education," "community education," and "place-based education" are all popular contemporary signifiers that serve to distinguish clusters of pedagogical practices that involve schools, classrooms, and students working together with individuals, groups, and organizations mostly located outside of schools. While such programs are driven by a variety of differently nuanced goals, interests, and aspirations, they share a commitment to the considerable educational merits of collaborative practices between diverse communities located in different social, ecological, material, and economic contexts and settings. Through such commitments, these programs nurture pedagogies that are not only about *what* we learn, but also about *why*, *where,* and with *whom* we learn.

School-community programs involve schools working with a large number of different groups including families, youth groups, heritage sites, science institutions, new social movements, government organizations, cultural groups, hobby groups, and businesses. In some cases, these communities are seen, perhaps, more as a "field-resource" with the potential to significantly enrich students' school-based learning as well as future social mobility. Such projects are conceived and structured to advance the interests of schooling by leveraging the expertise, assets, and resources of community collaborators. Other projects have different, potentially more far-reaching, desires that include school-based reform and community development and building (sometimes alongside school interests). In these cases, school-community collaborations offer opportunities to reflect and act in pursuit of better communities of practices both inside and outside of schools.

Given that school-community projects and programs capture such a wide range of educational initiatives, they defy a straightforward generic checklist of benefits and gains. Programs carry their own distinctive set of evaluative questions concerning how and whether they are working, why and for whom, and under what conditions. Some projects, for example, highlight the benefits of increased and more meaningful, authentic, longer lasting learning. Others explore gains in terms of increased social equality and inclusion, and others focus more on "community building" and/or local ecological restorations and local material enhancements. In the following text we offer brief discussions of selected school-community projects within three broad groups. We then turn attention to some of the tensions that this broad approach to science education presents.

Learning Science Out of School

There are a large number of documented projects in which school students work with a variety of different science-related community groups in out-of-school settings. Within these projects, students encounter science in "everyday" contexts and in so doing, advocates maintain, they develop the ability to learn and use science within "more authentic" settings. including museums, zoos, government organizations, and media. As practitioners and researchers persuasively argue, this type of learning is more meaningful because it is potentially more personalized, contextualized, voluntary, and self-paced. Indeed, much research suggests that exploring science in out-of-school settings can awaken a critical review of the benefits of learning science, as well as how learning might become more empowering. A large number of authors draw attention to the benefits of education projects that challenge youth to collaborate with communities in ways that make their contributions count. Léonie Rennie (2006) describes, to give a couple of environmental examples, educational projects in which youth work with community groups to raise awareness about poor air quality from smoke haze and wood burners and organize a campaign to reduce the indiscriminate killing of venomous tiger snakes. The success of such school-community projects Rennie accredits to a list of generic guiding principles:

- The issue under examination comes from the community and is not imposed.
- Local knowledge is required.
- It is educative.
- Schools are integrated to allow student and teacher participation.
- It involves negotiation and decision-making with the community.
- Outcomes indicate something worthwhile and tangible (Rennie 2006, p. 9).

Science Education as/for Community Development

In a series of influential studies, Wolff-Michael Roth and Angela Calabrese Barton (Barton and Tan 2010; Roth and Barton 2004) investigate students and teachers working with particular local rural environmental groups and urban youth groups on particular community-referenced projects. The studies involve students (and teachers) working with others within specific social, ecological, and economic contexts and settings with pedagogical goals of researching and better understanding shared issues and concerns and shaping common actions. They highlight some of the benefits that this pedagogical orientation provides. These include opportunities to experience the situated nature of knowledge and the interactions of multiple knowledge claims (in which science is one amongst many expert knowledge claims), and the nature and importance of collaboration with ethical responsibilities that active community participation entails (see Roth and Barton 2004). Such projects resist what Paulo Freire calls "banking models of education" and view young people as partners in education as/for social change allied with common social and ecological justice aspirations. This more political orientation provides opportunities to rethink more traditional meanings of "scientific literacy." Over the past decade or so, there is much empirical evidence coming from a variety of different sources that suggests that more locally situated, community-based, politically orientated science education has profoundly positive educational implications for all students, particularly including those who are marginalized by many traditional school-based practices.

Place-Based Science Education

Over the past few years, there has been a steady increase in "place-based" educational projects and theorizing. In much of the recent "place-based" educational literature, there is an emphasis on the prospect of resituating learning within particular communities with critical place theorized aspirations. As David Gruenewald – a high profile advocate of "place-based" education – writes: "human communities, or places, are politicised, social constructions that often marginalize individuals, groups, as well as ecosystems" (2003, p. 7). Approaches to place-based education often entail youth deconstructing the power dynamics inherent to the relationships that people have with places and then collaboratively reconstructing different, more environmentally and socially just relationships. There are a growing number of projects in science education that draw from and extend this approach. "Science in the City" (Alsop and Ibrahim 2008) is one community/place project in which the often "taken for granted-ness" of local places is revisited through activities such as neighborhood walks and photography. This provides a basis to identify issues for further science-based inquiry. Such inquiry has included research with a local medical laboratory to better understand a sister's illness and offer advice, building gardens to recapture hope from personal loss, and working with local fishmongers to better understand declining aquatic ecosystems and food chains. The project concludes with a celebration of practices and the circulation of a collaboratively written, community-orientated publication.

Some Tensions

Despite many advantages and increased attention in research and policy, there is still a relatively modest uptake of school-community programs in practice. Studies have explored this paradox and brought attention to a number of barriers, including increased safety concerns and administrative requirements, teachers lacking confidence and expertise in this approach, demands of establishing and maintaining community partnerships, and the seemingly ubiquitous and inescapable time pressures of covering traditional curriculum content.

As institutions of science education are being encouraged toward involvement with communities, many (if not most) are also becoming increasingly standardized (through jurisdictional and national curricula) and also more corporatized in nature. The general notion of community-based practices seeks to balance (to a greater or lesser extent) personal responsibility with collective interests and common identity. In contrast, critics of contemporary schooling highlight traditions of individualism, gatekeeping practices, meritocracy, and elitism. What increasingly matters to many schools and governments are economies of performance, examination results, and acceptance rates for further higher-level study. Given these seemingly deep-rooted cultural differences, it is perhaps not surprising that school-community programmatic collaborations can be difficult to establish and sustain.

There are also some theoretical tensions. As the above examples suggest, the concept of "community" has become freely associated with a host of different educational projects, benefits, and desires. The proliferation of the "community" label has resulted in a reduction of meaning and identity. Moreover, the longing for efficacious educational practices at times results in more than a hint of "essentialism" and "valorization." Communities are complex, multifarious social, ecological, and material manifestations, and while they offer interesting possibilities (particularly in their contrast to school practices), they are neither unitary nor without their own troubles. Some communities will be more educationally desirable; others will certainly be less so. Indeed, in some cases communities will be completely at odds with educational aspirations. The tendency in some educational writing and policy circles to take the concept of community collaboration as "unquestionably desirable" needs our continued reflexive attention.

School-community projects/programs add to an ever-growing list of so-called adjectival educations that demarcate pedagogical, policy, and scholarly turf. Many of these will feature in other parts of this encyclopedia. Subfields can build alliances and allegiances in which practitioners and researchers associate themselves with particular theories and goals; however, these orientations can sometimes take precedence over building broader educational solidarities. Indeed, in this respect, it should be remembered that the concept of community is itself a term of demarcation, which by its very nature is politically both inclusionary and exclusionary. To identify a community is to include and exclude some people on some grounds. Having said this, a shared sense of belonging and a shared sense of identity need not necessarily prevent welcoming others.

There are also associated tensions of "geographical localism." Many school-community programs place an overwhelming emphasis on "the local" and as such raise questions of geographic anchoring and parochialism. Within an era of increased political, economic, and social connectedness, these projects raise questions regarding the local and regional, at a time in which the global and cosmopolitan seems somehow inescapable.

The Future

Clearly school-community programs and projects have an enormous contribution to make to practice and research. While they are not without their own tensions and contradictions, there is considerable empirical evidence in support of far-reaching educational benefits and gains. They offer the prospect of enhancing teaching and learning and also provide a basis for rethinking the nature of science education and schooling itself. Clearly in the future they demand much greater attention in practice and research.

Community-based education has paid less attention to "on-line" communities. Given the popularity of social media, especially with youth, there is a pressing need, perhaps, to better understand and actively explore the possibilities of virtual community-based science education collaborations. This research agenda seems underdeveloped and yet is potentially far-reaching. The growing and impressive literature on school-community projects and programs provides a potential starting point from which to embark on these studies, while recognizing demonstrable differences between "virtual" and "real" educational contexts and settings.

Schooling of Science

Edgar Jenkins
Centre for Studies in Science and Mathematics Education, University of Leeds, Leeds, UK

Although much research is still needed, the schooling of the sciences (i.e., the way in which science subjects have been incorporated in the school curriculum) has received more attention than most other subjects of the curriculum (DeBoer 1991). Both historical and ethnographic studies (Goodson and Ball 1984) indicate the socially and politically constructed nature of school science curricula and, more particularly, the ways in which both content and pedagogy reflect several widely held assumptions about, for example, pupils' ability, their likely future occupations, the role of women in society, and, ultimately, about the purpose of particular types of curriculum or schooling.

The attention given to school science reflects the fact that aspects of the sciences, such as laboratory work, present unique problems. It is also an acknowledgement that accommodating the scientific disciplines in the curriculum challenged the historical basis of school education. That basis lay in the teaching of the classics and mathematics, subjects whose status as the foundation of a liberal education was legitimized and defended by the universities. In most education systems, the challenge emerged with particular force in the nineteenth century and was directed primarily at those schools such as grammar schools and gymnasia that enjoyed a close historic link with higher education.

The curriculum histories of chemistry, physics, and biology in these schools are different, largely as a result of differences between these subjects and their relative maturity when science was first schooled in the mid-nineteenth century. Despite the scientific revolution of the seventeenth century, physics was professionalized later than chemistry, and in many respects, it can be regarded as a subject constructed from a range of intellectually and socially diverse fields (heat, light and sound, magnetism and electricity, mechanics, and properties of matter) for the purposes of education. In contrast, inorganic and organic chemistry, with a common focus on understanding the preparation, properties, and analysis of materials, offered a more straightforward resource for curriculum construction: physical chemistry was not to gain a place in school curricula until the twentieth century. The timing of the introduction of chemistry into schools also reflected its contemporary salience as a discipline: if the case for teaching science in schools had succeeded in England a generation earlier, it may well have favored geology rather than chemistry. Although biology had long been institutionalized as zoology and botany, the universities offered no "model" upon which a school biology curriculum might be based. In addition, as a school subject, zoology, with its emphasis on anatomy and physiology, was widely judged appropriate only for future medical students, while simultaneously raising concerns about exposing young women to the more intimate aspects of the discipline. The study of systematic and economic botany, along with plant morphology and natural history, represented altogether safer educational territory. However, both botany and zoology were also open to the charge that neither provided an opportunity for experimental work in a teaching laboratory, perceived as an essential condition for accommodation within school curricula. It was not until the mid-twentieth century that satisfactory schemes of work involving observation and experiment and based firmly on general biological principles could be developed. Biology as a discipline therefore secured a place in most school curricula much later than either chemistry or physics.

Unsurprisingly, school science curricula in grammar schools and gymnasia became something of a preprofessional training, supported by a pedagogy similar to that used to teach undergraduates. School chemistry emphasized the preparation, properties, and uses of the elements and their compounds, together with qualitative and quantitative analysis. Physics stressed the importance of precise measurement, an understanding of the basic laws governing, for example, motion, electrical conductivity, and the transfer of heat, light, and sound, along with an ability to solve what quickly became a standardized set of associated calculations. Differences in the science curricula of these schools in different education systems were marginal, rather than fundamental, often reflecting country-specific manufacturing processes or national claims about the priority of scientific discovery.

Where the historic link between schools and universities did not exist, as in the case of the large numbers of schools created to provide public elementary education, the challenge of accommodating the sciences in the curriculum was different and the schooling of the sciences followed a different path (Layton 1973). The scientific disciplines were raided or adapted to construct curricula designed to meet different future social roles and employment needs. Titles such as "How electricity is made and distributed," "The science of common things," "The chemistry of everyday life," "Science in the Home," "Human Biology," and "Social Biology" are representative of many initiatives of this kind. In some education systems, broader courses with titles such as "Science" or "General Science" were developed but, despite some success, these ultimately failed to overcome the conceptual, linguistic, methodological, and philosophical differences between the contributing scientific disciplines and they fell out of favor as a demand arose for a greatly increased number of qualified scientific personnel. The challenge for pedagogy, too, was different. Laboratory-based work designed to introduce pupils to the grammar, syntax, and methods of science was replaced by practical activities more directly related to employment, to anticipated social roles, and, in some instances, to wider social and political concerns such as health, diet, and child rearing.

Pedagogy in all types of schools has also been subject to more specific educational influences, notably assumptions about how children learn and should be taught. In many Anglophone countries, the criteria used to determine the order in which topics should be taught was initially determined by the conceptual difficulty that each was presumed to present to students. Thus a course in elementary physical measurements would be followed by the study of heat, light, sound, and mechanics, followed by, or alongside, elementary chemistry. Although this criterion gave way to others, for example, the notion that the interest of children in science exhibited a rhythm corresponding to the rhythm of its history, it was not until the mid-twentieth century that research-based insights into children's learning and understanding of scientific concepts came to play a significant role in determining pedagogy.

In other systems, notably in continental Europe, where educational theorizing was differently conceptualized, the notion of "didactic" was of central importance in the schooling of science. The underpinning notion of didactic is the belief that it is possible to construct a scientific discipline (didactic) by drawing upon a range of other disciplines relevant to the processes of teaching and learning. The difference between these continental and Anglophone traditions remains important, and it is not merely semantic: it reflects contrasting views of what constitutes "scientific research" in education and thus of the role that disciplines such as philosophy, psychology, and sociology can and should play in curriculum construction and pedagogy.

The latter half of the twentieth century was characterized by profound changes in science, in society, and in their interactions and, in some education systems, by major changes in the structure of schooling. A growing postwar demand for qualified scientific personnel, prompted in part by the Cold War, prompted a global movement for school science reform (Rudolph 2002). In the 25 years or so that followed the end of World War II, the scientific content of school curricula was modernized, new assessment techniques developed, and pupils encouraged to learn by engaging in "hands-on" laboratory activities. In some cases, notably at the primary level of schooling, the reform drew upon Piagetian ideas about young people's understanding of fundamental scientific concepts such as mass and time, ideas that eventually led to the development of a substantial field of constructivist research. At the same time, the abolition of selective systems of schooling raised challenging questions about the educational function of school science and highlighted the problem of accommodating the different approaches to science teaching referred to above within a common secondary school.

By the 1970s, a number of other factors had begun to shape the schooling of science. These included the rise of environmental concerns, increased attention to long-standing gender and other equity issues, and the challenge presented by postmodern perspectives on science itself. In addition, there was anxiety, notably in the developed world, about a decline in the popularity of the physical sciences as subjects of advanced study and a recognition of the need for a curriculum response to the growing number of complex ethical and political problems posed by scientific and technological developments. That response took the form of an international science-technology-society (STS) movement (Solomon and Aikenhead 1994). Impelled by a mixture of motives and manifest in diverse curricula, the movement eventually owed less to the community of professional scientists within higher education than to initiatives by science teachers and researchers. Examples include the Science for Public Understanding Program in the USA and the Science and Society Project in the UK. Many of these initiatives made use of the growing power of information and communication technologies, especially the Internet which has become an increasingly important factor influencing how science is taught and learnt.

As the numbers of young people wishing to study science continued to decline in the closing decades of the twentieth century, doubts were raised about the merits of earlier curriculum initiatives as well as the mechanisms used to promote reform. When these doubts were reinforced by the disappointing results of surveys of the level of public understanding of science, attention inevitably focused on the issue of standards of achievement. This later acquired added political and educational salience as a result of international comparative studies such as PISA and TIMSS, the outcomes of which led directly to changes in the school curricula of several countries. The challenge facing all education systems, therefore, was how best to promote the higher and more general scientific literacy deemed necessary for a variety of economic, political, social, and personal reasons. In some systems, government responded to the challenge by taking direct control of the science curriculum and its assessment, specifying intended and measurable learning outcomes and offering suggestions for best pedagogical practice. Where central government control of schooling was not possible, as in the USA, it was necessary to respond in ways that accommodated the delocalized nature of curriculum control.

As governments have demanded greater accountability of investment in schooling, they have inevitably gained greater influence over what and how school science is taught and assessed. This has created an educational bureaucracy that, in many countries, has overturned the historic roles accorded to academia and science teachers to determine the form, content, and pedagogy of school science. The longer-term consequences of this shift in authority remain to be determined.

Mathematics; Pedagogical knowledge

This entry will consider how and why science and mathematics have been linked in teacher preparation programs in ways that influence notions of content knowledge and pedagogy.

How Similar Is Teaching in Mathematics Compared to Science?

While the obvious importance of mathematics to scientific endeavor might seem to indicate an obvious link between science and mathematics teaching and learning, the structure and guiding principles for school curricula in the two areas are substantially different (Siskin 1994).

Mathematics tends to have a highly sequential curriculum structure, whereas science curricula are organized around topics that are not tightly sequenced. The pedagogies in the two areas tend to differ, with mathematics teaching emphasizing sequenced practice in problem solving and science teaching incorporating substantial experimental work and practical application of concepts.

Studies of science and mathematics specialist teachers teaching across this disciplinary boundary have indicated a significant "boundary crossing" issue with teachers committed to distinctive aesthetic features of their preferred subject and to different narratives around which the subjects are made meaningful for students (Darby 2008; Darby-Hobbs 2013).

Policy and Practicalities Linking Science and Mathematics

Nevertheless, there are practical reasons why the two subjects are linked in the public mind and in teacher preparation programs. First, both subjects are grouped under the general STEM (science, technology, engineering, and mathematics) banner describing the areas that form the backbone of a nation's technological enterprises. As such, the problems of attracting and engaging students into science and mathematics subjects are related. Student attraction and retention in mathematics and physical science/engineering subjects have similar historical profiles. Similarly, there has been a similar trajectory of problems in attracting and retaining teachers of mathematics and of science. A search on science and mathematics education immediately identifies numerous government policy initiatives in many countries that treat the areas as strongly linked through their contribution to STEM professions. Policy initiatives focused on student and teacher attraction and retention into the STEM area lend credence the idea of linking the areas in teacher training.

Because of the substantial mathematics component of most science degrees, preservice teachers (PSTs) will often be qualified to teach in both areas, and combining them in a teacher preparation program offers efficiencies. In postgraduate entry programs also, mature age students with engineering or technology backgrounds will often have expertise and qualifications in and commitment to both areas. The opposite face of this coin is that elementary teacher trainees have been reported to experience similar issues with confidence and self-efficacy in the two subjects.

The reality in schools (in some countries at least – including Australia) is that in the face of a shortage of qualified mathematics or science teachers, teachers qualified in these subjects are the most likely to be called upon to teach across the science-mathematics subject boundary – to teach "out of field" (Ingersoll 2003; Hobbs 2012). Given the argument above, that the two subjects differ considerably in the structures and pedagogies of their traditional school forms, this would indicate another reason why PSTs in the two subjects should be exposed to the pedagogical traditions across the boundary and be provided with strategies for making the crossing.

In any teacher education program, there exists a tension between the need to introduce teachers to the pedagogical traditions and substantive knowledge of their specialist field and the need to develop their general pedagogical orientation and their identities as teachers per se. With regard to teaching and learning, this issue is informed by Shulman's (1987) description of teacher knowledges which include content knowledge (CK), general pedagogical knowledge (PK), and pedagogical content knowledge (PCK) which refers to knowledge of curriculum organization and structural traditions, of student learning challenges, and of teaching approaches specific to the subject. There are choices to be made as to where to put the emphasis in a teacher education program – whether to focus on maximizing knowledge of the chosen disciplinary area (e.g., science, or mathematics, separately) or whether to develop structures that allow more emphasis on general pedagogical knowledge with less time devoted to discipline specifics.

Given the likelihood that teachers in their career may be called upon to teach across a number of subjects, there is an argument that a prime aim of a teacher education program should be to produce teachers who are adaptable, able to take up challenges of teaching across fields such as science and mathematics. This is one aspect of the argument for bracketing science and mathematics teacher education.

Another argument was particularly strong in writing in the 1990s, advocating the integration of science and mathematics at the school subject level (Pang and Good 2000). This was a specific instance of arguments for curriculum integration more generally, pointing to the flexibility of integrated curricula and the enhanced possibility of building student knowledge around authentic, contextualized problems that drew on a range of disciplinary traditions.

Research in Science and Mathematics Education

Research often links science and mathematics teaching and learning. A number of journals cover both areas (Research in Science and Mathematics Education, School Science and Mathematics, Canadian Journal of Science, Mathematics and Technology Education). In the research literature, theoretical advances and perspectives have followed similar trajectories in science and mathematics education more so than for other disciplines. Constructivism for instance was a big issue in the 1990s in both subjects (Wheatley 1991), although the pathways it took and the presumptions made were different. Conceptual change approaches have been important in science education but have been pursued in mathematics also (Vosniadou 2008). Similarly, current concerns with social constructivist and sociocultural perspectives and the role of representations are current concerns driving much new thinking in both subjects. The work of Richard Lehrer and Leona Schauble, for instance, explores model-based reasoning and classroom representation construction in the context of both science and mathematics (Lehrer and Schauble 2004, 2005).

Educators calling for reform in the two areas have similar agendas; the emphasis in science is on inquiry approaches and the inclusion of socioscientific contexts into the curriculum to make science more meaningful. These reform agendas (Tytler 2007) critique the traditional transmissive pedagogies common in school science. In mathematics, there have similarly been strong movements towards problem solving and “real maths” with a contextual underpinning. The critique here has been the instrumental focus of traditional mathematics teaching. Calls for reform in both subjects emphasize higher-order thinking and scientific literacy/numeracy, as a major aim. Thus, insofar as teacher education programs draw on current research, productive links can be made between the research literatures in mathematics and science.

Keywords

Science education; Society

Background

Contemporary science education serves the dual role of training future scientists and educating future users of scientific knowledge. This presents science teachers with the challenge of developing both students' understanding of scientific knowledge and their awareness of the interactions between science and society to deliver the benefits of science while avoiding the pitfalls. The connection between science and society has become increasingly complex in light of the rapid advancements, in science and related technologies that permeate our lives, intertwining with consumerism, economic developments, and politics. This saturation is evident in the many science-related claims advertised by consumer products and the large-scale national development plans advanced by politicians to boost the economy that may ultimately endanger our natural environment.

The Aim of Science and Society Education

These developments have required that science students engage in increasingly complex inquiries from multiple outlooks when addressing science and society, including technological, epistemological, politico-economic, sociocultural, and moral/ethical perspectives. Such inquiries have evolved into different forms, as reflected by the jargon involved in the curricular movements that have sprung up in recent decades, such as *Science for All*, *Science-Technology-Society (STS)*, *Scientific Literary*, *Socio-scientific Issues (SSI)*, and, the latest, *Science Proficiency* (National Research Council 2007). The emphases of these curriculum movements with respect to science and society appear to have shifted from learning scientific concepts using related technologies and understanding such technological applications and their social and ethical implications to developing critical thoughts about scientific practices within society and their place within sociocultural contexts. The most recent of these emphases have included evaluating scientific evidence in authentic contexts, weighing the pros and cons of decision alternatives from both scientific and nonscientific perspectives, and formulating criteria underpinned by moral or value judgments to imbue students with a more thorough understanding of the role and limitations of science in society that cultivates informed decision-making congruent with this understanding. Thus, science and society education aims to develop not only scientifically knowledgeable citizens, but also critical thinkers who are aware of the scientific practices applied in society and capable of engaging in discourse at the science-society interface.

Implications for Teacher Education

To achieve this aim, teachers must develop a knowledge base comprising three interrelated components: content knowledge of the relationships between science and society; thinking processes involving argumentation, reasoning, and decision-making about socio-scientific issues; and the pedagogical knowledge and skills needed to lead students to achieve the aforementioned aims. Each of these knowledge components begs a multitude of questions that serve as a foundation for science teachers preparing to address matters of science and society. The content knowledge explores what roles science has played in the shaping of societal development and how the work of the scientific community has been influenced by the social, cultural, and political milieus. It also analyzes how the nature of science enhances and limits its role in society. Regarding thought processes, as students must learn how to determine the trustworthiness of science-related claims by evaluating scientific evidence and how to negotiate disagreements over conflicting science-related claims, teachers must discover what types of argumentation, reasoning, and decision-making frameworks are available to guide these processes. As for pedagogy, teachers must show students how to evaluate claims and evidence in authentic contexts that are much messier than the seemingly uncontested textbook knowledge and controlled experiments they have become accustomed to in laboratory environments. It raises the question: How can teachers possibly assume leading roles in an emergent area of science education in which they can claim no expertise?

Implications for Learning

Meeting these challenges requires that science teacher education be rethought, with new pedagogies grounded in research to enable teachers to take full advantage of the potential learning opportunities that science and society education offer. The learning experiences provided by these pedagogies should exhibit four essential characteristics. First, they should be contextualized and situated preferably in current socio-scientific issues to increase relevance and motivation. This would address the problem of learning canonical science in a decontextualized manner, as is commonly practiced in science classes.

Second, learning should be integrative so that the science and society components are not seen as merely an “expensive elaboration” of the curriculum in terms of time or as an “armchair discussion” that bears little relationship to a declarative or procedural understanding of science. Science and society education must be successfully integrated with conventional science educational goals to achieve a holistic science curriculum that produces and promotes scientific literacy. Such integration could be achieved by situating the learning of relevant scientific concepts and processes, along with the nature of science, in the context of socio-scientific issues. Because the scientific concepts involved might not be readily linked to textbook knowledge, self-directed learning strategies such as problem-based learning (PBL) might need to be employed to encourage students to apply previous knowledge and problem-solving skills to the construction of new knowledge that is essential to the issue being studied.

Third, learning should be interdisciplinary because the compartmentalization of knowledge is by no means conducive to learning in authentic socio-scientific contexts, which entails multi-perspective thinking. As a prerequisite, science teachers should give up a certain degree of territoriality to draw on knowledge and skills from disciplines such as citizenship and value education.

Fourth, the learning process should be collaborative and interactive because recent research has shown that the reasoning and decision-making involved in addressing SSIs are mediated by contextual variables (Lee and Grace in press). Given this, teachers must facilitate the social construction of knowledge and collaborative decision-making through group discussion and, if possible, cross-contextual or cross-cultural sharing that brings students’ backgrounds to bear in argumentation and decision-making. This collaborative knowledge construction process is congruent with how science knowledge is generated within the scientific community, how public policies are created in democratic societies, and how global issues are negotiated by international communities.

Conclusion

Considering the diversified and complex nature of the inquiries required by science and society education, the teaching of science and society defies any uniform teaching protocol or approach. Teachers must be flexible in organizing learning experiences that fit into their school science curricula and the wider societal context in which relevant socio-scientific issues arise.

Technology; Values

Introduction

Over the last three decades, there have been significant changes in teacher education and the place of science within this. For example, there has been varying emphasis on general science, integrated science, and STEM. This entry focuses on possible interactions between science and technology in teacher education.

Technology, here, encompasses more than just ICT. Rather, it is seen to be a dominant part of our culture and the world we inhabit. People develop and use technologies to intervene in this world to expand human and environmental possibilities. Technological endeavors encompass a broad range of activities including the transformation of energy, materials, and information in products, systems, and environments (Jones et al. 2010). Many school curricula package these as electronics and control technology, food and process technology, and materials technology and production. Within science education, technological examples are often presented to demonstrate scientific concepts. Context-based approaches to science education also often use technological examples to engage students in learning. Curriculum innovations such as science, technology, and society (STS) and Science, Technology, Engineering and Mathematics (STEM) expand on this to integrate technology in science. However, within these approaches, technology is often characterized and taught as applied science.

Science Teacher Education

In thinking about the role and place of technology in science teacher education, it is important to consider the characteristics and nature of technology (refer to entry on Technology Education and Science Education for a discussion of similarities and differences between science education and technology education, as well as the nature of technology). However, the distinction between science and technology is not often considered to be important in the teaching and learning of science. Neither is it at the forefront of science teacher education at both the pre- and in-service levels. This is likely because of the perceived similarities between the two fields, conflated with the perennial challenge of deciding which content to prioritize when only a limited amount of time is allotted to science and/or technology as part of a teacher education program.

The risk of not exploring the differences between science and technology can mean that preservice teachers and their eventual students develop limited understandings of the nature of each field. For example, science is often seen as the precursor to technology (technology as applied science). This can be reinforced by the frequent use of technological applications to exemplify a scientific concept. However, it does not lead to understanding of other possible relationships between science and technology. Similarly it does not provide students with opportunities to consider how technology shapes their world and how they might contribute and/or respond to this. As argued elsewhere, understanding the relationship between science and technology and society is about not only learning the "rules of the game" but being in a position to critique these rules and feel empowered to change them (Buntting and Jones 2009).

It is also important to consider both the nature of science and the nature of technology as part of teacher education so that early childhood and primary teachers, who often integrate curriculum areas in their classroom programs, can develop robust understandings of both in order that their teaching maintains the integrity of each discipline as an area of inquiry and development with its own sets of values and processes (Jones 2007). At the secondary level, newer technologies such as biotechnology often require that science specialists contribute to technology programs. Again, a robust understanding of the differences between the nature of science and the nature of technology is necessary so that students can be taught to understand what questions science (or technology) can and cannot answer.

International trends around the introduction of STS and Socio-Scientific Issues (SSI) require teachers who are confident in knowing what the science is, what the technology is, and their impact on society and social issues. Integrated approaches to STEM similarly require teachers to have an understanding of each of these disciplines and the interactions between them. These developments can engage school students and contribute to developing their understandings in and about science. However, they add complexity to science teaching and learning and teacher education in science.

An essential part of teacher education in preparing generalist primary teachers and specialist secondary teachers is to expand preservice teachers' understanding of the nature of science and the nature of technology. In doing so, it is important that the similarities and differences between science and technology are explored. Focusing on the nature of science (and comparing it with the nature of technology) has the potential to expand both preservice and in-service teachers' concepts of science as well as enhance their confidence to engage with their students and also with a variety of science resources.

Conclusion

Given the traditional separation of science and technology as distinct school disciplines, supporting both preservice and in-service teachers to consider the nature of both science and technology will require deliberate intervention. Finding teacher educators who themselves have a robust understanding of the similarities and differences between science and technology – and what this means for science education – remains a significant challenge.

Science Books

Alice Bell
London, UK

Books have a long-standing high profile position in science education. It is hard to pin down precisely whether they have any significant educational impact. What is discernible is that they have impact ascribed to them, with scientists frequently referring to the inspirational power of the popular science books (and science fiction) they read as children. Books for adults are also often cited in terms of the public understanding of science and/or political support for science funding.

Overviews of the histories and ideologies of popular science aimed at adults are available elsewhere, so this entry will focus on some of the history and diversity of science books for young people. Most of the examples sit within the 7–11 years age range, largely because this is the age that children's popular science books are produced for. What might be defined as a children's science book will always be reasonably open as we might unpack any of the terms *children's*, *science*, or *book*. Indeed, the books themselves may help articulate the boundaries around such ideas.

Instructive and Amusing

For all that "edu-tainment" is seen as a new term, Arabella Buckley's 1879 *Fairy-Land of Science* is a classic example of the genre. Aiming to cash in on the Victorian mania for fairies, she cloaked the science in the language of fairy stories; her fairies were the forces of magnetism or gravity, with a message that the wonders of science were not only parallel to but could surpass the wonders of fairyland. A more explicitly masculine attempt to similarly apply narrative can be seen in *Peter Parley's Wonders of the Earth, Sea and Sky,* a "thrilling" nature of geology, geography, and meteorology popular in middle-class homes from its publication in 1837. The use of such fantasy and/or travel narratives is still applied today, taking nonfiction readers to semi-fantastical worlds constructed from scientific ideas. Such books might shrink a character so they are small enough to play with atoms or travel fast enough to explore relativity. (Joanna Cole's *Magic School Bus* series and Russell Stannard's *Uncle Albert* books are two popular recent examples.)

A common trait of nineteenth-century children's publishing that is less readily tracked today is an overt connection between studying nature and learning about God. Books would often invoke a sense of wonder by presenting science as a way to learn more about God's creation. In the contemporary scene, the glossier end of children's nonfiction – e.g., *Eyewitness* books – provides a good example of a similar, albeit less religious, appeal to wonder. Full of lavish color photography, the typography of such books is perhaps comparable to glossy magazines such as *Vogue* or *National Geographic*. In contrast, cheaper books such as *Horrible Science* and *Grossology*, which owe more to the aesthetics of *Beano* or *Nickelodeon*, are more likely to appeal to a perceived sense that young people enjoy scatological humor. This does not mean they lack an appeal to wonder; it is just a different style of fascinating they are appealing to, with perhaps less mainstream appeal. Indeed, the idea that only the childish would find this interesting (and that it is slightly taboo in adult life) is perhaps part of the appeal, as young people's media increasingly defines itself via an othering of or from adult life. Although books applying a less glossy aesthetic may also laugh at the pomposity of adult science life, they can also be very reverent towards scientific expertise (see Bell 2008).

Shopping for Science

Books sit in an interesting position economically and socially compared to much other public-orientated science communication. There is an upfront cost, compared to free at the point of click sites such as Wikipedia, or a museum or television show which might be funded by public, charitable, or advertising bodies. Reading a book also implies some time, although without much commitment. Whereas a degree course in a science subject takes significant time and money; a book – especially since the advent of paperbacks – is relatively cheap and portable, easy to keep in a pocket, and dip into around the rest of the day. This, in turn, arguably has an impact on the relationships they may assume with readers and the relationships between science and a public they may help produce.

To Fyfe and Lightman (2007), the idea that the popular science consumer may shop for science puts them in a relative position of power with respect to science. Rather than simply being talked down to – as one might imagine the traditional model for the public understanding of science – the consumption of popular science in a marketplace allows people some degree of choice. Such analysis, however, is based on a rather uncritical view of consumer power. For child consumers of science in particular, it is worth noting that although there are increasing numbers of science books pitched at the pocket money market (compared to glossier books designed to be given as gifts or school prizes), it is possible to argue that children's media are never really owned by the child, rather it is a matter of what adult authors, librarians, parents, and teachers think the child would (or should) enjoy (c.f. Buckingham 1995). It is also worth noting that when it comes to children's science publishing, many books are connected to formal learning, even carrying logos of government education. Such science books are often associated with the "topping up" of the education of middle-class children and, for a host of economic, social, and cultural reasons, are more likely to be used by a privileged few. Their role in supporting formal education might also mean they act as an encroachment of school life on more domestic "play" time.

Interaction

It is notable that the book is a rather individualistic way to consume science, compared to the more group-based experiences of schooling, television, or museum visits. Still, it is worth remembering that books always sit in a social network. For example, children's reference books stay around for decades after they might otherwise do, due to use as school prizes. Also, recent years have seen a rise in popular science book clubs (including those for children who used to judge the Royal Society's children's book prize) as well as authors turning to online social media in ways that not only promote their works and interact with readers but allow readers to interact with one another.

The chief form of interaction offered by children's science books is with the physical, not social, world. In some contrast to the literary/fantastical experiences referred to earlier, many science books promote a very hands-on way of learning science. Indeed, children's science books in particular are striking in their attempts to transcend the traditions of a book form. The more complex examples include stickers to move around (e.g., of partly digested food around a diagram of the gut or magnets hanging from the spine or embedded in pages), and the field of nonfiction pop-up books is flourishing. More simply, there is also a long tradition of books with instructions on how to perform "experiments" – actually demonstrations of known phenomena, they are not experimental – of which John Henry Pepper's *Boy's Playbook of Science*, first published in 1860, is an iconic example (see Secord 2002, for an excellent description to this). Books which play on the empirical associations of scientific work did not end with the *Playbook*. This is perhaps most noticeable in the US market, where instruction manuals for science fair activities dominate the children's science shelves. Still, arguably this is more activity than interactivity. If anything, it is largely a rather conservative form, sometimes dressing up fixed, stabilized, and reasonably old science as if it was fresh and young, but rarely offering anything new, or the opportunity for young people to creatively make something entirely new themselves.

Children's science books are a reasonably diverse field. There are trends as sketched here – of interactivity, reverence to scientific authority, and careful application of fiction for expeditionary purposes – but no tight hallmarks or standout literature in the field. It is common to end such pieces with a general open-ended statement about how the field is always changing and who knows what will happen next. However, despite being aimed at young people and about the supposedly ever changing field of scientific research, another characteristic of children's science books is that they tend to be rather conservative, often rooted in the science (and images of childhood) of at least a generation before the intended audience. It would be nice to think future authors and editors will find it in themselves to be a bit more innovative, but whether or not this happens remains to be seen.

Science Circus

Chris Bryant
Australian National Centre for the Public Awareness of Science, The Australian National University, Canberra, Australia

The circus proper has a great antiquity. The word derives from the ancient Greek *krikos*, which became, by an inversion, *kirkos* and thence the Roman *circus*. A circus is traditionally defined by its central ring in which performances take place. However, in recent years, it has come to mean almost any spectacular display, such as the American "barnstorming" flying circuses of the 1920s.

Travelling shows are as old as civilization. The first travelling performers probably appeared at the same time as the first villages and towns. Ancient Rome enjoyed its histrions, usually freed slaves who went about entertaining crowds with storytelling, music, songs, juggling, and acrobatics – what, today, we would call busking. In the Middle Ages, minstrels and jongleurs travelled between European towns fulfilling the same role. Miracle plays, in which religious scenes were enacted for delighted crowds, were also a feature of the Middle Ages. First an initiative of the people, they were later taken over by the guilds, each of which had developed its own play. Later, the plays were staged on movable carts and taken around so that more people could experience the wonder and the message. All of these forms were able to present secular, political, and religious information wrapped up as entertainment.

In the eighteenth and nineteenth centuries, and particularly in the southern states of America, travelling medicine shows flourished. While not exactly about science, more about snake oil miracle cures, there was a clear perception that placing a product in the enjoyable context of entertainment created a positive attitude toward the product, resulting in increased sales.

Among the first genuine travelling science shows – in this case the applied science of agriculture – was the Canadian *Better Farming Train*. Agricultural fairs, in which exhibits were assembled in one place to which farmers travelled, were a feature of the Canadian scene from 1894. As the distances involved were a disincentive to travel, in 1914 *Better Farming Trains* began to carry agricultural innovation by rail to farmers in rural Saskatchewan. Hundreds of thousands of people were educated and entertained between 1914 and 1922, when the program was discontinued.

Two years later, in 1924, Australia got its own *Better Farming Train*. It was based in Victoria, and like its Canadian counterpart, it carried pigs, cows, poultry, bees, dairy utensils, potatoes, bacon, tobacco, manure, fodder and pasture samples, and a range of expert lecturers. Between 1924 and 1935 it made 40 trips to ten regional centers. Lectures and demonstrations of infant welfare, cooking, and sewing were offered. The train served as an agricultural school, an experimental farm on wheels, and a chance for a day out for all the family.

While none of the above is a circus in the accepted sense of the word, they share the concept that the delivery of a message accompanied by entertainment is more effective than a message delivered on its own. The success of the *Better Farming Trains* was due, in part, to the fact that Canada and Australia were, at that time, large and relatively undeveloped countries with sparse up-country populations who found it difficult to journey to the cities.

One of the traditional values of the orthodox travelling circus is teamwork. Everyone lends a hand at the various tasks necessary to get a show ready. Erecting the tent, the “Big Top,” is a task that requires everyone’s muscles. The high-flying trapeze artist may be found later selling popcorn and ice cream to the public. The clowns may lend a hand cleaning up after the elephant.

In Australia, in 1986, a large van left Canberra to journey to Goulburn, about 80 km distant. It carried Dr. Mike Gore, some demountable science exhibits, four keen science students, and the germ of an idea. The idea was for a travelling science circus that would cross the length and breadth of Australia, bringing science to remote rural communities. It was a spin-off of Questacon – the Australian National Science Centre that started its embryonic life in the backroom of the physics department of the Australian National University (ANU), grew up in a disused primary school, and came to maturity as a major national institution. Gore was the first director, and the word *National* in the title caused him to grapple with the problem of reaching out to all Australians, not just the local region. With support from Shell Australia, support that continues to the present day, the Shell Questacon ANU Science Circus was born.

For 2 years the Questacon Science Circus was served by selected students from ANU who had been trained as explainers. With Questacon’s transformation into the national center, the decision was made to select a more nationally representative circus team. In 1987, therefore, the ANU and the center established a 1-year graduate certificate in science communication, the first of its kind in Australia and, probably, the world. Competition for places was strong as scholarships were (and still are) awarded to successful applicants. In 1991, the certificate was upgraded to a graduate diploma and in 2012 to a masters degree.

The circus is an institution in which the scholars undertake coursework at the ANU and develop a wide range of skills when on the road. These skills range from learning to present science shows live at schools and other venues, mastering the techniques of educational radio on school of the air, loading, safely, a giant articulated truck with exhibits, acting as floor managers when the circus sets up in show grounds, and becoming exhibit repairers to staffing the circus shop. No task is too menial, and while there are no elephants to clean up after, there are often over excited children!

The primary function of the circus is thus to take science and present it to the people of

Australia, especially the indigenous people, to show that it is both relevant to their lives and a stimulating and enjoyable enterprise. A secondary object is to let a number of gifted and confident young scientists advance their own development with the support of ANU and Questacon. The skills they acquire with the circus and its rapidly growing reputation are such as to make them much sought after in Australia and overseas.

There are very few science circuses. The Canadian *Super Scientific Circus* has been operating since 1994. In its own words, it makes *science fun and funny, using amazing and amusing magic tricks to create visual images for scientific concepts*. While it does not go on the road, it can be booked into theaters, performing arts centers, state fairs, schools, libraries, museums, and science centers. The author understands that it supercedes an earlier model in Ontario that was discontinued.

The success of the science circus in Australia is remarkable and it has won several prestigious awards. In particular, the association between the National Science Centre, the National University, and Shell, extending now over 26 years, has been highly commended. It is, however, worthwhile mentioning two aspects that, more than anything else in the opinion of the author, have led to this success. The first is the scholars themselves. The first team comprised only 8; in 2012 there are 16. They are uniformly young, intelligent, enthusiastic, and energetic. They stay with the circus for 1 year only and then are replaced by a new crop. Enthusiasm and innovation are thus renewed annually; each year a brand new team is sent out to schools and communities to carry the message of science.

The second reason is the accident of geography. Australia is huge (7.7 million square kilometers) with only 22 million people, 12.5 million of whom live in the five largest cities. The remaining ten million are spread across the country and make rare trips to the big metropolises. These are the clients of the circus, which travels thousands of kilometers each year. In England and much of Europe, a major city is rarely more than a short rail trip away. A science circus along Questacon lines would scarcely be viable although more local and smaller travelling shows have been successful. There are, however, other similarly large countries that might benefit, as experience in Canada has shown. Recent trials in South Africa have shown that a travelling science circus can be successful there, and a Cape to Sahara Science Circus is being considered.

Science Communication

Susan Stocklmayer
The Australian National University, Canberra, Australia

Science communication has been described as a process by which the scientific culture and its knowledge become incorporated into the common culture. This broad definition encompasses a variety of communication styles which may be envisaged as being distributed across a continuum. On this continuum, simple one-way communication of science is at one end, with many who term themselves *science communicators* engaged in one-way activity. *Science journalism* is in this category; it also includes informative articles in the press, screening a television documentary, placing science on the Internet, or presenting a new exhibition in a science center. There is clearly no expectation by the writers, designers, and producers that they will engage in two-way communication, but rather that they are *transmitting* information to whatever audience is willing to listen, play, read, or watch. One-way communication of science also promotes science careers and the need to improve the poor science performance of many school students. Many aspects of science education, with its prescribed learning outcomes, fall into this part of the continuum. It is not, however, the only or perhaps the ideal way to communicate science.

In the 1980s, the movement known as the *Public Understanding of Science* (PUS) became concerned for public scientific literacy. Efforts were made to improve public education in science, assuming a deficit in public knowledge which required to be filled. The assumption was that increased knowledge of science would result in increased acceptance of science. The PUS movement prompted the rise of science centers, festivals, and so on, all aimed at informing an uninformed public. The development of science performance skills in these informal learning arenas has given rise to a narrower definition of science communication as "the use of appropriate skills, media, activities, and dialogue to produce one or more of the following personal responses to science (the AEIOU vowel analogy): Awareness, Enjoyment, Interest, Opinion-forming, and Understanding" (Burns et al. 2003, p. 191).

The PUS movement of the 1980s also gave rise to science communication as an academic discipline. In the 1990s, a number of tertiary programs in science communication was developed under the umbrella of science faculties. This was a marked change from courses in science journalism taught by communication departments. Since the 1990s, science communication as a discipline has constantly been modified in the light of new perceptions of what it means to communicate science. What is now considered to be the ideal mode of communication has shifted from one-way transmission to some form of two-way, participatory practice. This therefore represents the other end of the continuum – a process of knowledge sharing and knowledge building that incorporates dialogue and consensus, decision-making, and policy formulation. The contribution of indigenous science is part of this knowledge-sharing approach.

Definitions of science communication which deal with diffusion of expert knowledge, or the media as the information source, do not incorporate this broader vision of what it means to communicate science. It is now widely recognized that knowledge *deficits* are not restricted to the general public or to *nonscientists*: they apply to all participatory groups, including *experts* (Stocklmayer and Bryant 2012).

The term *public engagement* has been coined to replace PUS. It acknowledges that the communication of science with a broad public is important, especially when concerned with issues of democracy. It is notable that notions of the nature of science are not the same in the public domain as they may (still) be in the classroom. Ideas about uncertainty of science, the views of science as an unchallenged authority or as a given body of knowledge, have all shifted in recent times as the concept of authority itself has altered. The rhetoric of public engagement has led to increasing attention being given to ways of involving the general public in scientific issues. This was summarized by the UK Research Councils (2002, p. 3):

> With the increasing recognition that dialogue and multiple inputs are crucial factors in underpinning sound decision-making in science, it has become accepted that two-way communication is a more robust way to address [this].

Research in science communication is therefore broad-based, since effective engagement requires contextual understanding of issues such as appropriate framing, belief, knowledge, cultural influences, and perceptions of risk. Of necessity, such research incorporates multidisciplinary approaches drawn from the sciences, the arts, and the humanities.

Science Community Outreach

Koshi Dhingra
Prestonshire Lane, Dallas, USA

Keywords

Community based; Identities; Role models

The mantra of "science is all around you" echoes through a multitude of classrooms and textbooks. However, as our youth step out of their schools every afternoon, there is frequently very little evidence of the value placed by society on science in their communities, and little connection is made between the science curriculum learned at school and student identities as they participate in their everyday life activities. Community-based science programs bring science to the neighborhoods in which the youth live and allow community members access to a wide range of scientific processes in familiar settings. They can be powerful experiences for all if they are well designed and situated.

Science practitioners, ranging from gardeners, farmers, and chefs to engineers and doctors, have science concepts and skills embedded in their daily tasks. When communities are able to highlight the relationship between these activities and science, community members who participate in such events stand to gain an appreciation of the value of science as well as the diversity of scientific understandings and their applications. Further, the fact that community members are involved in such presentations points to the feasibility of local people enjoying a relationship with science. The power of local role models can be great. Finally, because parents, particularly mothers, can engage in such programs, it is extremely valuable from a science education standpoint, since their influence on their sons' and daughters' academic interests is known to be strong.

An illustrative example of a science-related community-based program is the Contact Science program, launched in Texas in 2010 with the goal of bringing a set of diverse, engaging, and interactive science experiences to various communities in the Dallas Fort Worth Metroplex. It is the brainchild of Russell Hulse, Nobel Laureate in Physics, located at the University of Texas at Dallas. At the heart of the program were the design, construction, and placement of adventure stations around various themes in public libraries. These stations functioned as miniature lab benches and had real science tools as part of them. For example, the Electrical Adventures station included an oscilloscope and all the various components to allow for a wide range of experimentation with electricity; the Microworld Adventures Station included a high-end light microscope, as well as a "scope on a rope" that allowed users to look at a monitor to get close-up views of their skin, a leaf, clothing, or anything of interest. Each station had a computer guide with step-by-step experiments for the user to start off with, or the user could play with the components independently and truly experiment as they wished. Each station was designed so that it was convenient for the libraries to rotate the theme and materials every few months. The bench or base unit would stay at the library, but the oscilloscope and other equipment could be removed and easily driven over to a different library. In this way a group of libraries could get a new exhibit every few months. The key strategies used by Contact Science were, firstly, partnering with a system that was already designed to serve local communities, i.e., public libraries, and, secondly, focusing program experiences around authentic scientific tools. To this latter end, staff at the University of Texas at Dallas worked with the Science Museum of Minnesota, an institution that designs and fabricates exhibits for museums around the country. A good match was perceived between some of the lab bench-like exhibits that were on the museum floor and the nature of science activities to be placed in communities around the university. A productive working relationship emerged with Contact Science, with the collaborative adaptation of three of the museum's existing small, interactive exhibits for use in the community-based pilot program. Further, since the program was housed in a university, there was a natural partnership with university resources, particularly access to university student volunteers who would assist in providing additional programming, such as robotics workshops that were also held at these libraries, as well as to students and faculty who were interested in extending the reach of the adventure stations by adding demonstrations and facilitation. Involvement of these three different institutions (library, university, and museum) required considerable learning and working around the varying cultures of these spaces. However, the effects of using the resources present in each institution collaboratively in bringing thoughtful science educational experiences to communities made this a worthwhile effort.

Communities that are able to identify their science-rich resources and create spaces for people to come together to participate in various science-related activities stand to gain a population who can identify the ways in which science is relevant, interesting, and useful. Community spaces and groups such as public libraries, boys' and girls' clubs, girls' scout troops, and recreation centers have the advantage of a pattern of frequent and repeat visitation, unlike informal learning spaces such as museums. This allows for repeated engagement in science programs housed in these spaces, in contrast to the "hit and run" science that frequently occurs in informal learning spaces to which regular visits tend not to occur. Partnerships between institutions, such as museums, research centers, community spaces, and schools, can allow for the design of relevant, conceptually rich, tool-based science experiences designed to incorporate multiple entry points. Involvement by community role models, such as university and high school students and other professionals living in the community who volunteer as explainers or in other ways interact with users, can augment the power of such community-based science outreach experiences.

Science Curricula and Indigenous Knowledge

Michael Michie
Batchelor Institute of Indigenous Tertiary Education, Batchelor, NT, Australia

Keywords

Science Education in the Non-West

Curriculum can be thought of as what is required to be taught, its scope and sequence. This is usually in the form of documentation prepared by an educational authority to be used in schools and colleges under its auspices. In recent times some of this work has been done at a national level by agreement with state, provincial, and local educational authorities (where they exist) which may then modify and enact the curriculum within their domains. In some cases the curriculum may be prepared by recognized external agencies such as the International Baccalaureate. The curriculum differs from individual teacher's or school-based programs which are interpretations of the curriculum for individual school or classroom contexts. Universities usually prepare autonomous curricula although there are usually processes nationally and internationally to ensure comparability.

A related interpretation of curriculum refers to curriculum resources, a classroom resource which may have been developed by the educational authority, by an interested organization, or often by groups of teachers to implement the curriculum. Curriculum resources are usually considered to be a link between the curriculum and the classroom pedagogy; however, resources may be developed which are not based on the curriculum or reflect a particular interpretation of its meaning. Textbooks can also be considered as curriculum resources which should reflect the curriculum.

There has been some discussion of the inclusion of indigenous knowledge in the science curriculum in recent times, although previously there have been instances of the inclusion of indigenous knowledge in some ways, most frequently in textbooks. Critiques of this portrayal have focused on stereotypes which denigrate indigenous peoples and their knowledges. There has been advocacy for the inclusion of indigenous science in mainstream science courses primarily since the 1990s, and terminologies such as multicultural science and multi-science have been used by the advocates. This has been undertaken by both indigenous and non-indigenous scholars (including Aikenhead, Jegede, George, Kawagley, Cajete, Snively and Corsiglia, Stanley and Brickhouse, Cobern, Pomeroy, and Ogawa). Criticism of these approaches has been mainly made by a group of science philosophers who make a distinction between the universality of Western modern science as core science and the lesser position of indigenous knowledge and indigenous sciences. However, this argument has in some ways been circumvented in some countries where educational authorities have mandated the inclusion of "indigenous perspectives" across the curriculum, including the subject science. Other arguments include approaches to redefine Western modern science to be inclusive of indigenous knowledge (particularly approaches to African science).

Science and Indigenous Knowledge

Since the Rio Earth Summit in 1992, there has been an increasing recognition by some professional scientists of the role of indigenous knowledge, particularly in areas involving land management and the environment. At the UNESCO World Conference on Science for the Twenty-First Century, in 1999, there was a call for a wider use and support for traditional forms of learning and knowledge, as well as cooperation between holders of traditional knowledge and scientists to explore the relationships between different knowledge systems and to foster interlinkages of mutual benefit. As a consequence, in 2002 the International Council for Science (ICSU) prepared a report on science and traditional knowledge. It was pointed out by a subcommittee that traditional knowledge was informing science, particularly in nature management. They recommended that the ISCU and member nations should sustain traditional knowledge systems through active support to the societies that are keepers and developers of this knowledge, promote training to better equip young scientists and indigenous people to carry out research on traditional knowledge, and promote and develop research to better appreciate traditional knowledge. Just prior to the Rio+20 UNESCO conference in June 2012, an ICSU session on indigenous knowledge noted that indigenous and traditional knowledge has gained increasing recognition as an essential building block for global sustainability, as well as a change in relationship between scientists and indigenous knowledge holders. A shift away from the notion of scientific validation of extraneous knowledge and its integration into science was leading toward an approach anchored in the codesign of research and the coproduction of new knowledge to address complex emerging challenges. Diverse knowledge systems were becoming more valued because of the benefit of place-based knowledge systems of heightened local relevance.

Areas of knowledge production which have seen the interaction of Western scientists and their indigenous counterparts include (to use their Western names) ethnobotany and ethnobiology, archeoastronomy, and agriculture. These interactions have seen the exchange of knowledge by both groups of people in a variety of ways, including elders from both groups. This exchange is limited to fields of knowledge where some similarity occurs and varies because of the place-based nature of indigenous knowledge. Often the knowledge is referred to as indigenous science or a way of knowing or, if it is more specifically environmental, as traditional environmental or ecological knowledge (TEK). Occasionally the location of the knowledge will be specified, such as Maori environmental knowledge or the Yupiaq way of knowing. Thus, there is an attempt by some professional Western scientists to broaden the definition of science to become more inclusive of place-based indigenous sciences.

Some researchers in science studies have considered that although indigenous knowledges had lacked "the same authority and credibility as science because their localness restricts them to the social and cultural circumstances of their production" (Watson-Verran and Turnbull 1995, p. 116), there was now an explicit focus on the local as an implicit basis of scientific knowledge. It has been suggested that the ways of understanding the natural world that have been produced by different cultures and at different times should be compared on an equal footing. Such epistemological relativism was rejected by other science studies researchers. Although Western science could be considered to be a localized knowledge system, as are other ethnosciences, the notion that they are equally defensible was rejected. The standpoint approach was that different cultures' knowledge systems have different resources and limitations for producing knowledge.

Others who were researching indigenous knowledge and education considered that it was possible to produce a transformative science which would highlight the differences and complementarities between Western science and indigenous ways of knowing. Some wished to initiate "a conversation resulting in a critique of Western science that leads to a reconceptualization of the Western scientific project around issues of multiple ways of seeing, justice, power, and community" (Semali and Kincheloe 1999, p. 45). Their idea of an indigenously informed transformative science is not simply an addition of knowledge but "challenges the epistemological foundations of ethnoknowledge known simply as science" (p. 45). They also suggested that indigenous knowledge could transform education and that its inclusion in the curriculum leads to a needed interaction with "difference" for Westerners, leading to a heightened consciousness which is more empowering than "a narrow focus on homogeneous cultural traditions" (Semali and Kincheloe 1999, p. 47).

Science Education and Indigenous Knowledge: Multicultural Science Education

In the past twenty-five years, there has been much research in education in general and in science education in particular into indigenous ways of knowing. Multicultural science educators questioned whether the Western knowledge base was appropriate or culturally biased, specifically questions such as: "Whose culture are we teaching? Whose knowledge is of most worth? Who benefits and who is harmed by current approaches to curricula?" (Stanley and Brickhouse 1994, p. 387). It was suggested that holding a universalist position with regard to scientific knowledge gave a feeling of omniscience to scientific knowledge and has led to the destruction of other knowledge systems regarded as inferior by Western standards. What was advocated was a community of learners with "the capacity to generate and consider various possibilities for understanding and determining knowledge" (Stanley and Brickhouse 1994, p. 394). This was seen to lead to a science education from multiple perspectives rather than one perspective, although these other perspectives should not be given equal weight in the curriculum. Later, concern was expressed that universalist Western modern science could be taught as if it was neither controversial nor problematical and that multicultural education introduced students to new ways of thinking about the natural world helping them to understand not only other ways of thinking but also some of the fundamental understanding of Western ways of thinking.

The relationship between Western modern science and indigenous science, particularly traditional ecological knowledge, has been discussed in the context of science education. The local nature of traditional ecological knowledge and its transmission were considered as an oral narrative, and its place related to sustainable development. The relativist nature of indigenous science is a reflection of its local applicability, in contrast to the universalism of Western modern science. The spiritual base of traditional ecological knowledge is also seen as an impediment for it being considered as science by many Western scientists. What seems to be forgotten is that most indigenous sciences are accumulations of observations, refined over time, what is referred to often as "the wisdom of the elders." Other science educators suggested that Western science could be defined with sufficient clarity so as to maintain a coherent boundary for the practical purposes of school science curriculum, using the standard account for science, and that the boundary would exclude indigenous knowledge as well as other domains of knowledge. It was suggested that it would be better considered as a different kind of knowledge, valued for its own merits. From such a position it could maintain its independence from which it could critique the practices of science rather than be co-opted into a universalist science. Some indigenous science educators have seen the inclusion of indigenous education as being important, particularly in providing a more culturally relevant frame of reference for teaching science to indigenous students. Others, noting that teaching of science is mostly by Western teachers, were concerned that the treatment of indigenous knowledge would be oversimplified and essentialized to the point of becoming a caricature of its reality.

The incommensurability of multiculturalism and universalism was examined in the context of traditional ecological knowledge and Western science. It was pointed out that "the reduction of local contexts [of TEK] to scientific praxis is inherent to the transcendent nature of scientific knowledge and includes a loss of local heterogeneity, dynamic, and plurality; and transcendent scientific knowledge is useless unless local contexts are reduced to the conditions of scientific laboratories rather than remaining contexts in their own right" (van Eijck and Roth 2007, p. 18). It was concluded that traditional ecological knowledge and Western science were different but were useful in specific local contexts and that traditional ecological knowledge could relate to students learning to solve local problems.

On the other hand, there has been a negative response from a group of Western scientific philosophers critical of multicultural science, including traditional and indigenous sciences, and its influence on the science curriculum. The universalist position advocated mainstream Western science and was critical of multicultural science, particularly a form referred to as "robust" or "noninterventionist multiculturalism." Robust multicultural science was considered by these critics to be relativist and promoting equally validity with universalist Western science. A version of multicultural science termed "epistemic multiculturalism" was also considered incompatible with universalist science. Here multiculturalists were criticized in particular for attempting to broaden the notion of science to include ethnosciences, traditional ecological knowledge, and indigenous knowledges. In considering whether indigenous knowledge or traditional ecological knowledge should be included in the school science curriculum, a version termed "limited compatibilism" was proposed. By this was meant whether there were sufficient similarities between the indigenous knowledge and Western science, normally judged against Western science.

What is notable in the discussions of both the scientists and the science educators who are involved is the emphasis of place-based and local knowledge in the indigenous sciences and traditional ecological knowledge. How to implement this sense of the local through the curriculum and then into pedagogy is one of the difficulties being addressed by some multicultural science educators.

Science Curricula and Indigenous Perspectives

In the later part of the twentieth century, many countries reappraised their school curricula and developed national goals for education. In several of the settler states – those countries which had been colonized particularly by European countries but which had since become independent – the national goals included references to the original indigenous inhabitants. This occurred both in countries with a majority population of mostly European origin such as Australia and Canada and in those with a native majority such as South Africa. An outline of the Australian experience in endorsing indigenous perspectives is summarized here.

The first attempt to develop national goals for school education in Australia was at the end of the 1980s and was called the Hobart Declaration. Although education in Australia is controlled at the state or territory level of government, the federal (national) government is concerned with issues of quality of education across the nation. In a national project funded by the Ministerial Council for Education ministers, a series of agreed goals of education – the Hobart Declaration – was reached. These were to inform development of national curriculum across the eight identified curriculum areas, including science, as well as identifying a number of cross-curriculum perspectives. Item 8 read: "To provide students with an understanding and respect for our cultural heritage including the particular cultural background of Aboriginal and ethnic groups." The reference to Aboriginal culture was interpreted as applying in the teaching and learning of science and needed to become evident in science curricula developed nationally; it became commonly referred to as the "indigenous perspective."

The Hobart Declaration has been updated on two occasions, as the Adelaide Declaration (1999) and the Melbourne Declaration (2008). The Melbourne Declaration included providing students with an understanding and respect for their cultural heritage including the particular cultural background of Aboriginal and ethnic groups and giving all students the opportunity to access indigenous content where relevant. As well, within the goal of promoting equity and excellence, it included ensuring that schools build on local cultural knowledge and experience of indigenous students as a foundation for learning and work in partnership with local communities on all aspects of the schooling process, including to promote high expectations for the learning outcomes of indigenous students. This represents a shift through the declarations from solely consideration of indigenous knowledge to ensuring inclusion of indigenous peoples in all aspects of the schooling process.

There have been attempts to develop a national curriculum including science in Australia since the 1990s, and although its implementation by the various states and territories has been varied, these attempts have influenced the science curriculum in all jurisdictions. Its latest form is the National Curriculum: Science released by the Australian Curriculum Assessment and Reporting Agency in 2011, which covers the years from Foundation to Year 10. A cross-curriculum priority in the national curriculum, including science, is termed "Aboriginal and Torres Strait Islander histories and culture," although it is commonly referred to as the indigenous perspective. Indigenous perspectives in the science curriculum are incorporated as possible elaborations in the Science as a Human Endeavour strand rather than the Science Understanding strand. This has been seen by some commentators as continuing to treat indigenous knowledge as inferior to Western science knowledge. Some science educators have suggested that the discussion regarding the nexus between indigenous science and Western science could be treated as relating to the nature of science, which is implicitly within the realm of Science as a Human Endeavour strand in the Australian curriculum.

Similar processes incorporating indigenous perspectives into the science curriculum can be noted in the recent curriculum development in a number of countries, particularly Australia, New Zealand, Canada, and South Africa. Thus, it can be seen that the imperative to be inclusive of indigenous culture and knowledge has been taken up by curriculum authorities.

It has been advocated that indigenous science should be included in the science curriculum, for a number of reasons. Indigenous science could be seen as part of the way we can understand the world. Secondly, indigenous science could tell us something about Western science and science education. Finally, it was a way of achieving reconciliation between indigenous and non-indigenous peoples and a vehicle for social justice. Earlier, indigenous perspectives were perceived primarily as impacting on non-indigenous students. However, as seen in the commentary on the Melbourne Declaration, they have evolved to impact on the education of indigenous students. This included trying to reconnect indigenous learners with their roots and developing cultural citizenship, as well as expanding our knowledge base in a knowledge society.

The new South African science curriculum prescribes the inclusion of indigenous knowledge, allowing for localized content and accommodating different ways of learning although it is not always clear what this means. In common with curriculum documents in other countries, what is often described as indigenous knowledge are fragments which fit with Western science, compatible with the notions of oversimplification, caricature, and essentializing treatments suggested by some science educators but perhaps a pragmatic implementation of limited compatibilism also. However, there has been a call for indigenous knowledge to be included in Western science in several parts of Africa by a number of African science educators, both indigenous and non-indigenous (including Jegede, Ogunniyi, Semali, Okebukola, Gitari, Keane, and Malcolm), a call which resonates with that made by African scientists as well.

The development of a Maori science curriculum, *Putaiao*, in Aotearoa, New Zealand, in the 1990s, has offered a precedent for similar curriculum development elsewhere. In writing the Maori science curriculum, the Western science curriculum was reconstructed to match up with Maori understandings of the world; much of the Planet Earth and Beyond strand, in the Maori version, has gone into the Biological World strand, which was renamed *Mataora*. What is important for Maori it that this represents the joining of *Papatuanuku* (earth) with the rest of living things (as defined through science). However, there are a number of conditions imposed which limited the accessibility of students to the curriculum. Firstly, the document is written in Maori, for students who are learning through the medium of Maori. Secondly, there were issues regarding language at two levels. At one level there were differences which are apparent with the syntax construction between native speakers and second language learners of Maori. Then there were issues of a “standardized” Maori language in a country made up of various tribal groups with differing dialects.

From time to time indigenous influences on science curriculum have been put aside. In Hawaii a science standard called *Malama I Ka ‘Aina* was adopted in 1994. It incorporated an awareness of Native Hawaiian phenomena and supported culturally responsive, place-based curriculum. However, it was removed in 2005 on the recommendation by out-of-state consultants because it was seen as being too limited to Hawaiian culture, suggesting the political challenges to forms of multicultural science education were not completely aligned with mainstream perspectives.

There appears to have been limited critique of the role of the education authorities in implementing indigenous perspectives. One criticism would come about from the assumption that indigenous and Western knowledges run parallel, when they have been shown by a number of scholars that they have different characteristics. A second, related criticism would apply because the authorities subdivide indigenous knowledge according to the Western fields of knowledge, including science. As noted about, in school science curricula, there has been a tendency to fit the indigenous perspectives into the Western science curriculum structure. This has led to a simplification of the indigenous knowledge to the point of caricature.

Conclusion

There have been two approaches to the inclusion of indigenous knowledge in the school science curriculum. The first of these is by scientists working close to indigenous peoples who see indigenous knowledge as valuable, particularly as local knowledge. One of their strategies is to expand the definition of Western science so that it can include indigenous knowledges in a respectful way. They are supported by a group of multicultural science educators who also wish to be respectful of indigenous students' prior knowledge. The idea of expanding the definition of science and inclusion of indigenous knowledge in the school science curriculum is opposed by some philosophers of science. Separate from this and somewhat preemptive of the work by scientists and science educators is a move by many educational authorities to include indigenous knowledge across the curriculum, often referred to as indigenous perspectives. This includes in the science curriculum although it seems that often it is not clear what an indigenous perspective means. What is becoming clear from science, science studies, and cultural studies in science education is that indigenous knowledge incorporates a local perspective that complements the science one.

Science Departments

Wayne Melville
Faculty of Education, Lakehead University,
Thunder Bay, ON, Canada

Keywords

Head of department; Secondary science department; Subject department

The science department as a unit within secondary or high schools began to emerge in the mid-nineteenth century. Arising from the increasing differentiation of knowledge that accompanied the Industrial Revolution, the development of departments was intrinsically linked both to the prevailing sociopolitical forces of the time and to the rising status of the academic disciplines. As Layton (1973) notes, prior to the professionalization of science and the development of the department as an organizing feature of secondary schools, science education was heavily influenced by a concern for working from the concrete to the abstract. One of the most influential science educators of the time, Richard Dawes, was concerned that students should initially engage with science through the common things they saw around them and from this interest work toward scientific explanations of phenomena. His efforts were highly successful, to the extent that Dawes took on the role of instructing his teachers, and their apprentice teachers, in both scientific principles and the application of his teaching strategies.

The early rise of the science department is closely linked to the professionalization of science, a movement largely driven by William Whewell and the British Association for the Advancement of Science. Whewell argued that science, as a discipline, should be taught in an abstract form and should serve the goal of "mental training." It was believed that only the upper classes were capable of the "mental training" required by the high-status, abstract, academic disciplines, while the lower classes were only capable of simple, concrete thought. Secondly, the newly professionalized scientists worked to secure status, and hence resources, for themselves and their discipline, especially within universities. Academic disciplines accrued to themselves control over both content and the entry requirements to their discipline. Importantly, the universities were given the power to set entrance examinations, a move that was to have profound implications for teaching and learning in schools.

In order to accommodate the demands being placed on them by the universities, schools began to adopt standardized systems of timetables, lessons, and school subjects. The organization of school subjects reflected the university disciplines. This development began in Britain in the 1850s and was basically completed there in 1917 with the establishment of the School Certificate that defined both content knowledge and the evaluation of that knowledge and established preferred teaching strategies, for university preparatory subjects such as Botany, Physics, and Chemistry. This pattern was repeated across the British Empire and in the United States, where the Committee of Ten also expounded the virtues of "mental training." In schools, these subjects were to be taught by content specialists who could meet the expectations of the examinations. These content specialists were to form the first school subject departments. Science was seen as a specialist activity; hence there was little effort to develop the pedagogical skill of the teachers. Consequently, the role of the department was principally administrative, charged with ensuring that university entrance standards were met. The first modern usage of the term department was in 1905, and by the 1920s, secondary teachers in Western countries were being educated in the university disciplines, a development that reinforced the bonds between the discipline and the department. This strong historical link between the discipline and the subject is an important feature in understanding the function and power of the contemporary school department.

In the first half of the twentieth century, major demographic changes occurred in Western countries, in the form of mass immigration, increasing urbanization, and major changes in child labor laws. The huge increase in the public secondary school population, together with the loss of influence of the "mental training" view of education, profoundly changed the work of the department. While still seen as subject specialists, departments took on an increasing responsibility for pedagogy, supervision, and administration. In the 1950s, academic research began to focus on the potential importance of the department for improving the quality of science education. Research at this time suggested departments should maintain a simultaneous focus on supporting students, while also maintaining links to their associated academic, professional, and school communities. This research focus has developed sporadically over the past half century.

Siskin (1994) has defined four aspects of the school-based subject department that she believes are crucial to the delineation of the subject department in contemporary American high schools. The department, according to Siskin:

> . . . represent[s] a strong boundary in dividing the school . . . provide[s] a primary site for social interaction . . . [is] an administrative unit, [with] considerable discretion over the micro-political decisions affecting what and how teachers teach, and as a knowledge category influences the decisions and shapes the actions of those who inhabit it. (p. 5)

Working from these aspects and reflecting their evolution, science departments possess two concurrent functions within the school: the social and the organizational (Melville and Wallace 2007). The social function is a powerful one; within departments (particularly in high-status subjects such as science) teachers are socialized into what is important in their subject content, how it should be taught, and why it should be taught. This socialization shapes, and is shaped by, teachers who identify themselves primarily as teachers of science. This identification is founded on their university education in the sciences, an understanding of the language of science, and a common view of the place of science in society and education. In terms of professional learning, a shared sense of identity is foundational to the work of effective departments, as it allows teachers to trust the judgment and abilities of their colleagues and be prepared to learn from each other. Trust facilitates access to other's knowledge, for example, about content, pedagogy, and the relation of science to society.

The social function is foundational to the organizational function of departments, for their organizational power lies in the capacity to influence how and what teachers teach. Teachers educated into a discipline will generally replicate the academic traditions of that discipline; this is a principal reason why secondary teachers maintain their own practices in the face of efforts to reform teaching and learning (cf., Carlone 2003). Taken together, the social and organizational functions of departments give them tremendous political power with which to arbitrate their response to reform efforts. The members of a strong department may achieve an organizational consensus about what is important in their subject, with the important caveat that within science, teachers can, and will, disagree about the nature of the discipline and, hence, what constitutes "good" teaching. Such a consensus (if developed) is important for ongoing professional learning, as it allows for the establishment of clear goals for student learning. The establishment of consensus cannot, however, be assumed for departments, and there is always the risk that the consensus may be to not change what has "worked" in the past.

Traditionally within departments, the role of leadership has been the preserve of the officially designated, middle management, head of department (or chair in North America). Aside from the established concern for pedagogy, supervision, and administration, Brundrett and Terrell (2004) note that the role is increasingly perceived as being:

> Moral and . . . political . . . because it involves the creating, organising, managing, monitoring and resolving of value conflicts, where values are defined as concepts of the desirable . . . and power is used to implement some values rather than others. (p. 17)

Within the literature on departments, the notion of teacher leadership is being given increasing prominence. Teacher leaders simultaneously undertake and model their own professional learning, while working to build a culture of collaboration that benefits students. Such leadership requires the capacity of teacher leaders to function effectively across departments as both communities and organizations, for, in doing so, they can influence three key reform areas: to provide leadership in the promotion of teaching and learning of science, to develop learning opportunities, and to establish a capacity for reform (cf., Yager 2005).

Science Education in the Non-West

Iran's history as one of the oldest empires dates back to the seventh century BCE. Iranians were mainly Zoroastrians and considered themselves Aryan Persians. Over the pre-Islamic period, instruction in reading, writing, mathematics, medicine, and astronomy was accessible to privileged higher social classes. The wars between Arab Moslems and Persians brought the Old Iranian (Persian) Sassanid Empire and its central government to an end in the seventh century CE. The influence of Islam on Iran changed not only the political climate but also cultural worldview of Persians. Islamic teachings such as monotheism, justice, brotherhood, and equality for all human beings have influenced the Iranian mind.

After the arrival of Islam, Iran's history witnessed much social and political upheaval. Historians of Iran mention the tenth and eleventh centuries as the first golden age of scientific and social development (Nasr 2009). Iranian Moslem scientists extended the frontiers of science based on an inductive-deductive approach. Rhazes, Avicenna, Jabir ibn Hayyan, Biruni, and Kharazmi were among the Iranian scientists whose works were translated into Latin during Medieval and Renaissance periods, paving the way for scientists to build modern experimental sciences. The Moghul invasion in the thirteenth century, in contrast, triggered the fall of science in Islam and Iran. During the Shia Safavid period (sixteenth–eighteenth centuries), however, there was a second rise of scientific advancement (Velayati 2007).

Impacts of Social and Cultural Context

The rulers of Iran in the first half of the nineteenth century, after a number of military defeats, concluded that the weaknesses of the country needed to be addressed through the establishment of a modern educational system. Students were dispatched to European universities and the Dar-al-Fonun (polytechnic) was established at home in 1871. The Dar al-Fonun was the first modern college in Iran. At Dar al-Fonun, medicine, pharmacy, military studies, and engineering were taught by European teachers. Modernization of Iran's education system was based on the translation and adoption of Western knowledge and institutions. The use and adaptation of materials and technical and institutional developments without accepting the West's intellectual and cultural system was and still is problematic (Ringer 2013). The question is how to be modern without losing Iranian identity and integrity. Different answers based on different cultural and political directions have been offered for the question. During the Pahlavi dynasty (1926–1979), for instance, modernization followed secularization and centralization of education, with great emphasis placed on Aryan pre-Islamic identity. However after the Islamic revolution of 1979, the centralization continued but the Shia Islamic identity was underscored.

Directions

Education at Dar al-Fonun was elitist, the aim being the education of students for future government employee positions. However, education in the late nineteenth century, when early elementary schools were established, was mainly based on nationalism. The aim was the education of citizens. The discontinuity and lack of proper harmony between preuniversity and university education and the lack of an organic relationship with the work market have influenced science education in Iran. Iran's oil-dependent economy has hindered the attempts to surmount the disharmony. Not only has the governmental oil-reliant economy been a crucial factor in the persistency of the gap between education and the labor market but also a serious barrier to developing a knowledge- and technology-based economy. The two universal directions, preprofessional training and science education for citizens, have affected science curriculum in Iran. Likewise the Iranian Islamic worldview and a different cultural interpretation of science from the West have had a crucial impact. Iranians debate the nature of Islamic science and its relationship to science in general (Golshani 2004).

The orientation of science education in the new national curriculum of Iran is expressed as follows: comprehensive and holistic growth of students based on the assumption that acquiring knowledge in itself is a spiritual attempt that leads to a more profound and teleological understanding of the created universe and consequently to attain monotheistic insight as a component of the "good life" (*Hayat e Tayebeh*). However, in practice, the two following ideological trends are more noticeable: (1) preparation of students for entrance to universities in order for them to find their jobs in science and technology or governmental positions that lead to higher social status and (2) preparing students who do not want to have any profession or job related to science and technology but need to adapt themselves to a society that is increasingly getting dependent to science and technology.

Intended Changes

Since the late nineteenth century and with the expansion of new schools, policy makers and the general public have always paid attention to and facilitated qualitative and quantitative growth in science education**.** Changes in formal science curriculum can be classified roughly into six periods:

First period (late nineteenth century–1942): Prior to the nineteenth century, Iran had no specific aims and content for science curricula. Teachers would organize their teachings based on their own personal views. Mirza Ali Khan-e Moallem in 1911 and Mohammad Tadayon Birjandi in 1912 were the first textbook authors for the 5th and 6th grades. These books promoted the teaching of pure science. In 1912, a system of 6 years of compulsory education followed by another 6 years of non-compulsory education was enacted. Subsequently science curricula which included a list of syllabi for the two 6-year programs were designed, and a series of pedagogic principles were passed by the Ministry of Education. The syllabi contained content differences with respect to gender roles based on traditional Iranian society. Teachers taught content following predetermined principles. Gradually teachers were allowed to choose from a list of government-approved textbooks. In 1930, for the first time, the Ministry of Education published elementary textbooks and 10 years later published textbooks for high schools. These textbooks, called Vezarati (ministerial), were written by a team of university professors and experienced teachers. Although these textbooks were of fine quality and were welcomed by teachers, due to financial difficulties, the government was unable to publish and distribute them throughout the country. Therefore teachers were free to use Vezarati textbooks or pick from other textbooks.

Second period (1943–1967): Due to political and economic disorders caused in part by the Second World War, there was little planning or management of science education by the Ministry of Education during this period. All science curriculum development activities were surrendered to the free market. Although the competitive atmosphere motivated many to do research and develop science curricula, lack of guidance and supervision led to disorder in school science. In1963, Iran's Textbooks Organization was established and became the exclusive agency in charge of publication of textbooks. Dr. Mahmoud Behzad, the first director of the organization and the author of several science textbooks and teacher's guides, improved school science (Mo'tamedi 2012).

Third period (1968–1980): During this period, public compulsory education was increased from 6 to 8 years and the educational system changed to 5 + 3 + 4 model. Science was made compulsory at all grades. The aims of science education broadened and were influenced by science education in the USA. During this period, government political influence increased, and education became more centralized and was expanded. Returning to the practice of earlier periods, teachers were required to implement an official curriculum.

Fourth period (1981–1995): In the early years after the Islamic revolution, due to the heavy content load and teachers complaints, the content volume of science education slightly decreased. Parts of some science textbooks were revised to remove positivistic ideas. All in all the importance of teachers' role in science education and new science teaching methods were highlighted. Teachers who were found to be committed to Islamic teachings were selected to underline the Islamic values. Shortage of qualified science teachers as a result of economic difficulties, caused by the Iraq-Iran war, was noticeable in this period.

Fifth period (1996–2010): During this period, new science textbooks and teacher training curricula stressed constructivist approaches, collaborative learning, hands-on minds-on activities, descriptive evaluation, and content relevance for all grades. The educational material and information and communication technology were used to support teachers and learners. Research was emphasized, and some efforts were directed toward the development of theoretical indigenous science and also science education (Bagheri Noaparst 2011, Golshani 2004).

Sixth period (since 2011): In recent years, Iran has adopted a new philosophy of formal education and a reform of the national curriculum is being planned. Integration among different disciplines, attention to real-life interests, and educating creative and responsible students are among the main concerns. Science education in elementary and lower secondary grades is being redesigned, using a thematic approach with integrated learning activities. Upper high school education is based on separate disciplines. Promoting the professional position of teachers and a decrease in centralization are among the formal plans.

Science Education in Mainland China

Bangping Ding
Capital Normal University, Beijing, China

Keywords

Science Education in the Non-West

Introduction

The last three decades have seen a tremendous transformation of school science education in mainland China in terms of provision and access, curriculum and pedagogy, and assessment. In addition, there has been major transformation in science teacher education. In part these reforms of science education have been in response to international science education trends and reforms which have provided impetus and influence as the Chinese government has continually followed the policy of reform and opening up to the world. And in part the reforms arise from the rapid social changes that have taken place in the realms of Chinese economy, politics, and social life (Wei 2008).

As is the case with schooling in general within mainland China, it is generally recognized that Chinese science education has had little visibility internationally. This is most likely because of the lack of science education research done by Chinese science educators who can publish in major international journals of science education. In this entry, I provide readers with an insider's perspective. First, I give some background by highlighting the historical overview of science education in China. Second, I present a description of recent reforms of school science education reforms in mainland China. Finally I conclude with a summary.

Historical Background

Although modern science first came to China from the West with the Christian missionaries, initially in the late Ming dynasty and then in the late Qing dynasty (Wang 1997), it was in the first part of the twentieth century that the first generation of Chinese scientists who trained in the West grew up and worked in Chinese universities and research institutes (Wang 2002). The following facts clearly show that it was only a twentieth-century phenomenon for modern science and science education to establish themselves in China. The first national university, Peking University, was founded in 1898 by the Qing dynasty government, while the first modern school system was borrowed from the West by patterning from that of Japan in 1904. The first science society, i.e., the Science Society of China, was set up in 1915 by a group of Chinese overseas students studying science and technology in US universities (Wang 2002), and the Academia Sinica, modeled after the French and Soviet systems, was established in 1928, just a year before the nationalist government was established in Nanjing under Chiang Kai-shek.

Twentieth-Century Influences on Science and Science Education in China

In observing the history of modern science and science education in China, I use five lenses to put science education, formal and informal, in perspective: the nationalistic, the political, the linguistic, the cultural, and the pedagogical.

First, the nationalistic lens informs us that modern science and science education as imported culture from the West have been welcomed and embraced by Chinese people. Essentially this is because it is believed science and science education will rejuvenate and strengthen a China that has lagged far behind the West, scientifically as well as economically and socially (Wang 2002). Recently, Xi Jinping, head of the Communist Party of China (CPC) and chairman of the People's Republic of China, has called for the "China Dream," which clearly resonates with the nationalistic notion of saving China through science and technology, a lasting dream of the Chinese people for more than a century. The revelation of the nationalistic lens for the understanding of current science education in mainland China is that receiving a science education is for Chinese students to help rejuvenate and strengthen China, a kind of collective conscientiousness that has motivated generations of Chinese teachers and students alike to pursue teaching and learning science (and technology).

Second, in line with the nationalistic lens, the political lens provides us with an understanding of science education in China that is, in a sense, characteristic of Chinese education in general, tracing back to the early twentieth century. The May Fourth Movement of 1919, a significant protest movement at this general time, started as a students' protest against Western and Japanese encroachment on Chinese sovereignty at the Versailles treaty negotiations. Leaders of this movement, including a few scientists, called for the introduction of "Mr. Democracy" and "Mr. Science" into China to reform its traditional pattern of culture and politics (Wang 2002). As two banners of the May Fourth Movement, many of the Chinese intellectuals adopted ideas of science (Mr. Science) and democracy

(Mr. Democracy) to inject into the minds of generations of Chinese teachers and students alike, a desire of modernizing China partly by teaching and learning science and technology.

In recent decades, such a political motivation among Chinese science educators and students has shown itself under the communist regime as well, in which "love of science," a slogan together with others, has been instilled into the minds of young children of many generations.

The third lens, the linguistic one, connects with science education through the revamping of the Chinese written language. One of the most influential philosophers, Hu Shi (1891–1962), first studied agriculture in Cornell University in 1910 and, having found his interest in philosophy a year later, transferred to Columbia University to study philosophy under John Dewey. While still there as a doctoral student, he initiated a movement for the vernacularization of the Chinese language as part of the New Culture Movement early in 1917 (Wang 2002). This has had tremendous influence on science education in China, as it has made it possible to translate Western scientific terms into the modern Chinese written language.

Writing about the influence of the New Culture Movement on physics education, for example, Jianjun Wang (1997), a Chinese American professor of science education now teaching at California State University, Bakersfield, comments that

> Had physics been explained in classical Chinese, students would have been burdened by the tedious language decoding requirement. In reality, classical Chinese was too outdated, and used only in written communications among a small group of Confucian intellectuals. The thorough reform of classical Chinese in the New Culture movement had made physics more accessible to the general public, and differentiated physicists from classic scholars in terms of the language style. (p. 335)

Taking as an example, the modern term for science is *kexue*, whereas before the 1910s "science" was translated into *gezhi*, a term borrowed from the ancient Chinese set phrase *gewu zhizhi*. As we use Chinese characters in written language rather than phonetic writing, learning and teaching science in Chinese language presents special difficulty for students and teachers alike. For instance, the concept of energy causes misunderstanding for Western students. However, similar misunderstandings happen with another concept "force" for Chinese students. The Chinese term "force" in daily life implies "energy" or "power" to some extent (Gao 1998).

The cultural lens, the fourth one, brings us to an insight into how science education in mainland China operates, within and outside schools. Although modern science seems to be perceived to be universal everywhere across the world, science education, both formal and informal, within China is taught and learned against the backdrop of Chinese culture in general, thus coloring the curriculum, pedagogy, and assessment of science education.

This is given great attention by Keith Levin (1987), a British comparative educationist, who, in studying science education after a study tour of China in 1984, alerts his readers of the need to "recognize the unique features of provision that make it unlike that in other countries. These include . . . the cultural traditions that shape pedagogy, the ideology of the state, and the rapidity with which changes have been taking place in the recent past" (pp. 420–421).

And finally, the fifth lens, the pedagogical one, which is interwoven with the cultural lens, enables us to see "special characteristics of Chinese science education" (Levin 1987, p. 440). As modern science came to China at the turn of the twentieth century, European pedagogy was introduced into China simultaneously to fit with the newly established teacher education system. At the very beginning of the twentieth century, the German educationist Herbart's pedagogy and especially Herbartianism were introduced and immediately became prevalent across China by way of translating Japanese pedagogical literature. This school of pedagogy was to set the tone for Chinese pedagogy and had huge impact on teaching, learning, curriculum, and assessment of almost all school subjects, including science.

However, the pedagogical lens is diverse and complex in the landscape of Chinese education in general and science education in particular.

After the May Fourth Movement which broke out as a national protest against Japanese aggression, China moved toward US educational sciences, especially following the academic tour of John Dewey in China from 1919 to 1921. For the next three decades until 1949 when the communists came to power in mainland China, it was the American educational sciences – including curriculum theory and the then newly emerging science education research – which came to dominate Chinese pedagogical discourses and exert considerable influence on educational practice.

In the middle of the twentieth century, there was a dramatic turnabout in the pedagogical discourses and theories as the CPC won victory against the nationalist government under Chiang Kai-shek. In the 1950s, the American educational sciences that had been pervasive in Chinese science education were critiqued and swept away as bourgeoisie. Instead, the Russian pedagogy was introduced into mainland China, which emphasized didactics and subject didactics. As a result, the Russian educationist I. A. Kairov (1893–1978) took place of John Dewey in communist China.

In the 1960s and 1970s, after the Sino-Soviet rift arose in 1960, the Russian influence was criticized too, and China began to explore its own way to establish a pedagogy based on Marxism and Maoism with Chinese characteristics. However, the decade-long Cultural Revolution (1966–1976), which caused a catastrophe for mainland China, rendered Chinese education into a wasteland. For example, the course content of physics, which has always been “king” among secondary science subjects in China, was reduced in most regions to only four components, the steam engine, the internal combustion engine, the electric motor, and the pump (Amidei 1980; cited in Wang 1997, p. 337).

The year 1978 saw the beginning of a new era for mainland China, initiated by the CPC’s new policy of reform and opening up to the world under the leadership of Deng Xiaoping (1904–1997). Russian theories of pedagogy were again introduced into mainland China, together with North American educational science and European pedagogies. For the past three decades or so, both the Anglo-American “educational science curriculum” paradigm and the Continental-European “pedagogy-didactics” paradigm have converged in mainland China. This has resulted in a mishmash of pedagogical or educational discourses, which show themselves in many textbooks, with titles such as *Curriculum and Didactics of Physics*, *Curriculum and Didactics of Chemistry*, and *Curriculum and Didactics of Biology*, in use for the preparation of science teachers, both preservice and in-service, in Chinese universities and colleges. Without question, these textbooks and others relevant to science education provide science teachers with the main professional knowledge base which, in turn, comes to influence science education practice in mainland China.

Recent Reforms in Science Education

With the historical background described above in mind, I focus in this section on recent reforms in science education in mainland China. Since 1978, when China emerged from the disastrous Cultural Revolution (1966–1976) and entered a new era heralding reform and opening up, Chinese science education has experienced two main stages of reforms. These reforms have gained their driving forces both from the dramatic social change and transformation within China over the last 35 years and from learning from other countries, especially the USA. The first stage of reforms lasted from 1978 to the end of the twentieth century, during which science education regained its status in the Chinese schooling system and then started to reform, while the second stage began around the turn of the new millennium and continues today. It features a more conscious combination of internationalization and localization of science education in mainland China.

The First Stage: Reinstating and Reforming School Science (1978–1999)

The first few years of the late 1970s and the early 1980s saw the reinstating and reestablishing of the schooling that had been destroyed at every level during the disastrous Cultural Revolution. From the mid-1980s to 1999, precollege science education was fine-tuned and consolidated with new syllabuses for primary science and biology, chemistry, and physics for junior high schools (grades 7–9) and senior high schools (grades 10–12).

In primary schooling, “nature” as primary science became part of the curriculum again. Although the course had a similar nomenclature as it did before, its structure, content, and pedagogy changed considerably as it borrowed directly from the reforms of primary science education in the USA. Beginning from 1977, Brenda Lansdown (1904–1990), a Harvard professor of science education specializing in primary science, came to China for academic visits many times, involving herself deeply in the reforms of Chinese primary science. One of her major works – *Teaching Elementary Science: Through Investigation and Colloquium* (Lansdown et al. 1971) – was translated in 1984 into Chinese and printed many times and has since become a primer for primary science teachers, both preservice and in-service.

In terms of discipline structure, “nature” as primary science emphasized conceptual understanding of science rather than presenting just factual knowledge about nature, as it had done before in China. The curriculum content covered in the course and in student textbooks was systematic, coherent, and balanced in terms of physical science, life science, and earth and space science, i.e., the modernizing of primary science was in line with the US elementary science at that time.

Based on the reform experiences of the 1980s, “nature” as primary science in the 1990s became more consolidated as the new syllabus of 1992 for “nature” appeared and new textbooks in line with the syllabus for pupils and teacher guides were available.

In secondary schooling, science education in mainland China was heavily influenced by the USA as well. In 1979, Paul DeHart Hurd (1905–2001), then emeritus professor of science education at Stanford University, headed a group of American science educators that visited China, the first such visit since 1949. In response, Ye Liqun (1921–2000), then the head of People’s Education Press, led a group of ten Chinese science educators to visit the USA at the invitation of the US Ministry of Education in 1982 (Ye 1982). Both these visits opened the horizons on the part of Chinese science educators and effected a change in policy of science education in mainland China.

Another influence of American science education on mainland China came from taking advantage of the USA and other then industrialized countries’ science curriculum projects and materials developed in the 1960s and 1970s to update and modernize the curriculum of science disciplines for mainland China. In developing science programs for physics, chemistry, and biology and textbooks of each discipline for students and teacher guides for science teachers, Chinese science curriculum developers (scientists, didacticians of science disciplines, and experienced science teachers) in 1977 examined and adopted much from other countries, such as Japan, Western Europe, and most commonly the USA. They paid particular attention to the US curricula such as PSSC, CHEM Study, CBA, BSCS, and ESCP and took ideas from them for use in the unified textbooks they compiled for physics, chemistry, biology, and geography, respectively. In general, it appears that “teachers found many topics to be too theoretical for the majority of students to comprehend at the grade level for which the texts were originally written” (Hurd 1985).

As in primary schools, science curricula in secondary schools were revised and fine-tuned beginning in 1988 and completing in 1992, when new versions of physics, chemistry, and biology were proposed and new editions of textbooks for these science subjects compiled accordingly. This new wave of reform in secondary science focused on the following changes:

The Change of Science Education Goals. Due to the promulgation of the 9-year compulsory schooling law in 1986 by the central government, science education in junior high schools began to change its goals from a somewhat elite education model to a mass education model, so students’ interest in physics, chemistry, and biology were more emphasized in the syllabuses of each science discipline (Wei 2008).

One Syllabus Versus Various Textbooks. Formerly Chinese science education had been characterized by only one syllabus for each science subject at the secondary level and only one kind of unified textbooks for each science subject according to this syllabus which was produced by the official publishing house – the People's Education Press. In 1988 the Ministry of Education followed a new policy of "one syllabus vs. various textbooks" so that different types of high schools could choose them according to their needs and levels. Characteristic of these new textbooks were more up-to-date and refined scientific knowledge, more attention to development of competences in students, more emphasis on what was termed "double basics" (basic knowledge and basic skills), and strengthening the linkage between science education and the social and personal life of students. For instance, the idea of STS was introduced to serve the purpose of connecting (scientific) theory with practice (i.e., social and personal life), and STS contents were added into these textbooks (Wei 2008). In spite of these endeavors, however, the dichotomy of education for quality (*suzhi jiaoyu*) as a new policy of the Ministry of Education and examination-oriented education (*yingshi jiaoyu*) as a reality of the status quo of Chinese education was becoming more and more serious.

Integrated Science Programs on an Experimental Basis. One of the significant breakthroughs in science education reforms during this period came from Shanghai and Zhejiang province. In 1988, the Ministry of Education allowed both to experiment with their own curriculum and textbook production. In science education, both Shanghai and Zhejiang province started an integrated science program for grades 7–9 students in junior high schools. Despite strong opposition from conservative forces when the new curriculum was implemented in the 1990s, the integrated science curriculum in Zhejiang province made progress and converged into the new wave of national science education reforms in the new millennium.

The Second Stage: Science Education Reform Featured with a Combination of Internationalization and Localization (2000–2013)

Around the turn of the new millennium, a new wave of reform in schooling in mainland China began with an outlook toward the twenty-first century. To a large extent, this wave of reform in school science was more consistent with the mainstream of international science education reforms than previous reforms had been, just as the Chinese economy began to be more integrated into the world economy.

The new millennium saw the promulgation of the Ministry of Education's guiding plan titled "Framework for Basic (i.e., primary and secondary) Education Curriculum Reform" in 2001. It also witnessed the shift back of educational discourses from didactics to curriculum studies, such as "curriculum standards," which had been prevalent in the nationalist era of the 1930s–1940s. This now took place of "syllabuses" which had been in use since the 1950s when mainland China learned from the Soviet Union in many respects, education included. For the first time in Chinese educational history, primary science was to become a national curriculum that would replace "nature" and involve every child in science learning from grades 3 to 6.

In accord with the "framework" mentioned above, curriculum standards for primary science (grades 3–6), for junior high school science (grades 7–9), and for junior high school physics, chemistry, and biology were produced by committees of curriculum standards writing teams consisting of science educators and experienced teachers and published by the Ministry of Education in 2002. For senior high schools (grades 10–12), curriculum standards for physics, chemistry, and biology, respectively, were published by the Ministry of Education in 2003. In these science curriculum documents, such discourses as "scientific literacy," "inquiry-based teaching and learning of science," and "nature of science" were officially adopted, as by then the American science education reform documents of "Project 2061" (AAAS 1989) and the National Science Education Standards (NRC 1995) had all been translated into Chinese and became the most important reference materials for drafting Chinese science curriculum standards. Thus there was further internationalizing of science education in mainland China.

In contrast with the former syllabus for separate science disciplines, the new science curriculum standards have embedded the following basic ideas: science for all, promoting the development of every student, embodying the nature of science, emphasizing scientific inquiry, and reflecting the developments of contemporary science. To a large extent, these standards have integrated the science disciplines, since the conception of scientific literacy encompasses the overall purpose of science education throughout the science curriculum from primary schools to senior high schools. “Science literacy” is defined as consisting of four dimensions: (1) scientific inquiry (processes, methods, and competencies); (2) scientific knowledge and skills; (3) scientific attitudes, emotions, and values; and (4) the relationship of science, technology, and society (STS). To implement these new science curriculum standards, new textbooks have been compiled for primary science, integrated science textbooks for junior high, and physics, chemistry, and biology textbooks for both junior and senior high schools. Junior high schools are expected to choose either the integrated science textbooks or separate science disciplines for their students.

In order to promote the science education reform, one of the most important measures taken by the Ministry of Education is to train science teachers. In many universities and colleges, newly established centers of the curriculum reform have been founded, and science educators there plus temporarily employed experienced science advisors and teachers have become trainers. They offer short-term courses (normally 3 or 4 weeks) consisting of lectures given by scientists, didacticians of science disciplines, and expert science teachers, observing excellent science lessons given by expert teachers, participating in discussion and interaction with peers, etc.

The experimental exception to the national primary science education program is the “Learning by Doing” project. Originally imported from the French “La main a la pate” program in 2001, the “Learning by Doing” project was initiated by the China Association for Science and Technology (CAST) and the Ministry of Education jointly under the leadership of Prof. Wei Yu. It focuses on children in kindergartens and elementary schools having exploration study through hands-on activities. At present, nearly 20 regions across the country are involved in this project.

Summary

Science education in mainland China has experienced a fluctuation full of ups and downs over the past century. Originally imported from the West, it is clear that science education has become institutionalized in the Chinese schooling system and has tried to permeate the Chinese culture. Over the past three decades, science education in mainland China has been more and more integrated into the mainstream of international science education reforms, yet at the same time it has retained the Chinese way and thus is different from that of other countries in many ways.

Science Exhibits

Alan Nursall
TELUS World of Science Edmonton, Edmonton, AB, Canada

Science exhibits are displays that explore scientific objects, knowledge, process, and debate in an approachable, understandable manner. They deliver multiple levels of information and accommodate different learning styles.

Great science exhibits excite the emotions and stimulate the intellect while driving home an interesting, inspiring message about an aspect of science. After all, science exhibits are part of the informal learning experience, where emotional response usually paves the way for learning and engagement.

Science exhibits assume an endless variety of forms and styles, from dinosaur skeletons to gesture-controlled computers to dioramas to historical artifacts to interactive mechanical devices. The diversity of science exhibits is a reflection of the wide variety of institutions that create and house them.

History

Museums, in their modern sense as public institutions focusing on collections, research, and education, have been with us for over 500 years. The earliest museums focused on art and religious artifacts, and it was not until the eighteenth century, well into the Age of Enlightenment, when science emerged as a topic worthy of consideration for a museum.

The first science exhibits were collections of specimens gathered by nobility or other men of independent means. Naturalists, explorers, and traders were moving about the world with greater mobility and were able to gather impressive collections of specimens – common, rare, or just strange, the always popular "curiosities."

One of the earliest public collections of specimens was put together in the late eighteenth century by Sir Ashton Lever, whose initial fascination with birds led to the creation of an impressive aviary. As his live birds inevitably passed on, many were stuffed and mounted, growing into a formidable collection. His holdings expanded as all manner of other specimens were brought to him. His collection outgrew his country home near Manchester, and he moved it to his London residence and, in a pioneering move, opened it as a museum for public visitation in 1774.

While Sir Ashton showed the way, the British Museum began to amass and display the world's largest collection of natural specimens, leading to the creation of the separate Natural History Museum in South Kensington in 1881, creating a public treasury of the wonders of the natural world. In the early museums, exhibits were seen as basic teaching tools, unabashedly didactic and key to illustrating our rapidly growing understanding of the planet. Scientists combed the world for unusual expressions of the natural world, and thousands upon thousands of plant, animal, and mineral specimens were carefully collected and put on display, both for the growth of the science and for the edification of the public.

While stuffed animals and mounted insects made for a natural attraction, it was perhaps not quite so obvious that the stuff of science – the tools, technology, and engineering – also deserved pride of exhibition and scholarship.

Industrial society, in the form of tools, technology, and engineering, first appeared in museum exhibits in the Musée National des Techniques in Paris. A decree from the post-Revolutionary government in 1794 mandated the creation of a public depository for the rapidly expanding inventory of tools and inventions, plus the documentation that led to their creation. The physical facility opened in 1799.

At the dawn of the twentieth century, the newly founded Deutsches Museum in Munich took its exhibits in a different direction. Still didactic, still intent on teaching, it not only cataloged the past, it celebrated the contemporary. The Deutsches Museum was arguably the first institution to systematically collect and display the tools, instruments, and inventions of science and then add a layer of engagement through working models along with illustrations and diagrams explaining how things worked. It examined how technology affected the everyday life of Germans. The exhibits were more than a catalog of relics.

The idea of what a science exhibit could be evolved further in the 1930s with the opening of the Museum of Science and Industry in Chicago (1933) and the Palais de la Découverte (1937) in Paris. Both institutions developed exhibits that encouraged visitor involvement, whether it be walking through an enormous model of the human heart or actually conducting a simple experiment in a museum laboratory. These exhibits explored concepts like electricity and ecology and expressed science as a process, as opposed to just collections.

These important first steps were more fully realized in the 1960s and 1970s when exhibit designers began wholeheartedly to tackle the process of scientific investigation. In 1969, the Exploratorium in San Francisco and the Ontario Science Centre in Toronto opened their doors. The interactive science exhibit defined the entire personality of these institutions and captured the public imagination. The museum experience had been transformed from artifacts and specimens to the act of discovery itself. In these bold new institutions, the visitor became central to the act of learning. Artifacts and specimens were still present, but the most profound and popular exhibits were the ones in which the visitor took some control of the outcome and thus, in the well-designed examples, had a chance to behave and learn like a scientist.

There were levers to push, ropes to pull, balls to drop, and pendulums to swing. The choreography of action was intended to illustrate the laws and patterns in the world around us. After all, science simply states that the universe behaves according to a certain set of rules, and through experimentation and observation, we can figure out those rules. At the Ontario Science Centre and the Exploratorium, visitors were encouraged to test the rules for themselves. This gave rise to many famous and widely emulated exhibits – the Bernoulli Blower, the Van de Graaff generator, colored shadows, construction of catenary arches, and dozens of others.

Another great step forward in science exhibit content that gained momentum in the 1980s was the exploration of the social and cultural context of science, from AIDS to climate change to genetic modification to cultural bias in science. As science progresses, it not only increases our understanding and capabilities, it also often challenges our moral compass, and this is now a central part of the exhibit experience at many science museums around the world.

With the advent of ubiquitous digital connectivity, many exhibits are now being designed with internet elements as a core component. Prior to the 1990s, science centers and museums often featured exhibits that explained technology – the wonders of the computer and binary language and transistors. Those exhibits have largely disappeared, due in no small part to the rapid pace of technological change. Exhibits about technology show their age in short order.

As technology progresses, exhibits now feature technology as a central part of the experience. Multiuser touch screens, social media, mobile apps, and group interaction through smartphones are now a normal part of the exhibit landscape, but these advances will again soon seem quaint as new technology emerges and becomes even more an ordinary part of our everyday lives.

Signature Science Exhibits

Museums and science centers often have exhibits that are a core part of their personality and history. They develop and nurture these iconic exhibits to be part of their personality, part of their brand.

One of the best examples is the coal mine tour at the Museum of Science and Industry in Chicago. This exhibit is better referred to as an "experience," as it involves a descent into and tour through a simulated coal mine under the museum. The coal mine opened in 1933 and MSI calls it its first "interactive experience." It is a much-beloved part of the MSI experience. After 80 years in operation, and much retooling and upgrading, it remains a destination within the facility where parents who visited as children bring their children, passing on a sentimental connection to the museum from generation to generation. Similar sentiments surround the coal mine experience at the Deutsches Museum in Munich.

The Theater of Electricity at the Museum of Science in Boston is a core part of that museum's experience. It features massive electrostatic generators that were part of Robert Van de Graaff's teaching laboratory at the Massachusetts Institute of Technology (MIT). The artifacts are impressive in their own right, both technically and historically, but they are still operational and the museum uses them every day in a spectacular show on static electricity.

For decades, a Van de Graaff generator with a young girl's long hair billowing out above her head was the de facto brand image for the Ontario Science Centre in Toronto. The image wonderfully captured the essence of the interactive science center experience – exhibits that encouraged audience participation and which revealed spectacular and unusual results.

It is no accident that some of the largest museums in the world place dinosaur skeletons in positions of prominence. Since 1905, a massive diplodocus skeleton has dominated the Central Hall at the Natural History Museum in London. Iguanodon skeletons from a famous Belgian fossil pit have been the headline exhibit since 1882 at the Royal Belgian Institute of Natural Sciences in Brussels.

The Carnegie Science Center in Pittsburgh is home to a massive, highly detailed, and very much-treasured model railroad set in the hilly terrain of western Pennsylvania. It has been a work in progress at the museum since 1954. For 30 years, a live porcupine and beaver (actually, a succession of porcupines and beavers) have been unofficial mascots of Science North in Sudbury, Canada. The walk-through heart at the Franklin Institute in Philadelphia; the Paper Machine at Teknikens Hus in Luleå, Sweden; and the Gravitram at Questacon in Canberra (and other museums) are wonderful examples of exhibits that generations grew up with and that provide a "familiar face" for returning visitors.

Types of Exhibits

It is difficult to reduce the countless thousands of science exhibits to just a few categories, but there are some general broad groupings that help understand the character of an exhibit.

In reality, many exhibits will display elements of different categories, since there are no overarching rules for creating every exhibit. Each exhibit is an individual creation, and its success depends on how well its design deals with the intended message, visitor expectation, visitor behavior, and context.

Teaching Versus Learning

Didactic exhibits emphasize information and instruction. At its most basic level, a specimen, artifact, or phenomenon is presented with some combination of text, graphics, and audio to explain what visitors are viewing. This is very much a one-way teaching conversation from exhibit to visitor. It is perfectly appropriate for many exhibits, particularly when the item on exhibition has some profound historical or technical significance.

At the other end of a very broad continuum are the interactive exhibits that can be loosely categorized as "constructivist." Constructivism posits that learning comes from meanings created, or "constructed," by individuals building upon what they already know. In constructivism, learning is an active, social process. It may or may not come with instructions. It allows that learning takes time and that we build new knowledge through playing, testing, pondering, and thinking. Good interactive exhibits encourage this process by providing tools and context and put the acquisition of new knowledge, the learning, in the hands of the visitor.

Whether one is better than the other depends entirely upon the needs of the exhibit. In the end, the success of either approach, or anything in between, is only as good as its design and implementation.

During a visit to a science museum or science center anywhere around the world, a visitor can expect to encounter these types of exhibits:

Specimens

Specimens are the stock-in-trade of natural history museums – the bones, fossils, mounted animals, minerals, and other things collected from the natural world. They were also the very first science exhibits.

The earliest specimen-based science exhibits were heavily didactic, with an emphasis on teaching a specific piece of content, but usually with a sense of the dramatic. One of the earliest major science exhibitions was the Crystal Palace Dinosaurs, opened in 1854, a collection of life-sized dinosaur and mammal sculptures. It was a radical display in the mid-nineteenth century but then, as now, dinosaurs proved to be hugely popular with the public.

Some of the best-known and most popular exhibits around the world are based on outstanding collections of specimens. Museums off the beaten track, like the Royal Tyrrell Museum of Palaeontology in Drumheller, Alberta, or the Museum of the Rockies in Bozeman, Montana, attract huge audiences to see their magnificent displays of dinosaurs and other fossils.

Whether its fossils, minerals, gems, preserved animals and insects, bones, plants, or others, museums around the world give us a view into the wonder of the natural world through displays of their exhaustive collections.

But not all specimens are inanimate. At the Insectarium in Montreal, over 150,000 insects and arachnids are on display or in the collection. Live ants and bees are also on show in "vivariums."

Artifacts

Since the opening of the Musée National des Techniques in Paris at the very end of the eighteenth century, museums have been collecting and exhibiting the tools and technology that are the legacy of science.

One of the busiest museums in the world deals predominantly in artifacts of science and engineering – the Smithsonian National Air and Space Museum in Washington, D.C., where millions visit each year to see iconic airplanes and spacecraft, the real stuff of our technological history.

The Science Museum in London displays artifacts with profound historical significance, from the earliest surviving steam locomotive to a WWII Spitfire to early medical instruments.

Any museum is much more than just its artifacts, but through these collections of significant objects, we preserve, illuminate, and teach the history of science. And as an exhibit, the real artifact will always have much greater emotional impact on audiences than a replica.

Dioramas

Dioramas are the detailed recreation of a scene that incorporates three-dimensional objects surrounded by a carefully rendered background to provide context, perspective, and a sense of distance.

While dioramas are used in museums of all types, they are particularly associated with natural history museums as a technique for displaying posed animal specimens in portrayals of their natural environment. These displays can provide precise illustrations of animal behavior and habitat.

The earliest ecological dioramas are credited to Carl Akeley who created dioramas at several American museums. His exceptional craftsmanship is still on view at the American Museum of Natural History where the Akeley Hall contains what many consider to be the best dioramas ever created. His Mountain Gorilla diorama is perhaps the most famous.

Hands-On

The terms "hands-on" and "interactive" are often used interchangeably, but there are distinctions. Unfortunately, both terms suffer from vague, imprecise definitions and from overuse. They suggest an intent without providing any particular prescription for how to accomplish it.

Designers have tried to expand upon the term by coining variants like "hands-in" on "minds-on," encouraging greater consideration for how visitors manipulate and think about the challenges put before them.

One of the most ubiquitous interactive science exhibits, found in dozens of science centers around the world, is the Bernoulli Blower, first made popular at the Exploratorium in San Francisco. Frank Oppenheimer, the Exploratorium's founding director, used this exhibit as an example of how a well-designed interactive exhibit provided many different ways to interact. In this exhibit, a light beach ball or volleyball sits atop a stream of air directed upward through a nozzle. Visitors can tap on the ball and experiment with its movement in the stream of air. They may toss other objects into the stream or let their hair fly over their heads, or groups may toss the ball back and forth through the stream. Or some people direct the air up their shirts for the pleasant cooling sensation.

In this exhibit, there is no particular right or wrong. There are scientific principles that are illuminated and can be explored and toyed with, but at its core, the exhibit encourages experimentation and allows the visitor to take considerable control of the outcome. The exhibit is much less concerned with teaching a specific point than it is with encouraging visitors to observe and explore certain types of cause and effect.

Oppenheimer also felt that this may not be enough. With a little more thought and design, he figured this interactive exhibit could do an even better job of encouraging meaningful experimentation, and to that end, there are many variants of this exhibit in science centers around the world.

Science centers have been building "hands-on, interactive" exhibits since the late 1960s, and each one is still created from scratch, owing more to art than science, as each new exhibit sets its own rules for visitor involvement. As a result, in a visit to almost any science center, we see interactive exhibits that truly dazzle and others that fail to accomplish much at all.

Computer Based

Technology is allowing new techniques for engaging visitors in content. In the 1970s, 1980s, and 1990s, many science museums and centers developed exhibits about technology, introducing visitors to microprocessors and state-of-the-art tech innovation. Now that computer technology is so thoroughly embedded in our lives and advancing so rapidly, the focus has rightly changed to using technology to enhance exhibits and the visitor experience.

The museum world is embracing virtual exhibits – online catalogs, virtual reality, simulations, quizzes, multi-touch screens, smartphone apps, and countless others – and they are now an accepted, even expected, part of the museum landscape. Computers offer opportunities to simulate reality or construct scenarios that would not be possible in the real world. RFID chips allow visitors to track their progress through a museum. The Tech Museum of Innovation has built galleries of virtual exhibits in Second Life, doing things in the virtual world that are not possible in our physical space, extending the exhibit experience beyond the walls of the museum itself.

With the advent of more powerful processors, we are now seeing the first generation of "augmented reality" exhibits in which technology monitors physical interaction and provides real-time information or feedback. In an augmented reality exhibit, a museum visitor may manipulate an interactive exhibit, while a screen provides an animation that illustrates some element of how the physical interaction is controlling the environment. A smartphone or tablet pointed at an exhibit can produce a 3D avatar "host" who provides background information about the exhibit.

Outdoor Science Parks

Indoor environments come with restrictions. There is no wind and little or no natural light, and space is usually at a premium. Outdoor spaces provide the opportunity to create exhibits that involve the sun, wind, rain, and snow of the natural world.

They can involve water and sand and other materials that need to be tightly controlled indoors. And very often, the outdoors allows for very large exhibits that are impractical indoors, from large artifacts like airplanes to oversized levers that lift heavy objects to parabolic dishes that transmit whispered conversations across significant distances.

Unusual Media

There is no limit to the imagination found within science exhibits. The intersection of science, art, and other disciplines provides some of the most compelling artifacts of science.

A striking example is the Glass Flower gallery at the Harvard Museum of Natural History. It is a collection of about 850 plant and flower models, meticulously crafted from glass over five decades by a father-and-son team. The flowers were commissioned by a Harvard botanist who wanted high-quality models for instruction in botany. Exhibits like the glass flowers combine consummate artistic skill with scientific integrity.

Exhibitions of photography based on scientific images have become more common as imaging techniques have become more sophisticated. Images gleaned at the nanoscale or the cosmic scale come laden with scientific content and a profound aesthetic appeal.

Evaluation and Success in Exhibits

One of the most compelling questions about science exhibits is their effectiveness. Does an individual exhibit convey a meaningful message? Do exhibits increase an individual's understanding of science, and if so, how?

This is a difficult question to answer since museums and science centers are designed as places where individuals construct their own experience, choosing what to see, what to read, what to do, and how to explore the museum and its contents.

Researchers have tried to measure cognitive changes produced by exhibits and in a similar fashion to how we measure learning in schools. This has been problematic, since exhibits and the learning objectives for exhibits are different than those in the formal learning system. At school, specific content is taught and then retention and understanding by the student is measured, usually through exams. Exhibits don't work that way.

John Falk and Lynn Dierking have extensively studied how museum visitors interact with and learn from exhibits. Through their research, they have developed the "contextual model of learning" which proposes that how and what visitors learn in museums depend on their personal backgrounds, social interactions, and the physical environment. Decades after a visit, visitors often remember the physical environment in a museum more than individual exhibits. Understanding visitors' expectations and building appropriate physical contexts for exhibits are key to creating a powerful experience.

Research into how people learn gives strong clues about what sort of behaviors are indicative of learning. At Science North in Sudbury, Canada, Chantal Barriault identified a suite of behaviors that indicate different levels of cognitive engagement with exhibits. Evaluators observe visitors interacting with specific exhibits and track different types of behavior. Actions like acknowledging relevance and seeking or sharing additional information are strong indicators that learning is taking place, although the specific learning is often highly individualized for each visitor.

A related line of investigation has been intensively pursued at the Exploratorium in San Francisco. Their researchers measure exhibit effectiveness by assessing the quality of visitor interaction with the exhibit and the clarity of message the exhibit is conveying. They coined the term "Active Prolonged Engagement," or APE, to capture the key elements of a quality visitor experience with an exhibit. Visitors need to be *active*, doing things, in control of the outcome. Their exhibit experience should be *prolonged*, spending time with the exhibit to experiment and test. And they should be *engaged* and be stimulated intellectually and emotionally.

A framework like this provides an expansive, yet measurable, definition of what an exhibit should be. It provides a basis for carefully assessing an exhibit's effectiveness and is particularly useful for helping exhibit design team make an initial prototype better.

One of the biggest paradoxes in interactive exhibits is that it is possible that the activity, or the manipulation by visitors, can actually reinforce faulty impressions about how the world works. This is perhaps one of the biggest shortcomings of interactive science exhibit design, and it reinforces the need to prototype and evaluate exhibits, particularly interactive ones.

Creating Exhibits

The process of exhibit development varies widely between institutions and between projects, but there is a general road map that guides the process. Some museums have internal scientific and design teams to lead this process, but many rely on outside companies with specialized exhibit design, prototyping, and fabrication experience.

Museums and science centers usually create galleries or zones of themed exhibits. Exhibits supporting a similar theme are typically grouped together. This makes life simpler for the visitor, since they need cues as to how to behave (are these exhibits hands-on or not?) and what the overarching scientific and educational messages may be.

The first step is a conceptual plan that answers some key questions: Who is the audience? What are the educational/cultural/scientific messages? What will visitors do when they visit the exhibit? The conceptual plan lays the groundwork so that more detailed design has guidelines for development.

From the initial conceptual plan, ideas are refined to a schematic stage that describes what visitors will do with a specific exhibit, as well as the general dimensions and basic construction design.

Design development, up to and including final design, takes the exhibit to the level of detail necessary for fabrication. This is a challenging and complex process that requires creative, insightful solutions that are usually different for every individual exhibit.

During the schematic and design phases, prototypes are often constructed to try to answer very specific design challenges, especially for interactive exhibits. Prototypes provide important proof-of-concept feedback. They help designers understand how different materials work and how visitors will interpret instructions. It is unreasonable to expect that the first design of an interactive exhibit will work exactly the way it is expected to. Testing with prototypes, refinement of design, and listening to the exhibit users are all critical parts of creating good interactive exhibits.

In the 1990s, another important design element was introduced, that of "universal" or "accessible" design. This thoughtful approach to exhibit design provides equal access and enjoyment for everyone in the intended audience whether they are walking, wheeling, young, old, or physically disabled. Good universal design makes a better exhibit experience for everyone.

After the final design stage, specialized fabricators create detailed fabrication drawings and instructions so that they can build and install the exhibit according to the design team's vision.

Further evaluation of the installed exhibit helps an institution to refine and improve it so that visitors engage, explore, and learn.

Science Fairs

G. Michael Bowen[1] and John Lawrence Bencze[2]
[1]Mount Saint Vincent University, Toronto, ON, Canada
[2]Department of Curriculum, Teaching & Learning, Ontario Institute for Studies in Education OISE, University of Toronto, Toronto, ON, Canada

Science fairs are events at which students display and discuss investigations they have conducted in areas of science, mathematics, engineering, computer science, and other areas (for instance, in some jurisdictions, psychology-oriented projects are included). Most often, science fairs are competitive events where projects are ranked and prize winners are chosen, although in some jurisdictions (such as the CREST (CREativity in Science and Technology) event in Australia), there are noncompetitive events. Science fairs have a long tradition in many jurisdictions around the world; at a recent international competition event (the Intel International Science and Engineering Fair), there were projects from 70 countries. In the United States, the genesis of science fairs was a science club movement that began in the 1920s, building to 600,000 participants within 20 years. These led to the first National Science Fair in 1950, and over the following decade science fairs gained considerable prominence as science itself gained a higher cultural value (related to technology such as atomic bombs ending WWII, the development of television and higher public awareness of science accomplishments). Currently, a country such as Canada, in which a national science fair started in 1962, has half a million students conducting science fair projects each year. Other large-scale competitions, such as the European Union Contest for Young Scientists, had an even later beginning (the progenitor of the EUCYS competition started in 1968).

Science fairs can be considered part of developing students' science literacy skills. Although subject to debate, the idea of science literacy can be broken into three essential parts: (i) science "facts," (ii) science investigation practices (skills related to investigating and creating "facts"), and (iii) science social practices (how facts come to be developed and accepted within the community of scientists, and outside influences on them such as the public and corporations). School science is often critiqued for developing understandings of "facts" but not the other two domains of science literacy. In fact, some argue that the directed ways in which school inquiry tasks are engaged are antithetical to the nature of authentic science. Science fairs may address this by helping students develop their understanding of the other two domains of science literacy through encouraging students to develop open-ended investigations within which they present and defend their work to others (judges, as well as other science fair participants and even the general public).

Much like formal science conferences, science fair projects are usually poster based with some artifacts present from the investigation, often including a detailed log and report book. The projects are set up for public viewing and each student has to give a short verbal presentation of their work (now sometimes supplemented by computer slideshow tools or video). Criteria for the formal judging are often available to the participants, although judges ask their own questions during and after the presentation by the presenter. Because of these poster and verbal presentations, science fair projects develop students' skills over and beyond those of just "science" but also in areas of critical thinking, problem solving, presentation skills, writing skills, argumentation skills, and others that are present in curricular documents for topics other than science.

Despite the positives that science fairs may offer, there have been many criticisms offered over the past decades. The judging process can be problematic since, in many circumstances, projects are judged by persons with an inadequate background for effectively evaluating the particular projects (this happens at all levels of science fairs). A high degree of corporate sponsorship, to the point that the commercial sponsors' name is in the name of the science fair itself, is considered by some to be problematic because of influences it has on attitudes about science-in-the-corporate interest. There is some suggestion that a bias in judging toward commercially viable science projects has led to students focusing on projects that are instrumentalist in purpose, designed to address specific problems that have commercial implications, rather than conducting science projects that are more in the realm of "pure science." The competition itself can lead to students feeling discouraged when their projects are not advanced and do not win mention or awards, and, consequently, they can develop negative attitudes about science. There have been calls for an alternative to the ranking/ribboning/prize-giving in science fairs for over 40 years. Discussions of science fairs in the media often focus on projects which are commercially oriented and, also, have a strong focus on the size of the prizes available (a recent junior high project in the United States won over $110,000 worth of prizes) and arguably help perpetuate traditional stereotypes about the practice of science. Often, students with greater access to resources (mentors, financial resources, etc.) are doing well in science fairs because they have a broader network of support than is available to most students, and thus science fairs are reinforcing and replicating socioeconomic status through these high prizes. Anecdotal evidence suggests that in many circumstances, parents have perhaps too active a role in the conduct of science fair projects, particularly in younger grades. The role of "science communities" also is considerably underdeveloped in science fairs, with projects often being conducted by solo participants with little interaction with peers over the student's engagement in carrying out the project, although, often in senior projects, there is participation with (quite senior) mentors. A final criticism about science fairs is that they often seem to strongly reinforce students using "the scientific method" (which has been roundly discredited as representing the actual practice of science in both the sociology and history of science literature) and, thus, may be misleading students about authentic practices of science.

More recently, online "virtual" science fair competitions have begun to have some prominence. The first were held in the late 1990s but these were mostly small scale. In 2011, the Google Science Fair began and, in its initial offering, there were 7,500 projects submitted to it – which were subsequently winnowed down to 60 semi-finalists, from which three finalists (from each of three age categories) and a grand prize winner were determined.

Science Festivals

Jan Riise
European Science Events Association (EUSEA),
Onsala, Sweden

"Science festivals" comprise a large, growing, and diverse community of science communication events. In recent years, the number of events has increased dramatically, and science festivals can be found almost all over the world, from San Diego to Novosibirsk, from Mauritius to Iceland, and from China to Brazil.

Basically, the term "science festival" covers a public event where science is presented to the public. Initially the "festival" part referred to the similarity with arts, film, or music festivals but with science as the main content. Consequently, many festivals were organized as projects or even as public or private companies with multiple stakeholders. Others were smaller, organized by universities, research organizations, or nonprofit organizations.

A study carried out in 2008–2009 (Bultitude et al. 2011) points to the growing popularity of science events. Festivals have been particularly common in Europe, but new events are introduced all over the world, not least in the United States.

Edinburgh in Scotland staged the first annual International Science Festival in 1989, to be followed by several others in Europe during the 1990s. In 2001, the European Science Events Association, Eusea (originally known as EUSCEA), was founded. Now, 10 years later, the association has approximately 100 institutional members in 36 countries.

During the almost 25 years that have passed since the first international science festivals, the profiles, purpose, and philosophy of the events have evolved, and today's festivals display a broad range of activities, places, and formats. From the start, "raising public awareness of science and technology" often was the most important reason to organize an event. In 2012, "public engagement" and "public participation" have become equally, if not more, significant profiles of an increasing number of festivals and events.

Science education and science festivals, representing formal and informal learning, seem to form a reciprocally beneficial relationship. Many science festivals have a specific program targeted directly at schools, thus becoming a valuable additional activity to everyday work in school and to national curricula (Lerch 2005).

The face-to-face meeting between scientists and the public is a signature characteristic of science festivals. Another is the festivals' way of organizing events at "unusual places," where science not normally is discussed. Shopping malls, railway stations, and other public places create a neutral place and an environment that allows interaction between scientists and members of the public on equal terms.

The value of the direct meeting has been recognized also by science museums and science centers. To an increasing degree, exhibitions in these places are complemented by activities such as lectures, experiments, and science cafés. Such activities may well fall under the umbrella of "science festivals"; indeed, several members of the European Science Events Association are science museums and science centers.

The opportunity for the public to interact directly with scientists seems to be appreciated, by both parties. In recent years, science festivals and science centers have also used their goodwill and actual arenas for policy-based activities, such as citizen conferences, student parliaments, and citizen exhibitions. The position of a center or a festival as a neutral platform with a broad range of stakeholders is advantageous, although the mandate from policy makers is essential for the engagement of the participating members of the public (ZIRN and W-i-D 2011).

From a research point of view, science festivals are still to be investigated in more detail. Evaluations are carried out to some extent but with different methods and in different languages, and the results are not always publicly available (Bultitude et al. 2011). The number of published articles is low, but presentations at conferences such as Ecsite (the European network for science museums and science centers), PCST (Public Communication of Science and Technology), and AAAS (American Association for the Advancement of Science) regarding festivals and festival activities seem to become more frequent. The body of work being built up is beginning to provide a compelling case for the value of science festivals.

Science Fiction

Lindy A. Orthia
Australian National Centre for the Public
Awareness of Science, The Australian National
University, Canberra, ACT, Australia

Keywords

Movies; Novels; Radio; Science in fiction; Science-themed fiction; Television; Theater

Introduction

Some entertainment media products, such as movies and television dramas, are created specifically to educate people about science. Many more are created primarily to entertain but nonetheless contain scientific information, scientist characters, or representations of other aspects of science. This science-themed fiction – including animated sitcoms, novels, radio serials, plays, comics, narrative-based computer games, and more – has the potential to teach people something about science. That potential may apply during leisure time when people consume the fiction purely for entertainment, in the classroom when a fiction text is incorporated into the curriculum, and in informal learning environments such as science shows or community theater when fictional elements are used to market the event or to engage audiences.

Often the first thing people think of when discussing fiction and science is the futuristic and fantastical genre of "science fiction," hence the title of this entry. But other genres of fiction – historical, romance, comedy, soap opera, satire, thriller, and the rest – are just as relevant (indeed, often more relevant) when they involve science-themed ideas, settings, plots, and characters. The term "science-themed fiction" is therefore a better way of capturing this range of possibilities.

Professionals concerned about the public image of science, including science teachers, have traditionally been wary of associating themselves with the science in fiction for several reasons. The scientific information in fiction is often incorrect, making science's defenders worry that it corrodes the public's scientific literacy. Scientists are often depicted in stereotypical ways in fiction (as nerds, as mad or evil, as middle-aged white men in lab coats, and so forth), which is frustrating for people trying to break down stereotypes if they feel fictional scientists are undermining their efforts. In addition, the dramatic or comedic or romantic or speculative elements of fiction can be seen as superfluous to learning and therefore as a distraction from the serious business of science.

This wariness has abated in recent years with science teachers and science communicators increasingly interested in using fiction to engage students' interest. Creative teaching methods and better understandings of the way people process fiction have demonstrated its potential utility for science education.

The two most pertinent questions about fiction for science educators are:

- Do people learn science from the fiction they watch or read for entertainment?
- If a fiction text contains incorrect scientific information, how can it be used effectively to teach science?

Learning Science from Entertainment Fiction

There is evidence that people sometimes learn scientific information from the fiction they consume for leisure. Most of the evidence comes from research into science-themed television programs, particularly medical dramas and soap operas containing health information, so this discussion will focus on that.

It is important to qualify what is meant by "learn scientific information." The evidence we do have suggests that television audiences do not passively and uncritically absorb the science content presented onscreen. Rather, people are generally aware of television's production contexts and conscious that dramas and comedies are created to entertain not primarily to educate. Viewers therefore make considered judgments about what information to believe or disregard, what to find out more about, and which programs to trust.

Some television dramas have successfully communicated important health information, educating viewers or prompting them to seek further information about the topic by raising their awareness of it. In some cases, this has changed viewers' attitudes or behaviors, primarily when dramas have addressed personally relevant and taboo health topics such as HIV/AIDS, sexual health, and family planning. Salience is a key factor in learning, and learning science from fiction is a relatively short-term phenomenon unless the information is reinforced at the time through other fiction texts or sources such as newspapers, websites, and school lessons. Fiction is also most effective for health education when backed up by corresponding changes in society at large: for example, a program promoting condom use has little material impact if audience members cannot easily obtain condoms.

Television drama succeeds in teaching people health information for a number of reasons. Its spoken-word format reaches people who are illiterate or lack confidence in reading. The private location of television viewing enables health messages to be regularly delivered directly into people's homes. The entertainment focus of television drama is its greatest strength. The emotional problems and everyday ethical dilemmas characters deal with are a major draw card for audiences, so packaging health information into such situations and dilemmas, particularly if dramatic consequences ensue, can teach audience members about health. Information presented through highly emotional scenarios tends to make the information more memorable. Drama's nondidactic quality also appeals to audiences: they value the freedom to choose how to respond to any information presented, including the freedom to ignore it and just enjoy the show. Conversely, television audience members are frequently suspicious of documentaries because they feel documentary makers try to manipulate their beliefs by presenting their programs as "captured truth," when in fact they are constructed entities like other television products.

Television drama is particularly successful at science education if viewers feel that its characters, settings, and stories reflect their social reality and if the scientific information presented is relevant to their lives and community. Locally produced programs that are created and set in the countries or communities where viewers live are more likely to resonate with viewers. In some countries and communities, other fiction media such as community theater or radio drama can work equally well or better than television drama, if they are an accepted mode of entertainment for their audiences.

More research on this topic is needed, examining fiction media and genres beyond television drama and science disciplines beyond health. Greater methodological rigor is required too, to avoid limitations that render a study's conclusions questionable. For example, several researchers have used statistical correlations between people's understanding of a scientific topic and their television viewing habits to conclude that television fiction teaches people science (including incorrect or marginal science), but did not establish that television fiction was actually the source of the scientific information.

Teaching Classroom Science Using Fiction

Using science-themed fiction to teach science in schools has become increasingly popular in the twenty-first century. Up until the 2000s, there was little published work on this topic, only a small number of journal papers and books, including the landmark *Fantastic Voyages* (Dubeck et al. 1994), which detailed many ways teachers could use movies to teach science. In the early 2000s, more educators began publishing their ideas for using fiction to teach science, in books, academic journals, and websites (see, e.g., Cavanaugh and Cavanaugh 2004; Raham 2004). The published literature now includes effective ideas and even entire curricula for teaching physics, biology, chemistry, health sciences and medicine, earth sciences, psychology, engineering, environmental sciences, forensic science, and mathematics. Some of these have been used effectively to recruit nonscience students to science classes. While there is minimal quantitative evidence of their pedagogical value, what has been reported has been positive in terms of student numbers, student attitudes, and improved marks. Popular fiction themes have also been used as marketing tools to draw visitors to informal learning facilities such as science centers, often in record numbers, and with anecdotal evidence that visitors then visit other exhibits, their interest in science successfully piqued.

Most educators using fiction to teach science turn the weakness of incorrect fictional science into a strength, by prompting students to identify the factual errors in a movie clip (or a short television program, excerpt from a novel, etc.). When teachers present movies and other fiction texts in classes without prompting students to critique the factual errors, students tend to learn the incorrect science as if it were correct, so teachers are advised to be vigilant. Asking students to explain why the science presented is incorrect engages their critical thinking capacities, requiring them to apply their knowledge. More advanced classes can strive for higher-order learning outcomes. For example, students can consider (and calculate) what conditions in the story would need to change for the science presented to be correct. Some teachers use this approach to integrate multiple topics from the science curriculum, requiring students to employ different kinds of calculations or different areas of knowledge when critiquing a fictional scientific phenomenon.

Science fiction movies are most frequently cited as the type of fiction used this way. They have a unique capacity to visualize outlandish concepts such as global disasters, genetic engineering and cloning, space travel, artificial intelligence, and nanotechnology, enabling teachers to draw attention to the limits of real-life scientific knowledge by way of comparison. However, other kinds of fiction can be used to equally good effect. Appropriate fiction texts for this purpose usually have three things in common: (1) a demonstration of an incorrect (sometimes correct) scientific concept, (2) entertainment value to engage students' interest, and (3) stated parameters within which to explore the scientific concept. The first is an obvious necessity for teaching, and the second makes fiction fun to use rather than an additional burden on students, who may already be struggling with the scientific subject matter. "Stated parameters" here mean the set of conditions in which the scientific phenomenon is demonstrated in the fiction text, such as the size of a fictional hurricane, the speed of a spacecraft, or the source of genetic material for a cloning experiment. The parameters give students a starting point from which to calculate or evaluate the plausibility of the fictional scenario, much as worked examples in textbooks do.

Fiction has also been used to teach more socially oriented elements of science, such as the ethics of controversial science and technology or role-modeling good scientist behavior. Since ethics and other science, technology and society (STS) topics necessitate student engagement with human contexts – including understanding the feelings, values, cultural influences, power dynamics, political views, economic needs, and more that arise when people collide with science and technology – the ideal pedagogical tool will have those elements of human context as its core material. Science-themed fiction is one of the few resources available to teachers that situates science within a human context in this way. Its similarity to real life grants students some plausible stated parameters to work with (in this case human parameters), but its distance from real life enables classroom debates to maintain a hypothetical status unobstructed by the contingencies of real-world case studies.

An innovative approach to using fiction in the science classroom, which deserves further development, is to ask students to write a story about a scientist (Reis and Galvão 2007). Through this task, teachers can explore students' preconceptions about what science is, who scientists are, what scientific work is like, and where science sits within students' lives or the world as they see it. In line with work on redressing scientific misconceptions, this is a fruitful method of bringing to the fore ideas students have that they may not be fully conscious of thinking. The stories may then provide a focal point for discussion and for educating students about what science is really like.

Science for All

Peter Fensham
Mathematics and Science Education Centre,
Queensland University of Technology,
Brisbane, Australia
Monash University, VIC, Australia

"Science for All" is an aspirational phrase that has repeatedly embodied the hope that all members of society, and in the particular case of education, all students, will be able to share in some way in the richness of discovery, explanation, invention, and application that characterizes science as a great human endeavor. Probably first use of the phrase was as the title of a lecture in 1847 by James Wilkinson, a surgeon, in London. In his strong plea for sharing the benefits of science with society at large, he identified several points of hindrance that have been, and are still, evident in the many attempts that have followed to implement this aspiration through the education system.

One point was that the end for which scientific knowledge was sought and recorded by the learned and the end for which it is required by the multitude are not the same, but different. Others were that many scientists consider scientific knowledge as intellectual property to be transmitted unimpaired from generation to generation rather than rewriting it for public use and that they are more concerned to be judged by their peers than with relating the potential of their findings for the life of society. Recognizing and dealing with these insights about the nature of the gap between science and society have, alas, too often been forgotten or overlooked in the many twists and starts that science for the masses has taken in the intervening 150+ years. Wilkinson's points have repeatedly occurence in the numerous attempts in that time to enable Science for All to be the priority goal of school science.

In the years following Wilkinson's lecture, much more was done at the public level than at the school level to provide education in science to the masses. In the nineteenth century, the Mechanics Institutes in Britain and their counterparts elsewhere made lectures on science cheaply available to the public, and these were supplemented by a variety of science-based magazines. In the first half of the twentieth century, a spate of small books on aspects of science appeared, written by leading scientists enthusiastic to share their knowledge. The best-selling book, *Science for the Citizen* by Lancelot Hogben, met and enhanced an obvious public interest that nowadays is further stimulated and met by the natural history and science programs of the BBC and National Geographic.

With respect to school science, there was enthusiasm in England in the 1930s for the teaching of general science, as an alternative or precursor to the teaching of the separate science disciplines, and similar moves occurred in other countries. In each case these alternatives, in due course, languished when it became clear that the new approach was being associated with less academically oriented students and hence carrying less status than the traditional science subjects. As part of the 1960s era of new science curriculum projects, there was also a brief flourishing in pilot form of a Unified Science Education course in the USA and of the Schools Council Integrated Science Project (SCISP) in England that minimized the differences between the disciplinary sciences in favor of more general big scientific ideas, but these failed to become in any way mainstream.

In continental Europe the “didaktik” tradition in education, as compared with the Anglo-American tradition, has more clearly differentiated Wilkinson’s point about the scientific knowledge needed by scientists being different from the scientific knowledge needed by citizens as a whole. However, the specialist teaching of the science disciplines in Europe has militated against their knowledge being brought together in a way that addresses the multidisciplinary realities of science and technology in society.

Science for All next became a widely used slogan in the 1980s reflecting a widespread aspiration for a reform of school science education that would widen the contribution it could make to all students and not just to the minority of future science-based professionals, the primary beneficiaries of the 1960s reforms. The slogan was launched in a number of important national reports, Science for All Americans, Science for All Canadians, and in a UNESCO report, Science for All, generated in its Asia/Pacific Region. Each of these set out a broad brush case for this widening of school science’s target leading to a new set of aims for school science. The Canadian set was the most fulsome with science education being a preparation for the world of work and for moral development as well as the more customary aims of meeting the needs of the science career-oriented students and of the whole student body’s participation in science and technology situations. With the dawn of the twenty-first century, both the world of work (the demand for generic competences) and the ethical challenges (such as global warming, world health, the need for water, etc.) have added new complexities to the teaching and learning of science.

As in the earlier attempts to achieve Science for All, these intentions in the 1980s have also proved difficult to translate into an acceptable and operational curriculum for school science, although a movement to use the trio of the science-technology-society as a frame for school science showed promise for a few years in several countries. It seems as long as there is the expectation that school science will act as a preparation for, and a selection of the small proportion of students who aspire to high-status career courses like medicine and engineering, it will remain difficult to develop a similarly highly regarded and differently designed course of more general science study.

By the 1990s “scientific literacy” had replaced “Science for All” as a slogan, in part to give it a more operational tone and in part to ally science education with the preeminent position, particularly in relation to primary or elementary education, that number literacy and language literacy have always had. In 2007, Douglas Roberts used the new slogan to clarify the issue to which Wilkinson had pointed by defining two visions of scientific literacy: one turned inwards to the sciences themselves and one turned outwards to those real-world situations involving science and technology that we all, as citizens, increasingly encounter. The first vision leads to a curriculum in which what is to be learned is listed in terms of a logical development of separate science disciplines, albeit encouraging interaction of these in interdisciplinary phenomena. The second vision leads to a curriculum that is thematic in structure drawing on whatever disciplinary knowledge is appropriate and building up big scientific ideas and principles.

The task of balancing the science curriculum in terms of these two visions is now evident in recent curriculum documents around the world. The Twenty-First-Century Science Project in England is one example, as is the addition in Australia of "Science as Human Endeavour" as a new strand of science content. The OECD'S PISA project for assessing science learning has also encouraged these endeavours.

Science for Citizenship

Virginie Albe
Sciences Techniques Education Formation –
Ecole Normale Supérieure de Cachan,
Paris, France

Contemporary science curricula in many countries emphasize the importance of educating a scientifically literate citizen, who is able to participate in debates and decision-making related to the issues societies have to face in which science and technology are involved (e.g., energy resources and consumption, water, food and agriculture, human health, global warming, nanotechnology, information). Better informed democratic participation is the aim of science education. This can be related on one hand to a public distrust of scientific expertise in the context of recent health and environment crises related to science and technology (for instance, mad cow disease, the Chernobyl and Fukushima nuclear accidents, genetically modified food, the impact of genomics on medicine) and on the other hand to a problem in several countries of a decrease in the number of university students in science (particularly in physics). Democratic participation as an aim of science education may serve as an argument for the presence of science education in secondary education, or alternatively it may orient a deep change of science education curricula to meet the needs of youth in today's society. While many agree that an important aim of science education is to enable democratic participation, science education for citizenship is also a formidable task (Levinson 2010).

Legitimate concerns of citizens may be interpreted by some philosophers and sociologists as a symptom of a problematic increasing gap between science and society. From such a perspective, science and society are considered as separate spheres that may interact with each other. Some scientists fear that society's support for science through public funding of research may decrease and, hence, call for urgent action to improve public understanding of science. Science education is considered in this context to have a particularly important role. Science for citizenship is, from this perspective, considered to be a possible way to "reconcile" pupils (as current and future citizens) with science and technology, leading to an argument that scientists should engage in actions oriented towards schools. Depending on the nature of the pedagogical activities, science for citizenship may appear to be a slogan to popularize science or communicate the benefits of science and technology. This slogan aims at making science teaching more attractive while maintaining a tradition of the teaching of science content (and marginalizing knowledge of the nature of science or of history and sociology of science). Other scholars have argued, however, from the critical study of international surveys like PISA and other recent reform efforts, that "science for citizenship" is a renewed expression of an old hegemonic project to impose the values of Western societies upon the world (Carter 2008).

A more commonly held view is that "science for citizenship" invites science educators to engage in a deep reformulation of a school science curriculum that no longer meets the needs, interests, and aspirations of young citizens. If current social and environmental problems are to be solved, they argue, we need a generation of scientifically and politically literate citizens in the context of economic globalization, increasing production, and unlimited expansion that threatens the freedom of individuals, the spiritual well-being of particular societies, and the very future of the planet. To achieve such a goal, some argue that the science curriculum should be oriented towards sociopolitical action (Hodson 2003). From this perspective, science for citizenship implies the democratic participation of citizens in scientific and technological affairs (from public debates, to decision-making on socio-scientific issues, to science and technology research policy).

Within these various perspectives on science for citizenship, different perspectives on the "citizen" are apparent. A citizen may be reduced to a consumer of goods, if scientific literacy is developed in order to equip pupils to become sufficiently aware of science and technology for decision-making about purchases. On the other hand, a citizen may be considered a professional if science for citizenship is focused on work preparation. Or the focus may be on the "average citizen" who has to understand and cope with everyday phenomena and participate in political decision-making on issues that require an understanding of science and technology.

This is also an aim of those who advocate science education approaches such as science-technology-society (STS), science-technology-society-environment (STSE), and the discussion of socio-scientific issues (SSI). It is also closely linked to the vision of scientific literacy which Roberts (2007) names Vision 2.

Science for Girls

Dale McCreedy
The Franklin Institute, Philadelphia, PA, USA

The underrepresentation of women in science first became a focus in the late 1970s and early 1980s when two bodies of literature – feminist theory and the history of women in science – converged. What emerged was the realization that women in fields of science were not being adequately recognized and women in the process of choosing fields of study were not pursing science careers in ways that were consistent with their numbers or level of achievement.

Inequitable opportunities for girls to participate in science have been documented in schools, in programs outside of school, and even in the differential treatment offered by a parent or guardian at home. Enhanced awareness and interest in addressing the underrepresentation of girls in science led to a variety of programmatic efforts. While examples of gender inequity and stereotyping continue today, apparent in school texts, children's books and movies, classroom experiences, exposure to science toys, and other science-related experiences, there has also been great progress.

Data gathered by a variety of agencies (American Association of University Women 2010; National Science Foundation 2011; Department of Education 2012; National Science Board 2012) now focuses not just on science but on **s**cience, **t**echnology, **e**ngineering, and **m**athematics – often referred to as STEM. This statistical evidence suggests that there is greater equity in school and test performance, as well as class participation in the STEM fields. But even though girls and boys do not differ significantly in math or science performance, boys' confidence and interest in science majors and careers exceeds girls'. Women outnumber men in biology, psychology, and social sciences but are greatly underrepresented in engineering, computer sciences, and physical sciences. In these male-dominated areas, women earn less than 20 % of the bachelor's degrees awarded each year. This underrepresentation of females and minority groups in particular STEM fields remains a troubling issue.

Girls' Learning Preferences

Getting turned-off or pulled away from STEM careers, especially in the fields of physics and engineering, appears to be the result of an intricate web of experiences at home and at school, societal messages through media, toys, games, books, and expectations about what science is and who does it. A growing body of research on identity development posits that an important ingredient to a girl's ultimate engagement in STEM fields is her development of a sense of herself as someone who "does science." Important to note is that the percentages of women and men who are in STEM fields worldwide vary greatly, providing additional evidence that women's pursuit of science is not a capacity issue, but a cultural and/or environmental one.

A powerful strategy for encouraging girls in pursuing science as a hobby, interest, or career has been the development of girl-focused science programs outside of school. Informal settings provide unique opportunities to engage with and connect with science in an inquiry-based manner without the academic requirements of memorization and standardized testing. A strength of informal environments is support for science learning in ways that utilize learning strategies found most effective for girls. These include opportunities to investigate and learn in safe, nurturing environments, offering noncompetitive, nonjudgmental surroundings that often include opportunities for cooperative learning and exploration and activities that are personally relevant, process oriented, and socially impactful. While these experiences may be effective for all children, research suggests that it is these approaches that are particularly critical in engaging girls.

Informal Programs That Support Girls' Science Learning

There have been several hundred girl-focused programs supported by various federal agencies and foundations over the last decades. These programs focus not only on content and inspiring girls to pursue careers in science but also on developing confidence, positive attitudes about science, and a broader understanding of the ways in which one might engage in science learning and practice.

Informal science programs vary widely in their offerings and intended outcomes. Most efforts offer access to STEM learning through a variety of access points or strategies that may include:

- Female scientist role models
- Field trips
- Hands-on activities
- Project-based/inquiry-based opportunities
- Teaching others
- Working within science strong institutions, companies, or programs
- Career awareness and development activities
- Exposure to unique experiences

Activities can be extremely diverse, ranging from programming computers, or building and shooting off rockets, to digging for fossils, conducting a water study, or growing fruit flies.

Settings vary from museums and zoos to afterschool programs, outdoor classrooms, field-based sites, community-based organizations (CBOs), and clubs. Some of these programs last for an afternoon; others run intensively for years. While informal STEM programs may offer exposure to skills and practices, all vary not only in structure and intensity but also in their connection to a larger community of people committed to science and/or girls. The result is outcomes beyond science learning that include improved self-esteem, self-efficacy, and leadership skills.

Recommendations for Encouraging Girls in Science

While research about women's long-term participation in science resulting from participation in informal science programs is modest, there is evidence that informal STEM experiences can be beneficial in supporting and building capabilities, experiences, and confidence in science. Some recommendations to support girls in science include the following (Halpern et al. 2007; Afterschool Alliance 2011; McCreedy and Dierking 2013):

1. Integrating girl-friendly strategies
2. Providing experiences that enhance girls' beliefs about their abilities to participate in and contribute to science
3. Exposing girls to science careers and female role models in ways that illustrate their importance and value so that a career in science is seen as significant, and just as valuable as others, and a place where they could belong
4. Appreciating the benefit of providing multiple access points to science learning and continued support in pursuing and extending stem interests once engaged
5. Offering rich and diverse stem experiences and unique opportunities that expand girls' understanding about what counts as science
6. Providing opportunities that empower girls to take charge, teach others, and learn authentic science skills and practices
7. Integrating math into stem programs in authentic ways that do not position it as a gatekeeper or barrier to all pathways to science
8. Viewing stem as a vehicle for growth, appreciating that stem experiences and youth development can and do go together

Ideally, informal STEM learning experiences for girls, along with experiences they have at home, school, university, and the work place, build upon one another, as well as connect to and reinforce the countless other experiences in a girl's lifetime.

Science Kits

Gail Jones
Department of STEM Education, NC State University, Raleigh, NC, USA

Science kits have grown in popularity in recent years and have been increasingly used in elementary and middle school science instruction. Science kits typically include materials for students to use to do an investigation and instructions for teachers on how to use the kit as well as background information. Kits also may include supplementary materials such as related literature, other investigations, and suggested assessment items. Generally kits are created to be all-inclusive and are designed to be used with minimal preparation time. Most kits focus on a single science topic such as magnets or rocks.

Science Kits and the Curriculum

Early science kits were designed for students to use as take-home experiments that could be done as an extension of classroom instruction or as a family science activity. In the 1960s kits emerged as a tool to help teachers implement inquiry by providing materials and instructions. These kits were followed by longer-term kit programs that were designed to promote the development of inquiry skills by engaging students in experimentation. Science kits have emerged as tools for schools, distance education programs, and home use.

Today extensive kit-based science programs are developed and distributed by school systems, textbook publishers, and science supply companies. Science kits are also often available from institutions such as science centers and museums and are mostly designed for use in schools. These kit programs include a variety of topics and include kits for multiple grade levels. Most of the science kit programs have focused on the elementary grades, but there are now science kits developed specifically for middle and high school science programs.

In some school systems, kits are designed to be used as the science curriculum, but in many cases, kits are used as either a supplement to the curriculum or stand-alone units that can be implemented as needed. The inclusion of materials and directions for investigations is common to nearly every type of science kit. It is common in school systems that use kit-based science programs for kits to be refurbished centrally, thus removing teachers from the burden of locating, storing, or inventorying materials.

Challenges to Using Kits

Although there are distinct advantages for teachers to use kits (materials are provided and there is no need to purchase, store, or inventory materials), these very advantages for individual teachers provide significant challenges for school systems that must purchase kits, resupply the materials, and provide a distribution system for delivery and pickup. The effort for providing and maintaining materials shifts from the level of the teacher (and school) to a central authority. Often this change in responsibility is accompanied by a shift in funding for science from the school to a central school system program.

Kit Effectiveness

In general, research on science kits has shown that kits have a positive influence on teachers' and students' attitudes about science instruction and can promote the use of inquiry in science classes. Kit use has been shown to impact student achievement. Dickerson et al. (2006) examined teachers' use of kits with 2,299 elementary school students in three grades. Schools that used a kit program were compared to schools that did not use kits. Student scores on achievement tests were compared, and for 15 matched school samples, five of the schools that used a kit-based science program had statistically higher scores, and only one of the traditional science program schools had higher achievement.

A study by Jones et al. (2012) of 503 elementary teachers found that teachers' instructional strategies, classroom practices, and assessment varied according to how frequently teachers used science kits. Jones et al. reported that teachers who used kits most often were more likely to have their students design experiments and collect and analyze data. In addition, the teachers who used kits often were more likely to use small-group learning and alternative forms of assessment such as portfolios and notebooks. Teachers who used kits less often tended to report more traditional types of instruction, including having students practice for standardized tests.

Like other forms of curricular innovation, kits are most effective when they are aligned with teachers' existing beliefs and practices. Rennie et al. (2010) maintain that teachers need deep content and pedagogical knowledge to effectively implement inquiry with kits. For school systems that move to using kit-based curricular programs, these differences in teachers' experiences, competencies, and beliefs must be taken into account when making this kind of systemic change. But even with the challenges of implementing a science kit-based curriculum, schools often report improvement in teachers' confidence in teaching science as well as an increase in the use of inquiry.

Science Museum Outreach

Colin Johnson
Independent Educational Consultant, Cardiff, Wales, UK

As long ago as 2001, the director of the Science Museum of Virginia, Richmond, USA, in an article for *ASTC Dimensions*, described his institution as a "community powerhouse." He rightly pointed out that science museums and science centers have many roles to play in serving their communities, many of which can only be fulfilled through "outreach."

Outreach is capable of many definitions, but one which applies well here is "any systematic effort to provide unsolicited and predefined help to groups or individuals deemed to need it." This is not a new form of education: as early as 1891, the "science demonstrator" to the Birmingham School Board in England had adopted an outreach program which circulated science teaching equipment and samples to schools in a handcart. The motivation, then as now, was to provide resources where they were most needed – economically and efficiently and in a timely manner. Science museums and science centers embraced outreach from their early years. Museum loans of natural history specimens to schools were common during the twentieth century, and early-established science centers like the Ontario Science Centre were taking programs to remote areas (and, in the specific case of OSC, education programs for students and teachers in the schools for Canadian Forces based in Germany).

In the succeeding years, the reasons for conducting science museum outreach have become more subtle. A process which may have begun as a profile-building exercise or for meeting a resource deficit has evolved into a developed sense of responsibility for promoting community engagement – in ways that are

---

"This article was written in 2012."

similarly practiced by orchestras, football teams, opera houses, and theater companies. Such engagement may be socially motivated (e.g., in using outreach programs to promote social cohesion) or driven by a wish to take science directly to the public. An important element in science museum outreach activity is engagement with the formal education system through visits to primary and, less frequently, to secondary high schools.

Examples from around the world are now chosen to illustrate the various methods and motivations for delivering outreach programs from science museums and science centers. The broadcast media and online activity are excluded from this account, as they are treated separately elsewhere.

The Shell Questacon Science Circus claims to be "recognised as the most extensive and longest running touring science centre outreach program in the world." Using a large vehicle and a team of presenters, it offers school shows, professional development for teachers, a traveling science center for the community, and extension activities for senior high school students. This is a model which has been adopted worldwide and indeed was being used, e.g., by the Ontario Science Centre, as early as 1971. The Australian science circus has another purpose; however, it is a core component of the training of future science communication professionals who are following a Master's program at the Australian National University, Canberra. It has also undertaken an "ambassadorial" visit to China.

Science on the move, using vehicles ranging in size from caravans to tractor-hauled multi-wheel trailers can now be found on every continent. Heureka, the Finnish science center, has even offered science shows on cruise ships in the Baltic. PROMUSIT is the traveling museum program from MCT-PUCRS, the interactive Museum of Science and Technology run by the Catholic University of Rio Grande do Sul, Brazil. In operation since 2001, it carries 70 exhibits, a collection of interactive kits, and provides an air-conditioned auditorium within the vehicle. The DESTINY program in North Carolina, USA, originating in 2000, has two 24-place mobile laboratories operated by the Morehead Planetarium and Science Center. The MysteriX science truck from the Technopolis science center in Mechelen, Belgium, has been touring Flanders since 1998. It converts to a mobile laboratory with a themed program in which students have to solve a series of problems within a fixed time to prevent the world from being extinguished by "a mystery virus." In Mauritius, the Rajiv Gandhi Science Centre's "Caravane de la Science" provides interactive science demonstrations, exhibits, and film shows "to explain science concepts…and encourage critical thinking," while their science bus contains 24 interactive exhibits on the theme "We are one" – regardless of color, caste, or race, our bodily organs perform the same functions.

This last example hints at the importance throughout the world of using science outreach to support social cohesion and well-being. Science centers and other informal learning environments are increasingly concerning themselves with socio-scientific issues, sometimes with the aim of influencing attitudes and behavior. A recent study investigated the effects of an HIV-AIDS science theater presentation on the behavioral intentions of 697 South African students, a population facing extreme HIV risk.

Ecsite's PLACES project moves the sociopolitical goal to a policy-making level. Its aim is "to enhance the three-way conversation between science, policy makers, and society", and many European science centers are involved in its "Science Cities Workshops."

Family workshops conducted by London's Science Museum in three different prisons have helped in the difficult process of consolidating relationships between prisoners and their families. Thinktank in Birmingham, UK, has undertaken a series of programs with elderly residents in care homes, in some cases supporting those with dementia as well as age-related physical disability.

Such programs have been described as "citizen science," ultimately enhancing democracy as well as social and economic development, along with fulfillment for the individual.

Transport options must be appropriate to circumstance, and the Manthan Science Center, India, used a camel-drawn cart laden with posters and solar viewers for its participation in the "100 h of Astronomy" program of International Astronomy Year 2009. Elsewhere in the same country, it was possible in 2012 to visit the Science Express Train, with its exhibition on biodiversity and conservation, the "joy of science" hands-on lab, and a teacher-training facility. In Bogotá, Colombia, the Maloka science center has a Cycle Science program in which bicycles equipped with hands-on science activities tour the city streets on Sundays. It also reaches out to municipalities without roads or land access, using boats fitted out as floating classrooms with satellite internet connection.

The principle of the "circus comes to town" is widely adopted by science centers, with many examples of touring programs that settle for a day or two in places where families are generally to be found: shopping malls (an example from 2001 was Science on the Mall: large-scale interactive exhibits from SciTech, Aurora, Illinois), parks (e.g., the Science Picnics in Warsaw – "Europe's largest outdoor science popularization event" organized jointly by the Copernicus Science Centre and Polish Radio – and a similar event in Lausanne from the History of Science Museum), and beaches (e.g., Techniquest's 1996 PanTecnicon program on the beaches of Wales). The product of a science center background is the nonverbal theater show from "Science Made Simple" called Visualise, an extravaganza of visually exciting science phenomena, accompanied by mime and music. Activities of this kind are also offered by science centers to the growing number of "science festivals" that have blossomed around the world. EUSEA (mainly Europe) and the Science Festival Alliance (mainly the USA) are two coordinating bodies with an international remit.

In Brazil, São Paulo's "Science Station" reaches out to street children in the Lapa quarter of the city with Project Clicar, an ICT-based project which provides youngsters with their only address: an email one. Meanwhile in California, the Cal State Long Beach Mobile Science Museum visits children of homeless Long Beach families as part of a science education camp. In Mexico City, Universum works with the "Office for Attention to Vulnerable Populations" to bring health topics and the underlying science to disadvantage people in educational and disability care organizations. The Boston Children's Museum takes family learning opportunities to low-income public housing developments through its Go Kids program.

Integrating traditional knowledge and science, The Bishop Museum in Hawaii reaches out to underserved schools throughout the Hawaiian islands through its program "All Together Now," which aims to integrate the science with cultural stories, combining Western science with relevant cultural knowledge and practice. In Montana, a program with similar intent reaches out to the indigenous American Indians through the Blackfeet Native Science Field Center. In Western Australia, Scitech from Perth has, since 2007, visited every remote Aboriginal community every other year with student workshops, teacher development materials, and resource kits. The program, which can extend more than 3,000 km from the home base, involves significant staff training in cultural competencies and safety matters.

Sometimes, outreach is only "across the street" – the Ontario Science Centre's Flemingdon Park project – or aims to capture audiences who may be frightened of science: the Science ABC sessions from Science Oxford are for everyone who has never studied science or who has forgotten what they ever knew! At other times, it reaches out over considerable distances: OMSI, the science center in Portland, Oregon, has an award-winning program which it operates with library partners to provide underserved rural communities with access to science workshops. The Oak Hammock Marsh Interpretive Centre in Manitoba has a Wetlands Outreach program which covers a vast geographic area across three Canadian provinces – and Scitech in Perth operates across many thousands of kilometers in Western Australia.

Supporting schools is perhaps the most common motivation for science museum outreach programs. Examples divide into two kinds:

those which enrich or complement an already well-established curriculum, bringing unusual resources and/or specialized expertise to the classroom, and those which compensate for deficits in equipment or pedagogy. In simplest terms, these two approaches are found in the richer and poorer countries of the world, respectively, but the distinction is by no means clear-cut.

The Unizul Science Centre in Richards Bay, South Africa, offers various outreach programs, one of which is explicitly “compensatory.” Many high schools are struggling with large classes, limited equipment, and poorly qualified staff. The science center offers workshops at seven different rural locations to demonstrate practical work to matriculating students – work which is examined but seldom performed.

Of the “complementary” programs, there are many to choose from. Those interested in well-described examples could look at the Classroom and Assembly programs from the Science Center of Iowa, Des Moines, USA; the Bodyworks program from the Glasgow Science Centre, Scotland, UK; the Reach the Heights program from Techniquest, Wales, UK; Smart Moves, Science Play, and Maths Squad from Questacon, Canberra, Australia; Scientists on Tour from the Dundee Science Centre, Scotland, UK; Astronomy on Wheels and the Educator Loan Kit Program from the Fort Worth Museum of Science and History, Texas, USA; OMSI’s widely dispersed “traveling programs” for schools and teachers; and the Talk Science professional development program for teachers from the Science Museum, London. Commitment to lifelong learning, involving both schools and communities, is often espoused by science centers, a notable example being the Exploratorium in San Francisco, USA.

Conclusion

Most science museums and science centers succeed in maintaining a “baseline” offering of outreach programs, normally including:

- Support for schools’ classes, often with explicit built-in professional development for teachers
- Community projects intended to maintain the profile of the providing institution, often partnered with other family-friendly events
- Simple traveling programs (e.g., small-scale loan exhibits for classroom use, portable planetaria)
- Lecture programs, science cafés, and other “dialogue” style events

The more challenging and exciting examples of outreach are necessarily more resource-intensive and often tied to fixed-term grant funding, whether of a capital or revenue nature. Major assets such as sophisticated vehicles become increasingly expensive to maintain and operate and generally have a limited life engaging with the public. Programs focused on hard-to-reach audiences, whether for cultural or geographic reasons, require dedication on the part of the provider – both to the delivery and to the generation of recurrent funds for maintaining the operation.

Evaluating the impact of all this work offers the same challenges as the wider effort to understand the power of informal learning environments. All too often, the evidence for learning cannot be captured when the learner is exposed to the experience, and indeed, it is common for this evidence to become apparent only when a new context arises where the learner makes a connection with the earlier experience. Numerous individual outreach projects have been evaluated for their impact, with varying degrees of robustness, but no general study of this area appears to exist.

A further complication in assessing impact arises when an outreach project – as frequently occurs – has an evolving set of objectives during the course of its lifetime. Techniquest’s “Comm Quest” project began as a public showcase for interactive science in partnership with the Commonwealth Secretariat at the Commonwealth Heads of Government meeting in Durban, South Africa in 1999. It then toured the country as an educational resource, with excursions into public domains (e.g., shopping malls), and a dozen years later, it was still being traveled – under the name SciQuest – as an interactive science exhibition for communities.

Science outreach is widely practiced by research institutes, universities, medical institutions, and bodies like NASA which have a major responsibility for the achievement of a nation's technological ambitions. Very frequently, they operate in partnership with science museums and science centers, seeing them either as delivery partners or as gatekeepers to the formal education system. Most frequently the motivation is to do with building the public's awareness and appreciation of medical, scientific, and technological research. These programs, too, are building bricks in the "community powerhouse."

Science Olympiad

Vijay Singh
Tata Institute of Fundamental Research, National Coordinator, Science Olympiads, Homi Bhabha Centre for Science Education, Mumbai, India

The Olympiads are like the Olympics, but for academics, not sports. Unlike the Olympics which are held every 4 years, the Olympiads are annual events held in a different country each year. Further, the participation is limited to preuniversity students. These annual international Olympiads are held in a number of subjects: physics, chemistry, biology, junior science, astronomy and astrophysics, and mathematics, among others.

The Olympiads were initiated by teachers and academicians in USSR and the erstwhile east European nations about 50 years ago, in the late 1950s and 1960s. The Mathematics Olympiad was the first to be organized in 1959. Physics and Chemistry followed a decade later, in 1967 and 1968, respectively. Each of these began with half a dozen or less east European nations bringing together about five of their brightest students to a single location and posing a series of challenging tests. This trend has continued with the students being accompanied by two teachers who are called leaders and sometimes an additional observer teacher.

The theoretical tests are spare in nature. The number of questions is about 3–5 and the student is given 5 h to attempt them. Either one or two experimental tasks are assigned, and once again, the student is given ample time to complete them. The purpose is to test the student's creativity and innovation. The tests are designed by the host country. The leaders form the "jury" and vet the questions before these are presented to the students. To ensure confidentiality the leaders and the students stay in separate locations and are not allowed to meet during the testing period. The leaders are provided with the photocopies of their students' answer scripts and grade them independently of the host country. They are given an opportunity to discuss their evaluation vis-à-vis the host country's evaluation team during a moderation session. In other words the tests are ability and not speed tests and the process of evaluation is made as fair as possible.

Students who do well are awarded medals. Usually the top 10 % of the students are awarded gold medals, the next 12–15 % are given silver medals, and then those in the next 15 % slot are given bronze medals. In some of the older Olympiads, there is an additional category called honorable mention for those who did reasonably well but did not bag medals. The detailed scheme for each Olympiad is quite involved and the above percentages for medals are approximate. The overriding concern is to promote goodwill, and hence, there is no official ranking of nations.

The Olympiads have impacted the educational curricula of several nations. Numerous textbooks and problem books based on national selection tests have been published. Several of the problems have been published in leading peer-reviewed science journals. Special journals devoted to problems and competitions are currently published. Teachers and resource persons associated with the Olympiads have been invited to serve on panels to design school tests and to improve the course content.

There has been a steady increase in the number of Olympiads. The Biology Olympiad was started in 1990, the Astronomy and Astrophysics Olympiad in 2007, the Informatics in 1989, and the Earth Science Olympiad in 2007, to name a few. Regional Olympiads have gained popularity. The Asian Physics Olympiad was started in 1999 and now has over 20 participating nations. Many of these are "official" in the sense that there are carefully laid out rules and statutes and that the host nation routes its invitation through the nodal agency responsible for the selection of the team via a high-ranking government functionary, such as the minister of education. In contrast there are a host of private Olympiads.

The Olympiads are held in different countries from year to year. They have grown in size. The Mathematics and Physics Olympiads boast of close to a 100 nations. Each participating country pays a modest "entry" fee and pays for its travel. The expenses for the stay and excursions are borne by the host country. The Olympiad serves as an occasion to showcase the culture and educational strength of the host nation to teenage students who would become the future scientific leaders of their nation. Every attempt is made to maintain bonhomie, cheer, and goodwill. The Science Olympiads are a celebration of the best in preuniversity science.

Science studies is an area of scholarship devoted to the understanding of science and its operations as well as its interactions with society. Though its borders are far from sharply defined, science studies is generally understood to encompass work done in any of the fields of history, philosophy, sociology, and anthropology of the natural sciences. Such work aims to understand, among other things, the conceptual, epistemological, social, and cultural aspects of the sciences and the communities of practitioners that pursue scientific research. These studies make up the core of the field. Other approaches include disciplinary work drawing from cognitive psychology, cultural and feminist studies, and other research and theoretical traditions. Scholars working within these various fields are most frequently interested in developing understandings of the natural sciences (e.g., physics, chemistry, biology, geology) but have also focused their attention on newer interdisciplinary fields such as biotechnology, biomedicine, computer and information studies, and technology itself as well as social science fields such as economics (Fuller 2005; Hess 1997; Sismondo 2009).

The field is sometimes referred to as "science and technology studies" in which case it goes by the acronym STS. This version explicitly adds technology to the mix, a move that not only places technology on equal footing with science but also acknowledges the recent trend by some scholars in the field to see science and technology as indistinct, recognizing that we have, in fact, entered a period where "technoscience" is perhaps a better description of what those engaged in scientific research actually produce. STS also serves, in some circles, as shorthand for "science and technology in society." Originally this denoted a distinctive approach in the field that sought to explore more closely the relationship between science and society (particularly to make science more accountable to public interests) in contrast to the epistemological and sociological practices of science in and of itself (Sismondo 2009). In the context of science education, this usage evokes the STS curricular movement of the 1970s and 1980s that situated science in the context of contemporary social issues, especially those related to the environment.

One of the primary goals of science studies, put simply, is to explain how science as an activity *works* using the methods of the social sciences and philosophy. The first systematic efforts to develop some extrascientific understanding of science in this way came in the field of philosophy where questions about the essence of knowledge extend back hundreds of years. The philosophers were later joined by historians, who sought to document the progress of scientific thought. While such efforts go back to the emergence of science as a clearly identifiable community of practice in the early 1800s, more formal efforts to chronicle the historical development of science, particularly with the aim of demonstrating its normative structure, came in the middle decades of the nineteenth century. From the mid-nineteenth century to the middle of the twentieth century, the history and philosophy of science stood alone as fields devoted to the understanding of science as a human activity.

It was only during the 1960s that science studies coalesced into an identifiable field. Important foundational work came from the sociologist Robert Merton (1910–2003), who articulated an early view of the social and cultural norms of science, and Ludwig Fleck (1896–1961). The work of Thomas Kuhn (1922–1996), however, particularly his seminal book *The Structure of Scientific Revolutions* (1962), was the catalyst that gave rise to science studies in something close to its current form. Kuhn's book, which offered what many saw as a radical account of scientific change over time, combined with the heightened attention to the role of science in society that came as a result of the massive government investment in scientific research during World War II and throughout the postwar period to shine a light on the functions of science. The new public investment in science and growing influence of technocratic government initiatives and outlooks led to the founding of new, interdisciplinary science studies programs in the United Kingdom that were originally designed to ease the transition to a society newly infused with high levels of science and technology (Edge 1995).

Although originally intended to engage in science education that would promote a humanized form of science more attuned to the needs of society, the new programs in the United Kingdom soon turned to more academic questions surrounding the very operations of science and the manner in which it generated new knowledge about the natural world. The most famous of these was the science studies program at Edinburgh University. Scholars in this program developed what came to be called the sociology of scientific knowledge (SSK) approach that called into question the authority and objectivity of science. Taking their cue from Kuhn's assertion in *Structure* that revolutionary changes in science occur by means other than rational consideration of empirical evidence, Edinburgh scholars such as Barry Barnes and David Bloor argued that the emergence of scientific theories is significantly influenced by the social and cultural commitments to which scientists adhere (Edge 1995).

It was this work that was largely responsible for what many referred to as the "science wars," which, in simple outline, consisted of sociologically inclined science studies scholars on one side who sought to problematize the certainty and authority that institutional science sought to project and scientists (largely) on the other side who resisted this critical examination of their enterprise and endeavored to expose what they believed was less-than-rigorous intellectual work. This genre of science studies, they argued, betrayed a lack of scientific understanding and ultimately demonstrated the vacuous nature of their assertions. A significant amount of the conflict centered on the "Sokal hoax" of 1996. The "science wars" largely passed out of attention not long after the turn of the twenty-first century. Science studies work, however, continues in all the fields mentioned above. Among the subsequent threads of scholarship still being pursued are laboratory studies that seek to carefully document the day-to-day production of knowledge, cultural histories of various disciplinary fields, and philosophical analyses that seek to understand the epistemological practices of science in its natural settings (Fuller 2005; Zammito 2004).

Research in science education and science studies has intersected in a number of ways beginning in the 1970s and 1980s. Two of the most prominent areas of contact have been related to science curriculum and pedagogical practice. With respect to curriculum, there has been, perhaps, no more sustained research focus than that dedicated to conceptualizing some view of what many have called the "nature of science" and incorporating it into the school curriculum. Work in this vein goes back at least to the World War II era with Harvard president James Conant's efforts to teach about the nature and process of science to Harvard undergraduates in the 1940s. At the precollege level, researchers following the recommendations of various national policy documents have similarly sought to capture the essence of science in order to place it in the curriculum with the belief that some understanding of the nature and process of science is key to a meaningful and socially relevant understanding of science. Although there appears to be consensus on the importance of understanding something about science and how it works, the accuracy and usefulness of the particular curricular portrayals of science advocated have been debated. Insights from the science studies literature have been central to these ongoing discussions.

Scholarship from science studies has led to pedagogical experimentation as well. Recent work on seeing science as a practice consisting of discipline-specific conceptual frameworks, specialized vocabulary, norms of argumentation, standards of evidence, representational tools, and so on has prompted science education researchers to examine the ways classroom instruction might be tuned to simulate certain aspects of scientific practice. Research on student modeling and argumentation are two prominent areas of such work. The history of science (another domain within science studies) has been used as a resource for alternatives to traditional instruction in science as well. Historical case studies or narrative accounts of scientific advance have long held out promise of productively engaging students through a more humanistic approach to science teaching, although the potential of this approach to scale up has not yet been demonstrated.

Beyond the sphere of the school science classroom, science education researchers have explored questions of scientific literacy or how citizens engage with science in their daily lives using insights from various science studies fields. Conversely, science studies scholars – particularly those in the history of science – have begun to examine how pedagogical practices and texts have emerged and functioned in the reproduction of various communities of scientific practice through history. Such work highlights the value and productivity of the growing mutual recognition of the science studies and science education research communities.

Science Teacher Education in Mainland China

Science Education in the Non-West

Introduction

As in many other countries, the science teacher education system in mainland China is a part of the teacher education system of the country. Chinese science teacher education system has undergone tremendous transformation and change since its advent in the early twentieth century, from first transplanting foreign teacher education systems one after another, then through the process of indigenization, to finally forming "the Chinese model of (science) teacher education" (Li 2012, p. 417) with distinguishing features of its own. Today, Chinese science teacher education is very much *sui generis* in that on the one hand it has adopted and indigenized both Anglo-American elements and Continental European elements, including Japanese and Russian influences, and in that on the other hand it has inherited "Confucian epistemology and pragmatism" (Li 2012, p. 417).

In this entry, I first present a historical context in which I briefly describe how Chinese science teacher education system was initially in place. Then, I provide a detailed discussion of the reform and current state of Chinese science teacher education, followed by particular consideration of elementary science teacher education and then secondary science teacher education. Next, I highlight some problems and/or challenges that have arisen in the new millennium that have faced Chinese science teacher education in mainland China. Finally, I conclude with a summary, characterization, and conceptualization of Chinese science teacher education.

Historical Context

In ancient China, there were both public (official) and private schooling systems with teachers transmitting Chinese culture for more than 4,000 years without a break. However, there had been no specialized teacher education system in China until around the turn of the twentieth century when the Western teacher education system was transplanted into China via copying the then Japanese teacher education system (which in turn mainly emulated those of Germany and France at that time).

According to Li (2012), a noted researcher on the Chinese history of education, now working with the Chinese University of Hong Kong, the modern Chinese (science) teacher education system has gone through four stages: (1) establishment (1897–1911), (2) institutionalization (1912–1949), (3) reinstitutionalization (1949–1993), and (4) professionalization (1993–present). During the first stage and the first decade of the second stage, Chinese science teacher education was heavily influenced by Japanese science teacher education in terms of system and program and by taking in pedagogical ideas and theories from Germany, especially Herbart and Herbartianism. Thus in preparing school teachers of science, student teachers would study Herbartian pedagogics (including didactics or Didaktik), educational psychology, and subject didactics (Fachdidaktik), the trio core courses in pedagogical studies of teacher education programs that have since set the tone for and had a lasting impact on Chinese science teacher education until today.

The first institute for training school science teachers, *Nanyang Gongxue*, was founded in 1897 in Shanghai. *Nanyang Gongxue* (the forerunner of Jiaotong Universities in Shanghai and four other cities in mainland China and one in Xinzhu, Taiwan) consisted of four schools: a normal (i.e., teacher training) school, an affiliated elementary school, a secondary school, and a college of higher learning. Following *Nanyang Gongxue*, in 1902 several independent normal schools were established in Wuhan, Hubei province; in Nantong, Jiangsu province; and particularly in Beijing, where, what was called the "Institute for Normal Education" (later to become Beijing Normal University) was added to the newly established Peking University (*Jingshi Daxuetang*). Peking University, the first modern national university in China, had been founded in 1898 by the government of the late Qing dynasty (Li 2012).

These newly founded normal schools across the country and the Institute for Normal Education within Peking University (*Jingshi Daxuetang*) laid the foundation for establishing a national system of teacher education. Thus, in 1902 and 1903, the government of the late Qing dynasty promulgated the first national educational legislation, thereby creating a modern school system based on the model borrowed from Japan. According to the newly promulgated legislation (*Guimao Xuezhi*) of 1903, every county or prefecture should open a junior normal school and every province should open a senior normal school, in order to train teachers for local elementary and secondary schools, respectively (Li 2012). These normal schools were completely transplanted from Japan in respect of their structures, contents, and even the style of school buildings.

Beginning in the early 1920s during the second stage of institutionalization (1912–1949), China began to turn to the USA for a model of education in general and of science teacher education in particular. This was partly because of Japan's aggression to China, which aroused strong feelings among Chinese people against everything Japanese and partly because a large group of US-educated Chinese scholars returned to work in Chinese universities and government agencies and came to dominate Chinese educational circles. It should also be noted that US emerging educational sciences, including curriculum theories and science education research, especially John Dewey's modern theory of education as opposed to the so-called traditional theory of Herbart, attracted many Chinese educators at that time. As a result of these factors, China finally jettisoned the school system that was copied from Japan in 1922, and in its stead introduced a new school system, a 6-3-3-4 system, which was modeled on the US school system. For the following three decades from the early 1920s to the late 1940s, Chinese science teacher education was likewise modeled on the US science teacher education. In correspondence with this, the textbooks of science methods courses in Chinese teacher education programs at colleges and universities at that time were full of US educational ideas and theories, although the titles of such textbooks were still *Jiaoxuefa* (i.e., Didactics) in Chinese, as before.

After the Communist Party of China took power in 1949, during the first decade of the third stage of reinstitutionalization (1949–1993), there was another dramatic shift in education, including science teacher education. This time China sided with the Soviet Union in the socialist camp. As the ideology of the state changed, so did the teacher education system, the dominant pedagogy, and science education programs as well. In terms of the science teacher education system, in 1952 the Chinese communist government issued a policy of restructuring higher education throughout mainland China, and under this policy, a closed, independent teacher education system modeled on the Soviet system was established. All primary school teachers were trained in closed, independent normal schools, who only studied some high school level science courses. All secondary science teachers were prepared by closed, independent normal colleges and universities, with student teachers who would be teaching in junior high being trained in 2–3-year normal colleges, while student teachers who would be to teach in senior high being trained in 4-year normal colleges and universities. In this system of science teacher education, secondary (both junior and senior) science teachers were trained in separate departments of the normal colleges and universities, such as the department of physics, department of chemistry, and department of biology. In this way, for example, a student teacher of physics education had to study physics courses exclusively for 4 years in addition to courses on politics, physical education, foreign languages, and, of course, pedagogical studies. This rigid structure of science teacher education has remained basically unchanged until today, although the whole system of science teacher education has become more open and flexible, as described in the following sections.

Reform and Current State in Science Teacher Education

Reform in Science Teacher Education

Since the start of the fourth stage of professionalization (1993–present) mentioned above, science teacher education has witnessed a major transformation again as the Chinese government began to "embrace a sweeping wave of neo-liberal ideology, e.g., marketization, privatization, and decentralization" (Li 2012) in 1993. This shift in policy has effected considerable change in the (science) teacher education system in the following respects.

First of all, the Law of Teachers of the People's Republic of China, the first such law in mainland China since 1949, was enacted in 1993, signaling a new era of teacher education reform. The law regulates the legal rights and responsibilities of teachers as professionals and mandates a national teacher certification system.

Second, the Chinese government restructured the (science) teacher education system by introducing a mechanism of competitiveness in conducting teacher education, that is, entailing a teacher education system that is chiefly reliant on independent normal colleges and universities while allowing comprehensive universities to develop teacher education programs. Meanwhile, within the normal colleges and universities, teacher education programs and non-teacher education programs go hand in hand, thus breaking the closed teacher education system that originated from the Soviet Union.

Third, two new science teacher education programs have been initiated since the 2000s. One is an undergraduate science teacher education program that aims to prepare integrated science teachers for primary school and junior high school as the current new science education reform dictates. At the time of writing (2013), there are 65 colleges and universities that provide such a program. The second new science teacher education program is intended for practicing science teachers as well as for newly graduated bachelor degree holders who are encouraged to pursue a master's degree program in science teaching and even a DEd program in science teaching, in order to enhance science teachers' status and level of professionalization.

And finally, a discussion of the change that has arisen in science teacher education research and development is in order here. As indicated above, science teacher education research and development in mainland China takes the form of developing subject didactics of science disciplines, such as didactics of physics, didactics of chemistry, and didactics of biology, which is congruent with subject specialization in school science teaching. This is a tradition formed in the early 1900s when China introduced German pedagogics and didactics into the pedagogical courses of teacher education and reinforced later in the 1950s when Soviet pedagogy and didactics were introduced again. Therefore, most science teacher educators in colleges and universities call themselves didacticians of physics or chemistry or biology (Ding 2013). Similarly, most of them identify themselves with their subject associations of science subjects, such as the Association of Physics Didactics, rather than the newly established National Association for Science Education founded in 2009.

However, in respect of the research and development of subject didactics of science in mainland China, a new trend has occurred over the past decade in that didactics has met curriculum studies and the two have merged and been integrated to become a new hybrid pedagogical discipline for science teacher education. This situation has happened in the context of the new curriculum reform that began around the turn of the new millennium when curriculum studies were reintroduced from the USA in the 1990s. Thus curriculum studies since have flourished and developed significantly, and this has paved the way for some didacticians of physics, of chemistry, and of biology to take ideas from curriculum studies into textbooks of subject didactics of sciences intended for prospective and in-service teachers of science. Correspondently such textbooks more and more have taken the titles of "curriculum and didactics of physics" (of chemistry, of biology, and even of science), a newly formed characteristic of science teacher education less seen in other countries.

Elementary Science Teacher Education

Like elementary science, elementary science teacher education has had a long past but a short history in China, as is the case in many other countries. Before 2000, elementary science was called "nature" (*Ziran*) as one of the auxiliary subjects in elementary schools and was generally taught by nonspecialist teachers with a tenuous background in science. As a matter of fact, "nature" was on the school timetable but not taught in many schools, especially in rural primary schools. It depended on whether the school principal placed importance to the subject or not. This was the case mainly because elementary science teachers were not specially trained, although some of them might have gained good in-service training while in teaching. For example, in the late 1970s and throughout the 1980s, Brenda Lansdown (1904–1990), a Harvard professor of science education specializing in primary science, came to China for academic visits many times and gave several workshops on primary science teaching in Beijing and other cities. This prepared a large cohort of primary science teachers from across the country who have become specialist primary science teachers and even today continues to have an impact on the professional development of primary science teachers.

Around the new millennium, the science curriculum reform for the 9-year compulsory schooling decided that "primary science" in place of "nature" as a required subject would be taught from grade 3 to grade 6 in all primary schools. Since then many normal colleges and universities have begun to provide 4-year teacher education programs for primary schools as demands for the qualifications of primary school teachers rise. In these teacher education programs, some of the student teachers select to study more science courses so that they will serve as specialist primary science teachers. This is the case especially in metropolitan cities such as Beijing and Shanghai, as well as provincial capitals and coastal cities. As a result, more and more specialist primary science teachers are prepared by primary science teacher education programs in colleges and universities, although it should be acknowledged that there are many 2–3-year local (normal) colleges still turning out elementary teachers who receive less training in science.

The current science curriculum reforms have also provided a new impetus for the professional development of primary science teachers. Primary science teachers in mainland China consist of two cohorts, with one being specialist science teachers who have stood out as excellent primary science teachers or graduated recently from elementary science teacher education programs in normal colleges or universities and the other being nonspecialists who teach other subjects like mathematics as well as science. So at school level, the specialist primary science teachers may serve as science coordinators helping other teachers improve their science teaching, while at the district, county, and/or municipal levels, some of the outstanding specialist science teachers are selected as science teaching researchers (*Jiaoyanyuan*), whose tasks are to provide in-service training or professional development for primary science teachers.

Secondary Science Teacher Education

Preservice Science Teacher Education for Secondary School. In secondary schools, grades 7–9 are junior high school and grades 10–12 senior high. Except in Zhejiang province and in Shanghai where school science in junior high schools has been taught as an integrated subject since the mid-1990s, subject-based science subjects, i.e., physics, chemistry, biology, and partly geography (natural geography), are taught by different subject teachers. In senior high schools, science is always taught as separate science subjects by different subject teachers. Under this circumstance, preservice science teacher education programs in colleges and universities are conducted in separate departments (or colleges/schools) of sciences in collaboration with the department (or college/school) of education, a tradition that dates back at least to the 1950s when China restructured (science) teacher education system patterned after that of the Soviet Union. For example, all student teachers in physics study in the department of physics, while all student teachers in chemistry study in the department of chemistry, and so on. The departments of physics or chemistry provide subject-based science courses and subject didactics courses (didactics of physics, didactics of chemistry, etc.), while the department of education gives other courses on pedagogical studies, including pedagogics, psychology of education, and educational technology. In many cases, both junior and senior high school science teachers are prepared by 4-year teacher education programs, conferring BSc on graduates. But in some rural areas, junior high school science teachers usually receive 2–3 years college education in local normal colleges, as was the case for all junior high school science teachers before 2000.

Over the past decade or more, preservice science teacher education for secondary schools in mainland China has seen new trends. This is partly as a result of the expansion in enrollments of postgraduate education and partly due to the difficulty of employment for some of master's degree students in science. First of all, some postgraduate students with a master's degree in science are encouraged to work as science teachers, and they have come to form a new cadre of school science teachers, especially in what are so-called model high schools (*Shifan Gaozhong*) in towns and cities throughout the country. Second, some outstanding high schools in metropolitan cities such as Beijing, Shanghai, and others have recently even attracted PhDs in science or in science education to their teaching force. Third, in both undergraduate and postgraduate science teacher education programs, some of the student teachers are offered the opportunities to study half a year or 1 year as exchange students in the universities of industrialized countries on government or interuniversity scholarships, thus facilitating the internationalization of science teacher education for mainland China. Hopefully, there is every reason to expect that these new trends in preservice science teacher education will improve the quality of science teacher education significantly.

Professional Development of Secondary Science Teachers. In-service training/education or professional development for teachers of science (and other subjects) also has a significant place in China. It is also unique in that while it is rooted in both foreign theories and practices which have been indigenized, it is simultaneously predicated on Chinese traditions and experiences.

To start with, as there is only a short period of time (6–10 weeks) devoted to professional experience or practicum teaching in schools for preservice student teachers, beginning science teachers in mainland China usually have an induction period of 1 or 2 years in schools where they are employed to work, which is the so-called mentoring practice on the job. During this period, beginning science teachers are assigned to work with experienced teachers as dyads, thus forming a relationship of master and apprentice. This kind of "cognitive apprenticeship" is a very effective experience of learning to teach for beginning science teachers, because experienced teachers as senior people with wisdom are highly respected in the Confucian culture.

Secondly, the established system of the teaching researcher (*Jiaoyanyuan*, hereafter referred to as *JYY*) has been in place since the mid-twentieth century and is a significant feature of professional development. Who is a teaching researcher or *JYY*, and what does he or she do in the professional development for science teachers? (Ding 2013)

A teaching researcher or *JYY* is not a member of staff in any school. He or she works with a unit (i.e., the division of teaching research, or *Jiaoyanshi*) embedded in the administrative body of education at the various levels of the county, municipality, or province. For example, in Beijing, there are more than 120 teaching researchers of physics, chemistry, and biology at secondary school level, who are working with the district educational bureaus or with Beijing Municipal Educational Commission. These teaching researchers or *JYYs* used to be excellent school teachers, and now they are responsible for the professional development for science teachers (Hewson 2007) in the field of their own school subjects.

As teacher educators of school science teachers, teaching researchers or *JYYs* are different from science teacher educators in colleges and universities in that the former (JYYs) are practitioners with both rich experience and theoretical knowledge of pedagogical studies and they focus on practitioner research into science teaching, curriculum, evaluation, and professional growth and development for science teachers. On the other hand, the latter are academics much more interested in educational theory and research than the former. Specifically, the roles and/or responsibilities of teaching researchers or JYYs of science in mainland China include the following aspects:

1. **Research**. Teaching researchers or *JYYs* of science conduct research into curriculum, teaching, assessment, and professional growth and development for science teachers in ways that concentrate on the practical issues and problems in the above areas in their school subjects. For *JYYs* of science, the practitioner research they conduct is often done *with*, rather than *on*, school science teachers, and findings resulting from such research feed back to the *guidance* and *service* they offer to science teachers in order to improve science teaching and learning and to provide quality assurance of schooling in science.
2. **Guidance**. *JYYs* of science provide professional *guidance* for science teachers under his or her jurisdiction. Guidance rendered by *JYYs* concentrates on two cohorts of teachers: novice and leading teachers, for the reasons that the novice teacher will soon act as a qualified teacher, while the leading teacher will share his or her successful strategies or experiences with other teachers. For example, a *JYY* of physics at the Beijing municipal level may call a daylong professional meeting, whereby about 40 teaching researchers of physics and some of the leading physics teachers from the various districts and counties of Beijing (there are 14 districts and two counties within the city of Beijing) come together for learning about and discussing how inquiry-based physics teaching and learning is conducted in the classroom. These kinds of learning activities are often connected with the current curriculum reform policies, which school science teachers are required to implement and enact through the mediation of *JYYs* of science.
3. **Service**. It is also incumbent on *JYYs* of science to offer *service* to individual science teachers or a particular group of teachers to improve teaching quality by sitting in on and observing science lessons. For instance, if an experienced teacher of chemistry is asked by his or her school head to conduct an open

lesson (*Gongkai Ke*) for his or her colleagues to observe from the school or even from many schools in the district so that other teachers may learn from it, the *JYY* of chemistry in question is surely invited to give advice as regards how to best use the situation. Service afforded by *JYYs* of science also comes in the form of providing testing papers in school science subjects, for example, in the midterm or final examination each school year at county or district level.

Thirdly, the National Teacher Training Project (*Guopei Jihua*) has been initiated jointly by the Ministry of Education and the Ministry of Finance of China since 2010, whereby hundreds of thousands of practicing science teachers (and other subject teachers) have been selected to train in order to enhance the overall quality and professionalism. The National Teacher Training Project consists of two parts: the Project of Exemplary Teacher Training and the Project of Rural Key Teacher Training in central and western China. The provisions of the training are mainly located in normal colleges and universities, but sometimes also in leading high schools, with teacher trainers including university teacher educators, outstanding *JYYs*, and leading school principals and teachers of various subjects.

Problems and/or Challenges

In writing this entry, several pressing problems and/or challenges in respect of science teacher education in mainland China have come to mind. First, although science teacher education as indicated above has formed a unique Chinese model of (science) teacher education (Li 2012), can we say that this model is able to meet the needs of preparing high-quality teachers of science for mainland China? Second, inquiry-based science teaching and learning is singled out as one of the most important objectives of school science education both in mainland China and internationally. This is obviously a big challenge for both Western countries and China as well. Can the current Chinese science teacher education reform meet the challenge? Third, Chinese science teacher education research has adopted the tradition of German Didaktik (Fischler 2011), and meanwhile it has also accepted the Anglo-American tradition of science education research. In recent years, Chinese subject didacticians as science teacher education researchers have tried to integrate both the traditions in order to form a hybrid "curriculum and didactics of science" for various school subjects of science. Obviously, this seems to be another rigorous challenge for Chinese science teacher educators. To what degree can they succeed in making the integration? There are, of course, many other serious problems and challenges facing Chinese science teacher educators, but these problems and challenges stand out more manifestly and awaiting being addressed more urgently.

Concluding Remarks

Counting *Nanyang Gongxue* as the very first normal school that offered science teacher education in 1897, Chinese science teacher education has since undergone 116 years of development so far. The past century has witnessed a succession of identifiably historical pathways of science teacher education, each of which was appreciably marked by learning from other countries, sticking to China's cultural tradition, and adapting to social needs and changes influenced by a complexity of contemporarily political, economic, and educational factors. By integrating various elements from Japanese, Continental European, Russian, and Anglo-American models of science teacher education, there seems to have formed a *sui generis* Chinese model of science teacher education, based on Confucian epistemology that emphasizes the conception of "Chinese harmonism," expressed in the Confucian idea of "seeking for harmony but not the sameness" (*he er butong*) (Wang 2013). "With its core features of independence, openness, adaptability, and diversity based on Confucian pragmatism and epistemology," the Chinese model of science teacher education, despite its problems and challenges, "can provide alternative ways of thinking about the reform and change" (Li 2012) of science teacher education in the globalized world and, hopefully, will contribute to world science teacher education in the future.

Science Teachers' Professional Knowledge

Hongming Ma
Faculty of Education and Arts, Federation
University Australia, Churchill, VIC, Australia

Keywords

Science teachers' professional knowledge; Subject-specific knowledge; Teacher knowledge

Introduction

Science teachers' professional knowledge, or science teachers' knowledge, is a specific category of "teacher knowledge." Understanding the nature of teacher knowledge (science teacher knowledge in particular) and how it develops is important not only in (science) education research but also in (science) teacher education processes and practices.

Conceptualization of Teacher Knowledge

The meaning of "teacher knowledge" as a construct has evolved over time as it has been interpreted and cast in differing ways from diverse perspectives by different scholars. The main tension that underlies the understanding of the nature of teacher knowledge can be traced back to the dichotomy between theory and practice. With an interest in the epistemological aspects of research programs on teacher knowledge, Fenstermacher (1994, p. 3) made a distinction between "the knowledge that teachers generate as a result of their experience as teachers" and "the knowledge of teaching that is generated by those who specialize in research on teaching." He designated the former as "teacher knowledge: practical" and the latter, "teacher knowledge: formal." He argued that both theoretical and practical knowledge can enjoy legitimate epistemological status in knowledge claims as long as the demands for justification are meet.

Most research programs in the 1960s and 1970s were concerned with formal knowledge and involved understanding teacher knowledge from a theoretical or propositional stance. In these research programs, teachers were the objects of research, the "known" in Fenstermacher's term, and the researchers often saw themselves as producer of knowledge about effective teaching. The 1980s saw the rise of several new research programs with a particular interest in teachers' action in practice and the beginning of the shift in focus from propositional to practical knowledge. In these research programs, teachers were seen as the "knower" and the coresearcher or coproducer of knowledge about teaching (e.g., teacher as researcher). Researchers adopted various terms to refer to teacher knowledge, each emphasizing a particular characteristic of teacher knowledge. These terms included "personal practical knowledge," "professional craft knowledge," "practitioner knowledge," "knowledge in action," and "local knowledge."

It would be more productive to see Fenstermacher's distinction as a heuristic device in analyzing teacher knowledge claimed in various research programs rather than as exclusive categories that reinforce the dichotomy of theory and practice. Teacher knowledge is a complex construct in which knowledge and beliefs, conceptions, and intuitions are intertwined. Practical knowledge (such as routines and procedures) and propositional knowledge (such as theories, concepts, and principles) are often interrelated in teaching practice. A comprehensive review of perspectives on teacher knowledge and how it develops is offered by Munby et al. (2001).

Subject-Specific Knowledge and Science Teachers' Professional Knowledge

In an attempt to answer the question "what knowledge is essential for teaching?" Shulman and his colleagues based their research program on studying specialized knowledge for teaching in different subject areas. Shulman (1987) proposed seven categories of teacher knowledge: (a) content knowledge; (b) general pedagogical knowledge; (c) curriculum knowledge; (d) pedagogical content knowledge (PCK); (e) knowledge of learners and their characteristics; (f) knowledge of educational context; and (g) knowledge of educational ends, purposes, and values and their philosophical and historical grounds. Shulman's model made an important contribution to the research on teachers' subject-specific knowledge and has promoted the idea of a distinctive knowledge base for teaching as a profession.

Building on Shulman's theoretical framework and other researchers' work in the field, Abell (2007) proposed a modified model for mapping research on science teacher knowledge. This model highlighted the relationship between general pedagogical knowledge (instructional principles, classroom management, learners and learning, and educational aims), knowledge of context (students, school, community, and, districts), science subject matter knowledge, and pedagogical content knowledge for science teaching. She described science subject matter knowledge as including syntactic knowledge (knowledge of scientific inquiry skills and investigations) and substantive knowledge (knowledge in chemistry, physics, biology, and earth and space science). Pedagogical content knowledge for science teaching includes orientations toward teaching science, knowledge of science learners, knowledge of science curriculum, knowledge of science instructional strategies, and knowledge of science assessment.

Pedagogical content knowledge (PCK) is conceived as a specific form of teacher knowledge. Researchers who ground their work on pedagogical content knowledge find it a unique concept in promoting the professionalization of teaching. It is different from content knowledge in that it emphasizes the particular context of teaching and the interaction between teacher and student. It is also different from general pedagogical knowledge, because it is closely related to teaching particular subject matter. However, there has been more controversy regarding the connotations of pedagogical content knowledge than the definitions of science subject matter knowledge. Researchers have different views on the composition of pedagogical content knowledge, and they interpret the elements of this concept in different ways.

Implications for Science Education Research and Science Teacher Education

Research programs on science teacher knowledge have included both practical and propositional knowledge within the knowledge base for teaching. Teacher knowledge is a multidimensional concept. As a result, research programs adopt multiple instruments and methods. In some areas, such as science teacher subject matter knowledge, researchers share more common language in elaborating terminologies, describing theoretical frameworks, and comparing findings. In areas like pedagogical content knowledge, where researchers still do not agree about terminologies and methodologies, research programs are less cohesive, and researchers continue to seek common ground and to develop a research agenda both conceptually and methodologically. Despite these differences, researchers share the ultimate goal of improving student learning by improving teaching practice. It is hoped that understanding different aspects of teacher knowledge and their relationships will contribute to substantial improvement of teaching practice.

How the understanding of teacher knowledge (science teacher knowledge in particular) informs teacher education programs and policies is an important question. Teachers develop their knowledge from diverse sources, including daily practice and experiences, formal teacher education courses, and professional development. Recognizing that knowledge gained from all these sources can be integrated by teachers to form a conceptualization that might guide their teaching practice, teacher education program design and policy making have experienced a transition from emphasizing subject matter knowledge understanding through the specialist nature of pedagogical content knowledge. At the heart of science teacher education and development is the need to pay careful attention to not only what professional knowledge is but also how it develops and changes over time.

Science Teaching and Learning Program

The Science Teaching and Learning (STaL) program is the result of a collaborative project between the Catholic Education Office Melbourne, Australia, and the Faculty of Education, Monash University. The program aims to provide professional learning that supports the development of science teachers' practice (across years K-12), both individually and collectively (Berry et al. 2009). The program challenges teachers' existing understandings about conditions which enhance quality science learning and supports teachers to critically reflect upon, research, and report their understandings of their teaching and develop new knowledge of practice (Loughran 2006). To achieve this, teachers are provided with time to trial new ideas, information to consider alternative practice, and opportunities to both discuss their learning and recognize the emergence of new professional insights. The culmination of this knowledge resides in participants constructing and sharing "cases" of reflective practice drawn from their resultant classroom experiences.

Underpinning Program Principles

A number of assumptions about teacher professional learning underpin the STaL program and therefore shape the program's structural design and approaches to teacher learning. The first assumption is that change in practice occurs most effectively when it is self-directed and focused on individual needs and concerns. Therefore, placing the ownership of the learning directly in the hands of the teachers themselves is a guiding principle which underpins facilitator behavior in the program. Secondly, teaching is seen as problematic. Through the STaL program, science teaching is presented as dilemma-based requiring teachers to continually make judgments about what are appropriate actions in a given situation at a given time. Following from this is the assumption that there is not just one way of doing teaching (Loughran 2010). Each participating teacher is expected to hold some commitment to change and bring their expert judgment to bear on how change might be implemented in their practice.

Working from these assumptions the program seeks to empower participating teachers to identify alternative approaches in science teaching and recognize the impact of these approaches on student learning. It seeks to assist teachers to articulate explicitly what they value in their science teaching and encourage them to observe or notice any tensions which exist between what they say they value and what they actually do in their practice (Smith 2010). The program also seeks to support teachers to consider and create new conditions for learning in their own classrooms which realign professional thinking about quality science teaching with practice.

Conditions are established within the program to specifically attend to the learning needs of teacher participants. These conditions include realistic time for learning, interactive workshops, school-based support, and specific program time devoted to case writing. The program is spread across the school year as a 5-day program and takes place in two blocks of two consecutive days and a final day devoted solely to teacher case writing. Teachers are accommodated overnight for each 2-day program, demonstrating an explicit valuing of teachers as professionals and providing extended opportunities, both formal and informal, for teachers and facilitators to work and talk together. Sessions which explore a variety of aspects of science teaching and learning are conducted throughout the program, and teachers are encouraged to discuss and explore ideas in relation to their own teaching context and across the different contexts of primary and secondary schooling. A minimum of two teachers from each school are expected to attend the program, to assist with embedding teacher learning within a school context once the program itself has concluded.

School-Based Aspects of the Program

School-based meetings with program facilitators are conducted regularly throughout the program and are a valued and integral part of the program's design and philosophy. These school-based meetings provide an opportunity for participating teachers to reflect on areas of their science teaching so that they can identify the aspects of their practice which they want to understand more about and enable them to collect data from their classrooms related to their specific science teaching concerns. The discussions which occur in these meetings potentially stimulate rich insights for each teacher into their teaching and their students' learning of science (Berry et al. 2009). These discussions assist teachers to identify the aspects of their practice which they would like to share and to clarify their ideas in preparation for case writing.

Case Writing

The use of cases within the STaL project assists teachers to sharpen the focus of their practice on the learning of students and in turn enables them to see their own teaching through different eyes. The cases, which are published in a book form, help teachers to articulate what were previously implicit beliefs or feelings about practice (Lindsay 2012). The cases then provide a vehicle for sharing teacher knowledge from which other teachers can learn.

Case writing has a significant impact on participants as having their work published affirms them as professionals and affirms the specialist knowledge that they hold as teachers.

Theater

Drama/Theater in Science Education

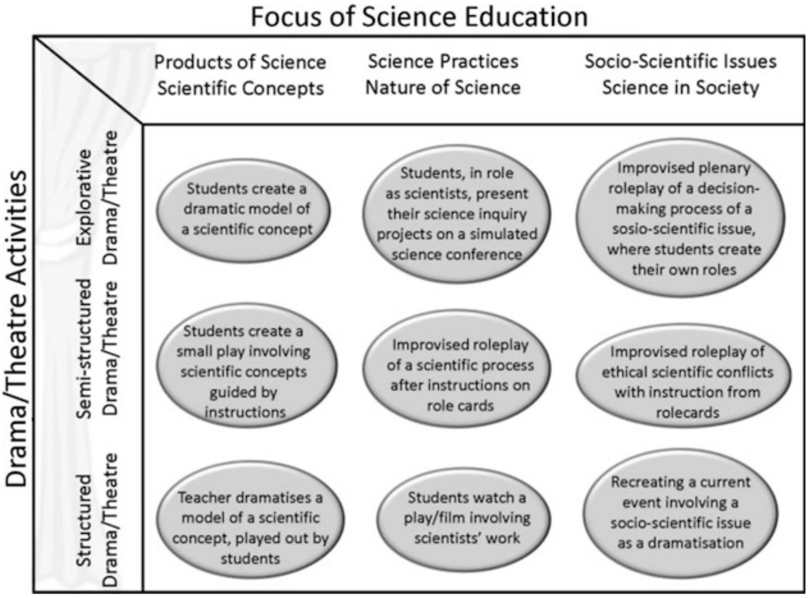
The liberal arts and science have traditionally been seen as two very different subject areas, indeed different cultures, and education seems to maintain this divide. However, they have much in common. Imagination and creativity play a critical role both in learning an art form such as drama and in learning science. Thus, these two disciplines can mutually help and inspire each other.

"Theater" and "theory" have a common etymological root in the ancient Greek verb "theorem," which means to see, to view, or to behold. The theoria in ancient Greece viewed the dramas of everyday situations and extracted truth. This kind of knowing, attempting to draw universal generalizations based on specific observation, is also viewed as a key epistemological feature of scientific explanations. The use of drama in a well-considered manner, guided by reflective science teachers, may provide empowering learning environments for students.

Perspectives of Science Education

There are many different examples of how drama and theater activities can be used in science education (see Fig. 1). Most traditionally, students explore the academic side of science with its products, models and scientific concepts that explain natural phenomenon. Within the known framework of scientific theories, students may, for instance, play electrons in a circuit to illustrate and get a deeper understanding of the scientific concept of electricity. The process of transferring the model or description from the textbook to a three-dimensional live model requires the students to reconceptualize their knowledge. Through the process of social interaction that involves both verbal and physical activities, students increase their understanding. In addition, teachers have an expanded ability to assess students' understanding immediately under the course of the activity and give feedback to deepen the students' understanding.

Another important perspective of science education is scientific processes, which involve understanding science practices and nature of science. Scientific processes are centrally concerned with scientists' experimental and



Science Theater/Drama, Fig. 1 Overview of aspects of theater and drama activities in science education, inspired by Ødegaard (2001, 2003)

conceptual work, both in the laboratory and elsewhere. The students' only experience of this is often through predesigned laboratory exercises, which do not authentically reflect the scientific process. In particular, the important communication process between researchers, in which discussion and debate occurs, is seldom mentioned. Letting students take on the mantle of an expert and role-play scientists doing scientific inquiry reveals many aspects, both practical and social, of scientific practices to the students. Also, once given insight into a set of science stories, students will have the opportunity to understand that nature of science is not the same as predesigned laboratory exercises. Through stories of science and experiences in enacting scientists, students are offered more possibilities to gain insight into the reality of the process of scientific practice. Many students find drama methods lively and stimulating and thus more memorable. They give a sense of the richness and complexity of the events they relate to, beyond that of simple textbook or other written accounts.

In addition, classroom dramas and theater-related activities are beneficial for focusing on the science in society perspective and socio-scientific issues in science education. Just as a well-known method in science is to make a simulation in the laboratory of a phenomenon in nature, so it is possible to simulate societal processes that relate to science, for instance, an international environmental conference, a consensus conference, or other democratic processes. The real world is brought into the classroom in the context of practical action. Divergent interests and ethical conflicts are essential to decision-making processes, as is also shown in all good plays and dramas. In role-play, the conflicts, combined with the personal relations the students develop to the issue, make them able to act. Students explore situations that create empathy and identification; thus, thoughts, knowledge, and feelings are stimulated and give room for action. Science is recontextualized to a situation where it has human scope and force. The cross-curricular potential in drama gives the opportunity for a style of learning that does not break knowledge and skills into artificial units, but permits exploration of the world using whatever medium is appropriate.

Aspects of Theater and Drama Activities

Dramatic activity may vary and take many different forms in the classroom. The drama may be structured in a way where students enact pre-prepared roles within a known framework of, for instance, scientific theories (e.g., playing electrons), or the dramatic activity may be impulsive, creating the moment, as it were; students have to improvise who they are and what to say. At any point along this continuum, a drama can be more or less spontaneous. An intermediate form could be an improvised role-play with a structured frame (e.g., role cards that describe the participating roles).

Another continuous variable is the degree of teacher involvement, that is, whether it is the teacher that impels the drama or the students. A group of students who create their own model of a scientific concept are together reconstructing knowledge so as to enhance their conceptual understanding. In order to guide the students, it may sometimes be necessary for the teacher to provide scaffolds in complicated scientific matters.

Dramas may also be characterized according to whether they are presentational or experiential. Presentational dramas have a major emphasis on communicating something to others outside the drama (e.g., the teacher, peers, or parents). They can be seen as plays with many theatrical features. When a small group of students dramatize a scientific concept (e.g., make a "meiosis ballet"), the intention is often communication to others. Another option is that students watch a play performed by others who, for instance, want to communicate issues involving science or scientists' work. This may give students a common experience to reference when, in this case, trying to understand nature of science. The experiential dramas, however, have focus on attempting to *live through* some aspect of an experience and exploring an opinion or attitude (e.g., a role-play with role cards about ethical issues in biotechnology). However, the division is not clear. When students themselves make a presentational drama of a scientific issue, it can be seen as an inquiry process, where imagination and creativity play a crucial role in making representations of science concepts. Thus, through the presentational drama, students may experience insights that deepen their understanding of scientific issues, giving the drama experiential facets.

Science Tourism

Jan Packer
School of Tourism, University of Queensland,
Brisbane, St Lucia, QLD, Australia

Science tourism is travel outside one's usual environment to learn about or participate in science. It includes specific types of tourism that are motivated by an interest in science, visitation of attractions that present science, travel to sites or events of scientific significance, science volunteer tourism, and school science field trips.

Many different types of tourism are **motivated by an interest in science**. Nature-based tourism, which includes more specific subtypes such as ecotourism, geotourism, and wildlife tourism, relies on immersion in and interaction with nature. Nature-based tourism activities include hiking; bird watching; snorkeling; whale watching; stargazing; visiting geothermal sites, alpine areas, deserts, and rainforests; and a multitude of other activities, all of which provide important opportunities for science learning. Such experiences are often enhanced by the provision of environmental interpretation, which aims to communicate scientific concepts while also creating opportunities for visitors to understand, appreciate, and enjoy the natural environment. Interpretation might be delivered by signs, brochures, displays, park rangers, or tour guides and is specifically focused on the natural features or species that visitors can experience firsthand at the site visited. Nature-based tourism has an added advantage in that it provides a financial incentive for the conservation and sustainable management of natural resources. Other types of special interest tourism with a science focus are also emerging. For example, space tourism offers opportunities for recreational space travel that may involve not only learning science but also participating in research activities while in orbit. Another emerging form of tourism known as “last chance tourism” involves traveling to places that are threatened by environmental factors such as climate change or overpopulation, in order to experience and learn about these places before it is “too late.”

Tourist attractions that specifically present scientific information include zoos, aquaria, botanic gardens, planetariums, national parks, science centers, natural history museums, and space museums. Social history museums and art museums may also host special exhibitions that present science either as their main purpose or incidentally, e.g., the popular *Body Worlds* exhibitions, *Leonardo da Vinci* exhibitions, and *Titanic* exhibitions. Visits to historical sites provide opportunities for learning about archaeology, architecture, or the science of conserving or restoring artifacts. Scientific information is often presented and interpreted at sites of important engineering feats, such as bridges, tunnels, and dams. Even a visit to a theme park can be enhanced by a presentation of the principles of physics that underpin the operation of amusement rides.

Tourists increasingly search for unusual and unique experiences. These may include **travel to sites of scientific significance, travel to witness science phenomena, or travel to attend science events**. Examples of significant sites are the Galapagos Islands, where visitors can follow in the footsteps of Charles Darwin; the Kennedy Space Center, where visitors can take a tour of NASA’s launch sites and even view a launch; and the European Organization for Nuclear Research (CERN), where visitors can learn about the fundamental research done at the world’s largest particle physics laboratory. Tourists also seek out the former homes of, burial sites of, or memorials dedicated to famous scientists, such as Isaac Newton, Marie Curie, Nikola Tesla, Albert Einstein, and Alan Turing. Science tourists may visit astronomical events such as eclipses, transits, or aurora that can only be viewed from particular locations; biological events such as coral spawning; or unique geological or geothermal phenomena such as unusual rock formations, glaciers, volcanoes, or geysers. Science events such as science festivals, conferences, and climate summits attract both scientists and hobbyists from around the world.

Science tourists can **volunteer to join a research expedition**, such as those organized by the Earthwatch Institute, where they can work on projects in wildlife conservation, rainforest ecology, marine science, and archaeology. This provides both a source of funding and practical assistance to scientists in collecting field data.

Finally, when school groups take **field trips** for the purpose of learning science, they also are participating in science tourism. Engaging in hands-on learning in real-life contexts enhances student motivation and increases the likelihood that science learning will be transferred to situations that students encounter outside of the school environment.

Increasingly, tourists seek travel experiences that engage them intellectually and develop their breadth and depth of general knowledge and understanding of the world. Travel offers many such opportunities for experiential learning in unique and unusual contexts which are likely to be both memorable and deeply rewarding for participants. Science tourism is thus an effective and increasingly important contributor to the lifelong learning of science in out-of-school contexts.

Context

Introduction

Over the years, a range of factors including increased attention towards science and social responsibility, the prevalence of socio-scientific issues such as genetic engineering and nuclear power, a desire to humanize science, decreasing enrolment in physical sciences, and a surge of interest in the environment, have provided a fertile ground from which Science Technology Society and Environment (STSE) education has emerged. Originally, this movement began as Science Technology and Society (STS) education and then later evolved to include the environment (STSE). In this entry, we use STSE throughout, understanding that its roots are STS.

At a macro level, STSE education examines the interface between science and the social world. It is an umbrella term that supports a vast array of different types of theorizing about the connections between science, technology, society, and environment, and places science squarely within social, technological, cultural, ethical, and political contexts. At a micro level, STSE education includes decision-making, the coupling of science and values, integration (with other subject areas), nature of science (NOS) perspectives, and action. For many, STSE represents a shift from the status quo, a post-positivist vision for science education that emphasizes a *science for all* philosophy. What is clear is that there is no single, widely accepted view of STSE education. STSE in theory and practice emerges from different places for different people, influenced by particular contexts and circumstances and used for different purposes.

One of the earliest mentions of STSE appears in an article written by Jim Gallagher (1971) in *Science Education*. He argued strongly for a broader model of science teaching that included understanding the conceptual and process dimensions of science, as well their relationships to technology and society. Joan Solomon's and Glen Aikenhead's work (see, e.g., Solomon and Aikenhead 1994) did much to bring STSE to the fore. A range of significant texts during the 1980s and 1990s marked an ongoing commitment to STSE education and a collective desire for fundamental change in school science. Today, this desire for change in school science continues. For many jurisdictions STSE has become an important part of school science curriculum and the student experience.

Structure of the Field (STSE Theoretical Frameworks)

From what has gone before, it is clear that STSE is a complex construct. Other than a few broad principles, it is difficult to define what exactly constitutes STSE education. Indeed widely differing discourses have led to an array of distinct approaches, programs, and methods. To a great extent this is simultaneously the strength and weakness of the STSE movement. Despite this fluidity, over the years several have tried to develop classifications or typologies to pinpoint a structure for STSE and guide its further development, particularly its implementation in classrooms. However, it is important to note that these various schemas are not easily comparable. In particular no one is more comprehensive or more correct than the others. Rather the various efforts provide insight into different dimensions of the topic.

Ziman (1994), one of the earliest advocates of STSE, provides a general conceptual framework, useful for locating STSE and supportive of a multiplicity of approaches for its implementation. According to Ziman (1994), STSE contains philosophical, sociological, and historical dimensions, which in themselves can serve as approaches for implementation. Additionally, he proposes that STSE contains other ideological dimensions suggestive of other approaches, for example, utilitarian (vocational, relevance), transdisciplinary, and problem-based approaches. While Ziman's work is mostly philosophical and theoretical in nature, Aikenhead (1994), on the other hand, has written extensively about the spectrum of meanings and degrees of STSE inclusion found in existing science courses and programs. He captures the relative importance afforded to STSE by analyzing content structures and methods of student evaluation within a wide variety of science courses. Aikenhead's classification consists of eight categories that represent a spectrum. At one end (category one), STSE content is given the lowest priority compared to traditional science content, while at the other end (category eight), it is given highest priority. The eight categories are as follows: (1) motivation by STSE content, (2) casual infusion of STSE content, (3) purposeful infusion of STSE content, (4) singular discipline through STSE content, (5) science through STSE content, (6) science along with STSE content, (7) infusion of science into STSE content, and (8) STSE content. It is important to note that this scheme does not attempt to link STSE to any particular set of educational goals or priorities nor does it address specific teaching methods. In other words, Aikenhead's work describes *how* STSE might be integrated into the science curricula, but not the *why* and *what* of STSE education.

Pedretti and Nazir (2011) provide a classification that tackles these latter aspects. They provide a typology of possibilities for STSE education or what they call "currents" through consideration of the overall aims of science education, perspectives from the psychology of education, and examples of strategies or pedagogy for science programs. Within their typology, they identify and explore six currents in STSE education: (1) application/design, (2) historical, (3) logical reasoning, (4) value centered, (5) sociocultural, and (6) socio-ecojustice. They characterize the sociocultural current, for example, as promoting an understanding of science and technology within a broader sociocultural context, while engaging in an analyses of the complex social structures within which science operates. They link this current to the overall aim of teaching science as an important cultural and intellectual achievement and identify its dominant approaches as holistic, reflexive, experiential, and affective. Examples of pedagogical strategies include the use of case studies, storytelling, and integrated curricula. While Pedretti and Nazir are careful to caution that their classification is not exhaustive and that no current is "better" than the other, they suggest that their typology can be used by educators for critical analysis of the various discourses and practices within STSE, as it exists today.

Challenges to STSE Education

STSE programs and themes have been developed worldwide, at the elementary, secondary, and tertiary levels. In general, programs have been designed in an effort to interpret science and technology as complex socially embedded enterprises and to promote the development of a critical, scientifically and technologically literate, citizenry capable of understanding STSE issues, empowered to make informed and responsible decisions, and able to act upon those decisions. In Canada, for example, several provinces have continued to emphasize STSE as an important part of school science and retain it as an integral and primary focus of K-12 science curricula.

Although (STSE) education has gained considerable force in the past few years, it has made fewer strides in practice. An emphasis on STSE education presents challenges for educators – both practical and ideological in nature. Many have written about the practical challenges inherent to adopting an STSE approach. Practical challenges and barriers include the following: lack of time and resources, assessment issues, lack of professional development opportunities in STSE, and issues related to teacher confidence. Many fear that extensive coverage of socio-scientific subject matter devalues the curriculum and may alienate some science students. Furthermore, STSE instructional strategies often include, for example, town halls, debates, and role-plays. These activities (with their focus on decision-making, ethics, action, transformation, and empowerment) are not traditionally part of science teachers' repertoires.

Fewer, however, have written about the ideological bents and assumptions that underpin different formulations of science education in general and STSE education in particular. For example, a view that science education should be focused on teaching science content (a predominantly transmissive view) rather than focused on social reconstruction and change (a transformative view) can produce radically different experiences and challenges in the science classroom. For example, coupling science and values education can be problematic for some. How do educators reconcile teaching about science and values? How does a teacher position himself/herself? How do teachers address personal values in the classroom and accommodate diverse views, cultural contexts, and ways of thinking about the world? Action and the politicization of science present another set of problems. The notion of a sociopolitical science curriculum that promotes social justice and transformation provides a very different vision of science teaching and science education, and for some, this can be disconcerting. Such competing ideologies represent a major shift in the way that science education and therefore science teaching are conceptualized and may challenge science teachers' professional identities. These practical and ideological challenges provide rich avenues for future research in STSE education that is rooted in classroom praxis, pedagogy, teacher professional development, and student learning.

STSE and Other Related Movements

STSE has evolved to include other movements and manifestations. In Pedretti and Nazir's (2011) mapping of the field, they use the metaphor of currents to describe the evolution of STSE over time. According to them, STSE education is comparable to a vast ocean of ideas, principles, and practices that overlap and intermingle one into the other. At any one time the field has been characterized by certain ideas coming together to form discernible currents. These currents are constantly changing and shifting according to the context in which they occur. It can be argued that new and emerging currents remain within the STSE fold because they share a similar post-positivist view of science and science education discussed earlier on.

Two currents or movements that have evolved over time and which are particularly strong today are socio-scientific issues (SSI), based on the work of Dana Zeidler and his colleagues, and environmental education (EE). It can be argued that SSI and EE share similar principles, visions, and pedagogies as STSE education (although proponents of these movements may argue differently). The SSI movement pays particular attention to the ethical aspects contained within socio-scientific issues. It focuses on the moral and character development of students. Zeidler's work takes a justice-based, cognitive moral developmental approach to science education. He proposes the use of carefully selected problems from the domain of science to stimulate moral deliberation and consequently moral development in science classes. The SSI model is fortuitously supported today by a resurgence of interest in values education worldwide. Environmental education is another strong current within STSE today. EE, in general, has been gaining momentum worldwide, as the idea of humankind's negative impact on the environment and the consequences for the continued existence of all life on the planet becomes increasingly accepted. STSE has always shared many of the philosophical and educational ideas underpinning the ecojustice movement. In particular, EE derived from an STSE base tends to emphasize the economic and sociopolitical aspects of environmental problems and the need to provide people with the tools (skills, knowledge, and dispositions) to actively transform society. Citizenship that promotes civic responsibility (to humans and non-humans), agency, and emancipation are key features of this current.

In conclusion, STSE education situates science in a rich and complex tapestry – drawing from politics, history, ethics, and philosophy. Although a challenge politically, ideologically, and practically, STSE presents an opportunity to learn, view, and analyze science in a broader context while recognizing the diversity of needs of students and classrooms. STSE, in its many forms and currents, brings relevancy, interest, and real-world connections to the science classroom.

Science, Technology, and Engineering Interrelationships: Assessment of the Understanding of

Edys Quellmalz
WestEd, Redwood City, CA, USA

Keywords

Assessment; Engineering; Interrelationships; Science; Technology

In most reports setting forth frameworks or standards for science, technology, and engineering, the three domains are described as related by their focus on systems in the real world yet different in the roles that the disciplines play in understanding and modifying the world. The definitions for this entry are based on documents produced by national sets of experts in which the relationships of science, technology, and engineering are described. Definitions of science, engineering, and technology can be culled from these frameworks and standards developed by engineering and science organizations, as well as from standards for engineering and technology for state, national, and international assessments.

These definitions of science, technology, and engineering are the starting points for developing assessments of understanding of the ways in which they are related. This entry begins with a summary of prominent conceptualizations of science, technology, and engineering. The definitions are followed by descriptions of an assessment framework that can be used to select or develop and assessments of understanding the similarities and differences of science, technology, and engineering. Descriptions of some potential types of assessment tasks and items to test understanding of the interrelationships of science, technology, and engineering are provided.

Definitions of Science, Engineering, and Technology

Science refers to understanding and studying phenomena in the natural world, while engineering and technology are applications of science to create the human-made world. Engineering is defined as a systematic and iterative approach to designing objects, processes, and systems to meet human needs and wants. Technology is defined as any modification of the natural or designed world developed to fulfill human needs or desires. Technologies, therefore, are products and processes resulting from application of engineering design processes. Technologies also often function as tools and processes used to support engineering design.

Sources of Conceptualizations of Science, Technology, and Engineering

Framework for K-12 Science Education and the Draft Next Generation Science Standards

The framework provides a broad description of the content and sequence of learning in science and engineering expected of all students by the end of high school. Science disciplinary core ideas, crosscutting concepts important in all disciplines, and practices describing the ways scientists and engineers work are presented. Engineering and technology are included as applications of science. Core ideas are specified for physical, life, and earth and space sciences and for engineering and technology. These key disciplinary areas are integrated with foundational crosscutting concepts such as cause and effect, systems and models, and patterns. The science and engineering practices include skills for asking questions and defining problems, developing and using models, planning and carrying out scientific investigations, analyzing and interpreting data, and using mathematics and computational thinking.

Engineering is used to mean engagement in a systematic design practice to achieve solutions to particular human problems. Technology is used to include all types of human-made systems and processes. Two core engineering ideas are specified. The first is engineering design – how engineers solve problems. The second core idea is understanding of the links among engineering, technology, science, and society. Engineering design is subdivided into three components: (1) defining and delimiting a problem, (2) developing possible solutions, and (3) optimizing the design solution. Links among engineering, technology, science, and society are partitioned into (1) interdependence of science, engineering, and technology and (2) the influence of engineering, technology, and science on society and the natural world. The framework describes grade band end points for each of the three components.

The draft Next Generation Science Standards provides more specific guidance for assessing scientific ideas and engineering design that produces and uses technology. For example, performance expectations have been developed that integrate the engineering core ideas with crosscutting concepts, such as systems and models and cause and effect, and also with science and engineer practices.

Technology and Engineering Literacy (TEL) Framework for the 2014 National Assessment of Educational Progress

TEL framework is unique in its focus on assessing the interrelationships of engineering and technology. In the framework, technology and engineering literacy is defined as the capacity to understand technology and engineering design principles and to use and evaluate engineering design processes (NAGB 2010). Technology and engineering literacy is divided into three assessment areas, design and systems, information and communication technology, and technology and society. Within design and systems, three subareas of essential knowledge and skills were identified: nature of technology, engineering design, system thinking, and maintenance and troubleshooting.

Principles for the nature of technology expand the scope of common conceptualizations of technology beyond computers and the Internet. The broader view includes every way people manipulate the natural environment to satisfy needs and wants. Therefore, technology includes all the various devices and systems that people make to fulfill some function. The framework lays out key principles for the nature of technology: (1) technology is constrained by the laws of nature; (2) scientists examine what exists in nature, and engineers modify natural materials to meet human needs and wants; (3) technological development involves creative thinking; (4) technologies developed for one purpose may be adapted for other purposes; (5) science, technology, engineering, and mathematics and other disciplines are naturally supportive; (6) the pace of technological change has been increasing; and (7) tools help people to do things efficiently, accurately, and safely. The framework then lays out assessment targets for grades 4, 8, and 12.

The engineering design subarea in the TEL framework is described as an iterative, systematic process for solving problems. The process begins with stating a need or want and the criteria and constraints of the challenge. Then potential solutions are explored referencing relevant scientific and technical information. Potential solutions are compared, and models and prototypes are constructed, tested, and evaluated to see how they meet the criteria and constraints of the problem. The results of the engineering design process will be technology in the form of either a product or a process. The framework specifies key principles of engineering design and proposes assessment targets for grades 4, 8, and 12. Two additional components of design and systems are systems thinking and maintenance and troubleshooting. For each component, principles are identified and assessment targets for grades 4, 8, and 12 are presented.

The framework also specifies components, principles, and assessment targets for grades 4, 8, and 12 for the prominent technology area of information and communication technology (ICT). ICT is presented as a separate assessment area within technology and engineering literacy because of the central place ICT plays in learning and functioning in school, the workplace, and daily living. ICT subareas to assess include understanding and use of technologies for (1) construction and exchange of ideas and solutions, (2) information research, (3) investigation of problems, (4) acknowledgment of ideas and information, and (5) selection and use of digital tools.

Each of the frameworks and standards described above can serve as resources for specifying the interrelationships of science, technology, and engineering to be assessed.

Evidence-Centered Assessment Design

The focus of this entry is on methods for assessing understanding of the interrelationships among science, technology, and engineering. The selection or development of assessments will depend on the purposes of the assessments and the interpretations of the data. An assessment may be intended to provide diagnostic feedback and be used in a formative way to allow adjustments during instruction to improve performance. An assessment may be intended to serve a summative purpose to report on the status of proficiency at a point in time. These purposes will have implications for the criteria used to select, design, or interpret assessments.

A useful framework for understanding the structure of assessments is evidence-centered assessment design (Mislevy et al. 2004). Evidence-centered design is intended to structure an assessment argument. The argument begins with the claim that specified knowledge or skills have been learned. Evidence to support the claim comes from the types of questions or tasks that will elicit observations and performances of the targeted knowledge or skill. Summaries of performances, typically in the form of scores to be reported and interpreted, then complete the argument. Evidence-centered assessment design tightly links the targeted knowledge and skills (student model), with assessment tasks and items to elicit evidence of these targets (task models), with specifications of how the evidence will be scored and analyzed to report proficiencies (evidence model). The evidence-centered design framework can be used to analyze and evaluate existing assessments or to guide the systematic development of new ones.

The essential first step in assessing student understanding of the interrelationships of science, technology, and engineering will be to settle on the definitions of science, technology, and engineering and to specify the similarities, differences, and roles to be tested. The features and functions would become the first component of the student model. A second component of the student model would be the cognitive demands or levels of reasoning required. Cognitive demands could range from identifying definitions and lists of similar and different features to analyzing the roles of science, technology, and engineering in scenarios; to actually applying ideas and practices in relevant problems involving the use of science, engineering, and technology; and to evaluating others' applications of science, technology, and engineering in a range of scenarios.

The engineering design process creates plans for developing solutions. Solutions may be tangible artifacts or technologies, such as digital devices or farm machinery. Solutions may rely on scientific knowledge and new or improved technological processes such as more efficient manufacturing procedures or pharmaceutical clinical trials. These solutions are technologies that have been developed to address needs in areas of the designed world such as medicine, agriculture, energy, transportation, manufacturing, and construction. Students tend to think of technology in terms of computers and digital technologies, not in terms of the artifacts and solutions engineered in the many other areas of the designed world. Students are expected to understand that there are technologies in all these areas, from pills, plows, plugs, planes, and pinions to pickup trucks. Specifications of the knowledge to be tested will need to decide what students need to understand about the distinctions and overlaps among science, technology, and engineering. It is likely that such discriminations would be part of a more comprehensive assessment of scientific, engineering, and technology problems and contexts in which they occur. Therefore, statements of what the student needs to know and the level of reasoning for showing it will become the assessment targets of the student model.

In evidence-centered assessment design, the task model specifies the kinds of contexts, problems, and items that would elicit evidence that the students understood the relationships of science, technology, and engineering. Simple items could list features of scientific ideas and practices, engineering design processes, and technologies and have students select examples of their appropriate use to given problems. Descriptions of needs addressed by an engineering project that is producing solutions could include questions to determine that students understood about the role of scientific knowledge contributing to the solutions and whether new tools or new processes are technologies. Tasks and items could be designed around scenarios presenting scientific questions and engineering design problems in a range of applied contexts. An overarching problem could be to select scientific knowledge, technologies, and engineering processes to use in attempting to solve the problem or to critique descriptions of their appropriate use in scenarios.

The SimScientists program has developed simulations to assess understanding and use of science and engineering practices for a number of science systems (Quellmalz et al. 2012b; http://simscientists.org). As shown in Fig. 1, a scenario was developed in which students are working to establish a sustainable research center in Antarctica. By harnessing available sunlight and wind, scientists at the station are able to generate electricity, which can be used for the electrolysis of water, which in turn results in the production of hydrogen gas. The simulation-based assessments have been designed to assess core ideas about atoms and molecules, changes in state, properties of matter, and the science practices of designing and conducting investigations. The scenario could be augmented with sets of tasks about the design, testing, and troubleshooting for an energy production, conversion, and

The research center uses wind and sunshine to generate electricity. You can use the electricity to create hydrogen without producing any pollution!

Now that you have a way to generate hydrogen gas, your next task is to find out how to use hydrogen for cooking.

You need to know what conditions caused a reaction in the flask. You will need to answer the following questions about hydrogen gas.

Does hydrogen react with oxygen if there is a spark?
Does hydrogen react with oxygen whenever they are mixed?
Does hydrogen react with nitrogen if there is a spark?
Does hydrogen react with nitrogen whenever they are mixed?

Review your trials and decide if you have enough information to answer the questions to the left.

- If you want to review one of your trials, click the VIEW button for that trial.
- You can then click RESET to start that trial again.
- If you need to run another trial, click NEW TRIAL.
- When you are satisfied with your trials, click NEXT.

Science, Technology, and Engineering Interrelationships: Assessment of the Understanding of, Fig. 1 SimScientists simulation-based assessment

storage system that contributes to a sustainable research center.

As foundational computer models of such systems, natural and man-made, are developed, they can support the development of tasks to assess science, technology, and engineering concepts and practices and also to assess twenty-first-century skills such as communication and collaboration (Quellmalz et al. 2012a). For example, students could be asked to construct descriptions for the Antarctic Research Center Board for a proposed sustainable energy plan or to critique if solutions proposed by others meet the design constraints. A virtual collaborator could be queried to seek relevant information about the trade-offs of alternative sustainable energy treatments.

The assessment evidence model would involve determining what kind of scoring and reporting would convey that the student understands the similarities and differences and roles of the three areas. Specific reports about progress and proficiency on the assessment targets would be needed.

The assessment selection or development can use the framework of evidence-centered assessment design to guide analyses of existing tasks and items or to guide the development of appropriate tasks and items. The framework would ask if the knowledge to be tested is clearly specified (student model) and if the tasks and items will provide evidence if the knowledge and practices have been applied in a range of areas such agriculture, medicine, and manufacturing. The framework would also ask if the scoring and reporting clearly allowed decisions to be made about whether the understanding of the interrelationships of science, technology, and engineering is sufficiently strong. The decisions could then be used diagnostically to inform further instruction or to inform a proficiency report. The key to sound assessment is that the assessment argument is clear and supported.

Engineering; Technology

Historical Foundations

Historically, science had a place in education before the time of Plato and Aristotle (e.g., Stonehenge). Technology gradually increased since early human inventions (e.g., indigenous tools and weapons), rose up dramatically through the industrial revolution and escalated exponentially during the twentieth and twenty-first centuries, particularly with the advent of the Internet. Engineering accomplishments were evident in the constructs of early civil works, including roads and structural feats such as the Egyptian pyramids. Mathematics was not as clearly defined BC (Seeds 2010), but was utilized for more than two millennia (e.g., Archimedes, Kepler, and Newton) and paved its way into education as an essential scientific tool and a way of discovering new possibilities. Hence, combining science, technology, engineering, and mathematics (STEM) areas should not come as a surprise but rather as a unique way of packaging what has been around for centuries. For education, the acronym STEM has emerged to initiate innovations in curriculum design and practices mainly towards facilitating career choices in these much needed fields.

What Is STEM?

STEM education is an opportunity to develop competencies in high-demand fields. Engineering education has not been included traditionally in school education; however, its inclusion presents hands-on problem-based activities for fusing science, technology, and mathematics to engage students in engineering innovations. The scientific and mathematical undertakings towards devising technology with the assistance of Internet information and communication have facilitated engineering advancements across a range of fields (e.g., chemical, structural, mechanical, civil, software). The abundance of engineering positions and scope for increased developments has lead towards engineering education beginning earlier within school systems (e.g., primary and middle schools).

Various countries are positioned to promote STEM education. In 2008, the US government commissioned reports on how to transform STEM into implementable educational programs and, early in 2010, President Obama committed $3.7 billion for STEM education in his 2011 budget (National Institutes of Health 2010). Malaysia, as another example, up to 2012 had outlaid significant funds for up-skilling STEM teachers across their country, particularly with the uptake of degrees from outside providers, and the UK is establishing national STEM education networks (e.g., see http://www.dcsf.gov.uk/stem/). There are STEM education initiatives in Australia, for instance, the Department of Education, Science, and Training (DEST) supported financially 355 projects conducted between 2005 and 2007, out of which 83 projects combined the STEM areas (see http://www.asistm.edu.au/asistm/). Although these initiatives were largely isolated occurrences involving pockets of partnerships that did not appear to have significant impact on schools outside the original arrangements, they commenced a process towards forming a national STEM agenda.

STEM Education

In a resource-driven world, university enrolments in STEM areas have not met career demands, which is a rationale for profiling STEM education. Importantly to the STEM agenda is the focus on females, as they are largely underrepresented in STEM at the university level. For example, in 2012 there were only 11–15 % undergraduate enrolments in engineering across Australian universities with the 2009 Melbourne Declaration advocating a STEM education agenda by building the capacity of STEM teachers. Part of the reason for low female involvement in STEM fields lies in stereotyping female competencies; hence, there are calls for establishing a gender equity curriculum for STEM education to overturn stereotypical views, especially during the early years of education and into the STEM workforce. Furthermore, the underrepresentation of females in STEM areas has driven researchers to explore ways to uncover how to engage and motivate females into these fields. Websites have been launched to address the gender gap in STEM areas such as engineering (http://www.engineergirl.org/), which in particular aims at educating middle-school females. For both genders, educational advancements must include hands-on activities that aim to increase students' confidence and interests in STEM.

Ongoing STEM development

Further developments in STEM education are needed to initiate, promote, and sustain its theoretical structure in education, some of which can include establishing STEM education forums. For instance, the first international STEM in Education conference in 2010 (http://stem.ed.qut.edu.au/) provided a platform for educators to share knowledge in and across their respective disciplines. The conference moves around internationally (e.g., Beijing Normal University, 2012 and University of British Columbia, 2014) to engage educational communities in the STEM education fields. Indeed, other STEM conferences (e.g., www.genderandSTEM.com and the UK STEM Annual Conference) are sprouting up around the world to facilitate conversations on relevant STEM topics. STEM education holds promise for educating current youth into high-demand STEM careers emanating from a worldwide growth in developing and manipulating resources.

Scientific Language

Agustín Adúriz-Bravo, Andrea Revel Chion and Alejandro P. Pujalte
CeFIEC-Institute of Didactics of Science, Universidad de Buenos Aires, Buenos Aires, Argentina

Keywords

Argumentation; Interpretive system; Language; Meaning-making; Metaphor; Science

There is nowadays extended consensus around the recognition that scientific knowledge is "dependent inextricably on language and language is also central to our ability to think [scientifically]" (Evagorou and Osborne 2010, p. 136). Language thus becomes a key element in science education: it is a tool that allows us to understand the natural world, to express our ideas on it, and to develop scientific knowledge. This paramount role of language in supporting science learning processes was acknowledged at least five decades ago, notably through the seminal work of Jerome Bruner; such acknowledgment can be attributed – at least partially – to the dissemination of Lev Vygotsky's ideas in English. However, it was not until the 1980s, and following developments in the philosophy of science and in educational studies, that science education research began to pay attention to the linguistic aspects inherent to science teaching. As a consequence of this new focus, in the last two decades, a thriving research line has emerged, with several theoretical perspectives that focus on different aspects of the issue of scientific language in the classroom (e.g., Sutton 1996; Lemke 1990; Sanmartí et al. 1999).

Sutton (1996), in his now classic paper *Beliefs about science and beliefs about language*, portrays two distinct epistemic functions of language in science: language can serve *as a labeling system*, to tag and transmit established pieces of knowledge, or *as an interpretive system*, actively used to generate and consolidate new understandings. In that text, Sutton is advocating for shifting from the positivistic emphasis on language as a means of conveying conceptual information toward the constructivist idea of understanding language as a way of meaning-making.

Adhering to such characterization of scientific language for the science classes would import the need to introduce students simultaneously in the patterns of reasoning and the patterns of language that are developed in the context of doing science. Along this line, Evagorou and Osborne (2010, p. 138) claim:

> [B]ecause reading and writing are activities that are constitutive of science, and because the language of science is complex and foreign to many students, we see teaching science as fundamentally a process of teaching a language – one in which the teacher has both to help students to interpret and construct meaning from scientific text and one in which they must provide opportunities to develop their fluency and capabilities with that language. In the classroom, three main forms of language are used as tools for understanding, communicating, and developing knowledge: talk, writing and reading.

In the same spirit of the previous paragraph, Lemke (2001) argues that we could understand science education as a "second socialization": an enculturation into a subcommunity – science – that has its own representations, methods, ethos, and jargons. This theoretical approach should motivate us to examine how people learn to talk and write the language of science while engaging in specific scientific activities, such as observing, experimenting, debating, or publishing. In his well-known book *Talking Science*, Lemke (1990) equates science learning, at least partially, to learning to "talk science." This implies moving away from science lessons dominated by a "triadic dialogue" centered on teachers' talk – as in the classical IRF (initiation-response-feedback) sequences. Here, Lemke introduces a very suggestive idea: talking science could be considered a very elaborate social process, modeled on the metaphor that science is a foreign language that students have to learn.

In his own words:

> Learning science means learning to *talk* science. It also means learning to use this specialized conceptual language in reading and writing, in reasoning and problem solving, in guiding practical action in the laboratory and in daily life. It means learning to communicate in the language of science and act as a member of the community of people who do so. "Talking science" means observing, describing, comparing, classifying, analyzing, discussing, hypothesizing, theorizing, questioning, challenging, arguing, designing experiments, following procedures, judging, evaluating, deciding, concluding, generalizing, reporting, writing, lecturing, teaching in and through the language of science. (Lemke 1990, p. 1)

Lemke concludes that we learn to speak the language of science in much the same way in which we learn any other language: practicing it with people who master it and using it in a variety of pragmatic communicational situations, where it should be employed in its most frequent typologies, genres, and text formats.

In accordance with this theoretical perspective, students must not only understand the main concepts implicated in the theories and models and grasp the scientific vocabulary, they also have to be able to apply the necessary language structures and patterns and use the correct discursive tools and rhetorical strategies. Consequently, they must be able to distinguish and make use of the different genres of science, such as descriptions, definitions, explanations, and argumentations. Specifically related with the use of the scientific vocabulary, there is a crucial point about the meanings of words: science teachers should make bridges between the everyday meanings of terms and their meaning in specific scientific contexts. This requires acknowledging that scientists use language in very special, highly stylized ways:

> Not only is there a specialist scientific vocabulary consisting of words which are recognizably unfamiliar but there are familiar words such as 'energy', 'power' and 'force' which must acquire new meanings. Moreover, the charts, symbols, diagrams and mathematics that science deploys to convey ideas, are essential to communicating meaning and students must learn to both recognize and understand their use. The challenge for the teacher then is to introduce and explain this new vocabulary; the challenge for the student is to construct new meanings from such a language. (Evagorou and Osborne 2010, p. 136)

There are a lot of unobservable entities that science teachers have to teach in the classroom, for example, cells or electric current. The teaching of such entities depends on the use of robust representations: a cell is represented as a brick, electric current is referred to in terms of water flow, and particles are depicted as balls. All of these are metaphors, i.e., *transferences* of meaning. According to the philosopher of science Rom Harré, through this metaphorical mechanism, new vocabulary can be created within the existing structure of any given language; this process secures the intelligibility of the term in the new context of use.

Analogies and metaphors are utilized to construct and scaffold students' understandings. They are also essential components of theories and allow the generation of mental models. Such models serve the purpose of providing plausible descriptions, explanations, and predictions about real systems in nature. Based on models, students can build a special kind of evidence-based explanation to give sense to the world around them; this kind of explanation is *argumentation*:

> Work in the specialized argumentative practices of the various disciplines suggests that students not only need to write in order to master the concepts and work of a field, but more particularly to develop competencies in the specific argumentative practices of their fields [. . .]. In addition to the genre-specific writing competencies, with associated argumentative patterns, students must begin to gain a feel for the argumentative forums and dynamics of their fields. They must learn the kinds of claims people make [and] what kind of evidence is needed to warrant arguments [. . .]. (Kelly and Bazerman 2003, pp. 29–30)

Kelly and Bazerman emphasize the importance of writing and talking in the language of the disciplines within the frame of ideas known as "writing across the curriculum" (WAC). They propose to engage students in instances in which they must produce arguments in the different disciplines and beyond them. From these arguments, students learn to talk and write the language of the different scholarly fields. In their framework, these authors indicate that argumentative discourse – that trying to persuade – would be one of the communicational functions that have played a significant role in the development of scientific knowledge, hence its importance in the learning of science.

Jiménez-Aleixandre and Erduran (2008, p. 4) also highlight the importance of scientific argumentation. This competence is

> instrumental in the generation of knowledge about the natural world [and] plays a central role in the building of explanations, models and theories [. . .] as scientists use arguments to relate the evidence they select to the claims they reach through use of warrants and backings. [. . .] [A]rgumentation is a critically important discourse process in science, and that it should be promoted in the science classroom.

They also propose that there are at least five intertwined dimensions or potential contributions from the introduction of argumentation in the science classrooms (cf. Jiménez-Aleixandre and Erduran 2008, p. 5):

– Supporting the access to the cognitive and metacognitive processes characterizing expert performance and enabling modeling for

students. This dimension draws from the perspective of “situated cognition” and the consideration of science classes as communities of learners.
- Supporting the development of communicative competences and particularly critical thinking. This dimension draws from the theory of communicative action and the sociocultural perspective.
- Supporting the achievement of scientific literacy and the empowerment of students to talk and write the language of science. This dimension draws from language studies and social semiotics.
- Supporting the enculturation into the epistemic practices of the scientific culture and the development of epistemic criteria for knowledge evaluation. This dimension draws from science studies, particularly from the epistemology of science.
- Supporting the development of reasoning, particularly the choice of theories or positions based on rational criteria. This dimension draws from philosophy of science, as well as from developmental psychology.

At the same time, the Group LIEC (at the Universitat Autònoma de Barcelona in Spain) defines argumentation as a social, intellectual, and verbal activity used to support or rebut a claim; when arguing, in addition to the content of the claim, its purpose and recipients are important. In order to argue, one needs to choose between different options or explanations and to provide reasoned criteria to assess the most appropriate choices (Sanmartí 2003). In order to learn argumentative competences, Sanmartí proposes that it is necessary to promote explicit instances to teach school scientific argumentation. This means teaching what are the main traits and characteristics of this genre and practicing this skill in relation with school science content.

The research on scientific language in the classroom reviewed here has as unifying thread the hypothesis that through talking and writing science, students can access to new epistemic levels. In their school science “texts,” students give meaning to the symbols, definitions, relations, and communicative patterns that support their use of scientific models. In turn, these texts produced in the science classes are a powerful tool for the (self-)assessment of learning.

Scientific Literacy

Rodger Bybee
Biological Sciences Curriculum Study, Colorado Springs, USA

Originating in the 1950s, the term “scientific literacy” has been used to express diverse goals ranging from a broad knowledge of science to a particular purpose of science education (Bybee 1997). In 1958, Paul DeHart Hurd provided a clear perspective when he described scientific literacy as an understanding of science and its applications to an individual's experience as a citizen. Hurd made clear connections to the science curriculum and the selection of instructional materials that provide students with the opportunities to use the methods of science; apply science to social, economic, political, and personal issues; and develop an appreciation of science as a human endeavor and intellectual achievement (Hurd 1958). Although there have been variations, Hurd's definition expresses the application of scientific knowledge to the situations individuals will encounter as citizens. This view differentiates scientific literacy from other goals of science education.

The general use of scientific literacy has the advantage of unifying the science education community by centering on what is perceived to be the primary goal. The disadvantage of using the term is the loss of its specific meaning which was an understanding of science and its applications to personal, national, and global perspectives.

In the year 2000, George DeBoer published a historical review of the term scientific literacy. There have been numerous different goals of science education, all related to scientific literacy. DeBoer suggested a broad conceptualization of scientific literacy, one allowing for variations in curriculum and instruction. The broad goal suggested by DeBoer is consistent with earlier definitions, namely, to enhance the public's understanding and appreciation of science. Here are critical insights about scientific literacy – it is about an adult population's level of understanding and appreciation of science, it changes with time, and school experiences certainly affect the public's attitudes toward science and their disposition to continue developing their understanding and appreciation of science (DeBoer 2000).

Across the decades, there has emerged a critical distinction, between an emphasis on education for future citizens and education for future scientists. In 2007, Douglas Roberts published a significant essay in *Handbook of Research on Science Education* (Abell and Lederman 2007). Roberts identifies a continuing political and intellectual tension with a long history in education. The two conflicting perspectives can be stated in a question – should curriculum emphasize subject matter itself, or should it emphasize the application of knowledge and abilities in life situations? Curriculum designed to answer the former, Roberts refers to as Vision I, and the latter he refers to as Vision II. Vision I looks within science disciplines: it is internal and foundational. Vision II uses external contexts that students are likely to encounter as citizens (Roberts 2007).

A significant contemporary issue for those developing standards, designing curriculum, and providing professional development is recognizing the difference between the two perspectives just described. One perspective centers on disciplines such as biology, chemistry, physics, or the Earth sciences. In this perspective, programs and teaching practices answer questions such as the following: What knowledge of science and its methods should students learn? What facts and concepts from science should be the basis for school programs? In contrast, there is a *contextualist* (Fensham 2009) perspective that will begin with situations that require an understanding and application of science. When thinking about standards, curriculum, and instruction from a contextualist view, questions center on the following: What science should students know, value, and be able to do as future citizens? What contexts could be the basis for science education? The difference between these two perspectives is significant because it has implications for curriculum emphasis, selection of instructional strategies, design of assessments, and professional education of teachers. The subsequent outcomes – what students learn about science, the attitudes they develop, the skills they acquire, and their ability to competently identify, analyze, assess, and respond to life situations – also differ significantly.

The Program for International Student Assessment (PISA), an initiative of the Paris-based Organization for Economic Cooperation and Development (OECD), reinforced the original perspectives of science literacy and Roberts' Vision II in the frameworks for 2006 and 2009 science assessments. The PISA Science assessments focused on scientific competencies that clarify what 15-year-old students know and are able to do within appropriate personal, social, and global contexts.

In PISA, scientific literacy referred to four interrelated features that involve an individual's:

- Scientific knowledge and use of that knowledge to identify questions, to acquire new knowledge, to explain scientific phenomenon, to draw evidence-based conclusions about science-related issues
- Understanding of the characteristic features of science as a form of human knowledge and inquiry
- Awareness of how science and technology shape our material, intellectual, and cultural environments
- Willingness to engage in science-related issues, and with the ideas of science, as a constructive, concerned, and reflective citizen (OECD 2006, 2009)

PISA Science implemented the definition of *scientific literacy* and its science assessment questions using a framework with the following components: *scientific contexts* (i.e., life situations involving science and technology), the *scientific competencies* (i.e., identifying scientific issues, explaining phenomena scientifically, and using scientific evidence), the domains of *scientific knowledge* (i.e., students' understanding of scientific concepts as well as their understanding of the nature of science), and student *attitudes toward science* (i.e., interest in science, support for scientific inquiry, and responsibility toward resources and environments).

In conclusion, for many with responsibility for national standards, curriculum materials, and assessments, the distinction between two interpretations of science literacy – "Vision I" and "Vision II" – is blurred. The dominant perceptions about the content and learning outcomes are Vision I; the principal (sometimes exclusive) emphasis is on discipline-based science knowledge and methods. An often unstated assumption is that if students understand science concepts, they will apply that knowledge to the personal, social, and global problems they encounter as citizens. That assumption could certainly be questioned. For those interested in scientific literacy, school science programs should incorporate Vision II clearly, consistently, and continually. Students should have experiences where they confront appropriate socio-scientific issues and problems within meaningful contexts. PISA Science provided an assessment model and, through backward design, the basis for curriculum and instruction for this view of scientific literacy.

Here is an essential challenge for twenty-first-century science education. Most school programs emphasize fundamental knowledge and processes of the science disciplines. These science programs are intended implicitly to provide students with the foundation for professional careers as scientists and engineers. With the centrality of science and technology to contemporary life, full participation in society requires that all adults, including those aspiring to careers as scientists and engineers, be scientifically literate. That is, they not only develop understandings of science fundamentals, they learn how to apply that knowledge to life situations.

The level of a society's scientific literacy depends on citizens' understanding, receptivity, and appreciation of science as a human endeavor with significant influence on their lives and society.

Scientific Literacy: Its Relationship to "Literacy"

Stephen Norris[1] and Linda M. Phillips[2]
[1]Department of Educational Policy Studies, Centre for Research in Youth, Science Teaching and Learning, University of Alberta, Edmonton, AB, Canada
[2]Canadian Centre for Research on Literacy, University of Alberta, Edmonton, AB, Canada

Discussions of scientific literacy often propose answers to one or both of two distinct questions: (a) What is the meaning of scientific literacy? (b) What is the significance of scientific literacy? The first question tackles the semantic issue of how individuals in some specific group (say, a particular society) actually could, or should, use the expression. The second question deals with what is important about scientific literacy conceived in a particular way.

Meanings of "Literate" and "Literacy"

In modern English usage, the words "literate" and "literacy" have two distinct senses. "Literate" is the older of the two words, having been traced to the Latin "litteratus," meaning "marked with letters," and occurring first in late middle English in the fifteenth century. "Literacy" did not appear in usage until the late nineteenth century, which is when the meanings of the terms started to change. During most of the history of its usage, "literate" meant generally to be well educated and learned. Since the late nineteenth century, it has also come to refer to the abilities to read and write text. The transition in meaning that began slightly over 100 years ago has had such an effect that the Oxford Dictionary of English in 2012 reported "ability to read and write" as the primary meaning of literacy and "having education and knowledge typically in a specified area" as the secondary meaning.

Conceptions of Scientific Literacy in the 1950s and 1960s

In the field of science education, it is the second of the Oxford Dictionary of English usages that usually is found: that is, scientific literacy referring to being educated and possessing knowledge in science and about science. The term appeared in the science education literature during the middle of the twentieth century, being used by American-based scholars to express the need to increase attention to science education. Early uses of the term were by McCurdy (1958) and Hurd (1958). McCurdy's desire was for an understanding of natural science to be part of a broad liberal education, in particular, to help allay confusions between science and technology that he saw as widespread in American society of the day. He sought a science course at the secondary school level that provided knowledge both of and about science through "familiarity with the history and accomplishments of science and its relation to the matters of everyday life . . . [and] emphasis upon the cultural roots and goals of science" (p. 369). Hurd saw the achievements of science as the defining characteristic of a modern society and took an "acquaintance with scientific forces and phenomena [as] essential for effective citizenship" (p. 13). He sought a science education both for continued scientific advancement and for enabling people to cope with change.

He recognized the enormous difficulty involved in selecting from the "tremendous volume of scientific knowledge and concepts" (p. 15) the small proportion that could be taught. His attention was more focused on learning experiences that foster "the development of an appreciation of science as an intellectual achievement, as a procedure for exploration and discovery, and which illustrate the spirit of the scientific endeavor" (pp. 15–16).

These early writers about scientific literacy all sought greater understanding both of and about science for members of society as a whole. This desire expressed their semantic notion of scientific literacy. Their reasons for seeking this goal expressed the values that they held for scientific literacy: the promotion of effective citizenship, the broadening of liberal education, the successful continuation of scientific achievements, the preparation to cope with a rapidly changing society, and the appreciation of and support for science.

By the mid-1960s, Pella et al. (1966) was able to define scientific literacy as "science for effective citizenship" (p. 199). This definition is skewed neither toward the sense of being knowledgeable in science nor toward the sense of being able to read science. Rather, the definition speaks more to the goals of pursuing scientific literacy than to what scientific literacy actually means. This coupling of goals to meaning became very common in discussions of scientific literacy over the past 50 or so years. Scientific literacy has become a programmatic concept, which is used not only to express meanings but also to urge particular educational objectives to reach favored moral and political ends. Pella traced the meanings of scientific literacy – science for the citizen and science for general education – through the two previous decades. He concluded that "The scientifically literate individual presently is characterized as one with an understanding of the (a) basic concepts in science, (b) nature of science, (c) ethics that control the scientist in his work, (d) interrelationships of science and society, (e) interrelationships of science and the humanities and (f) differences between science and technology" (p. 206).

Concern with Practical Problems

In the literature of the latter part of the twentieth century, most of the themes identified by Pella were maintained. However, many scholars began to think that scientific literacy conceived as such was disconnected or too far removed from the lives of nonscientific citizens. Thus, in addition to the focus on knowledge and understanding that was predominant in Pella's time, there emerged a growing concern with the possession of the kind of knowledge, understanding, and competence required to deal with practical problems that are science related, harking back to the early idea of science for effective citizenship. Discussions turned to such matters as the following: the ability to think scientifically about natural phenomena and to find answers to questions about them; the ability to use scientific knowledge and scientific ways of thinking in problem solving and in making informed decisions about one's well-being and that of others; the knowledge needed for intelligent participation by the nonscientific citizen in science-based social issues, including the knowledge needed to understand the issues and the communicative competence to reason about such issues with others and as they appear in various media; and the ability to think critically about science and to deal with scientific expertise, including the ability to make plausible assessments of risks, to formulate and evaluate positions on matters informed by science, and to offer and to assess arguments based upon scientific evidence to support those positions.

The Primary Sense of Scientific Literacy

Another line of thought, focusing scientific literacy on practical problems, that began to develop late in the twentieth century was that participation in public discourse about science-related issues requires an ability to interpret oral and written language and perhaps also to write on science-related issues. This recognition was the beginning of a turn in thinking about scientific literacy toward the primary sense of literacy, the ability to read and write. An early mention of scientific literacy in this primary sense was by Branscomb (1981), who in fact wanted scientific literacy to be understood broadly and was fearful that it might be defined "narrowly as the ability to read and write [science]" (p. 6), which in her view would exclude a large proportion of the population that relies on modes of communication other than text to gain information. In the science education field, early attention to the primary sense of scientific literacy was manifested in a special issue of the *Journal of Research in Science Teaching* (1994, Vol. 31, Issue 9) on the "reading – science learning – writing connection." In the ensuing nearly two decades, several variants have emerged of how the primary sense of literacy is related to scientific literacy.

Reading and Writing as a Central Scientific Practice

Scientists read a great deal. Evidence has shown that scientists derive most of their information through reading and read for nearly one-fourth of their total work time. Evidence also shows that scientists rate reading as essential. The award-winning and high-achieving scientists tend to read more than others. When writing time is factored in, scientists spend almost one-half of their working time involved in primary literacy activities. Science educators thus have begun to see reading (and writing) as core scientific practices. This change of perspective on the nature of science led educators to rethink the view that hands-on experience is *the* essential core of scientific practice and, as a result, the sine qua non of any respectable science curriculum. Once the view of scientific practice is altered to make room for literacy in its primary sense, failure to attend to reading and writing in science learning was interpreted as neglectful. Thus, by the turn of the millennium, several research programs were underway designed to develop an understanding of specific literacy practices that underlie science to incorporate those practices into science teaching and learning.

Reading and Writing as a Tool for Doing Science

Once the amount of time scientists spend reading and writing is recognized, the question naturally arises of the relationship between literacy and science. Observation, for example, has been seen as a defining feature of science, grounding its empirical character, and being used to distinguish science not only from creationism but also from philosophy and literature. In contrast, literacy practices often have been seen as tools scientists use to help them do science, as opposed to essential features of the nature of science. Thus, scientists might be described as readers and writers in order to accomplish their task of doing science, and students might be taught to read and write science as tools for learning science. The idea here is that the reading and the writing are not conceived as part of science itself, whereas, for instance, observation is.

Reading and Writing Science as Important for Effective Citizenship

Reading and writing science can be seen as important in science education because they afford citizens access to understanding articles about science in various media, including newspapers, magazines, television, and the Internet. The type of reading and writing seen as desirable is usually described as "critical," because the emphasis is on critically evaluating the conclusions contained in popular reports of science, communicating the substance of those conclusions to a third party, and engaging in social conversation about their validity. In contrast, the evidence overwhelmingly shows that students at all levels and the nonscientific public have difficulty interpreting such reports of science, even though they think the reading is easy. Their misjudgment has been traced to a method of literacy instruction in schools, colleges, and universities that emphasizes the recognition of words to the detriment of interpreting meaning.

Reading and Writing as Important to Learning the Nature of Science

The manner of language use helps define the nature of the practice. In school science textbooks and classroom instruction, language is used mostly to show, summarize, and define; to present facts and descriptions; and to develop vocabulary and descriptive accounts of natural phenomena. In science itself, language is used to demonstrate conclusions, to provide reasons for why things are as they are, and to argue for causal interpretations. During the first decade of the twenty-first century, science education scholars began to urge the point of view that science instruction can profitably capitalize upon the common epistemological footings of science and reading. Both science and reading involve inquiry, that is, analysis, interpretation, and critique. Thus, if science students are taught to interpret the meaning of science texts, to distinguish in those texts what is reported as observed from what is inferred, to identify the evidence offered for conclusions and the conclusions drawn on the basis of evidence, and to understand the descriptions of methodology, then through learning the nature of reading and writing science texts, the students will have learned something of the nature of science.

Reading, Writing, and Text as Constitutive of Science

A growing recognition in the first decade of the twenty-first century is that the two senses of scientific literacy cannot be understood independently. That is, there is no possibility of learning science without learning the literacy practices of science. The literacy practices are partly constitutive of science. Just as it is impossible to think of science absent its empirical character, the argument goes, it is impossible to think of science without its literacy character. That literacy character comprises all of the practices involved in producing and interpreting scientific texts, which are jointly and succinctly referred to as reading and writing in science. Therefore, it is impossible, according to this viewpoint, to be scientifically literate in the sense of having education and knowledge in science without being able to read and write science to a commensurate degree.

Scientific Values

Levent Cavas
Division of Biochemistry, Faculty of Science,
Department of Chemistry, Dokuz Eylül
University, İzmir, Turkey

Science plays perhaps the most important role in the understanding of the universe. Science moreover contributes to the formation of values that effect social values. Therefore, there are many important characteristics and values that must be considered in scientific activities. Scientific outputs produced under the light of scientific values are important and scientists value these outputs. The fundamental value that must be obeyed by scientists in their research is honesty. The scientist has to report her/his experimental results without any falsificitation. The scientist must report the results with exact and understandable statements and must give detailed information about the materials and methods which are used in the research. The scientist before carrying out scientific research should not expect any commercial contribution from the research. The scientist must pay attention to the results of scientific research that contributes to humanity.

The scientist should also pay attention to the possible negative effects of research. In order to transform the research by scientists into real scientific values, there are many and extra important rules which must be followed by the scientists: reliability, testability, accuracy, precision, generalizability, and the appropriate statistical methods (Allchin 2012).

First of all, for turning scientific research into real scientific values, the research that is carried out has a novelty and it should not be a repetition of previous scientific research. In addition, the scientist should report all scientific results without fragmentation. When the scientists write their scientific research reports, they should write original statements and always properly cite the research of others. At the present time, the language of most of the platforms, the scientific journals, where the scientific researches are published, is generally English. This situation sometimes causes problems for scientists whose native tongue is not English. Even scientific research that is well designed and achieves important results can be rejected by the journal peer review process when the English is substandard. As a result, the language of the scientist can cause serious delays in the publication of valuable scientific research.

Another important parameter that the scientist should pay attention to is the use and evaluation of appropriate statistical tools and methods for the numerical values obtained from scientific researches. It is very well known that the different results can easily be obtained from different statistical methods. Therefore, the scientists should know detailed information on the statistics. When the scientist reports scientific research, there are general rules to be obeyed. For example, in the introduction part, the current literature should be summarized, and the gap within current literature should be defined very well. In the materials and methods part, the scientist should give details about materials and methods that they used. Sometimes, in scientific papers, researchers give appropriate citations to methodological papers instead of writing detail on the methods. As it is mentioned above, the results should be given exactly and without any falsification.

The scientist should pay attention to the effects of observer and also placebo effects. Therefore, especially in drug design researches, double-blind control groups should be used (Allchin 2012). Results should be compared with current literature knowledge and the reasons of parallel and nonparallel results should be explained. Novel findings must be emphasized and explained as a guide for other scientists interested in carrying out similar investigations. Research must be presented in peer-reviewed journals, but reviews must be based solely on scientific value, not influenced the personal characteristics of the researchers such as nationality, race, and religion. The evaluation should be objective. Therefore, to prevent any bias, the referees should be blind to authorship. Thanks to these values, science continues to improve our understanding of the universe and to the improvement of our lives.

Virginia, Charlottesville, VA, USA

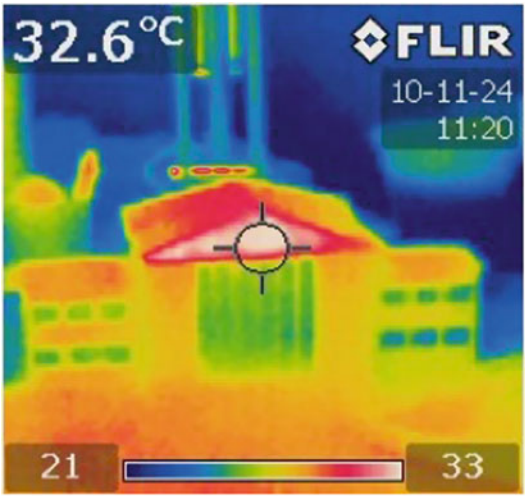
Keywords

Animation; Dynamic visualization; Simulation; Static picture

Scientific Visualizations

Visualization refers to either an internal or external representation of a concept, process, information, problem, or idea. Internal visualization encompasses a mental process whereby a person imagines some graphical or pictorial representation of information. An external visualization refers to an object or artifact that represents information graphically, pictorially, or sculpturally and may contain auditory or tactile elements. External visualizations can amplify the use or acquisition of knowledge by presenting large quantities of complex information visually. Both internal and external visualizations play important roles in science education in terms of representing science content, science processes, and the nature of science (Gilbert 2005). Indeed, researchers have argued that the mismatch between students' internal representations and the external ones presented in class or textbooks may account for some of the challenges in science instruction. Hence, much attention has been given to the careful design and application of external visualizations that are accessible to students and supportive of learning and instruction.

External scientific visualizations (henceforth scientific visualizations) can be used to communicate ideas and concepts and typically employ computer-based methods to represent theoretical concepts or physical data (e.g., from molecules, the human body, the Earth). Visualizations can serve to make abstract processes or concepts more explicit and concrete or to illustrate concepts that occur on very small (e.g., microscopic) or very large (e.g., astronomical or geological) scales. Instead of presenting complex data as sequences of numbers or text, scientific visualizations present data pictorially and graphically to take advantage of the human ability to process information and detect patterns through visual perception (Fig. 1).



Scientific Visualizations, Fig. 1 Infrared visualization of a model home (Image courtesy of Charles Xie)

Scientific visualizations can be grouped into three types: static, dynamic, and interactive visualizations. Static visualizations (i.e., images or graphs) do not change over time and do not allow any direct user manipulation. Typical static visualizations used in science include graphics, models, and diagrams found in research articles, journals, or presentations (for scientists) or in textbooks or lecture slides (for science students). Examples of static visualizations used in science education are models of atomic structure, pictures of organelles, or temperature isobars over a region of a country. Dynamic visualizations, or animations, do change over time or with user manipulation, resulting in the depiction of motion or progression. Examples of dynamic visualizations include animations of cellular processes, chemical reactions, or weather patterns.

Interactive visualizations differ from dynamic visualizations in that they are designed to be manipulated by the user, who thereby influences what the visualization presents. Simple interactive visualizations contain controls that enable the user to stop, start, replay, or step through an animation or sequence of static pictures. Complex interactive visualizations, like simulations or virtual experiments, are based on underlying computer models that enable users to change variables, parameters, or settings and explore resulting behaviors, dependencies, or outcomes (Fig. 2). For instance, a complex interactive simulation of electromagnetism might enable the user to change the "charge" settings and placement of

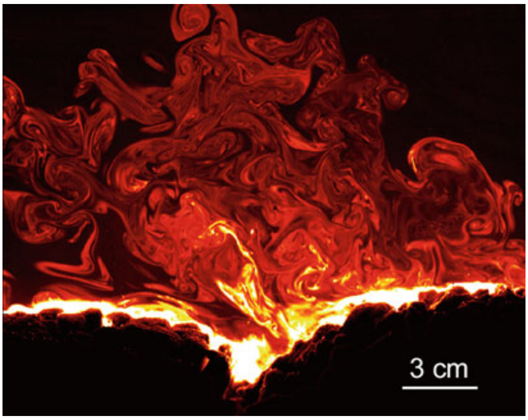
Scientific Visualizations, Fig. 2 Molecular Workbench simulation of cellular respiration that enables students to experiment with different settings (normal breathing, no breathing, cyanide, and rat poison) (Image courtesy of Charles Xie)

objects, resulting in observable changes to the electric field throughout the system. These visually rich, interactive visualizations enable students to construct their own understandings of complex phenomena by manipulating phenomena or processes that would otherwise be difficult or impossible to achieve in science classrooms.

Although scientific visualizations were first advanced as tools for practicing scientists, they have been adapted to help science students learn concepts and inquire about the world around them. For example, a scientist may use a dynamic visualization of fluid flow over coral reefs (Fig. 3) to communicate results about how corals exchange nutrients with the water; but students might use the same visualization (or a slightly simplified version) to learn basic



Scientific Visualizations, Fig. 3 Scientific visualization of fluid flow used to investigate how corals exchange nutrients with the water (Photo courtesy of Matthew Reidenbach) concepts of fluid dynamics. Students can gain practice in inquiry processes by making observations and inferences about visualizations and can learn to analyze data from the visualizations for purposes of addressing research questions. For example, learners might investigate infrared images of different conductors to explore questions about heat transfer. They might draw certain inferences or explanations from one set of images but could arrive at different conclusions when presented with a second set of images. Such investigations would support the development of inquiry skills as well as new understandings of the nature of science.

Different types of visualizations provide distinct affordances or opportunities for learning. Static visualizations provide students with concrete images of scientific concepts that might otherwise be too abstract, too large, or too small to be directly observed. For instance, static visualizations of electron orbitals can help students understand atoms, even though such orbitals are not actually perceivable, and only exist in a statistical sense. Importantly, such representations could also promote faulty interpretations, and developers of such materials must be sensitive to possible alternative interpretations that learners might derive. Students can refer to or engage with scientific visualizations at their own pace, returning multiple times, asking different questions, or debating their interpretation with peers or instructors.

Dynamic visualizations are often used for purposes of representing inherently dynamic processes such as rotations of molecules, DNA replication, or planetary motion. Dynamic visualizations can help students learn about complex scientific processes on very small or large scales that may not be easily communicated through sequences of static images. For instance, animations of cells dividing could help students understand the biological process of mitosis, or animations of electron movement in conductors could help students develop an understanding of electric current. As in the case of static visualizations, learners can make observations and inferences about dynamic visualizations and analyze that data to answer their questions and develop understandings about the nature of science. For example, two students looking at the same dynamic visualization might notice completely different events, which could lead to a discussion of how two scientists might differ in their interpretation of phenomena or experimental outcomes.

With simple interactive visualizations, such as visualizations with interactive controls, students can learn content at their own pace. For example, students using an interactive visualization of a cell can click on various organelles to obtain more information about the purpose of each organelle. This self-paced interaction allows learners to reach a better understanding as compared to just watching an animation passively. Complex interactive visualizations, such as simulations, provide a more extensive range of manipulations that can allow students to test their ideas, explore various conditions, and build a personal understanding of the relevant science concepts. Students can make predictions, test their ideas using the simulation, and receive feedback from the simulation itself that helps them consider revisions to their ideas or hypotheses. Simulations enhance inquiry-based approaches to science teaching, as students can engage in experimentation by manipulating variables and conducting virtual trials. For instance, in a simulation of natural selection, students could introduce mutations and explore their impact on population survival – something that is nearly impossible to do without interactive visualizations. Simulations can also contribute to an understanding that there is not “one” scientific method, as students may use multiple approaches to address the same research question.

Limitations of visualizations involve the inherent barriers of their particular representations. Static visualizations, for example, do not enable students to interact with the visualization and do not provide direct representation of dynamic processes. Simple dynamic visualizations that do not enable students to interact may result in students passively watching the animation without actively engaging with the information. Interactive visualizations enable learner control, but without adequate self-regulatory or self-monitoring strategies, learners may not take full advantage of the interactive affordances for learning. Visualizations are also limited to varying degree in the quality of their renderings, the complexity, or abstraction of information presented. Conceptual errors may have been introduced by attempts at simplifying scientific concepts.

Merely providing a learner with a visualization – whether static, dynamic, or interactive – does not guarantee that the targeted concepts will be communicated or learned. Research on learning with scientific visualizations highlights the importance of the design of the visualization, the design of supporting instruction, and the role of prior knowledge of the learner. Decreasing the unnecessary or distracting information while highlighting salient information will improve the accessibility and efficacy of any scientific visualizations (cf. Tufte 1990). Visualizations should be surrounded by supporting instruction that encourages students to make connections to existing ideas, reflect on their understanding, and revise their ideas. Instruction should also discuss limitations of any visualization employed, and what the visualization does and does not represent. For example, many images of atoms are presented in textbooks without explicit discussion regarding the limitations of the visualization. As a result, many students believe that we can actually see atoms directly, that atoms have color, that electron orbits have color and shape, and that chemical bonds are material objects – since they are often depicted as lines.

As with all instructional elements, students' prior knowledge will greatly influence what they learn from scientific visualization. For example, a visualization of cell processes may help a high school biology student to understand those processes more deeply, whereas a sixth grader might fail to understand the scientific content of the same visualization. Thus, design of both the visualization and the supporting instruction should pay careful attention to the expertise level of the intended audience. Pedagogical supports, such as lesson plans and assessments, and teaching notes, would also be important, to help teachers and learners derive the greatest advantage from visualizations.

Nature of Scientist-School Interactions

There are numerous ways in which scientists and other professionals working in science-related fields interact with schools to add value to formal science education programs. Some interactions are longer-term, ongoing relationships, while others are single occurrences. The nature of interaction varies widely and includes face-to-face visits as well as online interactions such as e-mail, Skype, blogs, discussion forums and chat rooms, or a combination of these. Some organizations and professional associations become involved so that their scientists can deliver specific outreach programs into schools. Universities may encourage their faculty to become involved in an attempt to attract more students to enroll in undergraduate studies at their institution. Particular industries may participate because they wish to encourage students to pursue science-related careers leading to employment in their field. The proportion of schools that have interactions with scientists is difficult to estimate but is almost certainly underrepresented in the literature because of the many interactions that are established through ad hoc, personal connections, such as a scientist being a parent at a particular school.

Scientist-school interactions may involve scientists working directly with students, teachers, or both. Types of interactions include a scientist presenting to a class or a number of classes; delivering a unit of work in conjunction with a teacher; mentoring students in open-ended science investigations; judging science fairs or other student work; participating in school science camps; supervising students or teachers undertaking research projects or work experience in the scientist's workplace; arranging student excursions to the scientist's workplace; assisting teachers, especially in primary or elementary schools, to identify and embed science in themed units of work; providing teacher professional development; and providing resources such as equipment or consumables.

Purpose

Regardless of the type or method of interaction, the broad purpose of involving a scientist with a school is to expose students to contemporary, real-world science and the work of science professionals. More specific aims are to stimulate and increase students' interest in studying science, increase students' awareness of careers in science, update teachers' knowledge of contemporary science, and increase awareness of the social and economic importance of science to the community. A secondary purpose, more commonly in primary or elementary schools, is to increase the profile of science in the school. Effective scientist-school interactions deliver successfully on these aims.

Contributions and Benefits

All scientist-school interactions share one distinguishing feature – the human element. For this reason they not only provide effective contributions to science content understanding but also demystify the image of scientists as being somehow different from ordinary people. Working directly with a scientist provides a unique, personal insight for students and teachers that is difficult to replicate with other curriculum experiences or programs.

The benefits of scientist-school interactions for the individuals directly involved have been well documented, and while the benefits for students and teachers may be obvious, the benefits for scientists are also significant. Benefits for students include increased engagement in science, the opportunity to see scientists as real people, having fun, increased awareness of careers in science, increased knowledge of contemporary science, and increased awareness of the nature of scientific investigation. Benefits for teachers include enjoyment from working with a scientist, updated knowledge of contemporary science, increased engagement by their students, increased confidence in teaching science, and increased profile of science in their school. Benefits for scientists include enjoyment from working with students and teachers, increased satisfaction with their own career, and increased confidence in communicating science. Scientists with school-aged children also report an increased knowledge and understanding of the school system as a benefit for themselves.

Characteristics of Effective Scientist-School Interactions

The success of scientist-school interactions depends on a variety of factors including thorough planning and preparation by the teacher so that the interaction, whether a single visit or ongoing relationship, forms part of a curriculum program; clear, mutually respectful communication between the scientist and teacher to clarify expectations of each other; the ability of the scientist to engage with students and teachers; and the flexibility of both parties to adapt as required. The question of whether longer-term, ongoing relationships are more effective than once-off, single interactions is worth considering. There is little on this topic in the literature, perhaps because longer-term interactions are not especially common due to the greater investment in time and effort that is required to sustain them. One of the documented characteristics of longer-term interactions is that the students and teachers develop a rich relationship with the scientist. This leads to additional benefits that range from simple efficiencies such as the scientist being able to find their way around the school through to the interaction adapting and becoming more refined as each party gains confidence and learns from previous experience.

Secondary Science Teacher Education

Tom Russell
Queen’s University, Kingston, Canada

Keywords

Knowledge; Learning; Science Teacher Education; Strategies; Teacher Education

Introduction

“We teach as we were taught.” These six words summarize the major challenge facing secondary science teacher education, both from the perspective of what science we teach and from the perspective of how we teach science at the secondary level. The tendency of new and experienced teachers to teach as they were taught has been recognized for decades. Less frequently discussed and explored is the tendency of science teacher educators to teach as they were taught. We now know from research a great deal more about so-called best practices and about how individuals learn. Unfortunately, it is simply not enough to present best practices and new insights into learning to new teachers as information. As they themselves struggle to find their pedagogical feet in practicum classrooms and early in their teaching careers, new teachers need to learn from experience as they also learn how to learn from experience. Secondary science teacher education requires carefully developed strategies for helping new and experienced teachers to change their teaching *habits* – acquired by watching their own teachers – as they change their teaching *frames*, the ways they typically think about how students learn science.

The Content of Science: What We Teach

Typically, the science content to be taught is set out for teachers in curriculum documents that differ from state to state and province to province. Each jurisdiction usually sets out additional requirements for attention to the processes of science as well as the content. In the context of secondary science teacher education, those learning to teach face the challenge of connecting science content to the everyday world of their students. Studying science in university courses in order to perform well on examinations is quite different from processing science content in ways that illuminate events in the world around us and help others to learn basic scientific concepts. Secondary science teachers also struggle with the tension between preparing a few students for further study of science and preparing all students for the understandings of science that help them see how biology, chemistry, physics, and earth and space science provide insights into everyday events from infections and reactions to collisions and earthquakes.

The Process of Science: How We Teach

Science teacher educators have focused for decades on issues associated with teaching science as inquiry and learning science for understanding of concepts rather than memorization of facts. Some universities have established groups that study how first-year university students learn a science subject; such research groups tend to focus on a single subject – biology, chemistry, or physics. These groups produce articles offering insights into the learning approaches and difficulties of first-year university students, and those insights can tell us a great deal about the learning achieved by senior secondary students who have gone on to university study. Knight (2004) has produced an outstanding analysis of the teaching of physics topics to first-year university students. His five recommendations (they are not easy to enact) should apply to all first-year university science teaching and certainly have implications for secondary science teaching:

1. Keep Students Actively Engaged and Provide Rapid Feedback.
2. Focus on Phenomena Rather than Abstractions.
3. Deal Explicitly with Students' Alternative Conceptions.
4. Teach and Use Explicit Problem-Solving Skills and Strategies.
5. Write Homework and Exam Problems that Go Beyond Symbol Manipulation to Engage Students in the Qualitative and Conceptual Analysis of Physical Phenomena (Knight 2004, pp. 42–45).

In this list we see clear and focused advice that reflects careful analysis of recent research on learning as well as Knight's study of his own teaching of physics students in their first year of university study. The advice is directly relevant to secondary science teaching. Each of his five lessons invites secondary science teachers to look carefully at their own teaching and at the learning of their students. This invitation is equally important for science teacher educators, who must consider whether or not this advice to science teachers can be applied to the work of preparing individuals to teach science at the secondary level. Knight's five lessons need to be modeled explicitly to beginning science teachers in order to provide them with personal experience of their impact on learning. The *phenomena of teaching and learning* tend to be more engaging than educational abstractions, and qualitative and conceptual analysis of *educational* phenomena certainly have an important place in secondary science teacher education. Teaching guided by Knight's advice is inherently complex and challenging. Modeling these principles and making it explicit that one is doing so is similarly complex and challenging; explicit analysis of one's own teaching as a science teacher educator may have more impact than any other strategy used with future teachers of secondary science.

Science Teachers' Knowledge of Practice

An important set of recommendations for secondary science teaching and teacher education appears in Loughran's (2010) consideration of the work of expert teachers. Drawing in part on his knowledge of the teaching insights developed within the Project for Enhancing Effective Learning (http://peelweb.org), Loughran presents six elements of expert teachers' knowledge of practice: prior knowledge, processing, linking, translation, synthesizing, and metacognition. Like so much recent research, Loughran highlights the importance of identifying and responding to students' prior knowledge; again, this is a significant consideration for science teacher educators. Processing, linking, translating (moving ideas from one context to another), and synthesizing are important elements of science teaching; the corresponding challenge for science teacher education is to incorporate these elements into the preservice teacher education experience in ways that provide those learning to teach with opportunities to practice and thereby develop appropriate skills for teaching. Finally, metacognition is a crucial element of secondary science teacher education. New teachers need to be able to regulate and monitor their own professional learning, and they need to develop skills for encouraging their students to become similarly attentive to their learning of science. To encourage these elements of expert teaching in our secondary science classrooms, they must be included within the learning experiences of teacher education for secondary science.

The Importance of Prior Knowledge in Learning to Teach Science

Much has been written about the importance of teachers' identifying and responding to views of scientific phenomena that students hold when they begin a course in science. Much less attention has been given to the views of educational phenomena that prospective teachers hold when they begin a course in learning to teach science. Insights into one classroom of secondary science teacher education are provided in Bullock's (2011) fine-grained analysis of the learning experiences of five individuals in a physics curriculum methods course in a 1-year initial teacher education program. The focus of the analysis is on how learning in the methods course related to and interacted with learning in practicum settings. The participants in the study were interviewed four times through their program, first in a focus group and then individually to explore more fully the views expressed in each focus group. This unique study of science teacher education illustrates clearly and powerfully that the prior knowledge (including teaching habits and frames of mind for thinking about teaching and learning) that a prospective teacher brings to a science teacher education program is a major influence on what that individual takes from the program. Gone are the days when science teacher educators might assume that all their students leave their classes with the same messages, including the ones that they were trying to develop and convey.

Learning to Identify the Effects of Teaching on Students

Education generally and teacher education in particular often appear to be short on knowledge of what works in practice. While there is much discussion of evidence-based best practices, that discussion is rarely accompanied by consideration of the complexity of changing personal teaching practices, which are typically habitual. Hattie's (2012, p. ix) central message is "Know thy impact," and this message is as important for science teacher educators as it is for science teachers. Hattie's own words speak clearly. "A major theme of this book... is that the quality of teaching makes all the difference." "The message in this book is that teachers, schools, and systems need to be consistently aware, and have dependable evidence of the effects that all are having on their students – and from this evidence make the decisions about how they teach and what they teach" (p. 149). "What is asked for here is a culture in which teachers spend more time *together* pre-planning and critiquing this pre-planning, and working in teacher groups to interpret the evidence about their effect on students" (p. 168).

These messages come from an individual who has studied research on teaching and learning for many years and who is urging us to place the emphasis on evidence of the effects of our teaching on our students' learning. These messages have more significance for science teacher educators than for science teachers in secondary schools; those whose work it is to prepare individuals to teach science at the secondary level need to gather continuously the evidence that they are encouraging, challenging, and enabling new science teachers to develop habits of practice and frames of mind that permit them to know their impact on the students they teach. Hattie's approach has several unique features. While it is important to work from the empirical evidence available about a range of teaching practices, Hattie stresses the importance of gathering evidence of the effects of one's teaching in one's own classroom and working with other teachers in one's school or college of education to interpret that evidence and collectively plan further development of teaching practices.

The Importance of Experience: Metacognition and Transformative Learning

Mezirow's (1997) theory of transformative learning has significant implications for secondary science teacher education. Just as secondary science teachers seek to transform students' common-sense views based on personal experience into richer and deeper understandings based on principled analysis of scientific phenomena, so secondary science teacher educators seek to transform prospective teachers' common-sense views of teaching and learning into richer and deeper understandings based on principled analysis of classroom events. Three common themes in the theory of transformative learning are the centrality of experience, critical reflection on that experience, and rational discourse as a means of learning. Experience is seen as socially constructed, so that it can be deconstructed and acted upon. It is experience that provides the grist for critical reflection. Major challenges for secondary science teacher education and teacher education generally continue to be the development of skills of critical reflection on practicum experiences and the linking of those experiences to what is presented in education courses.

Having experience and learning from experience are obviously related yet they are not the same. Without careful analysis and discourse with others, what we learn from experience is likely to be both incomplete and flawed. Just as everyday experience with natural phenomena often leads to incomplete and incorrect understandings, so everyday experience of students in classrooms leads to incomplete and incorrect understandings of why teachers display particular habits in their teaching. Identifying assumptions and developing links between theory and practice are some of the many activities that fall under the term *metacognition*. Those learning to teach have rarely been challenged to become metacognitive and thereby come to understand the nature of their own learning processes. The end goal of transformative learning is professional autonomy, and secondary science teacher education needs to promote this goal at every opportunity.

Overview

To summarize, secondary science teacher education shares many of the challenges and responsibilities associated with teacher education generally. Because science considers the phenomena of the natural world, science teachers can provide many firsthand experiences to their students to help them to refine and extend the views they have developed from prior experiences. Secondary science teacher education has the additional responsibility of providing experiences that will enable future science teachers to consider the phenomena of the educational world. Becoming metacognitive about one's own learning and the learning of others is central both to learning secondary science and to learning to teach it. We often teach as we were taught because the habits of teaching and learning and the frames of mind for education that we developed as students observing our own teachers tend to be stable and difficult to change. For science students, science teachers, and science teacher educators, reframing our perspectives and developing new habits go hand in hand. The parallels between learning science and learning to teach science are numerous and significant. The research on learning in general and learning science in particular offers challenging insights that can help shape new and transformative science teacher education practices that move beyond teaching as we were taught.

Capacity beliefs

Self-Efficacy Beliefs for Science Teachers and Students

Teachers and students hold beliefs about their capabilities for teaching and learning science. These self-perceptions about personal abilities to manage engagement with science have been shown to causally influence success through motivation and the ability to do what is necessary in a given science learning environment. Such beliefs are known as self-efficacy beliefs and are different from more general beliefs of self-confidence and self-esteem in that they are targeted at specific future performance. Since all self-efficacy beliefs, including those for teaching and learning science, are malleable and have a causal relationship to success, it can be useful to include them in strategies to improve science education.

Self-efficacy study is rooted in Bandura's (1997) social cognitive theory and is composed of two dimensions: efficacy predictions and outcome expectations. These reflect the position that personal expectations of competence are tempered by the affordances of the context in which an individual will act. If a teacher or student expects that the environment in which they will teach or learn science will allow them success, then their chances of achievement are more likely (Dolin and Evans 2011). Conversely, when various factors exist which may inhibit successful science learning, then personal self-efficacies may be diminished. Studies show that while higher self-efficacies, motivation, and confidence to teach science often result from professional development, contextual outcome expectations may not be similarly elevated. For experienced teachers this may indicate a realistic assessment of the intractability of local teaching conditions including the perceived chances of actually making a difference with given students. Another explanation of increased self-efficacies and static outcome expectations after teacher development could be the inexperience teachers have at teaching with their newly increased capacity beliefs. Consequently, even though social cognitive theory includes both dimensions of self-efficacy (efficacy predictions and outcome expectations), studies also often look at the two constructs separately so that changes in efficacy predictions can be seen when different from outcome expectations.

High self-efficacies increase teacher and student motivation and success with teaching and learning science. Both are more likely to take risks, accept challenges, and try new ways of doing science when their self-efficacies are high. One of the most common uses of self-efficacy in science teaching over the past 20 years has been to gauge change in capacity beliefs during preservice methods courses and teacher professional development programs. A notable finding has been that an increased use of inquiry-based instruction of professional development is correlated with increases in self-efficacy (Dolin and Evans 2011).

Ameliorating Self-Efficacy

Given this potential, it is useful to know how personal self-efficacies are created and changed. Bandura (1997) describes four ways through which they naturally develop. Primary is the accumulation of **mastery experiences** relevant and specific to a future event through which we develop a sense of the likelihood of successful performance. When teachers have reasonable success with trying unfamiliar science teaching methods, they are more likely to predict that they will also experience some success at other methods they have not tried. Conversely, when students experience repeated failure when attempting to design an experiment with adequate controls, they will predict their continued failure and resist future attempts with such experimental design.

Another method by which self-efficacies are changed is through **vicarious experiences** where students may see peers similar to themselves competently conducting a science exploration and consequently feel that perhaps they too can do the same. This comparison with successful others raises their perceived self-efficacy at such tasks and means that they are more motivated to attempt explorations and more likely to do so competently. Conversely, a new teacher may hear from another science teacher that facilitating group work is not only difficult but likely to result in a loss of control over the classroom behavior. This message from someone the teacher compares themselves to may diminish their self-efficacy for using group work so that they may be more reluctant to attempt it.

The self-efficacies of both teachers and students are also affected by **social persuasion** from peers as well as from feedback to one another. When authentically encouraged or discouraged about their ability to facilitate or participate in a given science activity, teachers and students are more or less likely to be motivated to become engaged and their consequent success affected. The credible feedback which teachers can give to students about their ability to succeed at a specific science activity can significantly influence student self-efficacies and consequently their achievement. Likewise, genuine student feedback to teachers about their efforts can persuade teachers to attempt teaching strategies that may be new or uncomfortable to them.

Teachers and students partly use judgments of their own **physiological and emotional states** to decide how confident about a specific future task they feel. Teachers who are anxious about trying challenging teaching methods have reduced self-efficacies relevant to those methods and are less likely to take the necessary risks to attempt them. For students, anxiety about learning activities reduces their motivation to attempt them. As experienced teachers know, positive and negative moods for both students and teachers can contribute to self-efficacies and consequently the motivation to meet challenges.

Assessing Self-Efficacy

The quantitative instrument which has been most used for assessing self-efficacy among elementary teachers was developed by Larry Enochs and Iris Riggs' in 1990 and updated by Bleicher (2004). It consists of 23 five-choice questions with two integrated scales; one assesses self-efficacy beliefs for future science teaching activities and the other outcome expectations for those same actions. When used before, during, and after methods courses or professional workshops, relative changes in scores have provided teacher educators with information on change associated with professional development activities. Others have used qualitative assessments of efficacy based on interviews with teachers to judge changes. More recently, to narrowly focus on changes in efficacy beliefs, studies have looked at changes in beliefs associated with specific methods instruction, such as inquiry teaching (Dolin and Evans 2011).

Current Trends

Current work to improve science teaching and learning often focuses on purposefully using a combination of the four ways for developing capacity beliefs to raise teacher and student self-efficacies. Such methods assume that by intentionally focusing on raising these capacity beliefs, students and teachers will be more motivated and successful with science teaching and learning tasks. Most current efforts are aimed at both preservice teachers and experienced teachers participating in professional teacher development. Examples of such elements designed to increase self-efficacies in courses and workshops would include opportunities for teachers to try out new methods of teaching multiple times both with peers and then with groups of students and to get realistic yet supportive feedback each time. Such experiences in relatively controlled circumstances support increases in self-efficacy through **mastery**. Since each participant also gets a turn at teaching their peers, everyone gets to compare themselves with those they feel most alike and therefore through **vicarious** experience are able to raise their self-efficacies. At the same time, instructors as well as all of the teachers in the courses and workshops who witness the teaching episodes give critical yet supportive feedback to one another adding to capacity beliefs through **social persuasion**. Such microteaching experiences in thoughtfully structured circumstances have the potential to reduce **anxiety** and heighten moods as teachers gain specific confidence through incrementally successful experiences.

While this approach to increasing teacher capacity beliefs has shown positive results in motivation and success with science teaching methods, direct connections between the four ways for increasing self-efficacy and actual changes have not been made. Some current effort is aimed at discovering which ways are effective under which circumstances so that future intentional efforts to increase science teacher self-efficacy can be more effectively focused.

There has not been as much formal attention given to increasing student self-efficacy for doing science through conscious use of these four ways, although effective science teachers have long informally employed them for boosting pupil capacity beliefs. However, the implications of general self-efficacy studies are also applicable to managing science student self-efficacies (Pajares and Urdan 2006). Important for students is the expectation of desirable outcomes resulting from science activities. Perhaps more than for teachers, pupils' personal expectations of competence are diminished when they do not expect their efforts to be productive. Teachers can help students overcome this de-motivating effect of low expectations by authentically boosting student self-efficacies through well-structured mastery practice, opportunities for pupils to work with achieving peers, credible and supportive feedback, and attention to emotional barriers to good performance. The rewards are that students with higher self-efficacies are likely to put more effort into their academic work, stay with difficult problems longer, have more positive attitudes, and, in the end, achieve more.

Self-Study of Teacher Education Practices (S-STEP)

Amanda Berry
ICLON Graduate School of Teaching, Leiden University, Leiden, The Netherlands

Keywords

Practitioner research; Reflective practice; Self-study

Background

Self-study of teaching and teacher education practices, abbreviated as S-STEP, or self-study, is a genre of educational research concerned with examining and improving the relationship between teaching and learning in teacher education contexts. In self-study, the teacher educator him/herself is both the researcher and the main focus of the study. Self-study is concerned with the acquisition and development of teacher educators' knowledge of practice and how such knowledge can inform and enhance learning and teaching about teaching. The process of knowledge development in self-study is initiated through the teacher educator's capacity and willingness to publicly problematize his/her taken for granted beliefs and practices about teaching and learning; to be open to, and act upon, the curiosities, surprises, and challenges of everyday teaching practice; and to actively seek out alternative perspectives on practice.

The knowledge produced through self-study is intended both as a means of reframing the teacher educator's personal understandings of practice and stimulating the development of knowledge of practice among the community of teacher educators more broadly. An important function of self-study has been to promote the idea of teaching as a discipline and teacher educators' professional knowledge as specialized and unique.

Historical Roots

Self-study emerged as an organized field of research in the 1990s and was formalized with the founding of the Self-Study of Teaching and Teacher Education Practices (S-STEP) Special Interest Group (SIG) of the American Educational Research Association (AERA) in 1993. Since that time, self-study has acquired a scholarly and organizational presence in the international teacher education community and is recognized as a bona fide genre of research and topic of interest in teacher education practice and research. Consolidation of the field is evident through the production of an International Handbook (Loughran et al. 2004); a peer-reviewed, international journal, *Studying Teacher Education*; and a biennial conference, *The International Conference on Self-Study of Teacher Education Practices*.

Self-study is a qualitative research methodology that shares similarities with practitioner research, action research, and reflective practice. While the distinctions among these forms of research may be blurred, its explicit inclusion of "self" as the focus of study distinguishes self-study from other forms of qualitative research. Self-study researchers draw on a range of strategies in developing, conducting, analyzing, and representing their work. Mostly, these are typical of data-gathering approaches used in qualitative research. Important to self-study is that the researcher carefully selects a range of approaches to data gathering that offer multiple and alternative perspectives on practice. LaBoskey (2004) identified five key elements of self-study: it is self-initiated and focused, is improvement-aimed, is interactive, uses many strategies, and defines validity as a process based on trustworthiness.

Self-Study and Subject Matter

Self-studies are conducted by teacher educators in a broad range of topic areas, contexts, and locations, with many examples readily available in the literature. Typical themes of self-study research by teacher educators include the transition experiences of newly appointed, university-based teacher educators; studies of the implementation of particular philosophies in teacher education programs and courses; the development of subject-specific knowledge for teaching teachers; teacher educators articulating their pedagogy of teacher education; and teacher educators' efforts to address social issues of race, class, and gender.

Self-study has not typically tended to be based around any particular subject/content field. Rather, it has been the teacher education context that has been important. However, in recent times researchers in some areas have published their studies (see, e.g., social sciences (Crowe 2010) and mathematics (Schuck and Pereira 2011) with science education encapsulated in the work of Bullock and Russell (2012)).

Bullock and Russell's *Self-studies of Science Teacher Education Practices* (2012) illustrates how the interaction of science and self-study leads to new understandings of practice similar to those recognized in the science teacher research literature, including recognizing alternative conceptions and learners' prior views, facilitating a constructivist perspective, and confronting technical-rational views of teaching and learning.

Bullock and Russell's edited collection offers insights into teaching and learning about teaching through self-study across the fields of early career teacher educator practices, elementary/primary science teacher education, secondary science teacher education, and, preservice students' learning about science teaching and learning. Their text illustrates well how "self-study methodology offers one way to move beyond technical rationality toward a more productive understanding of professional knowledge" (p. 1).

Sex Education and Science Education

Michael J. Reiss
Institute of Education, University of London,
London, UK

The Lens of Human Reproduction

School and college science typically examines issues of sexuality through the lens of human reproduction. This immediately tends to assume heterosexuality. Biology is all too often presumed to be a neutral subject so that many biology teachers and lecturers continue to teach it as an unquestioned fact. In particular, differences between females and males are often presented as clear-cut and inevitable, and the study of school biology textbooks shows that they are often sexist and typically ignore lesbian and gay issues (Reiss 1998). For example, they often omit all mention of the clitoris and, when they do refer to it, frequently talk of it in a belittling way as the female's equivalent of a penis. Males are rendered visible, females less so; the female exists by virtue of comparison with the male. When homosexuality is addressed, it is generally portrayed as a sort of second-best option, which the reader may well grow out of. However, closer examination of sex in human biology provides plenty of space for critical reflection and allows for a richer understanding of what it is to be a sexual person.

Emily Martin (1991) has shown that while menstruation is viewed in scientific textbooks as a failure (a successful woman would have got pregnant), sperm maturation is viewed as a wonderful achievement in which countless millions of sperm are manufactured each day. Furthermore, sperm are pictured as active and streamlined, whereas the egg is large and passive, drifting along or waiting. The way the egg is portrayed in science textbooks has been likened to that of the fairy tale *Sleeping Beauty*, in which a dormant, virginal bride awaits a male's magic kiss. However, for well over a decade, biologists have considered the egg and sperm as *active* partners. Just as sperm seek out the egg, so the vagina discriminates between sperm and the egg, seeking out sperm to catch.

Social historical research on sex hormones documents that textbooks and scientific papers give messages that go well beyond what the data indicate. For example, since the 1920s it has been known that each sex contains the "other's" hormone (i.e., males contain estrogen and females testosterone). Nevertheless, school science textbooks often ignore both this fact and the close chemical similarity between estrogen and testosterone. Indeed, school textbooks more in line with the scientific evidence about the working of sex hormones would present femaleness and maleness on a continuum (a model common among academic endocrinologists since the 1940s).

The Impact of Faith Groups

School sex education is frequently a contested area for members of faith groups (Halstead and Reiss 2003). Generalizations are difficult because of the variations that occur both within and between religions. Consider, for example, Islam. A core belief of this religion is that God created sexual duality – i.e., male and female – in creation. In both men and women, there is therefore a natural desire for companionship with the other sex. Accordingly, celibacy is not praised. Rather, sexual union gives a foretaste of the joys of paradise, and sexual relations are recognized as one of the great signs of the blessings Allah has bestowed on humankind. While there is a gay and lesbian Muslim movement, there is overwhelming support in Islam for the teaching that homosexuality is unnatural and abhorrent. Muslims feel uncomfortable about sex education conducted within a secular framework, and there are three main aspects of much contemporary practice in Western school sex education that give rise to Muslim opposition:

- Some sex education materials offend against the Islamic principle of decency and modesty.
- Sex education tends to present certain behaviors as acceptable which Muslims consider sinful.
- Sex education is often perceived as undermining the Islamic concept of family life.

Christian views about sex, as about virtually everything, derive from five main sources: the writings of the Bible; the teachings of the Church down the ages; the conscience of individuals informed, they believe, by the Holy Spirit; their God-given, though imperfect, powers of reason; and the particular cultural milieu they inhabit. Marriage has a mystical element to it, the relationship between a married couple reflecting the relationship Christ has with his Church. Indeed, in the Roman Catholic tradition, marriage is one of the sacraments. Christian attitudes to sex before marriage have softened in recent decades. However, homosexuality remains contentious. Some argue that it is clearly prohibited by scripture. Others maintain that both the Old and New Testaments knew little or nothing about mutually faithful adult-to-adult expressions of homosexuality, instead prohibiting cult prostitution and pederasty.

Simulation Environments

R. Benjamin Shapiro[1] and Dennis Ramirez[2]
[1]Department of Computer Science, Department of Education, Tufts University, Medford, MA, USA
[2]Department of Curriculum and Instruction, University of Wisconsin, Madison, WI, USA

Description

Simulations are a representation of real or hypothesized phenomena used to support learning through illustration of and experimentation with the system. Simulations enact the dynamic processes of a system and often allow the user to manipulate key factors affecting the dynamics in order to explore possibilities, generate hypotheses, or test predictions. Learning with a simulation may be centered around understanding the rules and assumptions that guide the simulation's dynamics or manipulating variables that normally may not be accessible (National Research Council 2011). For example, an interactive simulation of Newtonian physics may allow users to explore and develop theories about mechanics by applying impulse forces to objects and observing the results (diSessa 1982; Clark et al. 2011).

Simulations are typically open-ended with no set directives or roles other than those generated by the user or context of use. In contrast, games and other pedagogies may incorporate a simulation as a part of the learning experience but add an explicit roles or goals that shape interaction. Learning experiences with simulations include (a) using simulations by testing out a variety of scenarios to discover the rules that drive an extant simulation and (b) constructing simulations by studying already occurring phenomena and abstracting/reproducing key concepts in order to virtually reproduce them. The process of simulation construction is often iterative, with learners generating and testing different theories in order to reproduce observed behaviors.

Single-Sex Classes in Science

Carolyn Jackson
Lancaster University, Lancaster, UK

Keywords

Science

Single-sex classes have been introduced into coeducational schools – and in some cases universities – in numerous countries, including Australia, England, New Zealand, Sweden, and the USA. Although a few coeducational schools have implemented single-sex classes throughout the whole school and across all curriculum areas, in most cases they are introduced in specific subject areas and/or for particular age groups. Often, they are introduced with an aim of fostering engagement of girls in "masculine" curriculum areas (e.g., math) or boys in "feminine" curriculum areas (e.g., languages).

Concerns about the underrepresentation of women, compared to men, in science, technology, engineering, and math (STEM) frequently underpin initiatives to teach these subjects in single-sex classes. Arguments for single-sex classes vary. Some argue that there are innate differences between boys and girls that means they learn differently and, therefore, need to be taught differently. However, there is very little evidence to support this argument. Furthermore, such views ignore evidence which suggests that variations within groups of girls and boys are as significant as those between them. On the basis of the available evidence, many scholars reject the notion that there are innate sex differences in learning styles. However, some of these scholars still see benefits in single-sex classes, but for reasons based on social, rather than biological, factors. In relation to STEM subjects, such social arguments tend to acknowledge the effects of long-standing associations between STEM subjects and masculinity, which can have implications for how girls identify, or not, with STEM subjects and also how girls are treated in classrooms. For example, research has suggested that in mixed-sex science classrooms, girls are often marginalized and sometimes sexually harassed; boys dominate the space and equipment; and girls' confidence is frequently undermined. By contrast, single-sex science classes tend to provide more supportive climates for girls in which they build confidence and realize that girls can do science.

Are Single-Sex Science Classes Beneficial?

Researchers have attempted to measure the effectiveness of single-sex science classes in relation to various criteria, including academic attainment; pupil self-concept levels; continuation of the subject beyond compulsory level; confidence; and attitudes toward, and enjoyment of, the subject. Taken as a whole, the findings are mixed, although the weight of evidence suggests that single-sex classes may be beneficial for girls in some ways, for example, in increasing confidence. Reasons for generally inconclusive findings include that many single-sex initiatives are short-lived and often the schools are not clear about the precise purpose of them. Also, schools often implement single-sex classes alongside other schemes or changes, so it is difficult or impossible to disentangle the effects of these. In general, the ways in which single-sex classes are introduced and executed are important determinants of their success; the commitment and support of staff, students, and parents to such initiatives are particularly important.

Criticisms of single-sex science classes frequently relate to how they are taught. For example, there has been important and sustained criticism of programs that treat girls and boys as homogeneous groups and that reinforce pernicious gender stereotypes by tailoring the curriculum in gender-specific ways. Similarly, male classroom teachers who encourage male bonding in all-boys' groups by fostering sexist, macho, or "laddish" attitudes and behaviors have been criticized strongly by pro-feminist and feminist researchers.

Overall, evidence about the benefits of single-sex science classes is mixed. To maximize the potential benefits of such schemes, it is important to be clear about the precise purposes; to ensure staff, students, and parents are well informed and committed; and to implement them in ways that challenge, rather than reinforce, gender stereotypes.

A Situated View on Learning and Cognition

The traditional view of schooling treats knowledge as an independent entity, consisting of abstract, decontextualized formal concepts, which should be transferred from an external source to the learner. A problem with teaching practices based on this view is that they often lead to isolated and inert knowledge. Knowledge domains acquired through traditional schooling are often learned and stored in memory isolated from each other and therefore difficult to access. Inertness of knowledge refers to the problem that students are not well capable of using the knowledge they have acquired to solve problems in practice.

The key idea of situated learning is that knowledge and cognition cannot be separated from the situations in which they are learned and used. The notion of authentic activity plays a key role in this view of learning and cognition. The activities through which people develop knowledge are an integral part of the knowledge itself. Understanding is developed through continued use of concepts in authentic situations. The meaning of concepts evolves through this repeated use and is dependent on the way the concepts are used in a particular culture. Concepts are like tools: the use of them is not self-evident but defined by the way the tools are used in a particular community of practice. In this situated view, learning must involve activities, concepts, and culture, as these three are interdependent. Learning is seen as a process of enculturation in socially organized practices, through which knowledge, understanding, and practices are developed. A student must enter a community of practice and its culture to be able to learn to use the (conceptual) tools in the same manner as the members of that community use them. To learn to think like a practitioner (e.g., a mathematician, chemist, biologist), a student must learn to use the conceptual tools in authentic practice. Students need to be able to use a domain's conceptual tools in authentic activity and to be able to observe teachers who, as experts in the domain, are using those conceptual tools in trying to solve authentic problems in the domain.

Situated Learning and Transfer of Learning

In the situated view of learning, students should learn cognitive tools embedded in the situations in which they are acquired and used. Consequently, the knowledge is bound to those situations. However, in education we often want students to learn to also use their knowledge in situations beyond those in which the knowledge was acquired. Therefore, a tension may exist between the desirability of situated learning and the transfer value of the cognitive tools that students learn. Transfer value presumes that thinking strategies are not exclusively bound to those situations in which they were learned, but that they can also be applied in novel situations and on novel problems. Two types of transfer are low-road and high-road transfer. Low-road transfer is achieved through continuous practicing of strategies, in a variety of situations, until they are automatized. High-road transfer is achieved through deliberate abstraction and decontextualization of strategies. These two forms of transfer have strong similarities with the ideas of "near" and "far" transfer that were used in many science learning studies in the 1970s.

Transfer rarely occurs spontaneously. Learners should explicitly be pointed to similarities between the situations in which knowledge was acquired and other novel situations or domains. The best way to achieve both situated learning and transfer does not seem to be to create a kind of compromise between the two, but to emphasize both actively and alternately.

A Cognitive Apprenticeship View of Teaching

The view that all learning is situated in nature leads to a view of teaching as enabling cognitive apprenticeship. A famous ethnographic study by Jane Lave among African tailors showed very vividly how new apprentices started to learn becoming tailors by participating in the periphery of a community of practitioners. Gradually, as they gained experience with the craft of tailoring, they moved from the periphery to the center of the community. In a similar way, in cognitive apprenticeship students are enculturated into cognitive authentic practices.

Learning is viewed as developing a way of thinking and acting that characterizes the culture of a community of practice. In this type of learning, knowledge is continuously connected to the thinking activities which construct, modify, and use this knowledge to interpret situations in that domain and to act in those situations. In this way teaching and learning of conceptual tools (knowledge, cognitive skills) is integrated with the learning and teaching of the subject domain. Domain knowledge ("knowing what") and strategic knowledge ("knowing how") are taught in continuous coherence. The role of the teacher is one of model, activator, monitor, and evaluator of students' thinking, learning, and problem-solving strategies. Teachers may model these strategies by making overt and explicit knowledge construction and utilization activities that usually stay covert and implicit. Teachers may activate students to use learning and thinking activities that they do not use on their own initiative by means of questions, assignments, etc. When students get more skilled in the use of certain learning and thinking activities (cognitive tools), the role of the teacher may change towards monitoring the use of these strategies in students' self-regulated learning and provide students with feedback on their strategy use. Finally, teachers may want to evaluate the quality of students' strategy use. This paradigm is known as situated modeling, coaching, and fading, an essential element of any apprenticeship model ("scaffolding").

Regarding the regulation of learning, cognitive apprenticeship is characterized by a gradual shift in the task division in the teaching – learning process from the teacher to the learner. First, an explicit control structure is offered to the students, and subsequently this help and support is gradually withdrawn. Simultaneously, students are stimulated to internalize this external regulation of their learning processes, and they are taught the skills needed to do so. Learning to think like a practitioner then means a gradual transfer of control over learning and thinking processes from the teacher to the learners, a gradual shift from external to internal (self) regulation of learning and thinking.

Implications for Science Education

Examples of situated learning and cognitive apprenticeship models in science education are Schoenfeld's teaching of problem solving in mathematics; Freudenthal's realistic mathematics education; context-based approaches in chemistry, physics, and biology education; and problem-based approaches in health and medical science education. In Schoenfeld's approach, students may bring problems to the classroom that teacher and students investigate together in a mathematical way. The teacher and students think aloud and make their mathematical thinking as overt and explicit as possible. In this way, students can witness their teacher's and fellow students' mathematical thinking in authentic practice ("modeling"). In realistic mathematics education, students work on problems that are derived from realistic situations connected to their concrete life experiences. The idea is that students learn mathematics by doing mathematics. The teacher guides the students in "mathematizing" the concrete, realistic problems and going through a process of "guided reinvention" to discover mathematical principles in the problems.

In context-based approaches to chemistry, physics, and biology education, students study authentic situations in society in which science knowledge plays a natural role. They work together on solving a certain problem in a meaningful context, guided by the teacher. Learning is aimed at the continuous connection of important (chemical, physical, biological) concepts to meaningful contexts that students are familiar with from their own experience. In problem-based health and medical science education, for example, the start of the learning process is a problem: a short description of a phenomenon about which students should acquire knowledge. These problems are mostly derived from authentic professional practices. Under the guidance of a tutor, students work together in small groups trying to understand, explain, and solve the problem, during which they develop learning goals for independent study. The knowledge gained from independent study is exchanged between members of the group and used to understand and explain the problem.

Slowmation

Garry Hoban
Faculty of Social Sciences, University of
Wollongong, Wollongong, NSW, Australia

Keywords

Animation; Multimodal; Representation; Slow animation; Stop-motion animation

A “slowmation” (abbreviated from “slow animation”) is a simplified way for university or school students to design and make a stop-motion animation that is played at 2 frames/s providing a slow-moving image that is narrated to explain a science concept (Hoban 2005). It is an innovative way for students to learn science because they engage with a concept in many different ways when creating a slowmation by (i) reading text/images and making summary notes, (ii) creating a storyboard to plan the explanation, (iii) making or using existing models, (iv) taking digital still photos of models as they are manually moved, and (iv) using technology to integrate different modes that make up the final animation.

The explanation can be enhanced with narration, text, or music and is an engaging way to learn because students conduct research and use their own technology to design a sequence of representations culminating in the slowmation, which is a multimodal digital representation (Hoban et al. 2011). The process is very accessible because students use widely available technology such as a digital still camera, a tripod, and any free movie-making computer software.

Through creating a slowmation, students make a sequence of representations as a *cumulative semiotic progression* and their learning is influenced by their prior knowledge, the affordances of the representations created, and the social interactions involved (Hoban and Nielsen 2013). Free examples, instructions, and resources can be found at www.slowmation.com.

Social Epistemology of Science

Steve Fuller
Department of Sociology, University of
Warwick, Coventry, UK

Keywords

Context of discovery/justification; Critical thinking; Philosophy of science; Scientism; Sociology of science; Veritism

Broadly speaking, social epistemology is concerned with normative questions surrounding the organization of knowledge, which is presumed to have an inherently social character (Fuller 1988). A natural way to interpret education in this context is as a promoter of democracy in the knowledge system, specifically by divesting innovative research of its originally elite character by including it in a curriculum available to many (Fuller 2009, Chap. 1). Thus, what first surfaced in specialist journals and monographs later appears in a more digestible form in widely used textbooks. Of course, if by "science" we mean the natural sciences, the relevant translations may require considerable effort. In any case, pedagogy is more than a simplified version of the research process. Rather, its challenge is to demonstrate an easier way to understand an important scientific finding than simply retracing the steps by which it was originally made. Thus, William Whewell (discussed below) distinguished what we now call the "context of discovery" and the "context of justification," the latter understood as the more efficient ex post facto way of reproducing the former. However, the relevant sense of "efficiency" is not merely a reduction in the number of steps needed to grasp the discovery but also an extension of the discovery's significance beyond the intellectual horizons of the original discoverer.

Positions in the social epistemology of science education may be understood in terms of the prospects of realizing this sense of efficiency. Pessimists generally believe that the most we can achieve is the reproduction of elite knowledge in relatively small groups through specialist science education, to which the rest of the population then learns to defer. This has been the path increasingly pursued by "analytic social epistemology," as discussed in the second part of this entry. However, the first part deals with the more generally – though not completely – optimistic approach to the task that has been undertaken in the history of the philosophy of science.

Philosophies of Science as Social Epistemologies of Education

Much of the philosophy of science has been informed, if not outright motivated, by science education concerns, ranging from the university to the school. The eminent natural theologian William Whewell, who coined "scientist" in the 1830s to describe a specialized profession, lobbied to include natural science instruction in Cambridge to enable students to understand the epistemic bases for the ongoing Industrial Revolution (Fuller 2000, Chap. 1). In practice this meant an appreciation of the method of hypothesis and the explanatory power of general theories. In a rather more democratic spirit, Ernst Mach campaigned at the end of the nineteenth century for using the applied arts and other forms of folk knowledge as platforms for formal scientific training in the secondary school curriculum (Chap. 2). He located the value of science more in its contributions to an individual's cognitive economy than in any high-order form of knowledge it might produce. This put Mach at odds with the professional physics community of his day, which stressed the worldview-building (*Weltbild*) character of the discipline. Nevertheless, his perspective proved influential on the logical positivist movement, several of whose members had come to be exiled from physics to philosophy for taking an unhealthy interest in grounding abstract physical concepts in the most widely accessible forms of reasoning and experience. Popularizations of this sentiment included Percy Bridgman's "operationalism," which influenced quantitative research methods in the social and psychological sciences, and Otto Neurath's universal picture language, "Isotype," which he envisaged as integral to workers' education in the promotion of socialism.

An interesting feature of the dispute between Karl Popper and Thomas Kuhn that would come to define much of the philosophy of science in the 1960s and 1970s is that both were involved in science education: Popper had taken a doctorate in educational psychology and began his academic career as a schoolteacher, while Kuhn's first post, which provided the backdrop to Kuhn (1970), involved teaching the history and philosophy of science to nonscience Harvard majors in a newly established "general education" program. Moreover, Popper's and Kuhn's understandings of scientific inquiry were strongly shaped by the two schools of experimental psychology – Gestalt and behaviorist – that were prominent in the middle third of the twentieth century. This led them to stress the broadly "constructed" character of scientific knowledge. But whereas Kuhn understood matters from the standpoint of those who inhabit the construction (i.e., the psychological subjects), Popper saw it from that of the construction's architect (i.e., the psychological experimenter). This led Kuhn to emphasize the relative difficulty and Popper the relative ease with which scientists can change their cognitive orientation. For Kuhn, science education instills a deep, perhaps even inviolable, commitment, while for Popper it provides no more than a convention whose value rests entirely on its consequences for inquiry (Fuller 2000, Chap. 6). Perhaps the most interesting twist that has been given to the constructionist approach by recent sociology of science has been Collins and Evans (2007), whose concept of "interactional expertise" is meant to capture how people not formally trained in a given science might learn enough simply by interacting with the relevant scientists to end up contributing productively to their work. It remains an open question whether this concept is better understood as an elaborate attempt for sociologists to gain the respect of scientists or an updated version of the project to democratize scientific knowledge originally championed by Mach.

Analytic Social Epistemology and the Socialization of Scientism

"Analytic social epistemology" refers to how social epistemology is practiced by the dominant school of contemporary academic philosophy (Fuller 2007). It has tended to interpret the problem of knowledge in science education as a matter of squaring the demands of truth, critical thinking, and trust in expertise. The juxtaposition of these concerns occurs against a presumed background tension between the norms of science and democracy. However, the relatively insular nature of this literature leads to some idiosyncratic framings of the issues that make it difficult for the tension to be expressed as such. "Truth" is typically understood via the doctrine of *veritism*, according to which a truth-oriented inquiry tracks reliable processes of knowledge production that inquirers may not be able to justify for themselves, in which case they may be rationally compelled to rely on the relevant experts. The question then is how to identify those experts. Depending on the students' cognitive development, they might assess competing arguments or turn to the arguers' track records, assuming that prior relevant cases to the one at hand are easily identified and are not themselves contested. Some of the feminist-inspired literature in this vein speaks of "epistemic injustice," which refers to people whose testimony is not trusted because of who they are rather than what they know (Fricker 1998).

As this brief description suggests, veritism fosters "epistemic paternalism" in the words of its leading proponent (Goldman 1999). Veritism's opponents point to a potential tradeoff between critical thinking and truth seeking: the former is valuable only insofar as it facilitates the latter. Yet, critical thinking is to an "Enlightenment" approach to education that would enable students to exercise intellectual autonomy, especially in response to classroom challenges to their default beliefs. This view, which harks back to John Dewey and entered analytic social epistemology through Israel Scheffler and his student Harvey Siegel (1988), gives pride of place to training the entire person to experience life in an inquiring frame of mind over simply ensuring that the student has acquired an epistemically prescribed set of beliefs (and the means required to access them). In the former case, science is simply a more technically specialized version of general life skills, whereas in the latter, "science" refers to the class of experts to whose judgment one should defer under the relevant conditions.

An interesting consequence of veritism's hold over analytic social epistemology is its transformation of the concept of *scientism*. In its original late nineteenth-century incarnation, scientism was a rather diffuse movement inspired by Auguste Comte's attempt to turn modern science into a new "world religion," one modeled on Christendom that would penetrate every aspect of people's lives while providing a universal basis for social cohesion. Although Comte called his movement "positivism," one might also include Marx's dialectical materialism in this development (Frank 1949). However, the most self-consciously active form of scientism was *monism*, whose German standard-bearers, the embryologist Ernst Haeckel and the chemist Wilhelm Ostwald, set precedents for promoting science as a total worldview in the twentieth century – Haeckel on Darwinian evolution and Ostwald on thermodynamics (aka "energeticism"). In each case, some sense that spirit "emerges" from a material complex meant that science could absorb rather than simply annihilate religion. In that sense, contra Max Weber, science could "re-enchant the world," so that, say, eugenics or energy efficiency might serve as the personal ethics corresponding to general scientific principles (Fuller 2006, Chap. 5). While the dawn of the twenty-first century appears to have reinvented this line of thought in, say, Richard Dawkins and James Lovelock, the doctrine that is nowadays both defended and attacked under the rubric of "scientism" does *not* normally refer to it. Rather, in the paternalistic spirit of veritism, "scientism" nowadays refers much more simply to deference to whatever "scientific consensus" obtains on policy-specific issues. In other words, for the analytic social epistemologist, science aims to replace not religious belief but democratic decision-making (Ladyman et al. 2007).

Social Networking

Christine Greenhow
Counseling, Educational Psychology, Special Education, Michigan State University,
East Lansing, MI, USA

Keywords

Facebook; Social media

Introduction

Technological advancements have contributed increasingly to young people's adoption of social media, a term often used interchangeably with Web 2.0 to refer to online applications which promote users, their interconnections, and user-generated content.

Social networking sites like Facebook and LinkedIn are a form of social media widely adopted among adolescents and college-age youth as a dominant technology-mediated leisure-time activity. Social networking sites are defined by the following socio-technical features: (1) uniquely identifiable profiles that consist of user-supplied content and/or system-provided data, (2) (semi) public display of connections that can be traversed by others, and (3) features that allow users to consume, produce, and/or interact with user-generated content provided by their connections on the site. Social networking sites are distinguished from other forms of social media, like wikis, by the emphasis they place on personal profiling features and interactions with other users' profiles and their shared content (e.g., text, hyperlinks, videos).

Social networking sites are used predominantly to connect with those one already knows and less for traditional networking purposes, but sites such as LinkedIn are designed explicitly for building one's list of personal contacts. Thus, social networking sites are Web-based services through which individuals can maintain existing ties and develop new social ties with people outside their network.

Social Networking in Education

Social networking can be integrated into educational practices in elementary and secondary school classrooms, higher education, and informal learning settings. Research on the use of social networking sites in education has focused on its use by students, especially college students, within a particular course, but less on uses for informal learning. Young people use social networking sites for a wide range of purposes, some of which are educational in nature. Learners can make use of their existing online socializing practices, leveraging their social networks for learning functions in direct and indirect support of education-related tasks and values. These social learning functions can include (1) obtaining recognition for and appreciation of creative work through feedback on their profile pages and (2) reaching out to former classmates to give or receive help in managing the ups and downs of high school or college life or even direct help with school-related tasks (Greenhow and Robelia 2009). Selwyn (2009) describes how students' education-related uses of the social networking site Facebook also included post hoc critiquing of learning experiences and events, exchange of logistical or factual information about teaching and assessment requirements, and instances of supplication and moral support concerning assessment or learning.

Clearly, the application of social networking for educational purposes poses some challenges. Kirschner and Karpinski (2010), for instance, found a negative relationship between time spent on Facebook and college grades. More recent research suggests that the manner in which social networking is used makes a difference in whether academic outcomes are positive or negative (e.g., Junco 2012). For example, posting status updates and chatting on Facebook were negatively predictive of GPA, while sharing links were positively predictive. Interacting with fellow students around curricular content or other learning-related topics may be expected to be positively associated with achievement but also with one's engagement in a practice- or interest-driven learning community.

Science Education

At the time of this writing, there are few published empirical studies on the use of social networking in science education. However, social networking in education generally can facilitate new forms of collaborative knowledge construction, communication, identity work, social capital, and civic participation, both online and offline. For instance, social networking can stimulate social benefits, online and offline, which can have implications for education. Social capital refers to resources or benefits available to people through their social interactions and is valuable to feelings of trust, reciprocity, and social cohesion. Researchers have found positive associations between students' use of their dominant social networking site (e.g., Facebook or MySpace) and both bonding and bridging social capital (Greenhow and Burton 2011). Students have reported that social networking is often part of their learning and high school-to-college transition strategy (Greenhow and Robelia 2009a, b).

Social networking can also enable innovative forms of peer collaboration (Zhang et al. 2009). In studying elementary school students within a formal classroom setting, Zhang et al. (2009) found that social networks within Knowledge Forum provided opportunities for students to connect to a broader network of peers and their ideas than they might have otherwise. This facilitated collective responsibility for the learning of the group and dynamic knowledge advancement over time through flexible, opportunistic collaborations, which in turn served to increase the possibility of diverse spontaneous inquiries, flexible participation from group members, and transparency. In particular, participants could see ideas taken up and modified by the group, which helped students grasp an overarching vision of the changing status of their community knowledge and the interactions taking place at the community level.

Collaboration and coordination among a range of participants may be facilitated by the following features typically present in social networking sites: (1) a nonhierarchical structure, where learners have ownership of and can contribute to a public or semipublic space; (2) the ability to asynchronously coproduce content; (3) automatic publishing capabilities; (4) the ability to adapt the layout or functionality of the environment; and (5) the ability to enable geographically distributed, opportunistic, flexible, and dynamic social arrangements rather than centralized or fixed arrangements.

Thus, social networking can play a valuable role in increasing the diversity of idea sharing and facilitating the cooperative or collaborative engagement of teachers, students, and others in the learning process. Students can use social media to provide feedback and support to peers and also share work with an audience beyond their teacher. Connections can be made with teachers, peers, or even students at other levels of education, across different physical locations, and outside specified class times and with the wider community.

In science education specifically, social networking applications can serve to increase students' interest in science-related issues. For instance, Greenhow and colleagues designed an educational application within Facebook called Hot Dish to allow users to post climate change news stories and comment on them as well as complete "eco-friendly" civic engagement activities, both online and offline in their local communities. Located as a tab within one's existing Facebook profile, the key features of Hot Dish included the ability to post original story entries; share articles from online sources; browse or read articles; curate, rank, and comment on posted entries; craft a personal profile; showcase users' statistics and contributions; and participate in Action Team challenges both online and offline (e.g., writing a letter to the editor, signing an online petition, volunteering for an environmental organization, recycling). The research team found that peer role modeling on this site motivated pro-environmental behaviors as well as argumentation about socio-scientific issues (Greenhow and Li 2013).

Applications like Hot Dish show that social networking features can facilitate information sharing about science issues, commentary and debate, and the completion of problem-solving challenges, activities that engage users in activism around those issues. Similar to gaming environments, users can earn points for completing offline challenges, which acknowledge individuals for offline behavior (e.g., environmental activism) and motivate others in the online environment to make their own behavioral changes. Similar data-tracking and representational features could be built into future science education environments to foster targeted learning (and teaching) behaviors, role modeling, or civic engagement.

Social Studies Education and Science Education

David Blades

Keywords

Citizenship; Science literacy; Social action; Social studies; STSE science education

Consider voting on a proposal to build a sewage treatment facility to deal with the sewage currently dropped untreated into a nearby body of water when the costs of construction and maintenance of the facility require an increase in taxes. In order to make an informed decision, voters would need enough science background to understand studies of the risk posed by the sewage to the water ecosystem, a good sense of what constitutes a valid scientific study, and a basic understanding of the potential and limits of the facility engineering and technology. This type of science-related knowledge and understanding is called "science literacy," and since the 1970s achieving the scientific literacy needed for active engagement in such personal and societal decision-making has become a fundamental goal of modern school science curricula. This approach to science was called "STS" (science-technology-society) (Yager 1996) or STSE when it included environmental studies. In the 1980s, the STSE approach was incorporated into the "Science for All" or "Public Understanding of Science" movements; a key feature of these movements was an emphasis on social action in and through science education (Hodson 1988).

However, STSE struggled to gain a foothold in schools, due to a number of complex factors. One was the inability of science to understand what is actually involved in effective political action and the history of social change. For example, to vote on the sewage treatment plant, citizens also need to understand economics, dynamics of local governance, geopolitical issues around locating the facility, and the possibilities for civic engagement. In schools these topics, in various incarnations, are generally the focus and territory of the school subject/curriculum area known as "Social Studies."

Parallel Developments of Science and Social Studies as School Subjects

Social Studies and Science as school curriculum areas each represent amalgams of different fields of study. General science, for example, typically includes physics, chemistry, biology, and Earth science; all fields of study concerned with the natural world. Social Studies includes a range of fields of study in the social sciences, such as history, sociology, geography, and civics, that are aspects of studies of the social world of human societies at various levels, times, and functions.

Social Studies came into being as part of the late nineteenth century humanitarianism movement that, in the early twentieth century, was adopted by progressive educators such as John Dewey. The key goal of the school subject "Social Studies" was the development of students' abilities to engage in social progress though democratic renewal. Dewey recognized that this development would not be effective unless taught in partnership with the skills and understanding achieved through interdisciplinary studies that include science and mathematics.

In the first half of the twentieth century, each school subject was continually challenged as a superficial merging of fields of inquiry that deserved their own subject status if students were to understand the underlying ideas and structure of each discipline. This was particularly true with History but also applied to arguments for an early cleaving of school science into the separate subjects of Biology, Chemistry, and Physics (Goodson 1987). Discussions concerned about what constituted a valid Social Studies or Science Education were further complicated by those advocating separate subjects of study in schools that seems to embody aspects of both Social Studies and Science, such as Geography and, in the second half of the twentieth century, Environmental Studies. The debate over what constitutes a valid study of nature or of society was also affected by the two World Wars that punctuated the history of the twentieth century. In science, the World Wars demonstrated the importance of technological innovation and the need for students to choose careers in science, technology, and engineering, while in Social Studies instruction in ethics and civic responsibility were seen as ways to work toward peace through the education of the next generation.

These complex, generative curriculum discussions were refocused in the industrialized Western world by the launching in 1957 of the first human-made satellite, Sputnik by the former Soviet Union. The effect of this event on science education curriculum reform in North America is well documented. What is less often recognized is that Social Studies as well went through a similar reform process approximately a decade later, becoming what was called the "new Social Studies." While science education moved toward a more technical, facts-based approach to science that emphasized the structures of science disciplines, Social Studies initially moved toward developing interdisciplinary studies that explored the "shared humanity" believed to be part of all social systems. The "new Social Studies" did not fare well as many (including parents, educators, and scholars) insisted on a return of the traditional Social Studies topics of national history, world history, civics, and government. Science curriculum reform initially seemed to be more successful, likely due to massive support by governments and the scientific community. However, by the mid-1970s, it was clear that science education was also in crisis; despite a clear goal of attracting men and women to a career in science, engineering, and technology, the new curricula and associated pedagogies were having the opposite effect.

Science and Social Studies: Interdisciplinary Partners for Social Action

STSE science education was, in part, an effort to redirect science education curriculum reform toward a more socially relevant approach to science education and, hopefully, attract more students to science-related careers. But STSE did not emerge as the major approach to science education in the world. Part of this was due to the development of international testing systems, such as initially TIMSS and then from the beginning of this century PISA, and outcomes-based curriculum development, both of which favor curricula emphasizing scientific content knowledge. In addition the development of a more conservative and economically competitive world, political climate moving into the twenty-first century has had similar impact. A key issue in the lack of adoption of STSE science education was the inability of this approach to science to adequately conceptualize the form, appearance, and direction of social action for students; that aspect of education was assumed to be the responsibility of Social Studies.

The separation of the two subject areas is today more acute and problematic than ever. As human populations continue to expand, citizens increasingly face difficult decisions about issues such as disposal of garbage and sewage, traffic control, homelessness, and continued urbanization. Many of these issues are linked to and affected by broader, global dilemmas humankind collectively faces in the twenty-first century, such as global climate change due to increased use of fossil fuels; trying to find ways to feed, clothe, and employ an increasing human population; the appearance of antibiotic-resistant strains of infectious diseases; and loss of biodiversity – as well as an expanding pollution of sources of freshwater and ocean habitats. As well, discoveries in science and technological innovations, such as the development of non-decomposing plastics, genetic engineering, and humanoid robots demand an increased public debate and involvement in the directions of science, engineering, and technology.

School science education can provide a foundation for students to acquire the literacy to understand the key science of these issues, but remains barren in the expertise to assist student development of effective avenues of social action. Social Studies, with a large repertoire of interdisciplinary understanding of the history of societies and how governments operate, can inform science students about methods of social engagement but is somewhat barren, except perhaps in providing a historical perspective, on the science knowledge needed to fully understand current and future issues arising from science discoveries and technological innovation.

Recent efforts to reconceptualize science education as a merging of science, technology, engineering, and mathematics (STEM) and STSE, and a rise in the discussion of values in science education (Corrigan et al. 2007) as well as what might constitute a “citizen science” education (Roth and Barton 2004) may yet serve to foster a more socially engaged science education while also inviting students to consider careers in science, technology, and engineering. But this reform still needs to form a school subject partnership with Social Studies to make progress toward Dewey’s vision of education as a vehicle of democratic renewal. The development of the Internet and social media in the twenty-first century may prove to be the most important technological innovations in this direction. While some argue that it is too large a challenge for the average citizen to think of their responsibilities outside their immediate social situation and geographical locale, there is emerging evidence that youth with access to social media, news media, and the Internet already see themselves as “citizens of the world.” Their global perspective presents an important and timely opportunity for the education of students as local and global citizens, aware of their civic responsibility and able to engage with their peers and others in a democratic, planetary discourse when dealing with urgent issues that cross borders, such as water pollution, climate change, loss of topsoil, and the continued development of technologies of destruction. As well, we look to this generation for the development of new, hopeful technologies that can feed and clothe the growing population and the scientific discoveries that enable a reengineering of societies toward sustainable practices that benefit all species on the planet. These are demanding expectations and to rise to challenge students need a generative, interdisciplinary education, especially issue-focused partnerships between Science and Social Studies.

Socio-Cultural Perspectives and Characteristics

Peter Charles Taylor
Faculty of Science, Curtin University, Perth,

Keywords

Ecological consciousness; Indigenous knowledge systems; Ontological relativism; Sciences of all; Sociocultural; Social constructionism; Worldview

During the closing decades of the twentieth century, science education researchers embraced personal construct theory and explored the many interesting ways in which students develop "misconceptions" of the natural world which differ significantly from the canonical scientific view. Pedagogical strategies were developed to enable teachers to detect and remedy these intuitive ways of making sense of everyday experience or, for most students, of the canonical representations contained in the artificial world of the science textbook. The later arrival of social constructivist theory emphasized the crucial role of negotiation and consensus in making sense collectively of personal experience. This resulted in more discursive learning environments in which students negotiate their developing canonical understandings. Science curricula and pedagogies shaped by constructivism and related theories, such as socially situated cognition, continue to work well in assimilating students into the canonical scientific worldview, which was born in the eighteenth-century Age of Enlightenment and has given rise to today's political imperative of *science for all*.

At the same time, however, a political awakening was taking place among science educators with a strong social conscience and a deepening concern about how science and technology are implicated in global crises, such as climate change, that are threatening the well-being of humanity and the planet's ability to sustain all forms of life. These radicalized researchers shifted their attention away from the dominant psychological focus on cognitive activity and embraced sociologically inspired investigations of the cultural relevance of science curricula to peoples worldwide. Researchers reached into other disciplines – philosophy, linguistics, anthropology, politics, and sociology – and adopted powerful sociocultural perspectives to explore critically the history, philosophy, and culture of science and science education.

Most sociocultural theories are underpinned by the *ontological relativism* of social constructionism (e.g., Berger and Luckmann 1966) which holds that explanations of the world are culturally and historically contingent. In other words, none of our explanations necessarily reveal the essence of "things in themselves”; instead, ideas, concepts, and theories are social constructs which are transformable. This transformative perspective applies to scientific knowledge of both the natural world and the social world. In the latter case, social activists are emboldened to transform seemingly natural attitudes and social actions that they perceive instead as cultural products. The rise of qualitative social science research paradigms – *interpretivism*, *criticalism*, *and postmodernism* – has greatly facilitated these transformative inquiries and interventions.

One of the first notable interventions in science education was conducted by critical feminist researchers who identified gender as a social construct rather than an inevitable result of biology. From this perspective, feminist scholars revealed and contested the implicit masculinist culture of science education, especially its girl-unfriendly representations of science in textbooks. Their research demonstrated how a dominant masculine culture had served as a barrier to girls’ participation and achievement in science and to their subsequent selection of science-related careers. The result of this research has been the development of gender inclusive science curricula and pedagogies; in many countries, girls are now outperforming boys in science and mathematics.

As science educators reached further afield, they encountered a range of sociocultural theorists whose powerful ideas have continued to challenge us to radically rethink the fundamentals of science and science education. The following is a small sample of the best known:

- The German Frankfurt School yielded Jurgen Habermas’ theories of *communicative action* and *knowledge constitutive interests*, which have helped to identify disempowering ideologies embedded in the social fabric of educational policies, science curricula, and pedagogies and have brought a moral/ethical perspective to considerations of what constitutes emancipatory social relationships in the science classroom.
- Notable among the French *poststructuralist* and *postmodern* philosophers are Jacques Derrida, Pierre Bourdieu, Gille Deleuze, and Michel Foucault whose sociocultural theories have fuelled deconstruction of the sociological foundations of education systems and institutions, of which science education is an integral part, revealing otherwise invisible economic, political, historical, and cultural assumptions and identifying whose (human) interests are not being well served.
- From Russia, Aleksei Leontiev’s and Lev Vygotsky’s *culture-historic activity theory* provides a framework for analyzing the dialectical relationship between social activities of individual actors (e.g., teachers, students) and the social structure of the organization in which they are embedded (science classroom, school, society). This social constructionist perspective also focuses on the mediation role of language in constructing meaningful ideas, with implications for the role of the child’s “mother tongue” in the science classroom.
- From the UK, *sociology of scientific knowledge* (*ssk*) *theorists*, especially David Bloor and Harry Collins, have drawn on the work of Thomas Kuhn, cultural anthropologists, and linguists such as Wittgenstein to portray science as “shot though” with social influences and scientific knowledge as socially contingent; good news for cultural relativists who advocate an inclusive “sciences of all” curricular standpoint.
- From various nations at the leading edge of political decolonization movements of the twentieth century, the *postcolonial theorizing* of Paulo Freire, Frantz Fanon, Gayatri Spivak, Edward Said, and Homi Bhabha has fuelled cultural studies researchers’ endeavors to neutralize the dominance of the Western modern worldview in science curricula and research, particularly for minority youth in Western countries and majority youth in recently independent nation states (with a special focus on indigenous people).

Sociocultural perspectives constructed from these sources (and elsewhere) are providing renewed impetus to *worldview* research conducted in the early 1990s by science educators such as Bill Cobern. Contemporary culture studies researchers are documenting indigenous knowledge systems (IKS; also known as traditional ecological knowledge (TEK) and funds of knowledge) embedded in traditional community practices of indigenous peoples worldwide. This research is enriching the fields of ethnoscience/mathematics established mid-twentieth century by researchers such as Ubiratan D'Ambrosio. For some time, culture studies researchers have been considering the thorny question of how to reconcile the tension between Western canonical science and indigenous knowledge in order to include IKS as a legitimate part of standard science curricula; the debate is ongoing. Leading culture studies science education researchers include Glen Aikenhead (Canada), Masakata Ogawa and Ken Kawasaki (Japan), Liz McKinley (New Zealand), M. B.Ogunniyi (South Africa), and Greg Cajete (Mexico).

Research employing sociocultural perspectives is transforming our understanding of science and science education and is enabling us to grasp the moral and ethical need for a *socially responsible* science education that prepares future generations with the knowledge and skills to resolve the legacy of global crises, especially loss of biocultural diversity. Indigenous researchers influenced by sociocultural perspectives are conducting studies of their local communities and designing culturally contextualized science curricula to contribute to young indigenous people embracing modern science while also learning deeply about and respecting their own indigenous knowledge, cultural identities, languages, and community practices (e.g., Aikenhead and Michell 2012; Afonso Nhalevilo 2013). By drawing on cultural traditions that honor the connectedness of people and the natural world, it is believed that indigenous knowledge systems will be a source of authentic *ecological consciousness* that can help to revive our sense of stewardship of the planet.

Dedicated journals such as *Cultural Studies of Science Education* and special issues of journals such as the *International Journal of Science and Mathematics Education* (Abrams et al. 2013) are important means for legitimating and disseminating this innovative research.

Sociocultural perspectives have helped us realize the pressing moral and ethical need to complement our endeavors to deliver *science for all* with well-researched curriculum perspectives on *the sciences of all*.

Sociocultural Perspectives and Gender

Kathryn Scantlebury
Department of Chemistry & Biochemistry,
College of Arts & Sciences, University of
Delaware, Newark, DE, USA

Keywords

Culture; Science education

A sociocultural perspective of science education infers that there is a dialectical relationship between cultural production and creation. Cultural production involves an actor's agency and engagement with schema. When cultural creation is passive, that is, an actor is not actively engaged with culture. When culture is enacted, actors are dialectically involved at both individual and collective levels with cultural enactment in social fields (Tobin 2012). Within a social field, an actor's identity is a combination of one's own construction of self along with how one is constructed by others. Thus, identity is simultaneously fixed and changing.

Gender is a social category and as such structures any social interactions, including those that constitute schooling and science education. As a social category, gender is constituted on the *structural*, the *symbolic*, and the *individual* levels in society. The *structural level* examines how gender influences the organization of society (Harding 1986), for example, examining the division of labor by gender. In science, there is a consistent pattern of more women working in the biological sciences compared to the physical sciences. The biological sciences are perceived as having stronger connections to humans and other living things compared with the focus in physical sciences on innate objects. The former being more feminine and the latter masculine is one explanation for this gendered pattern. The *symbolic* level of gender uses dichotomies where the oppositional pairs are assigned a feminine and masculine meaning (e.g., nature/culture, emotion/rationality, subjectivity/objectivity) that infers what are appropriate practices for women and men. For example, the symbolic level describes science as rational, difficult, and hard, with disembodied knowledge. Thus, both structurally and symbolically, science is a masculine gender practice. In contrast, teaching, especially children, is described as nurturing and caring, which is symbolically feminine. Gender at the *individual* level is influenced by structural and symbolic levels. However, a person's agency can change or modify one's identity based on gender because the levels exist in a dialectic that can impact and transform *structural* and *symbolic* gender. Participants' gendered identities are differentiated in different cultural fields. And one's gender is a major construct on how others construct our identity (Scantlebury 2012).

Typically, science educators use gender of the individual rather than a social context. And as such, gender is often conceptualized as a dichotomy of girls/women/boys/men with the associated descriptors for feminine and masculine traits. There is a lack of *knowledge about gender* in science education research. Many of the studies do not offer a critique of the "gender" concept but focus on comparing female and male students on variables such as achievement, participation, engagement, and attitudes toward science. Butler (1990) challenged the notion of gender by conceptualizing it as performative, and within this framework the research should focus on the intersections between gender, sex, and sexuality. However, science education research has not embraced that the term "gender" is broader than feminine and masculine nor has the field engaged in a critique of the heteronormative language and practices used in science teaching and curriculum materials (Scantlebury 2012).

Moreover, while it is important to consider how gender impacts at the individual, symbolic, and structural levels, feminist researchers view intersectionality as a critical analytical tool to examine how overlapping social categories such as gender/sex/sexuality, race, social class, language, religion, etc., impact a person's identity and also social categories at the symbolic and structural levels. A crucial aspect of *intersectionality* is to view the interplay between different social categories that are unbounded and intertwined and examines society's power hierarchies and differentials (Lykke 2010). This interplay of gender with other social categories can impact and influence participants' achievements and attitudes in science and science education, science pathways and experiences in education, and informal science experiences.

Calabrese Barton (2008) suggested that science educators could utilize the concepts of intersectionality, counterknowledge, and solidarity to define critical science agency. Counterknowledge foregrounds the knowledge and experiences of those who have lived on society's margins, and solidarity reflects how a collective can become agentic to change social structures (e.g., women's involvement with ecological feminism to improve living conditions for their families). Currently, many science educators use gender as a category when often their analysis is based upon girls/women/boys/men (i.e., biological) differences. In order to understand the increasingly complex social fields within science as culture, we should engage with poststructuralist perspectives on gender.

Socio-Cultural Perspectives on Learning Science

Wolff-Michael Roth
Applied Cognitive Science, University of Victoria, Victoria, BC, Canada

Keywords

Activity theory; Bakhtin; Contradiction; Culture; Dialectics; Vygotsky

Introduction

Sociocultural is an adjective that tends to be used in the Anglo-Saxon scholarly literature when research refers to and employs a range of concepts that have emerged in the particular domain of social psychology developed in the former USSR. Most fundamentally, the adjective is used to denote an epistemology that – in its original conception – uses society, culture, and history as the defining characteristics of human beings. It is also used to refer to a broad, internally highly differentiated movement with very different interests and approaches. The founder of this social psychology was Lev S. Vygotsky (1896–1934), sometimes referred to as the Mozart of psychology. After his premature death, Vygotsky's collaborators and students continued to elaborate and develop this form of psychology. Recent theoretical approaches in this perspective also include in their intellectual heritage the literary theorist and philosopher Mikhail M. Bakhtin (1895–1975) and his circle (V. N. Vološinov, Medvedev) (Depending on the language into which the works of these scholars are translated, alternative spellings of Vygotsky's Russian name (Rus. Выготский) include Vygotski (Fr., Sp.), Vygotskij (ling., Ital.) and Wygotski (Ger., Pol.); the name Bakhtin (Rus. Бахтин), depending on language, also is spelled Bachtin (Ger., Pol., Ital.), Bakhtine (Fr.), and Bajtín (Sp)). The Anglo-Saxon use of the adjective "sociocultural" actually is the result of an unfortunate, and likely politically motivated, choice to substitute the original Russian (from Vygotsky) and German (from Karl Marx) equivalents of *societal* with the linguistically associated but conceptually different adjective *social*. Together with society, Vygotsky, and his students and followers, emphasized *history* so that a more appropriate rendering adjective, as this occurs in some other languages, would be *societal–historical* (or cultural–historical).

Society as the Determinant Factor of Specifically Human Characteristics

The *societal–historical* perspective is fundamentally grounded in Marx's insight that what is specifically human is based on the societal relations in which an individual has participated.

Thus, Vygotsky chose to explicitly refer to Marx when suggesting that all higher psychological functions first are *societal relations* before being *psychological functions* that can be attributed to an individual. More recent analyses show that these functions operate, for the first time, in a societal relation between people. Thus, the ways in which scientists orient each other to, and come to understand, images at work are the same ways in which infants and toddlers and their mothers employ when they begin to read books. From this perspective, personality is the totality of the societal relations that a person participates in, and is subject and subjected to, at any one point in time. From this perspective, therefore, inequities in science achievements between students from the working and under-classes – including those living in poverty or the homeless – and those growing up in the middle and upper classes become understandable in terms of societal issues. In the latter classes, parents tend to spend more time with their infants, toddlers, and children – reading with them about animals or taking them to zoos and science museums – than those from the former classes, where families often struggle simply to make ends meet and to satisfy their basic needs. Thus, despite the rhetoric that comes with such agendas as *No Child Left Behind* (USA), the existing inequities in a society with respect to scientific understandings reproduce themselves with the different kinds of societal relations that children and youth come to participate in. In the Russian source language of the theory, therefore, as well as in the languages that retain the adjective, the *societal*–historical approach lends itself to critique – highlighted especially by those continuing Vygotsky's tradition, including A. N. Leont'ev, S. L. Rubinstein, and, subsequently, K. Holzkamp and the Berlin Critical Psychology group. The originators of the societal–historical perspectives recognized that psychology fulfills an ideological function and, in so doing, serves interests that tend to be those of the middle (bourgeois) class. The adjective *societal* explicitly makes this critical dimension possible, whereas the adjective *social* does not imply inequalities that derive from societal structure. The alternative adjective works against the ideology of an egalitarian society in which every individual is said to have the same potential and opportunities. This critical dimension of the societal–historical approach continues to be of importance in German-speaking countries and Scandinavia; but it is lost when the adjective is substituted by "social."

Marx's insight that *society* is what determines specifically human characteristics is saliently exemplified in the work with deaf and blind children conducted by Meshcheryakov. This work shows that without interactions with others, these children existed in a vegetative state, without any "innate" intention to explore, as Piaget proposed would be the case, and who did not stand upright let alone walk. These children were not incapable (e.g., genetically/intellectually). They subsequently developed specifically human capacities, including not simply learning to use material tools (like a spoon to feed themselves) but being guided to reflect on (by means of their developing intellectual tools) the material tools as objects in their own right. Some of these children, initially found in a vegetative state, subsequently developed to the point that they became university professors. That is, their explorative intentions were not "natural" and innate but rather developed while participating in intentional activities with others and reflecting on the objects involved in the activity and on the activities as a whole.

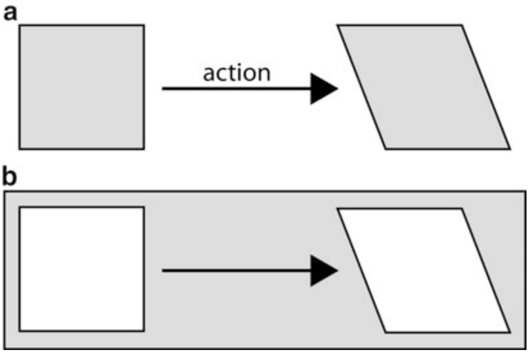
Unit Analysis Replaces Element Analysis

Theoretical Foundation

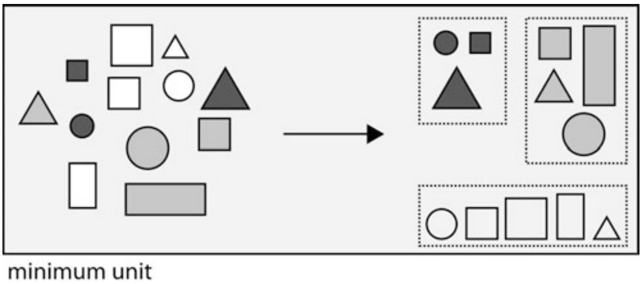
In the societal–historical approach, the unit of analysis shifts from the individual to the collective. Underlying the approach is the attempt to work against the reductionism of cognitivist and biological approaches to exploring learning. Vygotsky suggested that there are two types of analysis used in psychological research: analysis by means of decomposition of a whole into elements, comparable to the analysis of water in terms of the elements oxygen and hydrogen, and holistic analysis, equivalent to the analysis of water as hydrogen oxide. According to Vygotsky, the former is to blame for "all" the failures to understand psychological forms, whereas only the latter is the "correct" starting point for doing a first step in the direction of understanding the human psyche. Vygotsky metaphorically elaborated this contention by saying that to understand why water extinguishes fire, we need to look at the properties of water rather than at the properties of oxygen and hydrogen. When science educators research learning in terms of emotions, or beliefs, or mental frameworks, or conceptions, they reduce the complex human being to elements. This contrasts with the alternative approach that seeks to understand learning in the sciences from the fullness of (everyday) life. In the latter approach, learning in/of science is understood in terms of all the activities in which a person lives in the course of a day, week, month, or year rather than within a particular activity, such as the science classroom. *Perezĭvanie* – which translates broadly as experience and feeling – is one such all-encompassing, irreducible unit that comprises the characteristics of the person, characteristics of the environment, and the temporal unfolding of both.

The following analogy is useful for distinguishing these two approaches, these two forms of analysis (Fig. 1). In this analogy, we model the shearing process that turns a rectangle into a parallelogram. In the common (reductionist) approach, complex phenomena are reduced to elements that are thought to be composing the phenomenon, and these elements are individually considered. Thus, in the example, the element is a square (e.g., representing prior science knowledge). A shearing force external to the square (a cause, e.g., representing an experience) acts upon the shape, changing it into a parallelogram (e.g., postexperience knowledge) (Fig. 1a). That is, there is an observable effect. The parallelogram is another element or, rather, the new shape (form) of a given material entity.

Unit analysis is different; because it is intended to capture change itself, unit analysis requires a minimum unit of *change*. This situation is represented in Fig. 1b. The entire situation including square, parallelogram, change, and time is all part of the minimum unit. In contradistinction to the preceding analysis in terms of elements, all of the square, the dynamic of change, and the parallelogram no longer can be conceived independently. These are taken as different ways in which the unit *manifests* itself. This unit would therefore focus on learning rather than on prior and post-unit knowledge. This also leads to the fact that there are no longer independent causes and effects, a characteristic of all process philosophies from Heraclitus to the present day: A cause is a cause because there is an effect, and there is an effect because there is a cause. This actually captures the observation that in the consideration of processes, we can attribute causes only after having observed something denoted as the effect. In science education research, a teaching method such as the use of analogies might be said to cause higher achievement or conceptual change. Yet in any particular case, a student from an experimental group (using analogies) might achieve less than a student from a control group (not using analogies). That is, whether a science curriculum is a causal force bringing about learning or conceptual change can be decided only after the fact, only after making the observation in any particular case.



Socio-Cultural Perspectives on Learning Science, Fig. 1 Element analysis versus unit analysis. **a** In element analysis the square is the unit, which, subjected to a shearing action (cause), is turned into a parallelogram (effect). **b** In unit analysis, the entire process of change is included in the minimal unit; beginning, end, and everything in between are constitutive parts of the whole



Socio-Cultural Perspectives on Learning Science, Fig. 2 Fundamental to the conceptualization of the socio-cultural approach is that it attempts to grasp change. The minimum unit of analysis therefore has to be one of change rather than one in which elements are subject to external forces

A Practical Example: Classifying

Classifying is one of the core scientific skills. The research literature shows that from as early as 2 years to being a mature scientist, doing science involves classifying objects and events. In the example of the classification of objects typical for a second-grade classroom shown in Fig. 2, the entire activity beginning with the pile of objects until the point of three ordered groups would constitute the minimum unit for a unit analysis approach. This inherently implies all the interactions between students, between students and their teachers, the particular division of labor that was enacted, the forms of participation and the particular rules that were practiced, and the means of production in use. Thus, for example, in the case of leaf classifications, we might consider making available field guides. The societal–historical perspectives then would lead us to anticipate that classifying leaves with and without field guides will change the outcomes. There are studies that exhibit the considerable differences in classification if the field guides employ photographs or drawings, the latter, against expectations, making classification easier than the former. Also, students might create resources for classification, such as a plastic bag with core examples of different categories of leaves. In this case, the activity transforms itself, as new tools are produced and, therefore, change the nature of the activity. As a result, we should expect very different outcomes with the use of technologies. Moreover, from these societal–historical perspectives, we should expect the observed outcomes of activities to change if students are tested in the absence of such tools.

Classification also will be different as a function of culture. This was quite explicit in research that Luria – a founder and leader of what sometimes is referred to as the *Vygotsky circle* – conducted with Kazakh peasants. Asked to sort skeins of wool by color, they refused and suggested this was an impossible task as all the colors differed. According to a Piagetian perspective on human development, these peasants were of lower cognitive capacity than most Western children. However, it turns out that the experience of attending school changed the ways in which these peasants would classify. That is, the cultural and historical (presence or absence of institutional forms of learning) mediates classification and, therefore, the outcomes of the testing activity. We should therefore not be surprised if children growing up in an aboriginal setting with strong focus on cultural heritage – e.g., in Australia, in New Zealand, in Hawaii, or on the Canadian and US Northwest coast – should engage in leaf classification and other science activities related to nature very differently than students in more urban areas and surrounded by more typical Western culture. We should expect that the schooling of science, as well as the schooling of traditional ecological knowledge, would change the ways in which students understand and, therefore, how they would learn and develop with respect to scientific knowledge.

Implications of Unit Analysis

Choosing a minimum unit (category) that is change itself leads to the position that change is the norm (e.g., learning, development) and stasis (knowledge, conceptual framework/structure) is the exception. Whereas in the classical case change (learning, development) is problematic, in the societal–historical approach, stasis is problematic (knowledge, conceptual framework/structure). Every time students engage in and with science, they change – though the nature of the change is not predetermined. For some students, a given science curriculum leads to learning and conceptual change; for others, however, even the best-designed curriculum might turn them away from pursuing a career related to science.

Within this perspective, society – its material and cultural aspects – is understood as a self-moving system. There are no outside (divine or other) forces that bring about the change. In the same way, there are no outside forces that change knowing and understanding. Participation in the activity of schooling, concretely realized in the science classroom, *is* change. There is no being outside of consciousness (knowledge) that makes consciousness develop, in the way that it might appear in constructivist approaches (i.e., a subject constructs its knowledge as if the subject could exist outside of its knowledge). Vygotsky explicitly critiques this latter approach that makes thoughts appear to think themselves.

Vygotsky's coworkers, students, and followers point out that society and its history constitute the relevant unit for thinking about knowing, learning, subjectivity, and personality. The smallest unit, therefore, has to be one that has all the characteristics of society as a whole. This unit, emphasized especially in that perspective referred to as cultural–historical *activity theory*, is an *activity*. Examples of activities include farming, manufacturing, and, pertinent to the present context, *schooling*. To understand what happens in science classrooms, therefore, the smallest unit would be that of schooling (rather than the student, or a group of students, or a teacher, or classroom, or school, and so on). There then exists a whole–part relation between this smallest unit and those aspects in which it manifests itself: school, classroom, teacher, students, curriculum materials, and so forth. Thus, we cannot understand the science student independent of the schooling the student is experiencing: the whole (i.e., schooling) requires students; and to be a student in the way this term is commonly understood requires the societal activity of schooling. Taking only one identifiable part changes the whole and, because of the change in the totality of relations existing within the whole, each part also changes. Drawing on Vygotsky's water analogy, if we take away the hydrogen from water, what remains is a different whole: oxygen. Its behavior and characteristics are very different from the preceding whole, which while it included hydrogen had no behavioral or characteristic similarities with either hydrogen or oxygen. Similarly, if we were to remove all students from schooling, what remains would not be schooling in the way we know it.

In the perspective presented here, material and intellectual tools play an important role. Most tools are used to change the material world. Intellectual tools come in the form of signs, including the various forms of inscription scientists' use and language. These allow humans, as Vygotsky explicitly noted, to control their brains from without. To understand language as a *living* phenomenon, we need precisely such a unit. Thus, language is alive when it changes every time it is used, every time someone articulates a word. A language is dead (classical Latin being one example), no longer changes, when it is not used.

Inner Contradiction

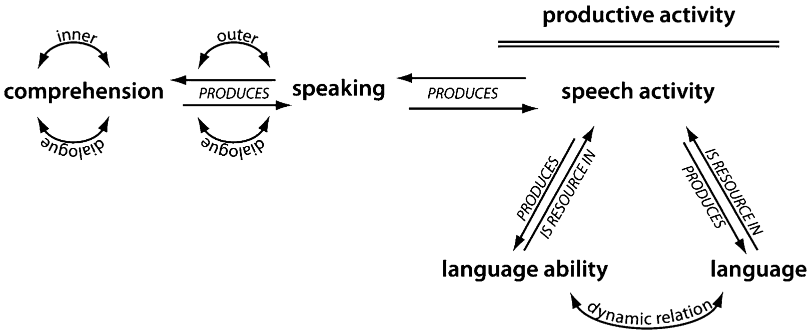
Contradiction is one of the most important categories in the formulation of the societal–cultural perspective on learning. This is immediately apparent when we consider the case depicted in Fig. 2 (and Fig. 1b). We can look at the unit and make one of two observations. These observations differ: the unit manifests itself in one or the other observation. That is, precisely because the minimum unit covers an activity from beginning to its end, we will make differing observations depending on the instant of time when we observe. There is a second way in which observations will differ: these depend also on where we look in the activity. We will make different observations when looking at one (e.g., a child) rather than another individual (another child, the teacher), at the materials (e.g., the after the first few objects being moved), at division of labor (which may change), and so on, even though all of these are part of the same unit (e.g., pereživanie). Classical logic suggests that these differences are the result of looking at different times or at different aspects (people) or the result of different people looking ("interpreting") at a situation. But Vygotsky's dialectical logic, which is based on taking a holistic perspective, suggests that the different manifestations are due to the *inner* difference *within* the unit considered – e.g., in Fig. 1b, the *unit* is a square and a parallelogram simultaneously – rather than *between* elements. Vygotsky explicitly rejects analysis by elements and suggests that only thinking in units will give proper theories of human learning and development.

A second form of *inner* contradiction exists in the fact that in societal–historical approaches, the material (physical) and ideal (mental) are theorized as two sides of the same phenomenon. What happens materially during a science laboratory experiment and the ways in which the events appear in consciousness are two manifestations of the same unit: the activity *as a whole*. Thus, children who classify the shapes in Fig. 2 not only do something materially but also find the material reality reflected in their consciousness and in their affect. Consciousness and affect are understood to be in a dialectical relationship, because each aspect is a manifestation of the current activity. These manifestations are not identical, though they are manifestations of the same (unit). Activities are characterized by their outcomes. Initially, these outcomes exist only on the ideal plane simultaneously with the reflection of the current material state. The participants in the activity orient to these anticipated outcomes. There is then an inner contradiction between the copresent reflection of the present state and the anticipated future state of the activity, the production process.

Dialogue and the Development of Speech and Language

To understand the dynamic nature of language, one has to theorize it as a moving phenomenon. Bakhtin and Vološinov therefore insisted that language changes every time that it is *used*, which always transforms the thing (e.g., Fig. 1b); moreover, they suggest for this reason that the word constitutes the same kind of dialectical unit. With every word or sentence usage, scientific language changes. This then explains how words, such as *atom*, come to be the same and different simultaneously not only from a historical perspective but also from the perspectives of individual development or that of language in a concretely unfolding situation. We can also understand the historically changing ways in the discursive organization of fields, for example, the changes from structure to function in the teaching of biology, or the changing ways in which an individual physics or chemistry teacher might talk about a certain topic from the beginning to the end of her career. The changes are not just changes in individual speech ability but changes in the language at large. Thus, Bakhtin provided a concrete analysis of the changing nature of the novel genre. He suggested that this change could not be understood if we aligned on some trajectory all the forms that the novel has taken historically. To achieve a coherent account, each novel had to be understood instead as a manifestation of current *general* culture and language. The changing nature of language, which occurs because mundane language is changing, leads to the different forms the novel takes. Every change of scientific language is a change in general language, which is the ground upon which any and all scientific languages are built.

Following Vygotsky and Bakhtin, who shared the conviction that dialogue is the origin of language, scholars working from this perspective tend to be very interested in the role of language in science learning. Pertaining to language, its use, comprehension, and development, everything is happening in real, affective–emotive societal relations where concrete speech activity



Socio-Cultural Perspectives on Learning Science, Fig. 3 Model of the relation between the different components in speaking and language

takes place (Fig. 3). Speech activity is subordinated to and constitutive of activity. Activity generates and drives speech activity, which, in turn, generates and drives societally motivated activity: There is a mutually constitutive relation. It is precisely here that we find the word, a phenomenon that integrates interlocutors: speakers and listeners.

Speech activity is concretely realized through speaking and replying, which is based on comprehension, including that of the speaker who comes to know his/her thought (after the fact) in the expressions used. Again, there is a mutually constitutive relation, as speaking concretely realizes speech activity but is produced in the service of the latter. In a conversation, there are interlocutors, who not merely externalize what is their own but who speak *for* the others using language that is not their own but has come to them from the other. Some science educators, therefore, suggest that "misconception" talk is inherently intelligible and shared: science educators understand this talk all the while knowing that it is different from the talk they intend students to use. To properly understand the phenomenon of speaking, it needs to be analyzed from the perspective of hearing, which implies comprehension. Comprehension itself is a dialogical process on the internal plane, and, in fact, all speaking has its genetic origin in *dialogical* speech. Thus, inner dialogue is the psychological reflection of outer dialogue, where it has its origin both at the cultural–historical (phylogenetic) and individual developmental (ontogenetic) levels (Fig. 3). The subjective reality of an *inner voice* is born in its *externalization* for the other. It therefore becomes what it is simultaneously for the other and the individual.

The generative role of speech activity *in societal relations* is shown in the model in Fig. 3 as the arrow from speech activity to language ability, whereby participation in the former is the origin of the latter. At the same time, language ability is a requisite in speech activity: the relation between the two is mutually constitutive. The same mutually constitutive relation exists between everyday speech activity and scientific language. Any change in everyday, scholarly, and aesthetic language emerges in and arises from common speech activity in societal relations, becoming a feature of language as a structured system. Simultaneously, there is always already a language that serves as a resource in scientific speech activity. As a result, we obtain a relation between individual language ability and the language of society. The relation between language as a societal phenomenon and language as a psychological phenomenon is a dynamic relation – and so is that of language as a system and language as a capacity. In terms of the perspective outlined here, speech activity is the category that sublates (overcomes and preserves) and therefore mediates between language as a system and language as a capacity, each of which is a (one-sided) manifestation of the overarching whole.

Thinking and Speaking

In the classical theoretical approaches from Aristotle to Augustine to present-day psychology, speech expresses on the outside what has been thought on the inside and, therefore, what is already represented in the structures of the mind (e.g., conceptions). In the societal–cultural approach, the relationship between speaking (the material dimension of an activity) and thinking (the ideal dimension of an activity) is much more complex. If we consider the situation of an individual student or teacher spontaneously speaking during a science class, then speaking and thinking are taken to be two related *processes*, each contributing to shaping the other, but neither taking precedence. In fact, the two processes are manifestations of one higher order process: *word signification* [Rus. *značenie slovo*] (Vygotsky) or theme [Rus. *tema*] (Vološinov). This overarching process makes it that the same word, even if spoken multiple times in the same unfolding situation, is never the same (never has the same function). Recent studies in science education – as those by Vygotsky and Bakhtin before – show that although there is a stable sound formation, intonation especially, in the articulation of a specific word, the placement of the same sound word changes how it is heard (semantics) and what it achieves (pragmatics). But what a science word achieves in any situation can be known only subsequently. Thus, individual speakers in spontaneous (science lecture) talk will find their thought in what they have actually said rather than expressing what has been thought out in all its details before speaking. Moreover, science education research has shown that language itself is a resource for articulating thoughts even when we have never had these thoughts before. Thus, when asked about some scientific phenomenon – e.g., distance, relative movement, and relative orientation of sun and earth – people respond even if they have never thought about it before. In fact, they may even say they have not thought of this before and still respond to the question. Thus, being familiar with sunrises and sunsets easily allows someone, a child or a Harvard graduate, with rudimentary language competencies to say that the sun moves – it rises in the morning and sets in the evening – rather than that the earth spins around its axis. Because of the everyday experience that the warmth experienced near a heat source changes with the distance to it, it is reasonable for someone to suggest that the earth is closer to sun in summer, especially if one has had no information to the contrary.

From this perspective, the word is not a property of the individual. Any word specifically, and language more generally, is a feature of culture and, by definition, impossible for one person. When a child talks about a phenomenon in a way that some science educators assert constitutes a "misconception," this misconception is enabled by and exists in language. Even if a sound or other sign was to be created and used by a single individual – e.g., Einstein's publication of the special theory of relativity – this would be based on the general practice of communicating by means of signs. Moreover, even when a sound word (science concept) is used for the first time, it implies the understanding of another. This is why other scientists could, for example, understand Priestley when he presented his ideas about "*dephlogisticated* air" (oxygen), even though the adjective had not existed before. Thus, with every sign initially used by one person also comes the possibility of general, shared use. Every idealization inherently implies reproducibility, both by the individual and other persons and, therefore, intersubjectivity.

Intellect and Affect

In the works of Vygotsky, Bakhtin, their students, and their followers, intellect and affect are theorized as two sides of the same coin. They are not independent, somehow *inter*acting elements that determine human behavior, as is conceptualized in most psychological theories. Piaget, for example, described affect as a sort of energy source (gasoline) to a motor (intellect) that does not change the structure of the motor. In the present perspective, on the other hand, intellect and affect are two sides of the same coin: different reflections of the same activity. This holistic conception of activity obviously also leads to the position that affect is not something that can be thought independent of intellect. According to Vygotsky, the separation of affect and intellect is the essential reason why traditional psychological theories fall short of understanding human behavior. This is so because there appears to be an autonomous stream of thoughts thinking ("constructing") themselves irrespective of the interests, motives, and impulses of the *whole* person. As recent research suggests, this means that to understand learning in the science classroom we need to look at the whole person, in the course of leading a life that includes but does not reduce itself to the science classroom. What we observe in the science classroom is a function of its place in a hierarchy of all the daily activities in which the person participates. This, as some studies in this field show, changes what we observe. If teaching physics is fourth in a list of importance for the teacher – following religion, family, and missionary activities – then what happens in and around the physics lessons will differ from observations we might make when teaching physics is the primary activity of the teacher.

From the perspective articulated here, affect and intellect are manifestations of the same activity. Affect is an indication of the difference between the current state of activity and its intended outcome. Being unable to progress through a science activity may be marked by both frustration (affect) and by the understanding that one is stuck (intellect). However, continuing with attempting to progress through the activity may lead to becoming "unstuck," which would be accompanied by more positive affect; on the other hand, not continuing is very unlikely to change the negative affective tone. Thus, even though both teacher and student might be frustrated about how far they are from understanding the task and each other, the only hope for getting closer to achieving their goals is to go on and to engage despite the frustration. Studies show that without this attempt to engage, there is no movement and students and teacher remain frustrated. With engagement, they can hope to get closer to the goal, which in turn tends to be reflected by more positive affect. Of course there is no guarantee that engagement leads to learning and more positive affect; quite the contrary, the parties involved might increase the distance to the intended goals of the science activities or come to understand that there are insurmountable barriers. In both situations, the tonality of affect will tend to be more negative.

Considering affect together with the expansion of action possibilities that emerge from cooperation with others leads us to understand two forms of learning: *expansive* and *defensive*. Expansive learning arises from the fact that in and through our participation, all of our action possibilities, our room to maneuver, and our control over conditions expand. Such expansion is inherently related to more positive affect. This might well explain why students often prefer working in groups. We engage in certain actions even though they may involve hardship when doing so increases our possibilities (e.g., success on an exam) once we are through the hard part (e.g., studying for an exam). Defensive learning denotes the situation where we engage in learning only to avoid sanctions (e.g., receiving a low grade, school suspension). It then becomes completely understandable that some students become perfect cheaters: To avoid low or failing grades, one can become good at a practice that avoids the real goal of the activity, knowing and understanding science, but still achieve the desired outcome (e.g., passing or high grade). When students do not accept the motive of activity, passing or high grade in science, then there is nothing teachers can do to motivate them: the students "don't care anymore." It is quite apparent that this societal–cultural perspective no longer requires us to operate with such concepts as individual motivation.

Learning and Development

One important aspect of the societal–historical approach that is often not well understood pertains to the distinction between learning and development. For Piaget, there existed two different processes, *assimilation*, in which new experience is associated to and understood in terms of existing mental schemas, and *accommodation*, a restructuring of mental schemas to make them appropriate for thinking about experiences that previously could not be understood. The two are very different, independent processes. For Vygotsky, on the other hand, learning and development are related; but learning, he insists, always precedes development. The two are related even though learning refers to a (quantitative) accretion of understanding and development to a qualitative change of understanding that is followed by a fundamental change in the forms of experiences that the person has. To understand this relation requires dialectical thinking, where, as developed by Marx, quantitative change leads to qualitative change. This change from quantitative to qualitative can be observed involving: (a) a particular form of initial understanding (conception); (b) objective changes in the environmental conditions that lead to a contradiction within the person; (c) the emergence of a new form of understanding (conception) existing *side-by-side with* the older type/s of experience; (d) change in dominance from the prior to the new form of understanding (conception); and (e) experiences in terms of the qualitatively new form of understanding (conception). Here, there are two qualitative changes: first, the emergence of a new form of understanding; and, second, the change in the nature of the dominant form of understanding. In this model, the older form of understanding (conception) is not eradicated, as some science educators have previously suggested has to occur in the case of misconceptions, but exists side by side with the older form of understanding (conception). This actually models quite well our everyday understanding that an astronomer can marvel at the beauty of a sun*rise* or sun*set*, a Ptolemean perspective, all the while using a Copernican perspective at work or while teaching astronomy. It has been shown that this societal–historical perspective can be modeled using catastrophe theory, a form of mathematics that combines quantitative and qualitative dimensions to explain the emergence of new forms (e.g., conceptions, talk), that is, morphogenesis.

An important concept that Vygotsky initially introduced to show how learning leads to development is that of the *zone of proximal development*. It was initially defined as the difference between a child's current cultural practices and those that it could enact in collaboration with a teacher or a more competent peer. The latter are said to *scaffold* the individual who is less competent at the task. For example, children in an early childhood science lesson may not arrive at the desired categorization of objects depicted in Fig. 2; they would be considered to be operating at one developmental level. But in the interaction with their teacher, they do achieve the categorization; in this societal context, they are operating at another developmental level. This change then precipitates operating at this more advanced level on their own because with the teacher they already operate at the higher level until they are in a situation to operate at this level on their own (similar to children learning to ride a bicycle by having adults first stabilize the bicycle until they can stabilize it themselves). In contrast to the nature-driven cognitive development in (Piagetian) constructivism, in the societal–historical approach development is mediated by culture.

In this example, the idea of the zone of proximal development is employed asymmetrically: metaphorically the teacher pulls the child to a higher level. However, new research in this perspective has shown that groups of equally capable students achieve *beyond* the developmental levels of any individual in the group. When children engage in the classification of objects such as depicted in Fig. 2, not only the product of activity but also the learning opportunities change if they work alone or in groupings with others, if they interact or not with the teacher. Moreover, recent STEM studies show that in groups with asymmetric experiences, even those to whom more initial knowledge is attributed learn from the group experience. Thus, for example, there are studies in science education showing that not only do science teachers continue to learn to teach while teaching (i.e., pedagogical content knowledge), also they learn and come to better understand the science content. That is, any time people work together in collectivities, that is, when they engage in societal relations with others, we can observe learning and development. Working in and as constitutive parts of collectivities leads to learning by expansion. It is likely for this reason that some scholars, such as Engeström and Holzkamp, have suggested alternative ways of understanding learning that occurs in relations with others. Thus, the zone of proximal development should be thought of in terms of the whole unit of analysis, which changes when a new form of activity is created in the collaboration of two or more individuals (cf. studies on coteaching science or studies on collaborative learning in the science classroom). As a result, there is a distance between current everyday actions and those possible in cooperation with others. In other words, the range of possibilities for individuals and their control over existing conditions increases in the cooperation with others for the purpose of achieving common, general goals; in this cooperation, any individual also increases control over individual conditions. Working with peers and teachers on the classification task (Fig. 2) in the societal activity of schooling not only expands what is collectively achieved but also what the individual can achieve, for example, the affective experiences that come from and with achievement.

Opportunities and Continuing Problems

The societal–historical perspective has proven to be of tremendous use for understanding and planning what happens in science classrooms. Most fundamentally, it shifts our attention from the individual to the collective (the group, class). With this shift, relations to others, language, and the all the material, cultural, and historical dimensions of the setting in which change and learning occur, all come to be made thematic. Despite the tremendous positive impact this perspective has had, there continue to be a range of problems. As science educators reading the works of Vygotsky, Leont'ev, Bakhtin, and other Russian scholars may note, there are sometimes tremendous differences in content and quality between the texts rendered in Russian and their native tongues and the English versions. This will not come as a surprise, as specialist scholars recognize the highly variable quality of translations into some Western languages. Some translations are more exact than others, that is, more in the spirit of the original Russian works. For example, the German and Italian versions of Vygotsky's *Thought and Language* are recognized to better represent what Vygotsky was writing and the spirit underlying his approach. The first English translation of this text omitted many crucial passages, and even the second, somewhat better translation has been criticized for leaving out materials or for incorrectly translating individual words and passages. It has almost completely changed the sense of what Vygotsky has written. The same is the case for the translations of Bakhtin and the members of his circle. Again, the English translations have been labeled as inferior to those that have been produced for other languages. One of the requirements for the continued evolving fruitfulness of the approach therefore would be better translations and a greater attention to the role of society, unit analysis, and the nature of a category (i.e., unit).

Sociology of Science and Science Education

Sociology of science offers a number of important contributions to the study of science education. The role of history and philosophy of science is well documented in the development of science curricular materials, but sociology has had a more minor influence in this area. Nonetheless, sociology of science offers an important alternative to the normative views of science often found in applications of philosophy of science to science education. Philosophy of science, particularly from the empiricist tradition, has tended to provide a normative account of theory change, with a focus on the rationality and structure of scientific theories. This has contributed significantly to science education by focusing on the importance experimental work and documenting the value of reasons for theories of conceptual change. History of science has similarly been drawn upon to provide case studies relevant to the development of scientific knowledge for the purposes of teaching concepts and theory change. Sociology of science offers a clear alternative by focusing on the social nature of scientific practices and studying such practices in contemporary settings.

Robert Merton (1973) was instrumental in the development of sociology of science as a field of study. He was concerned, in ways similar to philosophers of the time, with understanding how scientific knowledge was uniquely certifiable. His program of study documented the ways that knowledge in science was certified through social processes adhering to four institutional imperatives: universalism, communism, disinterestedness, and organized skepticism. While these norms were criticized in subsequent developments in the sociology of science, the program of research provided models for the empirical study of scientific practice.

A new sociology of science emerged from the philosophy of Wittgenstein's *Philosophical Investigations* (1958) and Kuhn's (1962) *Structure of Scientific Revolutions*. These sociological studies examined epistemological questions from an empirical point of view. Building on Wittgenstein the scholars sought to understand how meanings were embedded in social practices. These programs of study (e.g., strong programme, empirical programme of relativism) shifted away from the views of philosophy and Mertonian sociology concerned with verifiable and certified knowledge to leave questions about the resolution of controversies and conclusions open to empirical investigations (Kelly et al. 1993). Thus, such studies sought to study the *actual* practices of science through detailed, empirical study, prior to knowing whether a given social group's claims would count as science. This empirical stance and openness provided interesting applications for science education.

Science education has long been interested in promoting goals that include the conceptual knowledge of scientific theories along with knowledge of the nature of science. The sociology of science provides new insights into the inner workings of science and offers the potential to expand the repertoire about what counts as scientific practices in educational settings. Since much of the work of sociology of science has included ethnographic studies of sociocultural practices, discourse analysis of interaction, and institutional analysis, these methodological tools have been viewed as models for investigating the nature of science as it is interactionally accomplished in school science as through detailed, empirical analysis of social interaction. Thus, sociology of science provides ways of expanding what counts as science and ways of investigating science in schools, without specifying detailed normative accounts of scientific theories, practices, or natures.

Applications of sociology of science to science education have led to the empirical study of what counts as knowledge in educational settings. This stance directs attention to examining science-in-the-making as students and teachers seek to construct knowledge and propose ways of understanding through interaction. Such studies draw from educational ethnography and discourse analysis to consider how social practices are constructed, appropriated, and communicated through social interaction over time (Kelly and Chen 1999). Implications of these studies include the needs to consider the social practices that establish knowledge in educational settings. By examining the processes involved in knowledge construction, educational programs can build a more robust view of science and provide potential scientists and non-scientist citizens ways of understanding institutional values and social practices of science. Such examination can demystify the processes leading to scientific knowledge and offer a basis for evaluating the epistemic status of scientific conclusions.

Criticisms of sociology of science as a field are similar to those levied against the application of sociology of science in education. Such criticism focuses on the adherence of seemingly non-epistemic reasons appertaining to the development of knowledge claims. This criticism can be countered by recognizing that reason and rationality are themselves the products of social practices, relying on the social and contextual basis for meaning, institutionalization of norms over time, and the acculturation of members into particular ways of knowing for specific epistemic communities. Nevertheless, sociology of science has demonstrated that the sometimes contentious, agonistic nature of scientific debate that may not be most appropriate for learning science, including even the nature of science. Sociology of science and its implications need to be read and understood from an educational point of view, where considerations of social and cognitive development, pedagogy, and ethics are competing interests with notions of authentic scientific practices.

Increasingly sociology of science and its application in science education have become interdisciplinary. For example, studies from the anthropology and rhetoric science of science have informed both sociology of science and science education. Philosophers are increasingly acknowledging and referring to studies of scientific practices in developing epistemological accounts of science. Thus, the emerging of sociology of science with other empirical studies of science has led to the multi- and interdisciplinary field of science studies, where disciplinary boundaries are less certain or relevant. These science studies are relevant to understanding how scientific practices can be introduced, developed, recognized, and acknowledge in science education settings. The development of interests in environmental sciences, socioscientific issues, and argumentation in science education can be informed on the increasingly detailed, specific, and methodologically inventive science studies.

Socioscientific Issues

Dana Zeidler
University of South Florida, Tampa, FL, USA

Keywords

Learning; Pedagogy; Research; Scientific literacy; Teaching

Socioscientific issues (SSI) are a conceptual framework used to guide theory, research, and practice in science education with the ultimate aim of fostering scientific literacy. The framework draws on empirical research and scholarship mainly from psychology (developmental learning theory including moral reasoning and cognitive reasoning, character development), sociology (individual and group identity, community, formation of social norms), philosophy (metaethics, normative ethics, virtue ethics), and critical areas of science education that are conducive to the enactment of SSI in curriculum planning and pedagogy. In short, the SSI movement provides a conceptual framework that unifies multiperspectival epistemological orientations of students and considers the role of emotions and character as key components of science education. Used in their ideal form, SSI contain the following main characteristics:

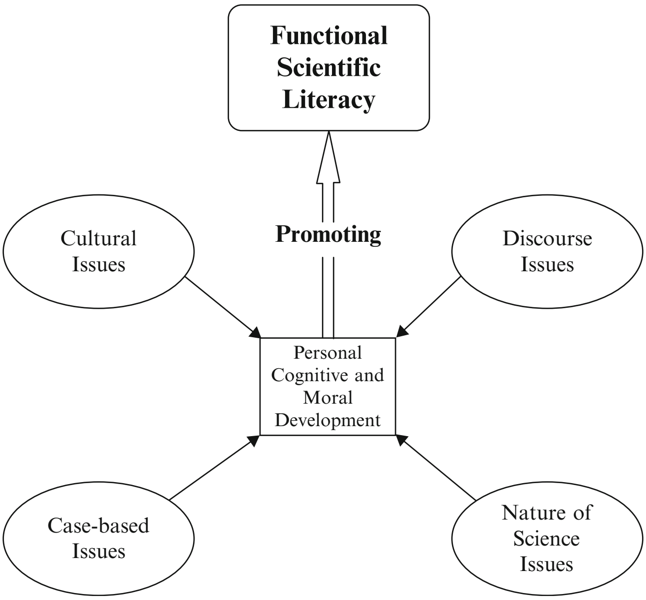
- Controversial and ill-structured problems that require scientific evidence-based reasoning to inform decisions about such topics.
- Deliberate use of scientific topics with social ramifications that require students to engage in dialogue, discussion, debate, and argumentation.
- Tend to have implicit and explicit ethical components and require some degree of moral reasoning.
- Formation of virtue/character as a long-range pedagogical goal is often associated with SSI.

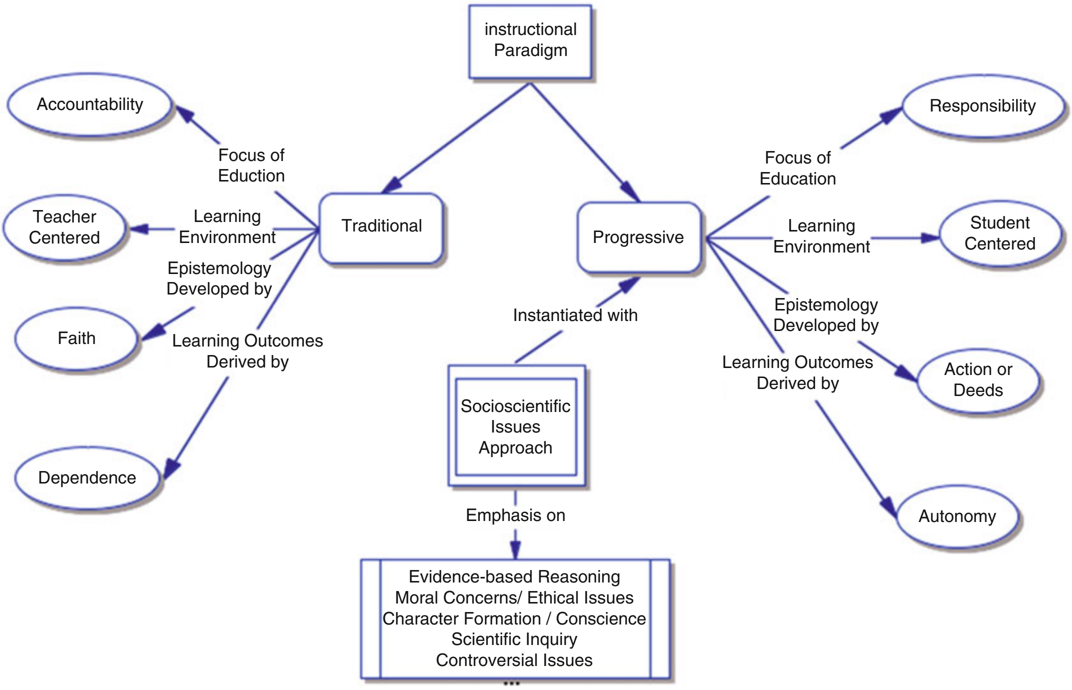
The overarching pedagogical goal is to engage students in the activity of science through exploration, inquiry, questioning, and discourse as they explore issues that are personally relevant to them, as well as relevant to societal and global world views. Deeper conceptual understanding of subject matter becomes necessary to more justly come to resolution of these topics.

Figure 1 depicts a simplified view of key areas of science education, prevalent in the research literature, that are typically tapped to provide a network of understanding while engaging in SSI curriculum development and pedagogy (Zeidler et al. 2005). These areas represent research programs in and of themselves, but can be tapped to help initiate SSI pedagogy. Likewise, there is a reciprocal relationship whereby SSI may help to foster developmental growth in these areas as well. At the center is the nurturing of constructs related to epistemological beliefs that subsume character, morality, rational evidence-based reasoning, emotive reasoning, empathy, caring, and the like – that all contribute to a “functional sense” of scientific literacy. The emphasis on “functional” is important in that it distinguishes between those individuals that may be technocratically competent and those that are ethically astute in the application of judgments that require technical competence – the latter comprising functional intellect and moral inclinations.

SSI are aligned with a progressive view of scientific literacy. Figure 2 contrasts traditional and progressive instructional paradigms and their associated outcomes. Of course, the figure shows extreme endpoints of a teaching continuum and

Socioscientific Issues, Fig. 1 Socioscientific issues framework





Socioscientific Issues, Fig. 2 Pedagogical continuum of learning traditions and outcomes

actual classroom practices may entail movement along different dimensions of the extremes. However, in its purest form, SSI pedagogy stands in contrast to traditional teaching practices and encourages students to prioritize multifaceted factors including interpreting issues, decision-making, solving problems, and engaging in argumentation(Zeidler and Sadler 2008). Certainly, the focus tends to be more on the students rather than the teacher. Attention to these factors is also consistent with ideas that define the "Vision II" orientation to science education found in recent literature.

The term "socioscientific issues" is sometimes written using a hyphen (i.e., socio-scientific issues). While this may be done to appeal to a sense of grammatical style, the use of the terms sans hyphen can also be understood to be quite deliberate. For some, the unassuming hyphen cleaves the social context that such issues entail apart from the science that undergirds them. While it may be suggested that this is an overly academic point, some view the distinction as fundamentally important. The argument is one that views the bifurcation of science into nonnormative components (e.g., data gathering, observation, predictions, scientific methods and processes) and normative components (e.g., prescribing courses of action, choosing to create selected products, decisions about what *ought* to be done) as one that is fraught with peril. While such a distinction is, arguably, conceptually important, it can create a splintered view that allows for the abdication of any sense of responsibility during the practice of science. Some science educators simply do not wish to inadvertently drive a wedge between science proper and the social context in which it resides. That separation is an artificial divorce.

Certainly, SSI can be used as a means to provide a context for argumentation about efficacy of scientific evidence without attention to moral reasoning. Likewise, SSI can be used as a context to develop argumentation skills without attention to the formation of character. Or perhaps SSI may be used as a context to develop more robust understanding of NOS but pay no attention toward an epistemology of human flourishing. This is one reason to choose to use the word "socioscientific issues" rather than the hyphenated version of the term.

The contextualization of scientific content into the problems, experiences, and interests of students' lives is of paramount importance in SSI pedagogy as well as curriculum development. For example, SSI can be used as a forum for the teacher to challenge students' core beliefs about subject matter and conceptual understanding of that discipline. The findings from research suggest that differences in content knowledge are related to variation in the quality of informal reasoning (Sadler and Zeidler 2004). More specifically, students that possess more advanced understandings of scientific knowledge relevant to the issue under scrutiny have greater quality or reasoning on SSI and generally commit fewer instances of fallacious reasoning flaws.

Likewise, SSI can be used as a forum for a teacher to challenge students' normative beliefs related to ethical issues surrounding a given topic. Students are expected to provide justifications for their beliefs related to stances on various topics and challenged to make reasoned judgments about scientific data. Students can also serve as their own facilitators as they discuss, debate, argue, and evoke related forms of discourse to collectively render judgments on vexing normative problems associated with particular issues. These features reflect the kind of sociomoral discourse that is a significant part of the SSI classroom. When students are compelled to consider counterpositions and evaluate evidence or claims from varied sources that may be at odds with one another or dissimilar with their own beliefs, cognitive and moral dissonance is generally created. Dissonance can further be assured when conflicting social norms must be prioritized (e.g., life, affiliation, law, morality and conscience, contract duties, obligation, upholding virtue, social contract, equity, relationships, etc.) thereby creating stronger moral tensions. Dissonance of this nature compels students to negotiate and resolve conflicts and enhances the quality of their own arguments or stances. Using argumentation provides a valuable means to challenge students' critical thinking and reasoning processes, and it mirrors the discourse practices used in real life in the advancement of scientific and intellectual knowledge. Alternative strategies to argumentation and debate include guided discussions led by the teacher and other forms of group inquiry to investigate common claims made in the media or reside in peer groups.

One of the more long-term and "deeper" goals of SSI pedagogy is aimed at the formation of character (Zeidler and Sadler 2008). In contrast to some notions of character education where students are expected to become socialized and compliant to prescribed norms, the development of character under the SSI framework is centered on the formation of conscience. This is accomplished through a process of normation and requires continuous self-reflection and reflexive thinking. It requires the individual to evaluation and scrutinizes their own reasoning and actions and asks how those tasks can be improved. In short, it is akin to seeking the development of conscience and the seeking of virtue in the Aristotelian sense of deeds par excellence. In this sense the development of character requires something more than mere metacognition; it requires the evaluation of actions in terms of their fit with context. This reflects the dual nature of developing conscience. On the one hand, it requires the ability to look forward and anticipate the possible consequences of decisions and consider important factors like long-term consequences, short-term consequences, impact on the physical and social environments, and impact on different stakeholders. On the other hand, it requires the ability to look backward and understand the historical factors that contextualize the boundaries of the issue at hand. This requires the cultivation of a collective social memory and empathy for past historical environmental and social injustices. It is by these processes that the long-range goal of character development is to be realized. Character by way of normation fosters the inclination to want to do what is right and match moral reasoning with moral behavior.

SSI education has been empirically investigated and particular outcomes have been documented in the literature (Zeidler et al. 2009). For example, studies have linked SSI to outcomes that are important both in science education and general education (Zeidler et al. 2011). Examples include outcomes that include (but are not limited to):

- Promoting developmental changes in reflective judgment
- Moving students to more informed views of the nature of science
- Increasing moral sensitivity and empathy
- Increasing conceptual understanding of scientific content
- Increasing students' ability to transfer concepts and scaffold ideas
- Revealing and reconstructing alternative perceptions of science
- Facilitating moral reasoning
- Improving argumentation skills
- Promoting understanding of eco-justice and environmental awareness
- Engaging students' interest in the inquiry of science

More recently, SSI research has been focused on cross-cultural comparisons and research has reflected international partnerships (Zeidler et al. 2013). It has been hypothesized by some that more advanced stages of epistemological reasoning allow individuals to apply a kind of socioscientific reasoning (SSR) akin to scientific habits of mind. SSR is a theoretical construct that entails the ability to tap key traits while negotiating SSI (Zeidler and Sadler 2011). These include skepticism, complexity, multiple perspective, and inquiry. Advanced levels of epistemological reasoning are desirable precisely because those stages allow for the integrated exercise of SSR. It should be noted that indirect evidence exists as well as analytic arguments for the importance and connection of SSR to SSI research and practice. This is certainly an area worthy of future exploration.

Assessment of SSI outcomes for research purposes has clearly been reported in the literature. However, large-scale assessment of SSI curriculum outcomes and instruction is challenging. High-stakes testing like PISA or TIMSS may simply be at odds with the highly contextualized nature of SSI instruction. Outcomes such as epistemological or reflective reasoning, civic engagement, character formation, and the like are simply not conducive to large-scale international assessments. However, there are multiple examples of products for evaluation useful for teachers to consider for their own local classrooms. Such products or artifacts might include:

- Written arguments
  - Poster board presentation
  - Position papers
  - Brochures
  - Letter to the editor (business, school officials, congress, senator, etc.)
- Discussion format
  - Small and large group settings
  - Individual participation within group
  - Debate, report to committee/commission/board
  - Use of effective questioning strategies
- Research efforts
  - Performance of investigative/inquiry research/survey
- Alternative media
  - Power point, video, reenactment, PSA, and video blog

There are numerous ways variant forms of rubrics can be used by teachers to assess the quality of students' evidence-based reasoning as well. Because of the unique nature of each science classroom and the characteristics of students' developmental abilities, the following combinations are left up to the individual teacher:

- Validity of evidence
  - Assertions backed by empirical data

Indicator questions: Validity of evidence – Are student assertions backed by empirical data? Was the correct interpretation of data or use of evidence relevant to position or argument?

- Source of evidence
  - Perceived credentials of study or researcher

Indicator questions: Source of evidence – Has the source of evidence been considered and/or weighted? Have the perceived credentials of study or researcher been examined? Where did the source of the data originate?

- Quality of data
  - Contrasting data based on implied or definitive findings

Indicator questions: Quality of data –Is contrasting data based on implied or definitive research? Have sample size, random versus nonrandom samples, age of data, kind of data, or other data-related issues that play a role in the evaluation of evidence been considered?

- Methodological factors
  - Features and design implications of study

Indicator questions: Methodological factors –Have design features and that have methodological implications of the study been considered?

- Scientific content
  - Interpretation of data in regard to science content

Indicator questions: Scientific content – Is the student's interpretation of the data correct? Have appropriate data in relation to the issue under investigation been selected properly? Have interpretation, weight, and meaning been considered?

The wealth of empirical data reported in the international science education literature supports the position that socioscientific issues are and continue to be a worthwhile use of classroom time that results in valuable pedagogical and developmental outcomes.

Student Peer Assessment

Angela Lui and Heidi Andrade
Division of Educational Psychology and
Methodology, University at Albany, State
University of New York, Albany, NY, USA

Keywords

Peer evaluation; Peer feedback; Peer instruction; Peer judgment; Peer marking

Definition

Peer assessment is a process during which students consider the quality of a peer's work or performance, judge the extent to which it reflects targeted goals or criteria, and make suggestions for revision (Topping 2013). Peer assessment is task specific; the assessment is of the quality of the peer's work, not a student's abilities or personal qualities. The peers can be in the same or different grade, of similar or different ability levels, and can be randomly assigned, teacher assigned, or self-chosen.

Although peer assessment can serve both formative and summative functions, it is important to emphasize the richness of information that comes from formative, non-evaluative peer feedback (Topping 2013). While summative peer assessment, also known *as peer marking* or *peer evaluation*, is usually limited to grading or scoring, formative peer assessment contains qualitative information on the strengths and weaknesses of another student's work as well as suggestions about next steps toward targeted goals and objectives. Therefore, while peer assessment can be used summatively, it is more typically applied in a formative fashion (Bryant and Carless 2010).

Theoretical Framework

Theory and research on peer assessment are grounded in scholarship on feedback, formative assessment, and constructivist learning. A constructivist learning environment that encourages trusting relationships and communication among peers allows for diagnoses of understanding and misconceptions, and honest feedback (Topping 2013). Feedback that is substantive, supportive, and timely can promote learning (Hattie and Timperley 2007). In terms of formative assessment, feedback to learners and teachers involves three main processes: (1) determining, clarifying, and understanding the goals, objectives, and expectations for the task; (2) gathering evidence of and interpreting students' current knowledge and skills through relevant performance tasks; and (3) providing feedback that teachers and students can use to move forward (Wiliam 2010). Under the right conditions, learners can provide useful feedback for each other through interactions between the *assessee* (the peer being assessed) and *assessor* (the peer providing the feedback).

Carefully structured peer assessment helps learners seek answers to three questions that coincide with the process of formative assessment described by Hattie and Timperley (2007) and Wiliam (2010):

1. **Where Am I Going? Goal Setting**
   An understanding of the learning goals for a task is a critical aspect of feedback. As such, one of the major components of peer assessment is the articulation of assessment criteria and expectations, whether through the distribution of rubrics, co-creation of

criteria, or explanation and discussion of expectations and goals (Topping 2013). Interactions between teacher and learners and between assessors and assessees about the criteria and expectations for the task can enhance understanding of where they are going, ensure similar interpretations of the goals by teachers and peers, and promote a shared sense of commitment to attaining them (Hattie and Timperley 2007).

2. **How Am I Going? Progress Monitoring**
   Another important element of assessment is information on the learner's progress toward the targeted goals. Such information can include feedback on the performance relative to the goals and expectations or as compared to prior performance. The use of a structured process of critique is helpful for ensuring constructive peer feedback.
3. **Where to Next? Moving Forward**
   The influence of feedback on learning is based on the learner's decisions about where to go next or what to do to deepen learning and improve performance (Hattie and Timperley 2007). Concrete suggestions for improvement and timely opportunities for revision are essential.

Important Scientific Research and Open Questions

Research in different countries has focused on the academic and social benefits of peer assessment; teacher, parent, and student perceptions of its value; and validity and reliability. Much of the available research has focused on writing and has been done in higher education contexts, although children as young as 9 years of age have been successfully involved in the process of peer assessment (Topping 2013).

Research suggests that there is a positive relationship between achievement and peer assessment, particularly in noncompetitive cultures and when learners are trained in constructive feedback techniques. For example, students who engaged in peer assessment that emphasized strengths, weaknesses, and suggestions for improvement of their writing tended to produce higher-quality final drafts than those who received only teacher feedback (Topping 2009, 2013).

Research has also revealed a relationship between peer assessment and social skills. When teachers create a classroom community where learning targets are clearly defined for students and constructive peer critiques are implemented for the purpose of revision, the frequency and quality of help seeking, help giving, and students' attitudes about asking for help have improved (Topping 2009).

Peer assessment can be beneficial to the assessor as well as to the assessee. Observing and critiquing a peer's work places sophisticated cognitive demands on assessors, including monitoring, detecting, diagnosing, and correcting performance and listening, explaining, questioning, and summarizing a concept. Taken together, these high-level cognitive processes can promote the internalization of knowledge and self-assessment by the assessor (Topping 2013).

Studies of the perceived value of peer assessment indicated individual and cultural differences. For example, teachers and parents of children in primary grades seem to value peer assessment more than the students do. Both primary and secondary school students without training or experience had concerns about this assessment practice, but in a study of students in secondary school, learners acknowledged the ways in which assessment of their peers naturally promoted thinking and reflection on their own progress and performance (Topping 2013). Learners tended to devalue peer assessment in high-stakes educational contexts, competitive classrooms, and when assessment was used for purely summative purposes (Bryant and Carless 2010; Topping 2013).

Research on the reliability and validity of peer assessment or peer marking has examined the degree to which learners' assessment of their peers' work is consistent with their teachers'. The results have been mixed. In instances when peer assessment was found to be inconsistent with teachers' assessment, the quality of training in peer assessment and students' level of involvement in the process were questionable (Topping 2013). In contrast, when learners were taught the appropriate processes, there tended to be surprisingly little difference between peer assessors' and teachers' evaluations. The more elaborated the feedback, however, the more variance there was between the responses of different assessors. In short, when students are trained in the assessment process, reliability is generally at least adequate (Topping 2009).

Although a significant amount of research has shown peer assessment to be a promising instructional tool, more work is needed to understand its implementation and outcomes and to address a concern about the generalizability of the technique across age, culture, and subject areas. Optimal peer feedback procedures should be determined for a variety of contexts in order to ensure high-quality implementation (Topping 2013). Research on peer assessment should expand to more comprehensively examine the elementary and middle school grades as well as language learners and students with disabilities. The role of peer assessment in contexts that stress high-stakes testing should also be examined. Finally, claims that the peer feedback process enhances the self-esteem and social connectedness of children who are socially rejected or disliked (Topping 2013) should be empirically tested.

Self-evaluation

Definition

Many terms have been used synonymously with self-assessment, including self-evaluation, self-reflection, self-monitoring, self-rating, self-scoring, self-marking, and self-grading (Andrade and Valtcheva 2009; Brown and Harris 2013; Falchikov and Boud 1989). Broadly, self-assessment refers to an evaluative process during which students assess and provide feedback on their own work. Falchikov and Boud (1989) suggest that self-assessment can serve both formative and summative purposes. From a formative perspective, self-assessment contributes to the learning process by focusing students' attention on areas in need of improvement: Students use their assessments to determine the extent to which they have met designated task criteria or standards and to identify areas of improvement. Serving a summative purpose, teachers can use student self-assessments for grading. Regardless of the purpose of self-assessment, Falchikov and Boud (1989) contend that self-assessment (a) is criterion referenced, meaning that the act of assessment must involve explicitly stated criteria, standards, or expectations, and (b) involves comparisons of one's own work to that set of criteria, standards, or expectations.

Broader and narrower definitions of self-assessment have also been proposed. Taking an expansive stance, Brown and Harris (2013) argue that the act of self-assessment should not be restricted to evaluating work against "socially agreed criteria" (p. 368) because doing so limits the ability to investigate and distinguish between the effects of different types of self-assessment. This broad conception of self-assessment involves students making formative or summative judgments about the characteristics of their work or capability to do work. The judgments may be quantity estimates, such as grading, or quality estimates, such as comparing aspects of one's work to a set of criteria.

Andrade (2010), however, proposes a narrower definition of student self-assessment as a formative, task-specific process during which students first generate feedback on the quality of their work by assessing the extent to which it meets explicitly stated criteria and expectations and then, through a process of revision, use their self-generated feedback to improve the quality of their work and deepen their learning. Andrade emphasizes the formative nature of self-assessment, indicating that self-assessment is done on works in progress in order to inform revision and improvement. According to this definition, a distinction is made between self-assessment and self-evaluation, the latter being a summative process whereby students assign themselves a grade. Andrade warns that summative self-assessment might not promote learning to the same degree as formative self-assessment methods because in summative self-assessment the students' intentions are to produce a desirable yet defensible score rather than to generate useful feedback for revision (Andrade and Valtcheva 2009). Andrade also made a distinction between self-assessment and self-reflection, suggesting that self-reflection is not task-specific, as it calls for students to make judgments about strong or weak abilities for the purpose of engaging in self-discovery and awareness.

Theoretical Background

The major theoretical premise of self-assessment is that it mentally engages students in a process that serves to develop academic self-regulation (Andrade and Valtcheva 2009; Brown and Harris 2013). Students with high self-regulatory skills take ownership over their learning and rely less on teachers to achieve challenging learning goals. The process of evaluating their own work can help students develop skills in regulating their performance and learning, which can lead to deeper, more meaningful learning and ultimately result in higher gains in achievement. Andrade and Valtcheva argue that self-assessment is an important component of self-regulation, indicating that self-assessment makes students aware of the goals of a particular task and prompts them to monitor their own learning by checking their progress in relation to those goals. Similarly, Brown and Harris suggest that engaging in self-evaluative tasks promotes the development of metacognitive competences essential to self-regulation, such as self-observation, self-judgment, self-reaction, task-analysis, self-motivation, and self-control.

Self-assessment can serve self-regulatory purposes by having students describe and generate feedback on their own work. Hattie and Timperley (2007) developed a three-step feedback model: First, focus the feedback on specific learning targets; then, have students consider where their work is in relation to those learning targets; finally, have students articulate what they can do to fill any gaps. To generate feedback using this model, students simply ask themselves: "Where am I going?" "Where am I now?" and "How can I close that gap?" Meta-analyses of feedback suggest that the quality of feedback can have a large effect on achievement, with an average effect size of 0.79 (Hattie and Timperley 2007). Hattie and Timperley suggest that effective forms of feedback contain information on how to improve performance on a specific task. Students generate this type of feedback when engaging in formative, criteria-referenced self-assessment. Formative self-assessment using rubrics, checklists, and journals has been associated with increased sophistication in the quality of students' writing, as well as increased mathematical vocabulary, better performance on word problems, and higher independence in mathematics problem solving.

Several methods of self-assessment have been devised to assist students in generating feedback on their learning. Brown and Harris (2013) state that methods of self-assessment generally ask students to evaluate either quantity or quality aspects of their work. Evaluating quantity aspects of one's work can include using a scoring guide containing correctly scored answers to assign a grade, score, or rank order or to estimate performance on a test or task. Evaluating quality aspects can include using a rubric to compare the quality of one's work or performance against a set of criteria.

In formative self-assessment, rubrics are often used to judge the quality of performance-based tasks such as writing, portfolios, and presentations. A rubric is a "document that lists criteria and describes varying levels of quality, from excellent to poor, for a specific assignment" (Andrade and Valtcheva 2009, p. 13). Rubrics not only support students in evaluating their own work but also serve as a teaching tool: Rubrics set the target for a task, describe both strong and weak work, and warn against the types of mistakes students tend to make on the task being evaluated. Once students have self-assessed their work using a rubric, they can revise it and use the rubric to repeat the process, at least until self-assessment is internalized. In addition to rubrics, Andrade (2010) suggested that checklists, journals, and student interviews can also be used to engage students in formative self-assessment.

Several important conditions should exist in order for students to receive the full learning benefits of self-assessment. Based on Brown and Harris' (2013) broad perspective, the form that self-assessment assumes, whether it is formative or summative, is irrelevant; effective self-assessment involves high mental engagement, is focused on the processes of self-regulation, and is scaffolded by the teacher. According to this view, good self-assessment is guided by the teacher and asks students to compare their performance against objective criteria, such as correct vs. incorrect test answers, or rubric-based criteria. Andrade and Valtcheva (2009) agree that teachers should play an active role in the self-assessment process, suggesting that teachers provide direct instruction on how to engage in self-assessment, give feedback to students on their self-assessment, and teach students how to use self-assessment to improve their work. Andrade (2010) argues that the climate of the classroom is also important to the success of self-assessment: Students need to perceive and understand the value of constructively critiquing their work and trust that their self-assessments will be respected by their teacher.

Andrade (Andrade 2010; Andrade and Valtcheva 2009) indicates several additional conditions for a formative, criteria-referenced approach, including the incorporation of a revision process during which students use their self-assessment feedback to improve the quality of their work or performance. Another characteristic of formative self-assessment is that students' judgments must not involve assigning a grade or score but should instead focus on identifying ways to revise and improve the work to meet the target criteria.

Important Scientific Research and Open Questions

Studies indicate that self-assessment is associated with learning and achievement. In a meta-analysis of 84 empirical studies of both formative and summative forms of self-assessment, Brown and Harris (2013) found a median effect size of between 0.40 and 0.45. This suggests that, on average, students who self-assess their work achieve almost a half standard deviation higher than those students who do not engage in self-assessment. The meta-analysis also suggests that self-assessment is related to gains in learning and achievement when students are (a) trained in self-assessment strategies; (b) provided guidance in self-assessment through models, correct answers, or teacher feedback; and/or (c) involved in the construction of task criteria and expectations. In addition, self-assessment that involved students in monitoring, rewarding, and making predictions about their achievement and accuracy as compared to objective criteria was correlated with gains in achievement.

Research investigating the accuracy of self-assessment has focused on the degree to which student self-assessments agree with teacher assessments. Young students tend to overestimate their performance by rating their work higher than the teacher, whereas older students tend to underestimate their performance and have ratings that correlate more strongly to teacher ratings (Brown and Harris 2013). The self-assessments of high-achieving, proficient students tend to agree more with teacher assessments than do those of low-achieving students. The research suggests that students' self-assessments agree more strongly with teacher assessments when students are taught to self-assess, have task-specific knowledge of the content, and know that their assessments will be compared to peer or teacher assessments. The tendency of students to inflate their self-assessments when they are counted towards a grade serves as a justification for the use of formative approaches to self-assessment (Andrade and Valtcheva 2009; Brown and Harris 2013).

Many questions about self-assessment are worthy of investigation. Although there is some evidence that self-assessment is linked to increases in motivation and self-regulation, the results from studies of this link are inconsistent (Brown and Harris 2013). Therefore, questions remain about the extent to which self-assessment contributes to motivation and the development of skills in self-regulation. Similarly, claims have been made about the effects of self-assessment on metacognition, yet very little research has investigated these effects. Research is needed to determine whether and how ongoing self-assessment experiences result in more and better metacognitive processing.

Little research has explored the relationship between the accuracy of students' self-assessment and gains in achievement. As noted by Brown and Harris (2013) and Andrade (2010), low-achieving students are often inaccurate in their self-assessments, yet they can still make gains in achievement through self-assessment. This raises the question of whether or not self-assessment accuracy matters. If accuracy of self-assessment is found to affect achievement, research should explore the components of the self-assessment process that contribute to improved accuracy in self-assessment.

Student Teacher as Researcher

John Loughran
Faculty of Education, Monash University,
Clayton, VIC, Australia

The idea of student teacher as researcher should sit comfortably with the intentions of teacher education and the process of learning to teach. It seems obvious that if student teachers are placed in positions where they can learn to challenge their existing views of practice through researching their own experiences of teaching, then such learning should be both valuable and meaningful in shaping their subsequent practice. Despite the apparent common sense of such a view, there is very little literature to suggest it is the case.

Project START (Student Teachers as Researching Teachers, Cochran-Smith 1991) is one of the few examples of the type of approach briefly noted above. Cochran-Smith described project START as being based on the notion of "collaborative resonance" because it was designed to "Prepare student teachers who know how to learn from teaching by inquiring collaboratively into their own practices and who help build cultures of teaching that support ongoing professional growth and reform" (p. 106).

Obviously, for a student teacher to learn about teaching through a student teacher as researcher stance, then such learning about teaching must be embedded in their experiences of teacher education. Project START did just that through a curriculum structured around opportunities for participants to engage in four kinds of teacher research – oral inquiry processes, essays, journals, and classroom studies – all of which were designed to raise questions and encourage data collection and analysis of particular aspects of learning about teaching. In many ways, project START focused on what Munby and Russell (1994) described as the "authority of experience."

Munby and Russell's research in the authority of experience in learning to teach led to two major student teacher as researcher outcomes as documented by Derek Featherstone (see Featherstone, Munby and Russell, 1997) and Shawn Bullock (see Russell and Bullock, 1999). Both of their accounts of researching their practice illustrated how, through creating situations that encouraged them to recognize and build on the authority of their own experience, their learning about teaching was substantially enhanced.

Featherstone's research clearly illustrated how his views of teaching and learning changed as a consequence of seeking feedback from his students about their learning in his classes. As a consequence of his careful "listening to his students," he found new ways to better construct his teaching in line with his hopes for his students' learning and their feedback on the quality of that learning. One particular aspect of his research was on the teaching of "natural succession" through which the data he collected and the subsequent analysis he conducted highlighted the value of purposeful inquiry into teaching by listening to, and learning from, his students. Featherstone's study showed how a student teacher as researcher stance fundamentally influenced his learning about teaching in very powerful and explicit ways.

Bullock, another student teacher who responded to the authority of his experience, launched into an extended research project in which he spent a considerable period of time documenting and analyzing his practice. As a consequence, he began to see differences between his views of science learning and the actual science teaching he was employing in the classroom. He therefore decided to step out and take risks in his practice and encourage the learning he hoped for rather than be secure in the teaching approach that gave comfort through traditional curriculum delivery. Although as a novice teacher he felt uncomfortable in not directing his students' learning of science in ways he was more familiar with, he soon saw the value in allowing his students to explore science for themselves. His experiences of learning to teach science through researching his practice created insights into teaching that fundamentally shaped his practice. Bullock's student teacher as researcher stance set an approach to learning about teaching that dramatically impacted his future career as he became a thoughtful teacher researcher and later teacher educator (Bullock 2011). In both cases, his grounding in researching his own practice as a student teacher gave him the impetus to do the same in his ongoing career.

In a longitudinal study over 3 years, Loughran (2004) documented his student teachers' research into their own practice. Again, the substantive approach was embedded in their own experiences through which they accepted greater responsibility for directing their own learning about teaching. Loughran encouraged the use of anecdotes as a catalyst for his students to study their practice. That approach served as a way of helping them to recognize the differences between what they were doing and what their students were learning and how they interpreted the gap between purpose and practice. Anecdotes encouraged his student teachers to draw on critical incidents in order to meaningfully reflect on their practice and pursue deeper understandings of the problematic nature of teaching.

His student teachers' projects consistently illustrated how they chose to revisit their own experiences and to begin to reconsider concrete aspects of their teaching that they could do something about. In so doing, they began to see new ways of investigating and interrogating their own learning about teaching and to build knowledge of practice that was informing and useful to them. Many of his student teachers' research studies were not pre-organized as a form of assessment per se, but rather developed as a response to emerging issues in their practice.

For those teacher educators invested in student teacher as researcher, a major hope is that novice teachers come to better understand the value of research in teaching and learning and to highlight how informative and applicable it can be to their classroom practice. Bullock's work is certainly a strong and important example of the value of setting such a foundation to learning to teach and illustrates well how important studying practice is to teachers as a way of improving the learning outcomes for their students.

Student Teachers' Needs and Concerns

Ingo Eilks and Silvija Markic
Institut für Didaktik der Naturwissenschaften,
Abt. Chemiedidaktik, University of Bremen,
Bremen, Germany

Student teachers enter the university training program to become a teacher first of all on the basis of having been a student in school for many years. Their a priori concepts about being a teacher and their beliefs about teaching and learning are mainly based on their experiences collected while having been high school students and by being a learner at university. Because many teaching practices in high schools all over the world, and also in universities, especially in chemistry and physics education, are not necessarily in line with educational theory, e.g., in terms of a student-centeredness and a constructivist approach to teaching and learning, the student teachers' a priori beliefs often tend to be very much teacher-centered, behavioristic, and mainly focused on rote subject matter learning (Markic and Eilks 2012). These beliefs mostly exist in the student teachers' subconscious and can act as filters through which new information about becoming a teacher is influenced and thus can act as hindering factors in student teacher learning. Unfortunately, learning within many teacher training programs follows similar pedagogies and therefore tends to reinforce these beliefs. Considering the impact of beliefs about teaching and learning in general and in science education in particular, there is a need to make student teachers' prior beliefs explicit and to confront them with modern educational theory, e.g., from the field of constructivist learning and student activating pedagogies. Making these beliefs and initial concepts explicit and confronting them with modern educational theory and vignettes from the classroom can be a first point for initiating conceptual change (Markic and Eilks 2012). This process of explication can help student teachers become more aware of the importance of unconscious beliefs and concepts about teaching and learning.

Recognizing the Nature of Concerns

Based on a constructivist approach to teacher learning, research has revealed that student teachers are able to substantially change their beliefs from traditional to modern beliefs. A core issue for this change is to allow student teachers to be confronted by, and thoroughly reflect upon, modern teaching and learning practices – beyond the practices of the university – as soon as possible. In so doing, student teachers have been shown to develop and change their perspectives on teaching and learning (Hoy and Woolfolk 1990). However, when entering school for teaching internships or after finishing teacher education, prospective teachers are confronted by many concerns.

Student teachers most frequent concerns seem to be related to their own subject matter adequacy and their potential inability to answer pupil's subject-related questions. But also questions of discipline, pupils' reactions to them, or the evaluation of their lesson plans and expectations of their supervising teachers are also areas of major concern. In the case of internships or being a trainee teacher, the student teachers also have concerns about other aspects of adequacy and personal evaluation, e.g., about the frequency of visits and observations by supervisors and about being graded themselves as well as their grading of their pupils. That means before entering schools their main concerns are in the area of subject matter knowledge, general educational skills, and formal aspects of the teacher education program. Before entering school there is much less concern about those topics which are typically the main part in domain-specific educational courses in teacher education, like knowledge about instructional design, methods of presenting subject matter, or assessment of pupils' learning (Fuller 1969).

It has been shown that in the first weeks of teaching, student teachers are mostly concerned about themselves, whether they have sufficient subject matter knowledge or being able to keep discipline in class. A poorly developed background in subject matter knowledge leads to many concerns and a lack of self-confidence to teach science and to react appropriately to pupils' questions (Appleton 1995). Lack of routines about working with the pupils also hinders teachers' organization of domain-specific learning processes. That means, in teacher training, there is first of all a strong need to develop good and broad subject matter knowledge in the domain of later teaching as well as developing standard routines to manage classroom organization. Other than with the subject matter knowledge and the question of discipline, student teachers' concerns about specific issues of teaching and learning science also play a role and may appear amorphous and vague.

Teaching Experience

After experiencing teaching science during their first teaching experience, many naive concerns become more concrete and real. While student teachers prior to teaching are mainly concerned about their subject matter expertise or skills in classroom organization, following their initial experiences in teaching, concerns shift towards the learning of their pupils and their influence on it. Concerns change from the areas of subject matter knowledge or general educational knowledge towards concerns about the student teachers' pedagogical content knowledge. A student teacher who is not familiar with the subject matter will have difficulties developing pedagogical content knowledge, e.g., how to deal with student alternative conceptions or how to select suitable models for explanation. Sufficient subject matter knowledge is a necessary prerequisite for the teacher to ask appropriate questions, suggest suitable investigations, or to assess student learning. However, this knowledge about, e.g., appropriate tasks, pedagogies, or students' alternative conceptions is not a part of the subject matter knowledge alone but needs additional well-developed pedagogical content knowledge.

Within the domain of pedagogical content knowledge, student teachers first of all need to develop their knowledge about pupils and their learning. This knowledge can also be of use in modifying and reconstructing student teachers' images of themselves as a teacher and about their own learning in teacher education. This self-reflected activity accompanied by a growing body of knowledge can help them to develop procedural routines to integrate classroom management and domain-specific instruction. Often, preservice programs fail to address these tasks adequately (Kagan 1992) and so these concerns persist until the student teacher learns how to confront and address them at a personal level.

Summative Assessment

Knut Neumann
Leibniz-Institute for Science and Mathematics Education (IPN), Kiel, Germany

Keywords

Accountability; Assessment; External assessment; Large-scale assessment; Monitoring; Summative assessment

Summative assessment refers to assessments which seek to obtain comprehensive information about student competence in a domain (e.g., science) for an evaluation of student learning. Teachers use summative assessment at the end of a unit or school year to gather evidence about students' mastery of the content covered throughout the unit or school year as a basis for grading. These classroom-based summative assessments are closely related with the learning aims of the instructional unit and thus the curriculum. However, summative assessments are also used by other agents within the education system, such as policy makers. Policy makers, for example, use summative assessments for monitoring the efficiency of parts of the educational system (e.g., specific curricula) or the education system as a whole (e.g., in comparison to other countries' education systems). These external large-scale summative assessments are not directly aligned with curriculum. However, in order to serve their purpose to measure students' mastery of the learning goals laid out in policy documents at a particular stage in the education system, they should be related to a model of students' progression in mastering the learning goals. Summative assessments need to build on a model of student mastery of the domain. In the simplest case, such a model embraces two levels, non-mastery and mastery. Typically students are considered to have mastered the domain or a particular aspect of the domain (i.e., one learning goal) when they achieve a minimum score on a set of tasks representing the domain or the particular aspect of the domain. At best, summative assessments are building on a model embracing a hierarchy of levels indicating different levels of mastery each represented by a specific set of tasks. In case of external large-scale assessments, these tasks are typically multiple-choice or short-answer questions. In case of classroom-based summative assessments, these tasks may include multiple-choice items but are also often based on more complex open-ended items.

Sustainability and Science Education

Ilan Chabay
IASS Potsdam, Institute for Advanced
Sustainability Studies e.V., Potsdam, Germany

We live in the "Anthropocene" era, an era in which human activity plays a significant role in shaping conditions on our planet. In order to survive as a species on Earth, we need to monitor, understand, forecast, mitigate, and adapt with the changing social, economic, biological, geological, and physical conditions on Earth. Successfully addressing these vital challenges requires a continuously iterative process of learning, building, integrating, and using knowledge, including that of natural and social science and humanities throughout society. This recognition presents new challenges that necessitate restructuring the purpose, content, and approach of education. The focus in this entry is on changes needed in science education for this to contribute to a sustainable future for all.

The United Nations Decade of Education for Sustainable Development (2005–2014) aimed to raise awareness internationally of the need for education that supported the multiple goals of sustainable development, as articulated prominently in the 1987 Brundtland Commission document *Our Common Future*. Sustainable development is defined by the Brundtland Commission as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." The term "development" is hotly debated in this context, with questions as to whether it should refer to human well-being, rather than only to the use of diminishing physical resources and the raising of Gross Domestic Product figures. The meaning of sustainability and sustainable development will continue to evolve and be debated. Nonetheless, the broad concept and the fundamental uncertainty of an evolving understanding of a rapidly changing world urgently direct our attention to changing how education can help humanity cope and adapt with the changes.

Important changes in science education – and indeed in all areas of education from preschool through lifelong learning – are needed to continue to prepare students to play a role in advancing knowledge in the sciences and, equally importantly, prepare children and adults to make informed decisions and take individual and collective actions in effecting a transition to a sustainable future for all on the planet.

Science education needs to adapt to fulfill the needs of society in the near and far term. The critical issue is adaptation to a changing paradigm of science, a new one that fully embraces a mix of mono-, multi-, inter-, and transdisciplinary research, that enables social innovation as well as marketing-driven technological innovation, that recognizes and incorporates a diversity of sources and forms of knowledge, that addresses ethics and values in the conduct of and choice of research in science, and that enables and encourages meaningful dialogue with stakeholders in society at large.

What then are the key elements of this new paradigm of science?

In addition to domain-specific knowledge from expertise in narrowly focused "silos" of science that is the core of the reductionist approach, multi-, inter-, and transdisciplinary science and systems thinking that draws more broadly from social and natural sciences and humanities perspectives is essential for addressing the complex challenges of a rapidly changing global system. Complex challenges – ones that involve a system or systems in which the components are coupled nonlinearly with feedback loops and time delays – require a system-level, holistic approach. Simply summing the behavior of the components does not provide an adequate understanding or description of the whole system. Since we as humans are inseparable and significant actors in the complex socio-ecological system of the planet, this makes the need for integrative, multi-, inter-, and transdisciplinary science processes essential.

Models and scenarios built from the output of models are essential tools in understanding complex systems. They facilitate our thinking about complex issues, which are generally characterized by both qualitative and quantitative information from multiple sources and high degrees of uncertainty in the information. Models are fundamental to the way human beings think. They are approximations of the behavior of phenomena and events of the world and reflect perceptions of patterns and efforts to categorize, explain, and predict future behavior of physical, biological, social, and economic phenomena and systems. Models are essential in organizing and interpreting information, whether implicit and intuitive, or elaborate mathematical constructs. Models are becoming increasingly important in social sciences, not only in natural sciences and engineering, where they are well-established tools (Klüver 1998; Lehrer and Schauble 2000). On one end of the scale, models may be greatly simplified associations, elaborated metaphors, or mental representations, or at the other end of the scale, they may be highly elaborated mathematical and computational constructions, such as system dynamics or agent-based models. The results produced from these models do not give "the answer," nor can they. What the results can provide is a set of potential options and new insights to be weighed and considered with due regard to stakeholder values, local conditions, and the fundamental limitation of any model as an approximation to address a specific question and fed by imperfect data.

Transdisciplinary science includes relevant stakeholders – i.e., those who may exert influence on or be influenced by the issues under consideration – in framing the research questions; collecting, analyzing, and interpreting the data; and communicating the knowledge developed through the research. This approach creates important opportunities for mutual learning among the researchers and the community in which the research occurs, thus potentially leading to more informed and effective public and policy decisions and actions. It also allows for discussion and consideration of the multiple values that typically characterize the views of societal actors, including the scientists themselves, regarding any given issue for scientific research.

How can science education develop and improve in the context of the Anthropocene and the new paradigms of science?

The structural and curricular changes in science education needed to respond to this new paradigm of science include the following:

- Improving and expanding problem-focused, project-based learning that draws upon multiple domains of knowledge as needed for the problem at hand
- Developing stronger collaborative and communicative skills
- Building an understanding of the uses and processes of modeling in science
- Incorporating greater consideration of social, ethical, and cultural aspects and implications of science and technology

Greater emphasis on learning to learn and learning critical thinking, rather than relying on mastery of an expansive but shallow knowledge base, is not a new issue and is not tied to sustainability, per se. Nonetheless, improvement in these aspects of learning is sorely needed to support learning that strengthens resilience and adaptability.

A key structural and curricular change needed in science education to respond to this new paradigm of science is change in the desired forms of learning, a change that maps onto the changes in science *per se* – from reductionist and convergent and bounded by the discipline divisions of the past to expansive, collaborative, and transdisciplinary.

These changes can be implemented at every level of education from preschool through tertiary education and in informal and lifelong learning contexts. Developing coherent pathways of learning from early childhood through university and lifelong opportunities should be a high priority in order to give learners at every stage of development a connected and progressively more focused set of thinking skills, knowledge, and insights. Of course, education of teachers and continuing professional development must be a major part of any strategy for any substantive educational change, and that is equally so here. So too, expanding change from an isolated lesson about change to design and daily practice in the operation of the classroom, school, and education system in each community or region is crucial (see, e.g., Stone 2009). New patterns of behavior and operation are far stronger "lessons" when seen and experienced in the daily environment than when presented only in abstract, didactic forms.

There are many examples of successful efforts to implement these approaches in many locations around the world, and a number of resources are available to support the transformation of education at various levels and different conditions and cultures. A few examples follow to indicate the range of efforts, levels, and materials available.

Encouraging students to engage with their community as part of their science education projects – e.g., measuring noise levels or collecting airborne particle samples on a filter in heavy-traffic areas and conducting citizen response to the measurements as surveys – provides experience with multi- and transdisciplinary science. This transdisciplinary research in which students are the stakeholders, as are the teachers and parents and members of a community, not only can change the motivation of students to engage more deeply with the science, but also give them practical experience in applying multidisciplinary knowledge and challenge theoretical knowledge with real experience. In yet another regard, this type of activity lends itself well to constructing and using computational models at age-appropriate levels to interpret the data gathered. This kind of activity has also been at the heart of some after-school programs and summer camps with an environmental focus.

Social choices can also be used to introduce modeling, starting with elementary school-age children. An example that engages children in modeling and empirical testing of their model is to build a simple model to illustrate and predict decision making by one of their cohorts. Ask a class where they think a certain child in another class will sit in the lunchroom tomorrow. Starting with a simple diagram of the space, including the entrance normally used, tables can be assigned with letters and chairs at the table numbered. Children will usually either just quickly guess a location or say they don't know. If they are asked what do you see when you walk in the lunchroom and what might make you choose one seat or another, then the class will start suggesting possible decision factors, such as the location of a supervisory teacher, being near a particular friend, being far from groups of younger or older children, distance from the end of the lunch line, or proximity to the windows. The factors are written on the board or set of cards. Once this process of elaborating factors that influence where someone might sit is completed, the factors can be ranked by priority. Out of this a simple decision tree can be illustrated. Then, the children can test their model by observing the path and choice of the child at lunchtime and later critiquing the model based on the outcome of their observations.

Modeling as a strategy for learning physics at the university and high school level has been strongly advocated (Jackson et al. 2008) and demonstrated and extensively tested in introductory courses using computational modeling (Chabay and Sherwood 2011). Computational agent-based modeling in social sciences has also been implemented at the tertiary and to a lesser degree at secondary levels by Marco Janssen and colleagues at Arizona State University.

Computer and mobile app games already on the market or readily modified versions of commercial games have been used in programs in and out of schools to involve students in a creative and learning processes (see http://www.futurelab.

org.uk/sites/default/files/Computer_games_and_learning.pdf). Since game engines actually are forms of computational models, they can be used to provoke discussion and exploration of how models can be used for decision making. In the wide and growing array of computer games now burgeoning on mobile platforms, games built upon models of politics and business have become "fair games," too.

A number of universities have formed partnerships with schools from preschool through secondary school in their communities and regions to support science education and other areas of learning. These provide incentives to students, particularly for minority and disadvantaged youth to stay in school and form relationships with higher education institutions. This creates an important, though often quite difficult, step in building a more coherent pathway through the educational landscape.

Informal learning environments – e.g., after-school programs, museums and science centers, public science events, and specialized camps – are very important in the landscape of science education (http://www.astc.org/sciencecenters/index.htm). Not only do they provide additional science learning experiences, often with good social, collaborative, multidisciplinary project focus, but they also create links with parents and other adults who become engaged in new experiences of science through their children or as part of adult groups. Science centers and museums are also important potential partners with global change research institutions and programs in that they can function as boundary institutions between local stakeholders and the researchers for mutual learning process.

Tangible and Embodied Interactions for Learning

James Slotta
Department of Curriculum, Teaching and Learning, Ontario Institute for Studies in Education, University of Toronto, Toronto, ON, Canada

Keywords

Augmented reality; Embodied learning; Immersive environments; Tangible interactions

Main Text

The goal of bridging the digital/physical worlds for purposes of learning has been pursued by science educators for more than 30 years, grounded in the work of Seymour Papert (e.g., 1980) and his work at the MIT Media Lab. One such project was that of LEGO/Logo (e.g., Resnick and Ocko 1990) which allowed children to become the designers and creators of their own physical interactive machines (e.g., robots, motorized cars, motion detectors, and various other simple digital transducers). Related efforts, using simple programming languages such as Squeak and Scratch, have enabled even young children to create software applications that control or coordinate such devices. For example, students could use Scratch language to program a computer-simulated race car and track, then build a real steering wheel using a paper plate that controls the race car by physically turning the wheel. Public interest has grown rapidly in such technologies, with students and citizens of all ages inspired to create compelling new forms of interaction with their physical or virtual environments. Active communities of “makers” have grown, fueled by “maker fairs” (conventions of enthusiasts), hackathons (an event where designers and developers come together and work on a shared project, such as software development for an educational purpose), and online exchange sites. Increasingly accessible hardware products have emerged, like the Arduino microprocessor kit and Makerbot 3D printer, which facilitate design and development efforts within these creative communities. In 2014, *Thingiverse*, an online maker portal, has over 50,000 open-source, user-contributed projects, illustrating the vibrant, active, and social nature of maker communities. This entry describes three forms of technology applications that hold great promise for science education: (i) embodied interactions

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

Tangible and Embodied Interactions for Learning, Fig. 1 With Arduino microprocessor and simple circuits made out of any conducting medium (including bananas), the sky is the limit of creative applications for tangible and physical computing

between the learner and her environment, (ii) augmented reality applications, and (iii) immersive environments.

Embodied Interactions for Science Learning

The term "embodied interactions" has been advanced to describe how students acquire knowledge of the world around them through bodily interaction with their physical environment (Barab and Plucker 2002). Recent advances in touch surface technologies, including Apple's iPhone and iPads, Microsoft's multi-touch surface computing, and interactive white boards have introduced new ways of sensing and manipulating our environments (Ishii 2007). Interactive wands like the Nintendo Wii allow users to control and manipulate images and events on large screens or projections by pulling, turning, flicking, or touching them. With the introduction of the Microsoft Kinect, users can now directly interact with computer-projected images or the wider three-dimensional surround, using computer vision that tracks their movements within the space – responding as they wave their arms, or interact with both real and virtual objects. In addition to early applications for interactive forms of gaming, these new technologies allow research of new forms of learning interactions. Science education researchers are now creating learning activities where students engage physically with their environment, moving or sorting tangible objects (i.e., that are tracked using computer vision), or interacting physically with virtual objects or environments. These activities engage students in exploring personally relevant and interesting topics such as climate change, ancient civilizations, or cooking.

Augmented Reality

Another emerging area within science education research is that of augmented reality, where information is mapped onto the physical environment, with additional layers of information allowing the learner to gain personally or contextually relevant information. Smartphones or tablet computers, with their built-in GPS features, make it easy to provide the learner with location-dependent information, allowing enriched experiences of museum visits, field trips, or a walk down the street. An application running on the learner's device (e.g., a custom "app" or a Web site within the phone browser) would present contextually relevant information, corresponding to the learner's physical location. Information can also be filtered so that it addresses the individual learner's specific interests or needs, adding a contextual layer. The smartphone's inertial detectors (i.e., the features that allow the screen image to "flip" when the phone is reoriented) or its built-in compass can also be employed as a means of allowing directional orientation. Research of augmented reality for science learning is still in its infancy, but is already playing a role in museum experiences, citizen science projects, online communities, and other forms of science learning.

Tangible and Embodied Interactions for Learning, Fig. 2 Large screen projections around the room displaying the immersive simulation as well as audio tracks of natural rainforest sounds transform a smart classroom into a rainforest in Southeast Asia

Immersive Environments

A final dimension of tangible and physical interactions for science learning is concerned with immersive environments. Early efforts explored online experiences, where students log into an Internet-connected computer-based environment, appearing as avatars (stylized representations of themselves, typically in cartoon format), giving the user a sense of presence, navigation, and interaction with others and with objects in the environment (e.g., similar to Second Life or World of Warcraft). In the *River City* project (Dede 2009), students enter a simulated nineteenth-century community where a mysterious disease is devastating the citizenry. Working collaboratively, and with assistance from helpful denizens and a variety of embedded clues and scaffolds, students must design and conduct experiments that help them isolate the cause of the (water-borne) disease, developing an understanding of the relevant biology and scientific practices. More recently, science educators have leveraged the physical environment to create immersive or embedded simulations, such as *EvoRoom* (Lui and Slotta 2012) where learners enter a room-sized simulation of a Sumatran rainforest, created using projectors that fill the walls with animations of various flora and fauna, as well as ambient media (audio track of insects, and even olfactory stimuli). Scaffolded by handheld tablet computers, students move physically around the room, collaborating with peers to investigate various flora and fauna as they evolve over 200 million years. This approach provides students with a powerful new form of embodied learning where they may develop a deep understanding of evolutionary processes (Figs. 1 and 2).

Teacher Contextual Knowledge

Allan Feldman and Benjamin C. Herman
Department of Secondary Education, College of Education, University of South Florida, Tampa, FL, USA

Keywords

Ethical, political, economic, and social factors; Pedagogical content knowledge; School culture

We define *teacher contextual knowledge* as simply knowledge of the context of teaching, where the context of their teaching includes who they teach (their students), where they teach (their classrooms, schools, communities, and so on), and what they teach (the school subject, the level, the curriculum, and its relationship to local, state, and national standards). Given this, teachers' contextual knowledge is acted upon by the ethical, political, economic, and social factors that influence teaching and learning in schools. It should be clear then that to recognize the importance of teachers' contextual knowledge is to reject "one size fits all" education initiatives (e.g., standardized curriculum) that assume that effective science teaching is context independent. In the remainder of this small entry, we provide a brief overview of the literature related to science teachers' contextual knowledge.

Although there is a more than 100-year history of research in science education, it is only during the past 25 years or so that attention has been paid to what teachers know, how they come to know it, and how they use their knowledge in the classroom. More recently, attention has been paid to not only the content of teachers' knowledge but also the context within which they teach. The importance that science educators place on knowledge of the context of teaching can be seen in the number of chapters devoted to it in the most recent *Handbook of Research on Science Education* (Abell and Lederman 2007).

Shulman developed the idea of pedagogical content knowledge (PCK) as consisting of repertoires that teachers have of the ways in which they can represent subject matter knowledge to their students. PCK includes teachers' knowledge and beliefs about the purposes for teaching a particular subject, knowledge of students' understanding of the subject matter, knowledge of the curriculum, and knowledge of instructional strategies. Knowledge of the context of schooling was seen to be distinct from PCK. Science educators early on embraced the notion of PCK and began to see the importance of the context of teaching and its relationship to PCK, such as the ways in which knowledge of educational contexts contribute to teachers' PCK (Gess-Newsom and Lederman 1999).

In 2001 Barnett and Hodson (2001) put forth a model of pedagogical *context* knowledge. Drawing from prior literature, this model describes the ways that science teachers can construct and employ an amalgamation of academic and research knowledge, pedagogical content knowledge, professional knowledge, and classroom knowledge while contemplating, designing, and implementing their science teaching in shifting and varied educational contexts. Specifically, Barnett and Hodson (2001) point out that teachers must learn about and navigate several interacting "microworlds" (e.g., science education, teacher professionalism, science curriculum, and school culture), each with its own culture and particular "knowledge, language, methods, rationality, criteria of validity and reliability, and values" (p. 440). In their model, teachers need to also consider, reflect upon, and determine the origins of their personal frameworks, skills, and beliefs. When science teachers gain the ability to navigate these microworlds and their own belief systems, they can use pedagogical context knowledge to develop a cultural awareness that involves “a) understanding the social location of particular clusters of beliefs and practices; b) acknowledging the context-dependence of most of what they think and do; and c) recognizing the existence of different modes of discourse, each having a distinctive sociocultural origin” (p. 440).

In addition to the work on teacher knowledge, there is a large set of literature in science education that looks at the relationships between context and the teaching and learning of science. This literature considers factors such as issues of racial, ethnic, language, culture and socioeconomic diversity, gender, setting, and how these factors intersect with the cultures of teachers and schools (Abell and Lederman 2007). Although discussions of teacher contextual knowledge allude to these factors, this other literature places them in the forefront of what teachers need to know and consider as they work within the highly diverse settings of contemporary schooling.

Teacher Craft Knowledge

Tom Russell
Queen’s University, Kingston, Canada

Keywords

Practical knowledge; Wisdom of practice

Craft knowledge is one of the missing pieces in the puzzle of high-quality teacher education and professional development. Craft knowledge develops as one makes sense of experience, but experience is limited or absent from many education courses (for preservice teachers) and professional development events (for those who are already teaching). Grimmett and MacKinnon’s (1992) definitive review of craft knowledge in the context of the education of teachers offers this perspective: “Craft knowledge represents intelligent and sensible know-how in the action setting” (p. 395). “Craft knowledge is essentially the accumulated wisdom derived from teachers’ and practice-oriented researchers’ understanding of the meanings ascribed to the many dilemmas inherent in teaching” (p. 428). Barth (2001) offers a similar interpretation: “*Craft knowledge* is the massive collection of experiences and learnings that those who live and work under the roof of the schoolhouse inevitably accrue during their careers” (p. 56). These statements confirm that craft knowledge is intimately linked to action, not to books and research reports; thus, it is knowledge that is not easily recognized, documented, or shared in the ways that propositional knowledge can be. Barth (2001) makes an important further comment: “Craft knowledge is rarely viewed by school people *themselves* as legitimate, rigorous, or useful” (p. 57). Neither the school-and-classroom culture nor the university culture readily acknowledges and celebrates the value of a teacher’s craft knowledge. The university’s difficulties in recognizing craft knowledge are apparent in its emphasis on the importance of research and publication, with little more than lip service to the development of excellent teaching skills.

In the context of science teaching, craft knowledge includes all that the teacher is able to do, from at least two major perspectives – science and pedagogy (the interaction between teaching and learning). From the perspective of science, teachers' craft knowledge includes the ability to manipulate scientific equipment successfully for teaching purposes and to recognize in each piece of equipment the scientific concepts that made it possible and thus are embedded within. From the perspective of pedagogy, craft knowledge includes the ability to identify what students already know and then construct experiences that will enable them to move their existing understandings closer to accepted concepts of science.

In the context of science teacher education, there are many challenges to the development of craft knowledge within traditional structures of preservice programs. Typically, those learning to teach spend much more time in education classes than in practicum classrooms. Developing craft knowledge requires firsthand experience of engaging students directly with equipment and with both familiar and novel teaching procedures. Those learning to teach have long valued practicum experiences more than education classes; perhaps they have realized intuitively that the craft knowledge they long to develop and master requires them to be active in a classroom. Only when individuals are active can strategies of reflective practice be invoked to interpret and consolidate what one is learning from experience.

Knight (2004) has attempted to capture the physics teacher's craft knowledge in a unique book that devotes a full chapter to each of the 21 major topics in the basic physics curriculum. In addition, he offers five specific principles to guide teachers' actions; these "five easy lessons" are not easy, but they are specific, practical, and grounded in recent research. One is "Focus on phenomena rather than abstractions" (p. 42); a second is "Deal explicitly with students' alternative conceptions" (p. 43). Knight provides detailed accounts of students' typical conceptual difficulties as well as teaching approaches (including experiments and demonstrations) that help to overcome conceptual difficulties. Because experience is required to appreciate the accounts of craft knowledge, books such as Knight's may be of more immediate value to practicing science teachers who already have considerable firsthand experience of the many ways in which students can misinterpret their previous experiences (which generate a kind of early craft knowledge) and their teacher's efforts to guide them to more useful interpretations. Similarly, the Project for Enhancing Effective Learning (http://peelweb.org) is an excellent source of written accounts of teachers' craft knowledge, with many contributions by science teachers describing teaching procedures that engage students in ways that foster metacognition rather than passive learning. These accounts may inspire further developments of a teacher's craft knowledge.

The craft knowledge of the science teacher educator who understands and values craft knowledge will include strategies for helping prospective teachers to understand and respect the differences between more familiar propositional knowledge and more tacit craft knowledge. Thus, the educator's craft knowledge would include structuring experiences and assignments that help beginners to describe and share craft knowledge gained in science classrooms. It would also include making explicit one's own craft knowledge as a teacher educator in order to model future professional development of craft knowledge.

Teacher Educator as Learner

Shawn Michael Bullock
Faculty of Education, Simon Fraser University,
Burnaby, BC, Canada

Keywords

Education; Knowledge; Learning; Teacher Knowledge

Introduction

The concept of a teacher educator as a learner might initially seem strange. After all, those entrusted with the task of teaching future teachers might be reasonably expected to have at least three particular kinds of knowledge: knowledge of disciplinary content, knowledge of how to teach disciplinary content (pedagogical content knowledge), and knowledge of how to teach others how to teach disciplinary content. By this rationale, knowledge of how to teach teachers requires mastery over both disciplinary content knowledge and pedagogical content knowledge. In short, one might expect that being a teacher educator requires knowledge of what it means to be a successful teacher in a particular content area, which also implies in-depth propositional knowledge of how to teach particular scientific concepts.

Professional Knowledge of Practice

A considerable amount of research in recent decades has problematized the view that knowledge of teaching, and thus knowledge of teaching teachers, is based purely on propositional ways of knowing. Beginning with Schön's (1983) work on knowing-in-action via reflection-in-action, a number of research programs have explored the ways in which teachers construct professional knowledge of practice from an *experience-based* standpoint. These studies have recognized that teachers construct a considerable amount of knowledge from professional experiences, particularly those experiences that are puzzling and novel or do not lend themselves to easy solutions. Teachers' professional knowledge might also be considered craft knowledge, created in a reflexive relationship between the teachers' explicit actions and their professional contexts.

One significant problem of naming and interpreting teachers' professional knowledge is that it is largely *tacit and unexamined*. Although teachers make any number of decisions and take numerous actions in the course of their duties as a classroom teacher, it is less clear that teachers can explicitly articulate why they chose to act in particular ways in particular situations. Loughran (2007) makes a strong case that science teachers should be supported as learners in their own right, so that they might understand and be able to explain the nature of their pedagogy in more nuanced ways – perhaps through action research – and thus enhance the quality of their students' learning.

Teaching Teachers

These ideas can be productively extended to the concept of teacher educator as learner in several ways. First, considerable evidence presented in the literature on the development of teacher educators demonstrates that experiences teaching in the elementary and/or secondary school systems are *not* sufficient preparation for the task of teaching teachers. There is something unique about the knowledge required to teach teachers that is different from the knowledge required to teach K-12 students. Second, knowledge of teaching teachers is, by and large, tacit and thus not as highly valued as other kinds of knowledge found in the academy (e.g., knowledge of a particular research discipline). Third, effective teaching often looks easy to the layperson; everyday classroom experiences often mask the deep professional knowledge required to make a learning experience productive. Knowledge of the discipline of teaching is not obvious. Neither K-12 students nor teacher candidates typically understand the complexity of making deliberate pedagogical moves; they have not developed the ability to link teaching strategies with learning effects.

Self-Study of Teacher Education Practices

A group of like-minded teacher educators came together in the early 1990s to offer the ways in which they had reframed their approach to teacher education to *teacher educator as learner*. This move occurred at the end of a decade of work encouraging teachers to reflect on their practice and thus to become learners, and the group's early motivation was partly a desire to model the behaviors they expected of their teacher candidates. The result is a research program known as Self-Study of Teacher Education Practices (S-STEP) (Loughran et al. 2004) that explicitly casts the teacher educator as a learner with the purpose of describing, analyzing, and interpreting individual and collective pedagogies of teacher education. Although S-STEP does not have an exclusive claim to the idea of teacher educator as learner, it is unique in that it explicitly requires its practitioners to investigate their own practices systematically and to make their learning about teaching teachers public and subject to the scrutiny of fellow researchers.

Self-study research tends to challenge an individual's prior assumptions about teaching and learning and be self-initiated, aimed at improving pedagogy, and result in making tacit knowledge explicit. Many self-studies involve a reflective turn, sometimes called a turn back to self, in which teacher educators explicitly state the ways in which their views about teaching teachers have changed as a result of conducting self-study research.

Self-study methodology is notable because it formally casts the teacher educator as a learner and makes the results of her or his investigations public to the research community. Despite the label of "self," many self-studies involve collaborating with critical friends – including other teacher educators and teacher candidates. Self-study takes seriously Loughran's (2007) assertion that science teachers and science teacher educators should "(a) challenge the taken-for-granted in their practice; (b) examine, articulate, and disseminate their learning through experience; and, (c) seek to continually ensure that practice and theory inform one another" (p. 1059).

Self-study research conducted with input from teacher candidates provides one way that teacher educators can model explicitly the practices they expect from their students. Knowledge of teaching is not static and it requires a teacher/teacher-educator-as-learner stance to discourage complacency and to develop an "authority of experience" (Munby and Russell 1994) over one's knowledge of practice. Several good examples of science teacher educators as learners are evident in the edited collection by Bullock and Russell (2012) which captures the essence of the authors' learning about the teaching and learning of science.

Teacher Preparation and Indigenous Students

Amanda Woods-McConney
Murdoch University, Murdoch, WA, Australia

A Note Regarding Terminology

There are multiple ways to represent "indigenous" cultures. Because this description is meant to represent an international perspective, the term indigenous is used with the understanding that locally accepted conventions and contexts reflect heterogeneity. Therefore, it is imperative to seek advice from local people about local conventions and contexts for terminology.

Challenges in Preparing Teachers to Teach Indigenous Students

Relationships between the institution of education and indigenous communities are quite complex. Many indigenous community members are frustrated by what some would call "neglect" of indigenous education and the lack of success for their students in the school system. For many indigenous cultures, the institution of school has been associated with strong negative feelings. Historically, teachers and schools were often at the front line in attempts to assimilate indigenous students (Brayboy and Maughan 2009). In many countries these attempts resulted in children being taken from their families and forced into residential schools. Although assimilation attempts are no longer an explicit part of current approaches (see acculturation), they are part of the history of the institution for indigenous communities and can contribute to negative feelings about school. Further challenges associated with indigenous students and schooling stem from a lack of alignment between current science teaching, assessment, and curricula with *indigenous knowledge* and *values*. An indigenous approach can be characterized by collective decision-making, sharing, and flexible conceptions of time, for example, which can be in direct conflict with a mainstream science approach. The clash of these different knowledge systems can be a challenge for students, communities, parents, indigenous education workers, and teachers. The clash is further exacerbated when nonindigenous teachers attempt to teach without an understanding of how to incorporate indigenous knowledge and values in the taught curriculum. In addition to challenges associated with the institution of education and the science curriculum, challenges also stem from the nature of teacher preparation programs themselves. Teacher education programs are typified by a full curriculum with little room for additional content, making it difficult to address issues associated with indigenous education. Even more important, students in teacher preparation programs are in the beginning stages of their own professional self-identity and may not have the necessary background experience or opportunity to reflect on their role in teaching indigenous students.

Indigenous Ways of Knowing and Preparing Teachers to Teach Science

One way to address challenges associated with multiple worldviews is to use a two-way teaching and learning approach. Two-way teaching and learning emphasizes collaborative connections among members of indigenous and nonindigenous cultures. With this approach, each culture is seen as having a great deal to learn from one another and learning is seen as a two-way transaction (Purdie et al. 2011). Fundamental to two-way teaching and learning in science is the understanding that indigenous students need to know and use nonindigenous science, but not at the expense of their own culture and knowledge. Similarly, nonindigenous students benefit from learning worldviews and knowledge systems different from their own. Although this approach is especially difficult in the tertiary setting, it can be achieved if prospective indigenous teachers are able to share their knowledge (see, e.g., Brayboy and Maughan 2009).

Science is especially suited for two-way learning and teaching because there can be areas of "common ground" in science content knowledge and indigenous knowledge systems. For example, students' observations and inferences regarding the natural world represent key components of skills and procedures in both science and indigenous knowledge systems. Recognizing and valuing this common ground between science content knowledge and indigenous knowledge has been an emerging point of interest with both nonindigenous and indigenous scientists working with indigenous communities in data collection, environmental impact assessments, and risk management plans (see, e.g., Indigenous Knowledge Systems at http://ankn.uaf.edu/index.html). Students, teachers, and education support staff would benefit from recognizing that students may have this place-based knowledge (Chinn 2012) and that science is not about worksheets and definitions or a separate discipline reserved for a few others. Instead, science curricula that value and incorporate indigenous knowledge are especially suited for helping facilitate science learning in school classrooms. However, without teachers' knowledge of *how* to incorporate indigenous knowledge in the taught science curriculum, activities or science content commonly becomes "bolted on" ideas that can caricaturize the content rather than lead to two-way understandings (see, e.g., http://8ways.wikispaces.com/Cultural+content). It is therefore essential that indigenous knowledge systems and the nature of science are included in the science methods' training provided in teacher preparation programs. At the same time, even if prospective teachers attempt to include indigenous science in their teaching, it is difficult for nonindigenous teachers to teach science to indigenous students. Prospective (and, arguably practicing) nonindigenous teachers need help on learning how to become culture-brokering teachers in order to understand students' prior knowledge and indigenous ways of knowing (Aikenhead and Michell 2011).

Teacher Professional Development

Barbara Crawford
Faculty of Mathematics and Science Education,
The University of Georgia, College of Education,
Athens, GA, USA

Keywords

Pedagogy; Education; Research; Teacher Education

Teacher professional development includes experiences designed to enhance practicing teachers' knowledge, attitudes, and skills, including science subject matter, new pedagogical approaches (teaching strategies and methods), alternative student assessments, use of technology, methods to teach students about scientific practices and nature of science, and more. The purpose of professional development is to ultimately enhance learning of students and their views of science. This is not to say that teachers are not professionals, and on their own accord, they do not strive to be the very best teacher. The growing knowledge base of teaching gives a reason for professionals to stay current with the ever-changing field of education. Currently, there is a great deal of interest in designing effective professional development experiences, given the explosion of scientific information, research on student learning, and increasing challenges of teaching diverse children in classrooms. During the years following a teacher's initial certification or license to teach science, it is important (and usually required by school districts/jurisdictions) for a teacher to continue to learn about new initiatives and findings in science and in education. These may include new learning technologies, the latest scientific discoveries in their fields, innovative science curricula, and new approaches to teach science. Professional development programs should provide teachers with continual learning experiences, as they continue their journeys to become highly effective teachers.

Variation in Programs

The range of professional development programs is great. These programs vary in many ways, including duration, content, and mode of delivery. Professional development programs differ in length from half- or single-day workshops to intensive multi-week programs, to full summer programs, and even to multiyear programs. The focus of a professional development program may be a particular science domain, such as biology, earth science, or physics, or an educational area such as inquiry, nature of science, use of learning technologies, differentiating curriculum for learners from diverse populations, or a combination of any of these. The mode of delivery may be face-to-face or remote online delivery. The location may be a teacher's school, museum, university, or science education conference site, or a teacher may go into the field or scientific research laboratory. In some cases teachers are immersed in learning science, through helping to carry out scientific research studies and/or in educational activities such as developing or adapting innovative curriculum. Many science teachers do not value professional development programs that are focused on general instructional approaches or educational issues, as much as those programs focused on science as content. There are recent studies that provide empirical evidence of the importance of science content knowledge in professional development programs for science teachers. Evaluators suggest that designers of professional development experiences (1) be clear about purpose and goals, (2) consider if the goals are worthwhile, and (3) account for how the goals will be assessed (Guskey 2000). The professional development experiences need to be systemic. In this sense, stand-alone, disconnected, and one-shot workshops do not necessarily align with overall policies of a teacher's school and may have limited long-term impact on a teacher.

The goal of professional development is teacher learning, including enhancement of knowledge of subject matter or pedagogical approaches, resulting in students' understanding science concepts and principles or developing greater understanding of scientific practices and nature of science. Almost two decades ago, Bell and Gilbert (1996), as reported in Hewson's (2007) review, studied 48 teachers related to their personal development, social development, and professional development over 3 years. Since this report there have been a plethora of reports examining different professional development programs in the United States and countries around the world, in order to better support teachers in the increasing challenge to teach diverse students in classrooms about science in our ever-changing world. Various elements in a professional development program include setting of goals, planning, enacting, looking at outcomes, and reflecting on the entire process (Loucks-Horsley et al. 2010).

Characteristics of Professional Development

Research studies have revealed that certain characteristics of professional development programs can significantly impact teachers. Characteristics that appear to effectively impact teachers include having a clear focus on science content, how students learn this content, and opportunities for teachers to be active learners of new content, which include teachers from the same school as participants, and for teachers to take on leadership roles. However, there is limited research at this time that provides direct evidence that connects these characteristics with increased student achievement. When planning professional development experiences, there are certain components identified by researchers to be very important. Components that professional developers should consider include the nature of the planning process, beliefs underlying effective professional development, the context of the professional development, and strategies deemed to be effective (Loucks-Horsley et al. 2010). In evaluating a professional development program, the evaluator should avoid common mistakes that include the following: (1) documentation is made instead of an evaluation; (2) shallow measures are used that are not true indicators of success; and (3) the time of the evaluation is too short (Guskey 2000).

Researching Professional Development

Research studies include small and large studies. In large-scale studies, participating teachers have identified some features of "best practices" in professional development. It is clear that one-day or short-term workshops are not as effective as sustained and intensive professional development experiences. Other important features include coherence of professional development goals and experiences with teachers' goals and school, state, and federal standards. Professional communication with teachers is also important. In regard to teacher professional development programs that focus on reform-based practices, such as teaching science as inquiry, Capps et al. (2012) conducted a critical review of the literature. These researchers concluded that although there are many reports of programs describing various features and outcomes, there were few empirical studies about professional development programs focused on inquiry instruction published in peer-reviewed journals. More empirical studies are needed specific to this area, given that teaching science as inquiry is an area of mainstream reform in science teaching.

Reform

As countries strive to carry out reform in teaching science, it is apparent that the teacher should be at the center of the reform. A major challenge for researchers is to demonstrate a link between a particular professional development model and the enhancement of teachers' knowledge; their beliefs of science; pedagogy; intentions to change their teaching methods; changes in actual classroom practice; and, ultimately, increased student achievement. It is important to shift research based on only teachers' self-reports to data based on classroom-based research. In that case researchers visit classrooms, as teachers carry out their new lessons. Actual classroom observations are conducted and analyzed. At this time, little empirical evidence exists that definitively demonstrates the effectiveness of one teacher professional development model over another. More studies are needed that utilize data across these four areas: teacher knowledge and beliefs, teachers' intentions, teachers' practices, and their students' learning. Although we have early case studies of single teachers, classrooms, and groups of students that lay the foundation for evaluating various kinds of professional development programs, more studies are needed that use quasi-experimental or experimental approaches. It is important to consider the context of the professional development program. In addition it would be very useful for researchers to carry out synthesis studies in the area of professional development. High-quality professional development programs may be expensive. We need to view professional development as an ongoing process and one that is complicated. We need to value and commit to investing in sustained and effective experiences. Otherwise, it seems unlikely that major changes will take place in science classrooms. Finally, it is important for researchers to communicate their findings to policy makers and stakeholders, in clear language, in order that investments can be made in effective programs.

New York, NY, USA

Keywords

Feedback; Learners; Research; Teacher Learning; Teachers as Researchers

Introduction

Consistent with Hannah Arendt's (1958) revelation that scholars have valued theory production to a greater extent than improved practice, it is reasonable to assert that research should provide balanced outcomes that yield deeper understandings of education and improved practice. In addition, teacher research can be viewed as an essential requisite of professional practice, a central role that occurs continuously. If teacher research is to attain goals of producing deeper understandings and improving practice, it is essential that curiosity is fostered about teaching, learning, and curriculum in a context in which all participants/stakeholders (e.g., teachers, students, parents, school leaders) are considered as resources for doing research and benefiting from it.

Structures, including policies and practices at all levels of education, should afford high-quality teacher research – as a requirement, not just as a possibility that is condoned with restrictions on the use of tools such as digital technologies (e.g., video and audio recordings). Appropriate research methodologies used by teacher researchers include interpretive approaches that incorporate making sense of experience, learning from others' diverse perspectives, and testing interventions intended to improve practice. Teacher research is applicable in any institution where science education is practiced, having the goal of improving and sustaining high-quality learning environments.

Social life is complex and enacted practices (i.e., social interactions) are distributed throughout a collective with and without awareness. Since these interactions are basic units for learning, it seems desirable for all participants to become aware of key interaction patterns, contradictions to them, and data that are salient to teaching and learning. Seeking answers to the following broad questions expands awareness and provides opportunities for individuals and collectives to consider change: What is happening? Why is that happening? What contradictions are noteworthy? And what changes are desirable? Such questions can initiate and sustain ongoing programs of teacher research in which teachers and students regularly review answers to each of these questions and discuss those answers with others in a class. Not surprisingly, analysis of video and audio files of science lessons can lead to the identification of practices that should be used more often, those that might be improved, and others that could be used less frequently and perhaps be eliminated.

Cogenerative Dialogue

Cogenerative dialogue (i.e., cogen) is an activity in which participants from a class can discuss specific examples of questions like those posed above and their associated responses (Tobin and Llena 2011). The number of participants in cogen can vary from two to many – criteria for selection include shared experience of an activity such as a science lesson; differences in social categories such as achievement level, race, native language, and sex; and opportunities to participate actively and equitably. During cogen all participants have a chance to speak and be heard, and all contributions are carefully considered in regard to their feasibility and potential to improve the quality of teaching, learning, and goals. It is important to listen, build understanding of others' contributions, and fully consider their efficacy. Recollections and associated stories about what is happening are important resources for cogen and can lead to striking changes in the quality of the learning environment. Also, analyses of video and audio files are usually part of cogen. Changes deriving from cogen include expanded social networks, increased strength of social bonds, emergence of solidarity, and increased magnitude of positive emotions that transfer to the classroom. Because cogen provides all participants opportunities to speak and be heard, it is frequently part of a methodology for teacher research, affording salient questions to be asked and answered.

Science in Teacher Research

Becoming aware may be sufficient for initiating changes. For example, alerting participants to characteristics considered as likely to be salient to their learning allows them to reflect on their own practices in relation to those characteristics and make significant changes in the incidence of mindfulness in science and science teacher education classes, quality of dialogic inquiry, and intensity of positive emotions. Similarly, awareness about physiological variables provides new foci for teachers' and students' reflections and possible changes. In some of the most recent studies, finger pulse oximeters have been used to provide participants with a personal display of pulse rate and percentage of oxygen in the blood. Teachers often have a high pulse rates and oxygen levels fluctuate from a saturation level of 100 % to low levels beneath the percentage considered safe for jet pilots to fly a plane (i.e., <92 %). Oximeters, which provide three measures per second for pulse rate and oxygenation, enable teachers and students to create personal and collective landscapes for pulse rate and oxygenation, from which they can identify patterns and contradictions that are relevant to their well-being. Participants often want to change pulse rate and oxygenation to levels they find acceptable. For example, teachers might find a pulse rate of 138 beats per minute unacceptably high in a context of an average pulse rate of 90 and standard deviation of 10 beats per minute. Similarly they might be concerned about oxygenation levels below 90 %, especially if such levels are sustained for meaningful amounts of time (i.e., more than just a fraction of a second). A low-oxygen scenario usually raises questions about saturation, especially because the standard deviation of oxygenation data for a teacher might be less than 1 % – that is, a question that arises is whether oxygenation levels of 99–100 % are problematic. Concerns such as these raise questions about whether changes are needed and, if so, how they might be enacted. Accordingly, collaborating with teachers to design and enact interventions to potentially change pulse rate and oxygenation of the blood leads to very new forms of teacher research.

Based on research on physiological expression of emotions and breathing patterns, another approach has been to design a breathing meditation intervention to ameliorate emotions (Philippot et al. 2002). During 3-min intervals at the beginning and midway through a class, participants stopped what they were doing and focused on their breathing, expanding their abdomen on the in-breath and contracting their abdomen on the out-breath – letting go of emotions and thoughts as they occurred. In this way teachers and students used breathing meditation to focus and alleviate undesirable emotions as they arose. Notably many participants used breathing meditation to reduce stress in out-of-school contexts. These approaches put into practice science in teacher research in new and interesting ways.

Teacher research is considered an essential component of exemplary science teaching, having the purposes of ascertaining what is happening in science education at classroom and institutional levels and dialoguing with stakeholders such as students concerning how to improve and sustain appropriately high-quality learning environments. As a central part of an enacted curriculum, teacher research should not be regarded as optional or, even worse, a detriment to learning. As science curricula are enacted, the research-practice gap should be eliminated by research that orientates toward high-quality teaching and learning.

Conclusion

As is the case with most research on teaching and learning, teacher research is an activity that can be enriched through collaboration of stakeholders, including teachers, students, administrators, parents, and university science educators. What is learned can potentially reform science education writ large, and for that reason collaboration of a multi-institutional, multivoiced nature is regarded as highly desirable.

Professional development; Teacher development; Teacher recruitment; Teacher shortage; Teaching force

Main Text

The single most important sector of school science education is the teaching force. However, in many countries, effective science teachers are in relatively short supply. European exceptions to this pattern include Finland, Spain, Scotland, and Northern Ireland (EURYDICE 2002). In some cases, recruitment of new teachers cannot keep up with the number of teachers changing careers or retiring (sometimes referred to as "wastage" as opposed to "turnover" which refers to people who take up a post at another school).

Science graduates have a range of skills which make them relatively highly employable. As such, many of the best graduates, particularly in the physical sciences, may never consider careers as a science teacher. Factors affecting their decisions may be related to the status of teaching in their specific society, the levels of remuneration in that society, a preference for working in a business or commercial environment, etc. In some countries, the prospect of having to teach across biology, chemistry, and physics (and, in some cases, earth science) may not appeal to graduates who see themselves as specialists in one science, although this appears to be very much less of an issue in those countries with long traditions of general or combined science courses – put simply, in those countries where general/combined science is the lived school experience of the graduates.

Many strategies have been used to increase recruitment. These include financial incentives ("golden hellos" or training bursaries), diversifying the available routes into the profession (so as to allow overseas and mature entrants to take up places), allowing unqualified people to teach, providing taster courses (opportunities to spend time in one or more schools prior to applying during or after undergraduate study), short-term appointments for leading graduates (such as the Teach First [England], Teach for America, Teaching Australia schemes), and booster courses to increase applicants' chances of surviving teacher training. It is also the case that teacher recruitment tends to increase when a country's economy is weak – teaching is seen as offering a secure if not particularly well-remunerated career.

Strategies aimed at improving teacher retention usually take into account the reasons why people leave the profession. Research – from England – across all subject areas suggests that among the main factors to influence teachers' decisions to leave the profession were workload (most important), the opportunity for a new challenge, the school situation, salary (least important), and personal circumstances (Smithers and Robinson 2003). A disproportionate number of leavers were either young, with a only few years' service, or much older and approaching retirement. Leavers tended to be female (often wanting to have a family and then return) and to come from the shortage subjects such as the sciences. Young leavers were more likely to cite salary and personal circumstances and less likely to complain of workload than the other leavers.

Strategies to reduce the numbers leaving the profession during initial teacher education or while they are in post include coaching, mentoring, appraisal, increasing opportunities for professional development, and financial incentives. Studies reporting on teachers' lives and careers tend to suggest that the quality of the school management and the level of support from fellow teachers are critical factors affecting how teachers feel about themselves and their work. A number of models of teacher development make reference to three or more dimensions of development including the personal, the social/school level, and the professional (knowledge, skills, etc.). Professional development aimed at increasing teacher satisfaction as well as effectiveness seems to work best when these factors are taken into account.

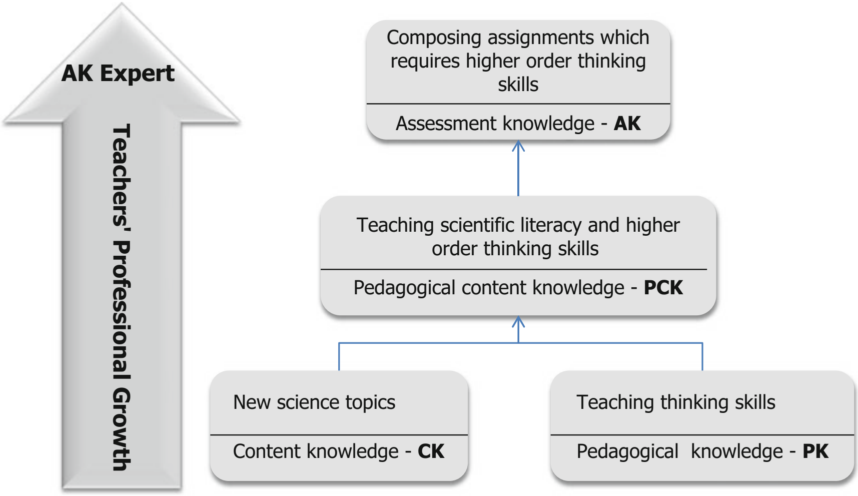
Teachers' knowledge of methods of assessment

Teachers' assessment knowledge, AK, is the knowledge and understanding teachers have about assessment, its value, its types, and its applications for evaluating students' learning outcomes. Assessment carried out in the classroom is designed both to help teachers determine what and how well students learn (assessment of learning) and to improve students' learning (assessment for learning) (Birenbaum et al. 2006). These two possible objectives of assessment are also referred to as summative and formative assessment, respectively. Most of the students' assessment mode and content are determined by their science teachers – the assessment agents. They choose what, how, and when to assess their students. Since new and challenging reforms in science education require teachers to teach for meaningful learning, science teachers are required to cope with new teaching methods and assessment that are aligned with these new methods (Abell 2007; Magnusson et al. 1999).

Teachers in general and science teachers in particular are important players in successful implementations of new curricula. While developing their content knowledge (CK) and pedagogical content knowledge (PCK), teachers need training and ongoing support in adapting to new content, as well as new pedagogical and assessment methods. Pedagogical content knowledge, as defined by Shulman (1986), is "a particular form of content knowledge that embodies the aspects of content and of teaching ability" (p. 9). Shulman's theory is related to content knowledge, general pedagogical knowledge (PK), curriculum knowledge, pedagogical content knowledge, knowledge of learners and their characteristics, knowledge of educational contexts, and knowledge of educational purposes and values. However, Shulman's theory did not focus on teachers' assessment knowledge. Over the years, this theory has been revised and extended by science educators. Magnusson and colleagues (1999) and Abell (2007) proposed a comprehensive interpretation of pedagogical content knowledge that included science curriculum goals and materials, science learners, and aspects of assessment knowledge, such as science assessment methods. They suggested that experienced teachers should



Teachers' Understanding of Assessment, Fig. 1 Stages in teachers' professional growth while teaching and assessing higher order thinking skills

know what aspects need to be assessed in a particular setting and used the term "knowledge of methods of assessment" (Magnusson et al. 1999, p. 108).

There is a gap between high-stakes accountability tests and students' learning outcomes resulting from small-scale curricular and instructional practices. Examples of such high-stakes accountability tests are Trends in International Mathematics and Science Study (TIMSS) and Progress in International Reading Literacy Study (PIRLS). This gap underlines the importance of teachers' assessment knowledge. This is even more crucial in view of the difficulties most teachers face while attempting to apply the variety of assessment methods in order to achieve useful and efficient classroom and individual students' assessment and to enhance their instruction. Encouraging teachers to design and implement suitable assessment tasks can broaden teachers' knowledge about students' learning outcomes and may serve as a way for them to decide if they need to repeat teaching of specific subject matter or skills. We expect science teachers to develop assessment knowledge for measuring not only learning but also scientific and thinking skills. Teachers do not always feel sufficiently prepared to assess their students. These feelings of inadequate readiness are noticeable especially when the teachers are exposed to new curricula and teaching methods. Without teachers' effort to align assessment with the latest education reform requirements, their students will not develop the required scientific and thinking skills.

Teachers' knowledge about assessment of learning and assessment for learning is an essential part of teachers' knowledge in general and pedagogical content knowledge in particular, especially in an era of science education reforms. In the past, but in many places even today, the most common way of assessing students has been the traditional form of a summative test. This sort of test usually examines content knowledge, and it does not assess higher-order thinking skills. In recent years, researchers have shown that teachers who applied formative assessment in order to promote students' higher-order thinking skills in a context-based environment succeeded in developing the desirable skills. According to Dori (2003), assessment tasks should cover a broad spectrum of cognitive capabilities, including not only low- or intermediate-order thinking skills but also higher-order thinking skills. The latter include analyzing data, asking questions, solving analytical and conceptual problems, drawing conclusions, constructing models, moving across different representations, designing new experiments, and transferring knowledge from one scientific domain to another. In order for teachers to be able to assess their students' higher-order thinking skills, they need to synchronize between their teaching and their assessment while keeping in mind their content knowledge and pedagogical goals. Researchers showed that teachers' lack of assessment knowledge limited their pedagogical content knowledge. Teachers' assessment knowledge is knowledge at a higher level, above pedagogical knowledge, content knowledge, and pedagogical content knowledge (see Fig. 1 based on Avargil et al. 2012).

In order for teachers to develop assessments that will support their students in meeting the recent science education reform requirements and expectations, they first need to broaden the spectrum of their pedagogical content knowledge. Having gained a sufficient level of pedagogical content knowledge, science teachers can then design assessment tasks that are commensurate with the new teaching methods and apply them in their science classrooms. Engaging in designing and implementing a range of assessment activities will, in turn, expand the science teachers' assessment knowledge.

Assignments science teachers develop may serve as a tool for defining their professional growth and assessing whether they have made progress beyond the PCK level and attained the assessment knowledge level (Avargil et al. 2012). Observing science teachers as they instruct their students how to apply feedback to improve scientific literacy and higher-order thinking skills is another means for teacher mentors to determine whether these teachers reached a satisfactory level of assessment knowledge.

Teaching and Learning Sequences

Dimitris Psillos
Department of Primary Education, Aristotle University of Thessaloniki, Thessaloniki, Greece

In science education one notable line of inquiry, aspects of which date back to the 1980s, involves the design, implementation, and validation of short, topic-oriented sequences for science teaching in several subject areas, including, optics, motion, heat, electricity, structure of matter, fluids, respiration, and photosynthesis. This work falls within a science education research didactical tradition in which teaching and learning of conceptually rich topics are investigated at micro (e.g., single session) or medium (e.g., a few weeks) level rather than at the macro level of a whole curriculum (1 or more years). Although various terms have been employed in the past, the term teaching-learning sequence (TLS) is now widely used to denote the close linkage between proposed teaching and expected student learning as a distinguishing feature of such research-inspired subject-oriented sequences. A TLS is both an interventional research activity and a product, usually lasting a few weeks, comprising well-validated teaching-learning activities, empirically adapted to student reasoning and often including well-documented teaching suggestions and expected student reactions.

The state of the art of TLS in 2004 was described in a special issue of the International Journal of Science Education (Vol. 26, No. 5, edited by Méheut and Psillos). The editors noted that TLS is a flourishing research sector, with several valuable empirical studies in various topics published over the last 30 years and that both theoretical positions and questions or issues regarding the character of research into TLS have been brought to the attention of the European (and indeed the worldwide) science education research community. Researchers generally agree that this sort of activity involves the interweaving of design, development, and application of a teaching sequence in a cyclic evolutionary process enlightened by rich research data.

Interest in design research and development has also spread to education research more generally, mainly in the USA, under the broad perspective of design-based research (DBR) (Design-Based Research Collective 2003). DBR has been advocated as an approach to educational research that seeks to provide means for developing innovative teaching and learning environments and at the same time to develop theories of learning and teaching adapted to specific contexts. Few references to TLS appeared in early DBR studies and vice versa, however, a situation which has only recently started to change.

Examination of publications concerning TLS- or DBR-based work brings to the fore certain common features. First, the work is interventionist, seeking to develop useful products, such as teaching materials, in response to emerging problematic situations and needs. Second, it aims to contribute to the development of educational theory embedded in specific contexts in normal classrooms. Third, the work is iterative, which implies that both product and design are tested and revised in several cycles. Fourth, it is usually carried out by teams involving both researchers and teachers. These features also constitute open issues that continue to be studied and debated by researchers.

Work in any design process involves drawing on several kinds of knowledge, including grand theories relevant to the problem. In the case of TLS, various grand theories of pedagogy, development, learning, motivation, epistemology, history of the subject, and sociology of education are possible sources. Theories like social constructivism may afford general suggestions that can contribute to design principles but have little to offer in designing teaching on a specific topic or providing answers to questions such as “how to deal with students’ conceptual difficulties in explaining situation X” or “how to prompt students to relate scientific knowledge to evidence during experimentation on topic Y.” Accordingly, certain frames or models for the design and development of a TLS have been suggested and used by researchers as intermediates between grand theories and subject-oriented demands. These are presented below.

Starting from Freudenthal’s position, Lijnse (1995) and the Utrecht group proposed a frame for developing “didactical structures” within an approach they called “developmental research.” Great attention is paid to the motivational and meta-cognitive dimensions and to the learning on the part of the teachers made necessary by such an approach. Some general indications concerning conceptual development are given, with three suggested levels: selection of focus, transition to a descriptive level, and, if necessary, transition to a theoretical level. In this frame it is suggested that the teaching-learning process be deconstructed into five phases: motivation, question, investigation, application, and reflection. In the context of developmental research, didactical structures are empirically regulated and iteratively refined, starting from a scenario describing and justifying (a priori) the design of teaching-learning activities and the expected teaching-learning processes.

The model of “educational reconstruction” (MER) developed by Duit, Gropengießer, and

Kattmann attempts to combine the German hermeneutic tradition on scientific content with constructivist approaches to teaching and learning. MER holds that clarification of science subject matter is an important issue if instruction in a particular science content is to be developed and is based on an integrated constructivist view. On the one hand, the knowledge acquisition process is seen as an active individual construction process within a certain social and material setting, while science knowledge, on the other hand, is viewed as a tentative human construction. The analysis of content structure leads to constructing the core ("elementary") ideas of the content to be taught. Designers' initial ideas about the construction of instruction play an important role in planning empirical studies on teaching and learning. The results of empirical studies dynamically influence the processes of educational analysis of the content, the setting of detailed goals and objectives, and the construction of instruction.

The "Two Worlds" frame was developed by Tiberghien and the Lyons group, in order to inform the design of TLS by drawing on the epistemology of experimental sciences and on Vygotsky's theory of learning (Buty et al. 2004). In a series of studies, the authors make a double categorization of knowledge into everyday knowledge and physics knowledge, each offering ideas for describing objects/events in the material world which may be linked via modelling processes to distinctive theories/models for interpreting, predicting, or explaining events in the material world. Modelling is treated as a foundation for scientific knowledge, and the physics classroom is viewed as a place where students are invited to participate in an educational community where one of the teacher's roles is to convey some of the knowledge and methods of scientific communities. Two specific complementary design tools have been developed for informing the design mainly of physics teaching: the "Knowledge Distance" tool, which potentially guides the framing and sequencing of the teaching content, and the "Modeling Relations" tool, which may guide the design of specific teaching activities at a more detailed level.

The Leeds group (Leach and Scott 2002) draws upon Vygotskian grand theory on meaning-making. Approaches of personal sense-making and a realist ontology have been integrated with this Vygotskian theory to develop a social constructivist frame on learning scientific concepts. This brings together the social-interactive and personal-sense-making parts of the learning process and identifies language as the central form of mediation on both the social and the personal plane. It draws upon sociocultural approaches in conceptualizing learning in terms of developing a new social language and in identifying epistemological differences between social languages and upon evidence relating to alternative conceptions in clarifying the nature of the learning required by students in order to make personal interpretations of the social language of science. The "Learning Demand" is a design tool that was developed for identifying the conceptual aims of science teaching at a more detailed level. Another design tool, the "Communicative Approach," focuses on classroom discourse. The verbal communication in the classroom is described in terms of two dimensions: authoritative/dialogic and interactive/noninteractive.

Seeking to design an effective TLS that also advances educational theory related to a specific topic, Andersson and the Gothenburg group (Andersson and Bach 2005) adopt a somewhat different perspective. They suggest that design work which aims to build insights into conditions that favor learning with understanding may or should develop "content-oriented theory" for specific topics. Content-specific theories should focus on specific issues such as students' understandings, the nature of the topic, and general issues such as the key role of the teacher as an agent of education and culture. In addition TLS work should design and test "useful products," such as teachers' guides and study material for students, which may be put into practice in various ways. They consider that designers of a TLS may provide either a detailed sequence of activities and suggestions to teachers or some general principles as well as the relevant materials so that teachers themselves will develop relevant activities. The authors and their colleagues consider that science education should develop as an independent domain rather than a kind of applied psychology

Working with TLS involves the conceptualization and treatment of situations and interactions that may be complex and therefore the refinement of these sequences to ensure that their work is of specific importance. There is general agreement that a TLS normally develops gradually through a cyclic evolutionary process informed by research data. This process results in the enrichment of the TLS with empirically validated student outcomes and contextual applicability. Such a design and development process tends to be iterative. It involves successive approximations of a desirable intervention. Each iteration helps sharpen aims and deepen contextual insights and contributes to the outcome of design principles drafted, products improved, and professional development opportunities for the participating team. Analysis, design, and evaluation take place within each iteration. Analysis primarily features assessment of harmony (or discord) between the intended, implemented, and attained learning. Its findings usually offer guidelines for design that target the closure of one or more gaps between the intended, implemented, and attained curricula. These guidelines take the form of design specifications that will shape the products of teaching sequences. As development continues, products may be partially or even wholly elaborated. At the conclusion of a design cycle, a product's stage of development influences the kind of formative evaluation activities that may take place.

Work on TLS provides a fruitful recent advancement of science education research and development of empirically validated products. This said, it is recognized that designers' and researchers' craft knowledge about effective practices is valuable for providing contextually valid answers to specific didactical issues and questions. The advancement of the dialogue between grand theories, design frames, methods of empirical refinement, and participants' craft knowledge is also considered to open new perspectives in addressing both the features of the design process and the expected products for improving science teaching and learning.

Teaching and Sociocultural Perspectives

Yeung Chung Lee
Department of Science and Environmental Studies, The Hong Kong Institute of Education, Tai-Po, Hong Kong, China

Keywords

Cultural influences; Science learning; Science teaching; Sociocultural perspectives

Background

The sociocultural dimension is an integral part of education systems, and classroom teaching and learning are neither culture- nor context-free. The learning of different subjects is bound to be affected to varying extents by the sociocultural backgrounds of learners and teachers, the political and sociocultural milieu, and the broader global education environment. Science education is no exception, despite the universal nature and empirical stance that are purported to be unique to science. The ideal vision of "science for all" implies that learning science and developing scientific literacy are a common entitlement of students, irrespective of their sociocultural background. However, a common consensus on what constitutes the aims, contents, and pedagogies of a "universal" science education has yet to be reached, and the ideal of equity of opportunity in learning science is far from a reality considering the uniformity of the learning materials, which is in stark contrast to the immense sociocultural diversity within and across various classroom settings. Readers may refer to the review articles by Cobern and Aikenhead (1998) and Lee and Luykx (2007) for an overview of how these perspectives impinge on the teaching of science. Three fundamental questions are pertinent when considering teaching and sociocultural perspectives and how the gaps in equality can possibly be bridged to achieve science for all:

1. What are the sociocultural perspectives that bear on the teaching and learning of science?
2. How are the teaching and learning of science influenced by these perspectives?
3. How can science teaching respond to the challenges posed by sociocultural perspectives? What is the meaning of sociocultural-sensitive teaching in achieving science for all in light of the sociocultural diversity among science students?

The Sociocultural Dimension with Respect to the Teaching and Learning of Science

If science education is regarded as a process of cultural transmission, like other areas of education, it will encounter obstacles when it meets with cultures that are at odds with or not in alignment with the culture of science. This transmission entails the crossing of cultural borders, particularly by non-Western students (Cobern and Aikenhead 1998). The literature reveals the interplay between a number of sociocultural factors, ranging from explicit factors such as socioeconomic status, language, schools, and the politico-economic milieu to more deep-seated ones such as traditions, religion, values, and worldviews, with globalization intertwining among all of these. Socioeconomic status and school factors influence students' chances of accessing the resources that are essential for achieving the goals of science education. The 2011 TIMSS study showed that schools with more resources had higher average student achievement than those that were under-resourced (Martin et al. 2012). It is not easy to pinpoint the exact reasons, but well-resourced schools are more likely to benefit from a higher-quality teaching staff, a technology-rich learning environment, and the support of laboratory facilities. However, the influence of the general socioeconomic climate on students' learning seems to work in a rather different way through influencing values at the regional or national level. The findings of the ROSE (Relevance of Science Education) project found, paradoxically, that the more developed the country, the less overall interest its young population seemed to have in school science. A possible inference is that children in developing countries see learning science in school as a privilege, whereas those in developed countries view it more as a duty or obligation, thereby affecting their motivation to learn science (Sjøberg and Schreiner 2010). The language environment in which science teaching and learning take place is another problematic issue. The use of English as the medium of instruction (MOI) due to the traditional dominance of Anglo or Euro-American culture in science and science education poses a barrier to learning, particularly in non-Western countries. Switching the MOI to the mother tongue cannot solve all of the problems, because difficulties abound in translating the culture-laden terminologies of science without distorting their meaning to a certain extent.

An example is the term "hypothesis," which is translated into Chinese as "assumption" rather than as "tentative explanation," thereby resulting in misconceptions on the part of the learner and even teachers and textbook writers.

Given these various influences on student learning, one would expect sociocultural factors to affect students to a greater extent than they do teachers, as the latter have already been acculturated in science. However, teachers are also liable to deep-seated politico-social influences that are manifested in different ways. Science teachers inevitably engage in power relationships with students, which may compromise the use of student-centered learning approaches. Teachers who adopt an authoritative stance in their relationships with students may be less inclined to use student-directed open inquiries or argumentation-oriented classroom discourse. This tendency is often exacerbated by the relatively large class sizes in less-developed countries, which make it difficult for the teacher to balance the need for classroom control and the desire to adopt a more open type of inquiry-based instruction to achieve important learning goals. Teachers are also under the influence of the mainstream values of the school, community, or society at large that may be at odds with their own beliefs or the goals of science education, thereby curtailing open discussion of some potentially controversial socio-scientific issues such as stem cell research or scientific theories such as evolution. These mainstream values are also likely to interact with students' own cultural values to influence their moral judgment and decision making on socio-scientific issues.

Responses to Address the Challenges from Sociocultural Contexts

In response to the problems associated with the sociocultural dimension of teaching and learning science, how can science teachers minimize the equity gap due to cultural diversity and help students to cross the cultural boundary, and how may they help students to view science and science learning in perspective while respecting the students' cultural diversity? It is perhaps instructive to identify the challenges faced by teachers before discussing potentially fruitful responses. Some of these challenges are outlined below:

1. To identify the disparity between students' cultural backgrounds and the culture of science and how the former may affect science learning
2. To be aware of the nature of teacher-student relationships and the school culture or ethos and their compatibility with the goals of science education
3. To reconcile scientific and nonscientific beliefs, e.g., religions, indigenous worldviews, and societal values that are deeply rooted in different cultures, while recognizing the important differences between the two
4. To be aware of the teacher's own thoughts and beliefs about the influence of sociocultural contexts on science teaching and learning
5. To provide a language-enhancing environment for non-English-speaking students while reducing the language barrier in science learning

Even with these daunting tasks to accomplish, sociocultural diversity need not be seen as a barrier to science learning. It could be perceived as an opportunity to encourage or challenge students to reflect on their own and other cultures in comparison with that of science. Through this reflection, they may come to a better understanding of the culture of science. To facilitate this reflective process, students should be made aware of the nature of science, including the subjectivity of scientific theories and their empirical and tentative nature, and contrast it with the underpinnings of their cultural or indigenous beliefs. For example, they could compare and contrast creationism with the Darwinian theory of evolution and indigenous medicine with modern health and medical science, leading to a personal view of the nature of the differences between science and their cultural beliefs and the unique contribution of both toward the construction of knowledge and society. Additionally, making use of students' everyday knowledge relevant to science practices and considering how science could extend their personal knowledge base may facilitate students in crossing the border between their own culture and the culture of science. Furthermore, non-English speakers could be engaged in inquiry-based learning that provides a language-enhancing environment to help them learn both science and language in a meaningful and synergistic way. However, responding to sociocultural diversity does not mean that teachers should undermine science or uphold scientism. On the contrary, teachers should communicate vividly to students how the substantial contribution of science to society was made possible by the use of creative thinking, scientific reasoning, and evidence-based argumentation and judgment driven by scientific attitudes, the integration of which has made science distinctive from other knowledge systems. As students' perspectives on socio-scientific issues are likely to be influenced by sociocultural or contextual settings, engaging different student groups in cross-cultural or cross-contextual exchanges on global or regional issues could extend their capacity for multi-perspective reasoning and metacognitive reflection, which are essential for consensus building and problem resolution in an increasingly connected and globalized world (Lee and Grace 2012).

Future Directions

A culture-sensitive science curriculum needs to be implemented to promote equity in science learning. Science educators and researchers should explore the meaning of such a curriculum and how it could be manifested in light of the nuanced sociocultural diversity within and among various student groups and the subtle influences of school policies, community values, and the politico-economic milieu. The literature shows that teachers can be empowered to turn the challenges of students' cultural diversity to their advantage by understanding and accommodating sociocultural differences, using students' everyday cultural experiences relevant to science, and facilitating intercultural understanding and exchanges. A future agenda for science educators and researchers should involve rethinking the meaning of "teaching science for all" from different sociocultural perspectives and how it could be incorporated into effective classroom practice.

Teaching for Conceptual Change

▶ Conceptual Change in Learning

Teaching in Play-Based Contexts

Hanan Sukkar[1] and Denise Chapman[2]
[1]Faculty of Education, Deakin University, Frankston, VIC, Australia
[2]Monash University, Melbourne, VIC, Australia

For some lay observers, play is mistakenly viewed as a leisure and uncomplicated activity done by young children. Lay observers may also see early childhood play-based settings as lacking academic opportunities for young children and may regrettably view the role of teachers in early childhood play-based contexts as simply custodial managers of chaos. However, a play-based context sets a stage for meaningful exchanges of thought that can beneficially challenge children's understandings and be particularly suitable for transforming children's everyday understandings to scientific knowledge.

While there have been shifts in theoretical approaches and differing texts on how one may view young children engaging in the human venture of science, early childhood play-based environments are settings for scientific inquiry, which can engender even the youngest of children to be critical thinkers, problem solvers, and reflectors of reason.

Play as a Context for Learning About the World

The concept of play is viewed as an essential means for a child to both explore and gain a better understanding of the world around them. When children play, it allows them to challenge their preconceptions, engage in safe risk taking, and encourage imaginative experimentation. Play can involve deep engagement about how and why things happen, as well as provide the driving force for experimentation and exploration. The companion to play is learning. Play is intertwined with learning, as it has been shown to bring elements of enjoyment and focus to learning experiences within play-based settings.

While the concept of play has been a key area of focus in early childhood education research, there is no firmly agreed-upon standard definition of the concept of play. Instead one's theoretical approach to children's learning appears to be the means through which the concept of play is described. For instance, a theoretical belief that situates play as an innate activity for making sense of the world would agree with Piaget's view that "play is the child's way of adapting to his or her situation in life, assimilating it and understanding it" (Ebbeck and Waniganayake 2010, p. 11). This view would see play as an intrinsic means for children developing representations of the world through a series of stages. However, a theoretical view that sees intellectual development coming about through social dialogues within specific context may align with Vygotsky's view that play leads development by lending "a space for the conscious realizations of concepts" (Fleer et al. 2009, p. 4). In brief, this view sees social interactions as providing the space for children to shift their understandings and that through play, young children can bring their everyday understandings of their world and use these to form foundations for higher-order thinking and learn scientific concepts. Vygotsky described children involved in play as thinking a "head taller" than their actual existence. Thus, the context of play provides space for "head taller" scientific concept learning. While there are other perspectives relating play and learning, most draw heavily on Vygotsky and Piaget's perspectives (Ebbeck and Waniganayake 2010).

There are different types of play that support learning, for example, those within social spaces, guided play (children engaged in pleasurable, spontaneous activities guided by adults which strongly support children's academic and social learning), object play (playing with toys and other objects which can lend insight into language and cognitive development of children with special needs), storytelling and fantasy, and play as performance. Despite the diversity in how children play and the differing theoretical perspectives on play, it is commonly agreed that with play comes opportunities for children to learn. More specifically, these diverse forms of play bring about varied opportunities for children to transform their understandings. Early childhood settings subscribing to play-based learning open the doors for children's everyday knowledge to be solidified and extended.

Play as an Act of Inquiry

Youngquist and Pataray-Ching (2004) argue that play associated with learning should be described as "acts of inquiry" rather than just "play." They contend that substituting the words "acts of inquiry" with the term "play" can bring about a new discourse that elevates the concept of play "as educational, meaningful, theoretically driven, and curricularly worthwhile in the academic setting" (p. 171). There is extensive research stressing the deeply intricate nature of play as well as proponents of play advocating for society as a whole to understand the fundamental importance of play, yet play is still often perceived outside the field of early childhood education as simple and devoid of academic rigor. Youngquist and Pataray-Ching (2004) suggest that talking about play as acts of inquiry allows play to be seen as it truly is – activities that entail complex critical thinking and reflection engendering new conceptual understandings.

When play is seen as an act of inquiry, young children can take a leading role in developing their own "action-ed" knowledge that is unique, meaningful, and co-constructed within the play-based learning context. Much like play, children learning about science can also be seen as engaging in acts of inquiry, as it entails children exploring and recognizing the science embedded within their everyday experiences.

Science as an Act of Inquiry

Real science begins with childhood curiosity, which leads to discovery and exploration. Babies engage in science through acts of inquiry, as they are born curious and interested in learning about their immediate environment. They use their senses for inquiry and depend on vision, touch, smell, sound, and taste in identifying the world in which they live. Infants explore and gain an understanding of physical and spatial concepts as they move around their environment by crawling, learning to stand independently, and mastering how to walk on different surfaces. At this point, they begin to interact more readily with the physical world and discover spatial awareness.

Toddlers can be viewed as little scientists. They are driven by great curiosity to explore the unknown. As 2-year-olds, they like to sort objects and put things into piles based on color, size, shape, or use. They enjoy filling and dumping experiences such as pouring sand and water into containers of different sizes. As children enter preschool or kindergarten, exploration continues. This time however, children begin to apply basic concepts to collect and organize information and answer questions. Preschoolers are naturally curious, often posing the question "why." Their desire to question, hypothesize, explore, and investigate is part of their very being. Young children's inherent sense of inquiry provides the foundation for scientific knowledge (Charlesworth and Lind 2013). This scientific knowledge is not science as a collection of facts, but instead looking at science as a means of dealing with and extending our everyday experiences.

Educators in the early years should endeavor to nurture, enrich, and sustain children's interest in scientific knowledge. Children's science experiences can be facilitated through the use of learning spaces that encourage children to observe, research, create, test hypotheses, and collaborate to find understanding (Campbell and Jobling 2012). Strategies for building upon children's everyday knowledge and leading them toward scientific understanding can also include the use of puppetry as well as the use of children's drawings paired with interviews about their understandings of particular occurrences. Early childhood educators can encourage both play and science by providing an abundance of materials that would allow children to measure, observe, weigh, and record the outcome of their play experiments. These catalysts to scientific thinking mesh well within play-based contexts. For young children, play and science are acts of inquiry on the world around them. The enthusiastic wonder with which children approach the world should be acknowledged and accounted for in early childhood programs.

Conclusion

Play is the platform for learning. It provides children with the space to be hands on, minds on, and action oriented (Campbell and Jobling 2012). Science is what children do and how they think about what they do. Science within play allows children to investigate, experiment, test, hypothesize, discover, and construct their own ideas, all of which enhance and build children's knowledge. Hence, science falls naturally within a play-based context, as it enhances and builds children's knowledge.

What Is Teaching Out-of-Field?

In 1990, "teaching out-of-field" was described as "education's dirty little secret." The label "out-of-field" has been used since the early 1980s to refer to qualified (or certified) teachers (usually) teaching a subject for which they have no formal qualification. While the term "teaching out-of-field" is used in the literature, it is still a relatively contemporary and contentious label that is not widely adopted by practitioners. The term is more commonly associated with secondary school teachers (or middle school or high school, typically students aged 12–18 years).

Generally, a teacher is considered "in-field" if they possess a minor or a major and a teaching qualification (including a teaching method) in that subject. However, internationally, no universal definition for a suitably qualified teacher exists because of differences in teacher education, accreditation requirements variation in school systems, and state certification processes. Consequently, there is no common understanding of what might be considered out-of-field. The issue is complicated further for teachers of science because, in some countries, science is taught at the junior secondary level (ages 12–15) as a generalist subject, encompassing the main science disciplines. Therefore, even teachers who are technically in-field in "general science" can experience problems associated with out-of-field teaching, such as when teaching physics with only a biology background.

Incidence and Reasons for Out-of-Field Teaching

Out-of-field teaching arises for a number of reasons, such as unmet teacher demand, poor school leadership and management, teacher choice, and alterative curriculum models where teachers teach in cross-disciplinary teams.

Ingersoll (2002) places at the heart of the issue, at least in US schools, not supply/demand imbalances and inadequate initial teacher education, but "the manner in which schools are organized and teachers are employed and utilized" (p. 24). Internationally, the OECD raise the equity issue, reporting that teacher shortage problems seem to be most acute in schools serving disadvantaged or isolated communities. Other studies examining the Australian science (and mathematics) teaching workforce indicate that the incidence of teaching mathematics or science out-of-field has been a long-standing issue in schools and thus is a constant reality facing policy makers and school leadership.

In Australia, various state and national surveys of the teaching workforce have identified that between 16 % and 20 % of teachers of junior science (years 12–15) lacked a minor in any university science discipline (see a discussion on this in Hobbs 2013a). Similar figures are being reported from Korea and South Africa, with much larger figures reported in the USA (see, e.g., Ingersoll 2002). Out-of-field teaching appears to be most widespread at the junior secondary levels compared to the senior years where teachers tend to be more correctly assigned.

Ingersoll (1998) raised concerns that the extent of teacher shortages is masked when underqualified teachers fill these positions, thus resulting in an unrealistic picture of the shortage of science teachers being reported worldwide. The reality is that many schools experience difficulty recruiting qualified teaching staff, and the problem is exacerbated by the aging staff profile, uncertainty about career pathways, and poor teacher retention partly as a result of job dissatisfaction. Ingersoll (2002) argues that top-down styles of school leadership that make decisions based on budgetary constraints rather than what is needed by the faculty have contributed significantly to the high proportion of out-of-field teachers in the USA.

Implications for Teaching and Learning

Out-of-field teaching places additional strain on subject coordinators and school administrators due to the extra support, mentoring, and resources required. In turn, school leadership that does not acknowledge the complexity of teaching out-of-field and the individual needs of the out-of-field teacher can have disastrous consequences for teachers, particularly novice (also called early career or beginning) teachers.

For the teacher, being technically out-of-field does not mean necessarily that he or she will not be an effective teacher. However, highly effective teachers have a deep understanding of the subjects they teach, they encourage the study of their subject, and value the surface and deep aspects of their subject. The question as to whether an out-of-field teacher has these subject commitments and depth of knowledge without the required disciplinary and methods background must remain central when decisions are made about who is teaching what.

Research often identifies a lack of content knowledge and pedagogical content knowledge as being the key issue for teachers (see, e.g., Wallace and Louden 2002). In Wallace and Louden's review of some of the research from the late 1980s and 1990s, they identify the following issues for out-of-field science teachers:

- Lacking a "repertoire of pedagogical content knowledge tricks" (p. 27), including the representations associated with the content and the learning difficulties and strategies for overcoming them
- Lacking a knowledge of timing of activities used within a lesson
- Activities that are used without certainty of whether they will work and how they relate to the concepts
- Use of less "risky" activities

- Rapid and frequent changes to lessons
- Inadequate explanations leading to teacher and student confusion
- Common reliance on traditional teacher-centered methods, such as reliance on the textbook
- Limited confidence to discern whether students have understood the content

Research has also found that teaching out-of-field can compromise "teaching competence"; can disrupt a teacher's identity, self-efficacy (see, e.g., Hobbs 2013a), and well-being; and is often associated with teacher strain and attrition (Ingersoll 2002).

Many factors can determine whether a teacher "feels" out-of-field, regardless of whether they are technically in-field or out-of-field (Hobbs 2013a), factors relating to personal resources of the teacher (such as knowledge, background, commitment, and adaptive expertise); their context, such as the administration practices of the school, constraints, and affordances associated with the geographical region, school size, teacher supply and demand, and policy climate; and the availability of support.

Novice teachers are often assigned out-of-field. They may be appointed to a position at the school on the proviso that they accept an out-of-field load, or as the least senior teacher in the school, they may be expected to "fill the gaps" at the junior secondary level. Unfortunately, novice teachers also have the highest attrition rates, particularly in the USA (Ingersoll 2002). Research is showing that beginning teachers are at greatest risk when teaching out-of-field because they have a limited knowledge base. Novice and experienced teachers respond differently to teaching out-of-field, with the more experienced teachers utilizing to their advantage their solid base of general pedagogical knowledge (Wallace and Louden 2002). "Through the authority of their experience, they have a meta-awareness of what needs to be done to teach well, and the limitations on teaching imposed by their lack of knowledge" (Wallace and Louden 2002, p. 218). In addition, Hobbs (2013b) has shown that the discontinuity (disruption to practice and identity) experienced by some mid- to late-career teachers who take on an out-of-field subject can lead to more directed and focused learning as they are more able to reflect on and distinguish between the practices they are moving from and into. Novice teachers, however, can lack knowledge in many areas of teaching, so crossing the boundary from an in-field to an out-of-field space simply adds to the already enormous load and is less likely to produce learning gains in the same way as it might for experienced teachers.

The effect of out-of-field teaching on student achievement, engagement, and attitude toward science has been the focus of some research, although the data is not necessarily consistent. Little research shows that a science-qualified teacher at the lower secondary level increases student achievement. Furthermore, there is no research that shows that a science-specialist teacher will ensure students are more engaged, although there is a plethora of research that indicates that teachers who are passionate about their subject, and students engaging with the subject, are preferred by students.

Teacher Learning

Table 1 provides a range of support mechanisms that teachers can draw on in their learning. The nature of support needed by out-of-field science teachers depends on where the difficulties arise for teachers, such as lacking content knowledge, poor management of students in the laboratory, or inability to link activities to content. It is through identifying discontinuities that teachers may be prompted to reflect, innovate, adapt, learn, and develop new or expanding identities. Because discontinuity is individually determined, one size fits all approaches to professional learning are inappropriate.

Whether a teacher seeks out or undertakes professional learning for an out-of-field subject depends partly on their orientation to that subject, such as whether they see themselves as simply filling in for someone, making the most of an

Teaching Science Out-of-Field, Table 1 Support mechanisms used by out-of-field teachers

Support provision	Sought support	Constructed resources
1. Support materials (a) Curriculum and syllabus documents (b) Provision of materials (c) Textbook 2. opportunity by endeavoring to maintain high levels of student engagement and achievement, or pursuing an interest because they have a high level of self-efficacy arising from positive historical interactions with the subject (Hobbs 2013a). Also, school leadership plays a strong role in supporting teacher development. Being aware of a teacher's area of need is important for school leadership to target their approach, such as providing out-of-field teachers with extra time for preparation and to work with subject-specialist mentors in the school area. Providing multiple opportunities to teach the subject can lead to a sense of success (Wallace and Louden 2002).

What Needs to Be Done

In light of the expected longevity of this issue, further understanding of its effect on all key stakeholders will inform appropriate local and systemic responses.

There are a number of ways that the problem of out-of-field teaching can be dealt with. Actions can be linked to three aims:

1. Reducing the need for out-of-field teaching
2. Improving the quality of out-of-field teachers
3. Increasing teacher readiness of teacher graduates

If the aim is to have enough qualified teachers, increasing the supply of science teachers is imperative. This may be done through governmentally supported initiatives to promote career change of professional in the sciences or to encourage recent science graduates to enter teaching. Yet another approach is for school leadership and management to ensure that adequately trained teachers are hired, allocated, and resourced.

If the aim is to improve teacher quality, then attending to the professional learning of out-of-field teachers is paramount. At both the school and the policy levels, there needs to be greater support for the retraining of out-of-field teachers so that they can be given the funding, time, and space to understand new and emerging teaching approaches. At the school level, conversations can be had with the teacher about subject allocation and the degree of support available and required.

If the aim is to ensure that teachers are adequately prepared for the reality of teaching, then some responsibility falls on teacher education programs to prepare adaptable and flexible teachers. Preservice teachers can be prewarned of the likelihood of teaching out-of-field, the skills, knowledge, and attitudes needed to be adaptable and flexible, and the variety of support mechanisms that can be provided, sought out, or constructed by them. Focusing on the development of resilience in preservice teachers may help them to accommodate new and different ways of thinking;

challenge their own beliefs, assumptions, values, and practices when faced with the dilemmas and tensions of teaching; and help them to employ proactive coping strategies.

Team Teaching

Stephen Keast and Rebecca Cooper
Faculty of Education, Monash University,
Clayton, VIC, Australia

Background

Team teaching is a term used to describe a collaborative approach to teaching and learning. Co-teaching, collegial teaching, cooperative teaching, and complementary instruction are but a few of the terms that are encountered when reviewing the literature related to team teaching. Much of the literature describes team teaching in a similar way to Buckley (2000) who viewed team teaching as involving a group of instructors working purposefully, regularly, and cooperatively to help a group of students learn (p. 4). Buckley's purpose was to shift teachers away from working as individuals in isolation and move them toward working purposefully in collegial teams with common objectives. Thus, the need to create a team seems important. Bess (2000) described teams as "a group of experts . . . continually engaged with one another, their institution and with their clients . . . they bring knowledge into the group, they learn from one another and they learn from the students they teach" (p. 209).

Team Teaching in Teacher Education

Bess's notion of team, in particular the ideas of continual engagement and learning with each other and students, formed the basis of the successful team teaching approach described in the work of Keast and Cooper (2012). They identified a number of benefits of team teaching in science teacher education including greater freedom to make decisions in the moment than when teaching alone, greater confidence to be more flexible with approaches to teaching, easier to take risks during teaching, providing a different perspective on the same teachable moment, encouraging analysis of critical incidents in the moment from a knowledgeable outsider's perspective, and the opportunity to monitor teaching and change the direction of the experience from outside rather than within the teaching.

They found that team teaching made explicit their pedagogical reasoning more often which helped their preservice teachers better understand the decisions their teachers were making as they were teaching (Keast and Cooper 2012). In many ways, this approach to team teaching opened up new opportunities for these teacher educators to more formally develop their pedagogy of teacher education and to model teaching in ways that challenged more superficial views of modeling as mimicry.

Technology and Science Education Research

This entry considers possible interactions between technology education and science education.

Although often perceived as being strongly related, technology and science draw on different knowledges and practices and at their core represent different ways of knowing. It is therefore important that a broad education reflects both the interrelatedness of and the differences between technology education and science education. In explicating the implications for compulsory education, we explore the existence of technology education as a discrete school subject, as well as its introduction and integration into the science curriculum. We then compare and contrast the nature of science with the nature of technology. Our argument throughout is that embedding a broadly defined notion of technology in science education has the potential to enhance students' scientific *and* technological literacy. However, this potential has yet to be fully implemented and realized.

While there is no doubt that we live in an increasingly technological world, it can be argued that human endeavor has always been essentially technological and that technology today is just an accumulation of that activity rather than something new and unique. Even sophisticated information and communication technologies build from previous technological developments. However, the rapidity with which technological change is occurring in contemporary society is unprecedented – and will by all accounts continue to escalate. As a result, there is an increasing need for formal education to equip students for a world that is rapidly changing. Both science education and technology education have central roles in addressing this need, each having unique and important contributions to make.

Worldwide, science education and technology education generally sit as two discrete learning areas within school curricula. This is largely premised on understandings of the differences between science and technology as distinct disciplines. For example, whereas science is primarily focused on providing coherent frameworks to understand and predict the physical and natural world, technology represents an intervening in the world to develop products and systems that address human-identified needs and opportunities. "Technology education," therefore, means far more than "information and communication technology" or computing skills. Technology education also differs from technology in education.

Technological endeavors encompass a wide range of activities, including the transformation of energy, materials, and information in products, systems, and environments. Just as the different disciplines in science differ in terms of knowledge, content, and processes, so do the different disciplines in technology. For example, the knowledge and work of an industrial technologist differs substantially from that of a biotechnologist. This highlights the need for thinking about "technologies" rather than technology as a single endeavor. Schools often reflect different technologies by packaging them into discrete subjects, for example, materials technology, food technology, and electronics.

Within national and state curriculum documents, contemporary technology education often represents a broadening of more traditional gendered skills and craft-based subjects. While skills development has remained a core part of this expanded curriculum trend, concepts associated with the nature and process of technological endeavor have been introduced with far greater prominence than before, and aspects such as design have become increasingly important.

While technology education has been expanding its brief, science curricula, too, have been broadened internationally. A widespread change has been to include greater emphasis on technological applications of scientific principles. This reform has been driven by the view that science is a foundational subject for technological development and was spurred on by postwar education and economic policy in the 1940s and 1950s and, in Western industrialized countries, the USSR's initial forays into space. There was also growing recognition that contextualizing students' scientific learning using technological applications has potential to increase student engagement and enhance their conceptual understanding.

Science, technology, and society (▶ STS) curriculum initiatives, pioneered in the 1970s, reflected "science for citizenship" and "science for all" agendas and offered tantalizing opportunities for more integrated approaches to science education and technology education. In the majority of cases, however, the emphasis in classroom practice has remained on science, with the social relevance of technology valued far more highly than concepts associated with the nature of technology. Similarly, policy initiatives around the science, technology, engineering, and math (▶ STEM) movement, underpinned largely by political rhetoric situating future scientists as key to economic advancement, have in reality resulted in continued emphasis on science and mathematics, with a lesser focus on technology and engineering. Even with the inclusion in science curricula of socioscientific issues (▶ SSI), where the issue is often associated with a technological outcome of science (e.g., genetic modification of organisms for enhanced crop yield), scientific knowledge and ethical dimensions tend to be prioritized over technological aspects. However, it is sometimes the broader technological context that needs to be considered in order for a full understanding of the ethical issues to be developed. For example, the outcomes that can be achieved in a strictly controlled laboratory environment often do not reflect the reality of full commercialization. By ignoring this aspect, the complexity of developing commercial products is underplayed, obscuring the wider knowledge base required for full product development and perhaps reinforcing an erroneous notion of science and technology as being both simple and value-free.

In the majority of science curriculum innovations, therefore, technological examples or contexts have been an add-on rather than being more fully integrated. While examples of genuine curriculum integration do exist (e.g., Rennie et al. 2012), these are far less common, and content is relatively open to debate. It is also not yet clear what authentic assessment of these integrated units might look like.

Where science education continues to be prioritized over technology education, a common reason relates to the historical privileging of science as an intellectual pursuit with higher social status when compared with the learning of technical or craft skills, which is viewed as less academic and has traditionally been linked with lower socioeconomic positioning. The result is a valuing of science over technology at the school level as well as by society more generally. Second, it is often left up to science teachers to implement initiatives such as STS and STEM, and so the science subculture within which the teacher is embedded influences how these innovations play out in the classroom. In particular, the strength of teachers' science understanding and skills when compared with their technological knowledge/skills often means that science learning is privileged over technology learning and so predominates.

To take a more integrated approach to science and technology education in order to enhance students' scientific *and* technological literacy requires the teacher to have robust understandings of both the nature of science and the nature of technology. The development of this understanding is not unproblematic. In particular, teacher practices have strong links with their initiation and socialization into particular subject subcultural settings. This often leads to a consensual view about the nature of the subject, the way it should be taught, the role of the teacher, and what might be expected of the student. If technology is being increasingly linked with science as an area of study, then it is important that we understand both science teachers' perceptions of technology and the ways that these might influence the incorporation of technology into science classrooms. There are also concerning indications that even when science teachers develop broader views of technology, they may revert to their previously held notions (e.g., of technology as applied science) when faced with disparities between their new views and their practice, or when entering areas of uncertainty (Jones 2012).

A further challenge to integrating science and technology education relates to students' understandings of each of these disciplines. For example, narrow concepts of technology among students can affect student's learning of technological concepts. Further, students' existing concepts may have greater impact on their technological practice than their teachers, and these existing concepts can be difficult to change. This can be particularly challenging where teachers' own concepts of technology are fragile. In addition, many of the STS and STEM exemplars available appear to prioritize scientific knowledge over technological knowledge and skills (Jones 2009).

While science and technology both influence the way we see the world, they do so in different ways. For example, science has a cognitive motive aimed at understanding the world, whereas technology has a practical motive, focusing on what could or should be rather than what is (Vérillon 2009). Another distinguishing element between the nature of science and the nature of technology relates to the emphasis on design in technology, as opposed to investigating in science – means-ends reasoning as opposed to cause-effect reasoning (de Vries 2009).

Unlike scientific knowledge, technological knowledge requires a normative dimension. In other words, technological solutions are based on human judgements and the pursuit of the best outcome in terms of human preferences, rather than the most accurate outcome in terms of empirical evidence. Whereas a scientist might seek to understand under what conditions water boils, a technologist investigates, for example, ways to boil water with the minimum energy input. In addition, technological solutions tend to deal with multiple physical, environmental, and social variables, resulting in outcomes that might be suitable only within their intended context. In contrast, the development of scientific knowledge proceeds by isolating variables and reducing environmental complexity, leading to theories and laws that are highly substantiated. Further, technological pursuits often involve a valuing of certain variables above others. For example, in the design and construction of a vehicle, consideration is given to reducing friction when motion is sought but maximizing friction during braking. Therefore, technological solutions depend on the desired outcome for each particular situation. This example highlights that the outcome of technological intervention is pragmatic knowledge and the production of artifacts (Vérillon 2009). In contrast, the purpose of a scientific investigation is the production of descriptive and explanatory knowledge.

Often, it is how scientific knowledge is applied that is of interest and relevance to students. Technological developments therefore have much to offer science education in terms of engaging students and demonstrating the relevance of the science content. However, using technological applications only to exemplify scientific concepts has potential to reinforce the notion that scientific knowledge leads to technological development – "technology as applied science." This could be through science enabling technology, science being a forerunner to technology, or science being a knowledge resource for technology (de Vries 2001). However, such a view precludes understanding of other relationships between science and technology, including both technological developments preceding scientific discovery (common historically, e.g., many of Thomas Edison's inventions) and technological developments enabling scientific discoveries (also common historically, e.g., microscopes).

In ignoring these additional interrelationships between science and technology, there is the risk of simplifying the complex knowledge bases needed for both understanding and developing new technologies. In other words, science is only part of the equation in many technological developments – and it is these technological developments that are associated with addressing many of the world's social, economic, and environmental challenges.

Understanding science and technology as different, but often related in a range of ways in different contexts, is therefore important for students. This is particularly true given the increasing iterative interactions between scientific and technological knowledge in many contemporary developments. For example, pharmacology offers a rich repository of scenarios where both scientific and technological knowledge are needed. The development of mobile communication devices, with increased miniaturization and sophistication, similarly highlights the multiple interacting influences of scientific and technological knowledge.

Clearly, teachers need to consider the similarities and differences between the nature of science and technology in order that they have an appropriately broad understanding of each. This will help them firstly to evaluate the appropriateness of incorporating specific examples of technological applications into science education programs for particular purposes and secondly to work toward enhancing the scientific and technological literacy of students.

The need for both scientific and technological literacy is being increasingly recognized by science education research, with major science education journals publishing special issues focusing on technology education, for example, *Journal of Research in Science Teaching* (*2001*) and *Research in Science Education* (*2001*). Within the first of these publications, Cajas (2001) specifically recommends that scientific literacy includes a better understanding of technology.

Enhancing students' understandings of the nature of technology in conjunction with the nature of science is important for both their future citizenship, as argued above, and for broadening career opportunities. While historically there may have been a strong separation between science and technology careers, there is now an increasing number of employment opportunities where science and technology come together in some form. For example, science funding increasingly focuses on the interaction of the scientific discoveries with technological development and end-user applications.

To conclude, current science education has a relatively well-established tradition of using technological applications and technological problem solving to contextualize science learning. While having the potential to enhance student engagement and learning, such use of technological examples to contextualize science teaching and learning is not likely to lead to better student understanding of either the specific technology or the nature of technology more broadly. There needs, therefore, to be clarity about the purpose of using the technological context and what it does – and does not – offers to student learning. If there is the desire to maximize opportunities to develop students' technological literacy as part of their science education, the relationships between science education and technology education need further exploration – by policy makers, curriculum developers, education researchers, and teachers.

Technology for Informal and Out-of-School Learning of Science

Sherry Hsi
Lawrence Hall of Science, Berkeley, CA, USA

Keywords

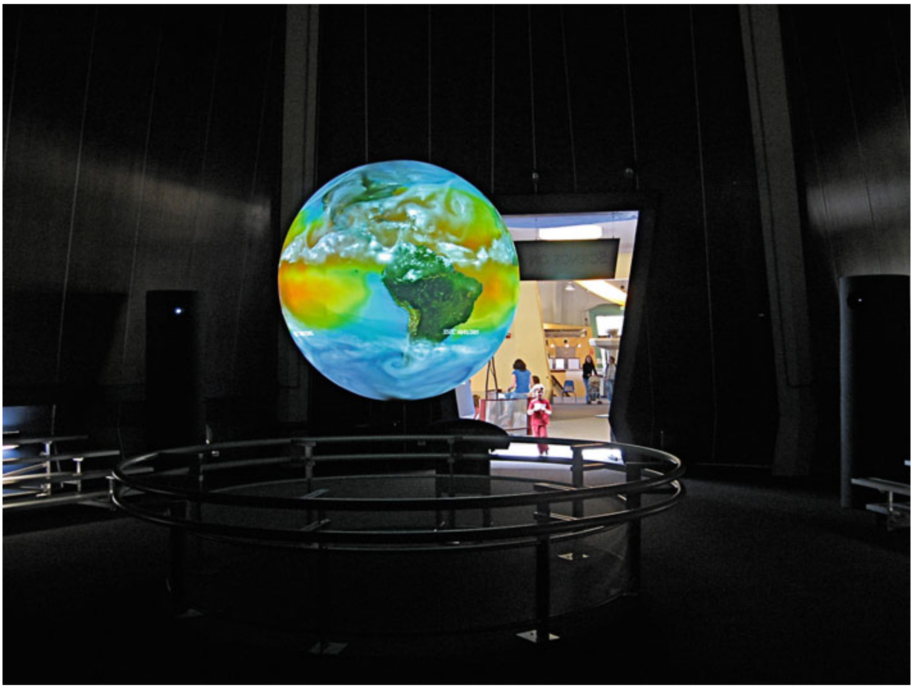
Citizen science; Informal learning; Museum learning

Learning that is supported in out-of-school settings is often referred to as informal learning, casual learning, extended learning, or free-choice learning. The learner voluntarily participates in activities, with his or her level of engagement growing out of curiosity or engagement in a social group or community. In contrast to formal schooling, informal learning has the characteristics of being fluid in activity and interactions, multigenerational, and even friendship-driven. The learner is often in charge of selecting the activities, location, and co-participants in the learning situation. Activities may be sponsored by particular institutions or programs such as science centers, libraries, museums, zoos, planetariums, aquariums, community centers, schools, or commercial firms. Alternatively, they may be completely unsponsored and spontaneous, occurring in a home, garage, or online environment.

In these out-of-school science learning environments, K12 teachers and students have a range of information technology appliances and applications with which to engage in informal learning. These include mobile devices, networked laptop computers, digital-game boxes, 3D printers, electronic kits, technology-enhanced exhibits, and other learning technologies. Science learning may also involve the orchestration of different technology components, digital contents, and platforms that together offer an infrastructure to support learners as they pursue a driving question, make a project, engineer an artifact, collaborate with peers, or play a game.

Museum-Based Learning: Technologies and Visualization

Some examples of informal learning technologies installed in science centers and museums include 2D and 3D visualizations projected in theaters, digital domes, or full spheres viewed by visitors including family groups. The National Oceanic and Atmospheric Administration’s “Science on a Sphere” is a 6-ft-diameter spherical screen (see Fig. 1) that displays colorful data about weather and other natural phenomena, projected onto the surface of the sphere from four external cameras. A museum educator can select different datasets to share, turning the projected sphere into a dynamic, colorful display, facilitating discussions with



Technology for Informal and Out-of-School Learning of Science, Fig. 1 Science on a Sphere at Berkeley Lawrence Hall of Science, UC (Photo credit: Tim Ereneta)

visiting school groups about science topics ranging from seasonal weather, geology, climate change, to astronomy. Similarly, interactive touch screen tables or walls are used to display visualizations of watersheds, paleontology, or marine algal blooms in river estuaries. Learners in such settings can even use their own bodies as controllers of projected video or animations, experimenting and manipulating the projected image to examine phenomena in an "embodied" way. Sensors embedded in exhibits can track how the learner's body moves and subsequently changes the projected images provided dynamic feedback. These kinds of experiences are designed to support learning while enhancing the learner's motivation and engagement.

Sponsored After-School Programs and Community-Oriented Workshops

After-school settings are also places where informal learning technologies are being used to support science, technology, and engineering education among school-aged children. One emerging model is seen in the community science workshops and science festivals, where individuals organize themselves into thriving local communities to fashion and craft creative digital media. Learning occurs through the creation and exchange of such media with peers and can happen in local community centers, schools, homes, shops, and storefronts. Social media, digital libraries, online discussion forums, and e-commerce sites are used to support such communities and bring people together online and face to face. For example, in a school, community center, museum, garage, or county fairground, a facilitator might show learners how to use various fabrication and design tools to create prototypes of artifacts. These tools may include computer-controlled milling machines, laser cutters, desktop 3-D printers, or programmable electronics and sensors. In the same way that desktop printers enabled self-publishing in the 1980s, personal design and manufacturing have been enabled by open-source programming tools (e.g., Arduino, 123D, Scratch) and low-cost personal fabrication technologies that empower learners to create tangible artifacts to take home for further reflection and play. Sometimes referred to as the DIY ("Do It Yourself") or the Maker Movement, education stakeholders are advocating such hands-on learning opportunities because they create rich opportunities for project-based learning and inclusion of engineering in the K12 curriculum and motivate students to consider engineering and technology-related careers.

Citizen Science: Information Technology to Support Science in the Community

Citizen science is a participatory approach to science education that engages students, amateur scientists, and the public in scientific research, enabled by technologies such as Web-based observation forms, probe ware, and digital imagery. Citizens are engaged in real science investigations on personal health (e.g., safe drinking water), regional livelihood (e.g., locally sustainable farming practices), or global issues (e.g., climate change or invasive species). Citizens can contribute observations of the natural world, such as counting the recent blooms, bees, or birds in their backyard. For example, the Great Backyard Bird Count project provides online tools to enable citizens to enter data collected from a 15-min observation in their backyards, helping scientists to track migratory birds or track invasive species. The FieldScope project from the National Geographic Society invites teachers and students to map a watershed with online tools that help them draw flow paths, enter water quality data, and upload photographs of a selected site. Additional visual layers can be selected to display data in the context of human geography, including sediments and land cover. Scientists then make use of contributions that are made by students or citizens to corroborate or augment their own datasets. Tools for these interventions may include cameras on users' personal mobile phones or specially developed Web applications for uploading and sending data to a shared database. Students can also engage in the data analyses through scaffolds provided by well-designed online tools. For example, the Zooniverse project invites the public to help identify objects they see in images of the seafloor, collaborating with oceanographers to indicate whether they see fish, scallops, and other organisms in a particular digital image and provide basic measurements through the "click and drag" of a mouse to describe whether the seafloor is sand or gravel. Such contributions from citizen scientists help the scientific project's team to classify from a collection of 40 million images, by HabCam, a habitat mapping underwater vehicle codeveloped by scientists, fisherman, and engineers. Information technology for citizen science has allowed the wisdom of crowds to help calibrate, validate, and gain consensus on data collected, engaging students and citizens in the practices of science.

Research on informal science learning can leverage novel approaches that embed technology as tools for research, evaluation, and assessment. Moreover, informal learning environments are creating opportunities to study learners' gains in content understanding and skill development as well as their engagement, beliefs (i.e., about the nature of science), practices, and motivation. While empirical studies of school learning have far outnumbered those of informal learning, there is a substantive body of research that investigates the impact of informal learning, including any contributions to science learning and interactions with school-based learning.

Technology for Science Education: History

Chris Quintana
Learning Technologies, School of Education,
University of Michigan, Ann Arbor, MI, USA

Introduction

As new technologies emerge, they are soon applied to educational aims. In science education, these efforts coincide with the rapid and continued advances in technology and the growing recognition that science education should go beyond teaching facts by taking a more project-based approach where students can engage in more substantive science projects. Thus, many technology projects for science education have included science inquiry activities, emphasizing science processes and methods in addition to science content (more information on many of the systems and research described here can be found in larger comprehensive reviews, such as National Science Foundation (2000) and Quintana et al. (2004)).

Early Technology Systems

Two early ideas about how technology could support science education were microworlds and probeware. The microworlds concept emerged from the work of Seymour Papert, who defined microworlds as "a subset of reality or a constructed reality whose structure matches that of a given cognitive mechanism so as to provide an environment where the latter can operate effectively. These concepts lead to the project of inventing microworlds so structured as to allow a human learner to exercise particular powerful ideas or intellectual skills" (Papert 1981). Computers provided a platform for microworlds that represented some real-world entity, i.e., the "constructed reality" plus a set of tools for people to build, interact with, and analyze that world. Some microworld systems allowed students to model complex systems and natural phenomena, providing a conceptual space filled with objects and agents that interact in ways defined by the student to facilitate active investigations and adjustments to the model over time. Logo, developed by Papert and his colleagues in the 1960s, was an early programming language that children could use to develop and explore microworlds.

Probeware involved the use of data acquisition devices for real-time data collection and software to analyze that data. Pairing data collection probes with computers led to the development of microcomputer-based labs (MBLs), where probes could be connected to computers so students could organize, visualize, and analyze the data being collected by the probes. This led to the development of probe kits, computer interfaces, and software that allowed probes to be used in science classrooms. Research groups such as The Concord Consortium, Computer as Learning Partners, and LetUS were early proponents of the probeware and MBLs, pairing these with classroom activities to guide teachers in using such tools within a science curriculum.

Microworlds and probeware were not necessarily new to professional scientists and researchers, who had already employed computers and data gathering probes for some time. With the advent of personal computers, student-appropriate versions of these tools emerged for science classrooms. Many systems followed in this tradition, such as NetLogo, Star Logo, Boxer, and Scratch. These systems were useful in their own right as modeling environments, with particularly strong applications in science. Microworlds and probeware were also significant because they laid the groundwork for new technology projects that expanded the level of science activity but retained an emphasis on inquiry, investigation, data collection, and modeling.

Personal Computers in the Classroom

The spread of personal computers in schools and homes and the increase in project-based science education in the 1980s and 1990s saw the development of technology tools to support students with various aspects of scientific inquiry. Microworlds and probeware provided some basic functionalities for performing and exploring scientific activities and phenomena, but this new generation of tools began to explore broader, supportive inquiry environments with various functionalities and scaffolding features to support students in the inquiry process.

Other software supported specific types of visualization to help students interpret scientific data using through accessible tools and representations. Examples of these types of tools include MyWorld, a geographical information system that supported middle school students with spatial visualization by overlaying geographically based data and maps. Another example was eChem, a molecular visualization tool for students to view molecules in different ways (e.g., ball-and-stick view, space-filling view, etc.) and interact with the molecules by spinning and moving them to see characteristics of the molecules.

Building on the microworld concept, projects moved beyond the use of visualization to help students build and think about scientific systems and phenomena. The Molecular Workbench project expanded on the visualization approach with an authoring system to support the creation of webpages that integrate text and functional components for chemistry visualization, simulation, and modeling. These components could be selected from an open-source library to help educators create a range of chemistry experiments, simulations, and curricula. Model-It was a general system dynamics tool for students to plan, build, and test models of systems. Students created system models by defining objects in a world, variable for those objects, and relationships between different variables. Students could then run the model to observe the changes in variable values due to the defined relationships and then iteratively refine the model. GenScope supported learning about genetics, with students creating different species of “dragons,” then comparing their genetic profiles with other dragon mutations and the larger dragon population. Students could modify the genetic profiles of their dragons and see the impact of those changes at the gene, cell, species, or population level.

Learning Environments

Further expanding the scope of student inquiry, other projects developed learning environments that supported the overall science inquiry process. Some of these tools could be thought of as process-oriented “shells” composed of a front end illustrating the different activities and subprocesses in the science inquiry process. Other tools for those different activities were then integrated behind this front end. Examples include the STAR Legacy system, Symphony, and ThinkerTools. STAR Legacy guided student investigations by representing inquiry projects as a cycle of steps, such as idea generation, research, and explanation. Symphony explored the notion of “process scaffolding” by integrating a set of planning, data collection and visualization, and modeling tools behind a front end that used process diagrams and reflective prompts to illustrate the main science inquiry process and activities. The ThinkerTools project used different visual representations of the larger inquiry process, providing students with associated tools needed for the different scientific activities in that process.

Other learning environments supported students with specific content domains or approaches to science inquiry, such as experimentation, design, or problem solving. The Learning through Collaborative Visualization (CoVis) project integrated different types of data collection, visualization, and analysis tools, plus a collaborative notebook, database, and mentor interaction to support collaborative student groups exploring weather and climate issues. The Biology Guided Inquiry Learning Environment (BGuILE) provided a set of tools for collecting, viewing, and comparing data, making field observations, and developing a scientific explanation. These tools were situated within a specific problem scenario that provided a framework for an investigation (e.g., investigating issues about finches on the Galapagos Islands to teach about ecosystems, natural selection, and changes in animal populations). Another example was the Knowledge Integration Environment (KIE) project and its successor, the Web-Based Inquiry Science Environment (WISE) project, which integrated different tools and materials with "inquiry maps," expert hints, reflection prompts, multimedia information and simulations, explanation and argumentation development, and templates to support different types of inquiry activities.

New Advances in Technology

As technology moves beyond the desktop computer, efforts continue to apply emerging platforms, paradigms, and devices for purposes of science education. Current efforts focus on mobile devices (e.g., smartphones and tablets), social media (Twitter, blogging, and wikis), and "mixed reality" environments where physical spaces or objects are embedded with technology. Some new projects follow the tradition of the inquiry environments and tools described earlier, but others are leveraging the unique characteristics of these new technologies to support new forms of science learning and instruction.

Mobile devices provide students with new tools to use in a range of science learning activities across formal (e.g., classroom, homework) and informal (e.g., parks, museums) contexts. Early tools included Chemation, a project for Palm devices that allowed students to create flipbook-style animations of molecules that reflected their understanding of chemical reactions. Other mobile tools allow students to collect scientific data in various locations. Some of these devices allow more traditional probeware to communicate with smartphones, tablets, or other proprietary mobile devices (e.g., the SPARK System) so students can collect numerical data for further study. Other projects, such as the BioKIDS or Project Noah, support students in collecting data and field observation to be used in subsequent inquiry activities. Recently, projects have made progress in the design and research of mobile inquiry environments. The Zydeco project, for example, supports not only the collection of different data (e.g., photos, video, audio, text) but also a broader set of science inquiry activities (e.g., planning, data collection and analysis, explanation) on smartphones, tablets, and the web.

Other projects are exploring more novel ways that mobile devices can be used in science education. One approach involves participatory simulations, where students use the mobile device to become agents within a simulation in a physical space, such as the classroom. Such simulations have been used to study epidemiology, population dynamics, and other complex systems. Thus, rather than create models and simulations on the computer, students essentially become the simulation, using mobile devices to display information about the agent they represent and the relationships with other agents (i.e., other students) in the physical space with whom they can interact, thus experiencing the system more directly.

Participatory simulations serve to bridge technological and physical environments, leading to new ideas about how the combination of physical spaces and technologies can support scientific activity. One approach is called embedded phenomena (EP), where computer displays or other data instruments are embedded into a physical space to represent some scientific phenomenon. The WallCology EP embeds computer displays in the walls of classroom to reveal an imaginary space behind the walls, where several species of digital insects inhabit various habitats and conditions. Much like students who explored microworlds, students in WallCology observe these new virtual features of their physical environment, taking data measurements, making observations, and testing predictions, then discussing their ideas. The EvoRoom project embeds and coordinates large displays (projectors and smartboards), mobile devices, and dynamic representations into the classroom space, creating an immersive rainforest simulation where students make observations and work with the dynamic visualizations of their collective inputs to discuss progress of the inquiry community.

Conclusion

Some consistent themes can be seen across the history of technologies for science education. Early ideas about probeware inspired tools to help students collect, visualize, and analyze scientific data. The microworld perspective has inspired environments that support students in the process designing and observing models and simulations. A lineage of progressively sophisticated tools has paralleled the emergence of increasingly responsive and well-instrumented environments that supported students as they investigate science ideas and methods. New technologies allow students to work with many forms of data, to collaborate dynamically with peers, or to become part of a "physical microworld" where Papert's notion of constructed reality is now enacted within a physical setting, augmented by virtual elements. New technologies will certainly continue on this trajectory, enabling students to actively engage in the scientific process with student-appropriate materials and representations while that promote deep interactions with peers and inquiry oriented forms of learning.

Technology for Science Education: Research

James Slotta
Department of Curriculum, Teaching and Learning, Ontario Institute for Studies in Education, University of Toronto, Toronto, ON, Canada

Keywords

Educational technology; Educational technology research

Main Text

There is a productive trajectory of research concerned with the role of technology in science education. Educational researchers have often situated their studies with science domains, given the structured and robust conceptual matter, the defined forms of problem solving and inquiry, or the available research funding (i.e., from governmental science agencies). Studies have investigated the nature of students' misconceptions and conceptual change, as well as problem solving, argumentation, collaboration, data analysis, design, scientific reasoning, and many other aspects of learning and instruction. Such studies typically employ computer and information technologies in order to support and investigate new forms of learning and instruction. New technologies included scientific visualizations (e.g., animations, simulations, etc.), probeware, models, data analysis, online discussions, and scaffolding environments (i.e., to support inquiry, knowledge building, and knowledge communities). Researchers have explored learning in science classrooms, playgrounds, households, museums, and other informal learning environments. Due to the wide scope of settings, topics, and approaches, it is not possible to address all aspects of the research, such as early work concerning educational radio and television (Tyack & Cuban 1995). Hence, the reader is encouraged to pursue the references cited, as well as the many substantive reviews that are available (e.g., Sawyer 2010). Additionally, the article in this Encyclopedia on the History of Educational Technology (Quintana 2014) presents an excellent summary – a history that has been driven largely by educational research.

Researching Science Misconceptions

Technology has played a prominent role in the research domain concerned with students' understanding of science topics, including the study of novice-expert differences (i.e., in knowledge, problem solving, and reasoning), and conceptual development. Many studies have explored the nature of student "misconceptions," with the aim of informing instruction that could help students to redress problematic ideas or build upon their existing understandings in a constructivist fashion. Researchers have designed computer-based materials that capture student ideas (i.e., by detecting patterns in their responses) and enable productive learning. In the ThinkerTools environment, for example, White and Frederickson (1991) investigated students' conceptions of force and motion using computer animations. Students could manipulate a simulated physical system in ways that would be difficult or impossible with a real-world system, all the while revealing evidence of the nature of their understandings. Using the Heat Bars simulation, Songer and Linn (1988) explored students' ideas about heat and temperature by allowing them to manipulate the material composition of a simulated bar (e.g., metal, wood or glass) and observe heat "flowing" through the bar. Many other studies explored computer-based tutoring environments, using artificial intelligence to create "models" of student reasoning, which were used to inform exchanges between the student and an automated tutoring environment (Anderson et al. 1995). Throughout the 1980s and 1990s, the computer emerged as a resource for researchers to capture, diagnose, and respond to student ideas, opening the door to a wealth of research about the nature of learning and instruction.

Scientific Models and Visualizations

Technology has also figured prominently in research concerned with the role of models and other scientific visualizations. Scientists and science learners engage with myriad forms of visualizations relating to conceptual or mathematical relationships, problems and solutions, or data tables and graphs. Scientists frequently make use of dynamic, computer-based simulations that support conceptualization or analysis, and visualizations are seen as an invaluable component in science learning. For example, sketches of molecular level concepts, like DNA, or processes, like mitosis, help to make the microscopic more visible and accessible to learners. The role of digital media has expanded greatly within every scientific discipline and, correspondingly, in science education. Computer-based visualizations offer clear advantages, such as the animation of concepts, ability to zoom in, rotate, play simulations backward and forward, or render events that can take generations to unfold into an observable timeframe. Science teachers often make use of visualizations using computer projectors or engage students with a myriad of Web sites using tablets, laptops, or computer labs.

Educational researchers have investigated the application of such media in learning and instruction: Should students make use of the same tools and representations employed by scientists? Should they engage with intermediate models, to help them gradually build more sophisticated ideas? How can multiple forms of visualization be interconnected, to support students? What kind of guidance is needed, and what forms of inquiry can best support students' and teachers' effective use of scientific media? How can visualizations support social or collaborative learning? A biological simulation environment called GenScope (Hickey et al. 2003) allowed students to manipulate the genes of a fictional species of dragon, then run the simulation through thousands of generational cycles, in order to study the variation of traits in individual dragons (e.g., "has wings," "breathes fire"). In another research environment called Model-It, students were supported in exploring the causal relationships within a system (e.g., a watershed ecology) using a dynamic modeling environment (Stratford et al. 1998). Other systems have investigated whether the linked usage of multiple representations for science topics can productively challenge students in the construction of scientific understandings. Several large research centers, such as technology-enhanced learning in science (TELS), have investigated effective designs of curriculum and assessments that integrate such materials and how students and teachers can best interact with them (Linn et al. 2006).

Technology-Enhanced Inquiry Environments

A third area of research is concerned with technology-enhanced learning environments that provide students with support as they engage in online inquiry projects, hands-on design activities, field-based research projects, or multiuser collaborations. Researchers design computer-based learning environments to embody their goals or conjectures about learning, embedding their hypotheses within materials, activities, and tools. For example, researchers who want to understand how students find and critique relevant resources have developed environments that include supports for the evaluation of evidence and formation of arguments (Bell 2004). To study how student reflections might foster understanding, learning environment were developed that included prompts and supports for student reflection. Such environments can support collaboration, design projects, experimentation, modeling, or various other forms of inquiry learning. For example, BGuILE, the Biology Guided Inquiry Learning Environment (Reiser et al. 2001), supported students in developing and testing their own scientific hypotheses about evolutionary biology, based on carefully constructed data sets. The technology environment supported students as they inspected data, read case studies, performed analyses, and created arguments. The Web-based Inquiry Science Environment (WISE) offers a scaffolding framework for short inquiry projects where students reflect on "evidence" (in the form of carefully designed or found Web sites), create their own artifacts (drawings, concept maps, etc.) and participate in online exchanges with peers. WISE can support a wide range of pedagogical designs, with more than 20 configurable inquiry tools and an authoring system that allows researchers or teachers to create any desired sequence of activities and materials (Slotta and Linn 2009). The notion of a learning environment that scaffolds students and teachers as they engage in new forms of learning and instruction is one that will continue to drive many lines of research and innovations for science classrooms.

Immersive and Multiuser Online Environments

Taking advantage of new technology features and functions, researchers have begun to explore how virtual worlds or multiuser virtual environments ("MUVEs") can support students or teachers in science learning. Not only could this approach potentially bridge individuals or groups that were physically separated, it might also allow for new kinds of interactions, experiences, or exchanges. For example, in the River City project (Nelson et al. 2007), a classroom of students gathers online (each student working at his or her own computer) to explore a nineteenth century American town that is afflicted with a mysterious health condition. Each student adopts a digital avatar and joins up with peers to investigate various sources of evidence throughout the town, collecting data, examining patterns, and speaking with local guides and consultants. The research on these environments suggests a great potential for shared online experiences, as reflected by the amount of activity devoted to such interactions by the gaming community. Educational researchers will continue to investigate immersive multiuser environments for science and other domains, with likely applications in K-12, home, and online learning contexts.

Distributed Learning Environments

Technology-enhanced environments have now escaped the confines of the computer screen. Recent advances in networked technologies and new technology platforms (e.g., tablets or multi-touch tables) have enabled the development of instrumented learning environments that employ wireless sensors, probeware, handheld computers, and other devices to support student activities across a wide range of learning contexts. For example, students might perform Web-based activities at home or in the classroom, then go out to the playground or local woodland and use a mobile phone or tablet to collect observations, which are then compiled into a larger data set to be used in subsequent inquiry activities (Songer 2006; Milrad et al. 2008).

Networked approaches have also been advanced, such as Mister Vetro (Loannidou et al. 2010) where students work in small groups to cooperatively control an animated model of human physiology that is projected on a large display before the group. Mr. Vetro has interconnected respiratory, circulatory, and nervous systems, and each student controls a different aspect of the simulation using their own personal handheld device (i.e., phone or tablet). The group explores the impact of different interventions (e.g., exercise, eating) on Mr. Vetro's physiology and must work together to keep him healthy. In another form of networked learning, Colella (2000) provided each student in the class with a small necklace containing an infrared transmitter and receiver called a "Thinking Tag," and organized them into a collective (i.e., the whole class) activity about disease transmission. Every student was a potential virus carrier, with the aim of greeting as many people as they could without contracting the digital virus. Initially, just one student started out with the virus, but after moving around the room for just a few minutes and interacting with peers (via infrared "beaming"), nearly every child in the class had become infected. By carefully designing instruction that incorporates these physical, embodied experiences, the teacher or research can help students gain a deep understanding of the pertinent science concepts (i.e., human body systems or disease transmission).

Social or Community-Based Inquiry

Other lines of research have employed technology to support whole class or even multiple classrooms of students inquiring together as a "knowledge community" (Bielaczyc and Collins 2006). Recent advances of Internet technologies have emphasized social forms of interaction, sometimes referred to as "Web 2.0," which include collaborative writing environments like wikis, social networking environments like Facebook, and content communities like YouTube. These developments have inspired educational researchers to create technology environments that support collaborative and cooperative knowledge construction. Scardamalia and Bereiter (2006) have explored the notion of knowledge building, where students in a classroom work as a knowledge community, using a technology platform called The Knowledge Forum with the aim of advancing ideas (akin to a community of scientists who work within a discipline). Peters and Slotta (2010) employed a wiki to engage five sections of a high school biology course (totaling 132 students) to cooperatively construct a comprehensive knowledge base concerning Canadian biodiversity. Once completed, this wiki (roughly 300 Web pages) provided all students with a well-structured resource for subsequent inquiry activities. As Web 2.0 and networked technologies become more accessible and familiar to researchers, we should expect more studies where students work collectively to contribute and evaluate content, interact with peers, and develop shared resources. Researchers will be challenged to conceptualize new forms of productive interactions for learning and instruction, and teachers will be challenged to develop new pedagogical understandings and practices required to coordinate such socially oriented approaches. Teacher practices and professional development will be an important aspect of such research.

Learning in Museums or Science Centers

Another area of research where technology has played an important role is that concerned with science learning in museums and other informal learning environments, such as aquariums, nature centers, or guided field trips to the local stream or forest. Researchers have designed engaging exhibits, activities, and materials that allow students to experience science phenomena in ways that are inaccessible to classroom instruction. Science centers and museums are investing in sophisticated projection systems for use in theaters, digital domes, or other interactive surfaces. For example, the Science on a Sphere, developed by the US National Oceanic and Atmospheric Administration, is a 6-ft diameter spherical screen that displays colorful images of a planet, moon, or star (e.g., weather patterns or solar storms), projected from four external cameras. Similarly, interactive multi-touch tables or walls are used to display visualizations of raindrops, rivers, watersheds, or microbes. One or more learners could then experiment and manipulate the contents of the displays to examine, for example, how microbes affect ocean temperatures or rain flows within a watershed. Using projectors and computer-vision techniques, students are asked to "kick" digital asteroids, projected onto the floor, to help them understand inertia and the physics of movement and collisions (Lindgren and Schwartz 2009). Such forms of media interaction are a frontier for learning research, often designed to support tangible and embodied interactions, where the learner's physical engagement with materials is seen as an essential aspect of the design (i.e., as opposed to simply reading or watching on a screen).

Future Research with Technologies

Technology has transformed nearly every major social institution, including business, government, the arts, and – increasingly – education. While one could argue that classrooms today remain largely the same in form and function as those of 50 years ago, there is evidence that technology is making an impact. Higher education is rapidly evolving through the impact of online learning, with "flipped classrooms," audience response systems (also known as "clickers"), and other innovations. In K-12 science classrooms, interactive whiteboards and computer projectors are increasingly common, and teachers are gaining prowess in how to use them. Students are empowered as never before, with the world of information and social networks at their fingertips (e.g., YouTube, Google, and many other sources of content).

Teachers can access resources, yet they are rightfully cautious in changing their practices without compelling evidence of success. To simply give a science teacher a classroom set of laptop computers, for example, would not be sufficient impetus or resource for her to begin using that new technology in a substantive way. Many questions remain. How should teachers engage students with such technologies in a meaningful way? What is the role of the teacher, when students are engaged online? What materials and what activities are the most effective? These questions remain largely unanswered, as educational research is still in the early stages of understanding how technology can transform science learning and instruction. Research is making some progress toward this end, as the above sections reveal. Investigating how technology can help students to develop deep understandings, interact productively with peers, and access scientific ideas is at the forefront of the research agenda. Educators will be able to access the body of empirical findings and the wealth of new materials and learning environments as they emerge.

Technology, Assessing Understanding of

Edys Quellmalz
WestEd, Redwood City, CA, USA

The definitions of technology for this encyclopedia entry are based on documents produced by national sets of experts. The definitions of technology are the starting points for developing assessments of understanding of its forms and uses. This encyclopedia entry begins with a summary of prominent conceptualizations of technology. Descriptions of some potential types of assessment tasks and items to test understanding of technology are provided.

Definitions of Technology

Technology is defined as any modification of the natural or designed world developed to fulfill human needs or desires. Technologies are products and processes resulting from application of engineering design processes and may often be based on scientific knowledge. Technologies also often function as tools and processes used to support engineering design which is defined as a systematic and iterative approach to designing objects, processes, and systems to meet human needs and wants. The effects of technology on society and the world are often cited as key concepts in understanding the needs driving development of technologies and the consequences of technology development.

Sources of Conceptualizations of Technology

Framework for K-12 Science Education and **the** ***Next Generation Science Standards*** (NRC 2011; NRC 2013). The framework includes engineering and technology as they relate to applications of science. Engineering is used to mean engagement in a systematic design practice to achieve solutions to particular human problems. Two core engineering ideas are specified. The first is engineering design – how engineers solve problems. Technologies may be used to support solving problems, and technologies may be the outcomes of the engineering design process. The second core idea is understanding of the links among engineering, technology, science, and society. The framework describes grade-band end points for each of the three components.

The *Next Generation Science Standards* (NGSS) provide more specific guidance for assessing understanding of technologies, their use, and their influences on society and the natural world, for example, knowing that simulations are useful for predicting what would happen if various parameters of the model were changed. Also, technology use varies from region to region and over time and is driven by findings from scientific research and by differences in such factors as climate, natural resources, and economic conditions. The NGSS present performance expectations that have been developed to integrate the engineering core ideas with crosscutting concepts such as systems and models and cause and effect and also with science and engineering practices.

Technology and Engineering Literacy (***TEL***) ***Framework for the 2014 National Assessment of Educational Progress*** (NAGB 2010). The framework defines technology and engineering literacy as the capacity to use, understand, and evaluate technology as well as to understand technological principals and strategies needed to develop solutions and achieve goals (NAGB 2010). The framework lays out three areas of technology and engineering literacy, the types of thinking and reasoning practices that students should be able to demonstrate, and the contexts in which technologies occur. Three main assessment areas are specified: design and systems, information and communication technology, and technology and society. Within design and systems, three subareas of essential knowledge and skills are identified: nature of technology, engineering design, system thinking, and maintenance and troubleshooting.

Principles for the nature of technology expand the scope of common conceptualizations of technology beyond computers and the Internet. The broader view includes every way people manipulate the natural environment to satisfy needs and wants. Therefore, technology includes all the various devices and systems that people make to fulfill some function. The framework lays out key principles for the nature of technology: (1) technology is constrained by the laws of nature; (2) scientists examine what exists in nature and engineers modify natural materials to meet human needs and wants; (3) technological development involves creative thinking; (4) technologies developed for one purpose may be adapted for other purposes; (5) science, technology, engineering, mathematics, and other disciplines are naturally supportive; (6) the pace of technological change has been increasing; and (7) tools help people to do things efficiently, accurately, and safely. The framework then lays out assessment targets for the nature of technology for grades 4, 8, and 12.

The TEL framework describes engineering design as an iterative, systematic process for solving problems. The process begins with stating a need or want and the criteria and constraints of the challenge. Then potential solutions are explored referencing relevant scientific and using technologies. Potential solutions are compared, and models and prototypes are constructed, tested, and evaluated to see how they meet the criteria and constraints of the problem. The framework specifies key principles of engineering design and proposes assessment targets for grades 4, 8, and 12.

The framework also specifies components, principles, and assessment targets for grades 4, 8, and 12 for the prominent technology area of information and communication technology (ICT).

ICT is presented as a separate assessment area within technology and engineering literacy because of the central place ICT plays in learning and functioning in school, the workplace, and daily living. ICT subareas to assess include understanding and use of technologies for (1) construction and exchange of ideas and solutions, (2) information research, (3) investigation of problems, (4) acknowledgement of ideas and information, and (5) selection and use of digital tools. Assessment targets for ICT at grades 4, 8, and 12 are presented.

The area of technology and society addresses the effects that technology has on society and on the natural world and the sort of ethical questions that arise from those effects. The area is further divided into interaction of technology and humans, effects on the natural world, effects on the world of information and knowledge, and ethics, equity, and responsibility. Assessment targets for grades 4, 8, and 12 are presented.

Each of the frameworks and standards described above can serve as resources for specifying the technology understanding to be assessed. In the following section, the use of a systematic assessment design framework is presented to support the selection or development of assessments.

Assessment Methods

Reference to the varying definitions and contexts of technology can provide the bases for core technology concepts to be tested. The assessments of understanding technology concepts may vary the cognitive demands or levels of reasoning required. Cognitive demands could involve simply identifying definitions and lists of features of technologies and their uses. Knowledge about technology tools is less challenging than knowledge about the functions they serve and how they may be best used. More demanding would be to require analysis of the selection, development, and uses of technologies as supports or products of engineering designs in the multiple contexts such as academic domains, agriculture, manufacturing, or medicine. The realm of ICT assessment invites assessments of understanding how digital and media tools can support a range of strategies such as planning, accessing and organizing information, representing and transforming information and data, analyzing and interpreting, designing products, critically evaluating, collaborating, and communicating (Quellmalz 2009). Assessments of understanding could also ask for evaluations of selections, development, or uses of technologies by others for specified purposes in multiple contexts.

Assessments of understanding technology in science and engineering could involve students' understanding of the use of science and engineering "tools of the trade," such as computer design software, simulations, modeling software, search engines, social networking, visualizations, and graphs (Quellmalz et al. 2009). Understanding of technology in science and engineering could also involve reasoning about the technological artifacts and processes suited to addressing stated needs. Scoring and reporting of responses to these types of tasks and items would then provide data that could be used diagnostically to inform further instruction or to support a summary proficiency reports.

Television

Anthony Dudo
Department of Advertising & Public Relations,
Moody College of Communication, The
University of Texas, Austin, TX, USA

Social scientists have long been examining mediated depictions of science and technology with hopes of better understanding their influence on learning, opinion formation, and behaviors relative to scientific issues. The majority of this research has traditionally focused on journalism, but in the 1980s, researchers began seriously considering the role of television as a potential platform for informal learning about science given the medium's role as the public's primary science touch-point.

The majority of these early examinations found mostly unfavorable portrayals of science and scientists. This research – mostly qualitative – suggested, for example, that commercial television disseminates primarily dubious images of science, minimizes the inherent uncertainty of the scientific process, and shows scientists as extraordinary and vastly different than ordinary citizens. Quantitative assessments conducted by communication scholar George Gerbner and his colleagues during the 1980s also indicated that scientist characters in primetime television programming suffered a higher ratio of negative characteristics (e.g., evil, disturbed, villainous) and were more likely to be victims of violence, as compared to other occupations.

More recent analyses, however, suggest that television depictions of science and scientists have become less negative. A report conducted in 1999 for the US Department of Commerce suggested that the television landscape no longer demonstrated any type of systematic negative portrayal of scientists. And an empirical analysis of primetime TV programming broadcast between 2000 and 2008 found that while scientist characters are uncommon in these shows, when present they are considerably more likely to be categorized as "good" than as "bad" (Dudo et al. 2011).

A more granular strand of research in this area has examined the depictions of science and scientists in both educational and entertainment television programs targeted toward children and middle schoolers. Some notable findings from the studies examining children's science shows (e.g., *Bill Nye the Science Guy*, *Beakman's World*) include that science is often shown as fun, a solution to problems, truthful, and a part of everyday life. These studies also find, however, that these TV shows paint mixed pictures of scientists, in some cases depicting scientists as elite and predominately male Caucasians, while in other cases depicting science as being intended for everyone and gender neutral (e.g., Long et al. 2010). In sum, although there is no singular theme about science or scientists present in television programming, recent research suggests that there may be an overall trend within television away from the historically negative portrayals unearthed in early examinations of the medium.

The research examining portrayals of science and scientists on television has fueled a line of work examining how these portrayals contribute to public understanding of and attitudes toward science (e.g., Nisbet et al. 2002). These studies have been guided primarily by two theoretical frameworks – cultivation theory from communication studies and social cognitive theory – and have found highly variable audience effects. Some of this work has looked for correlations between the amount of time viewers spend watching television and their general attitudes toward science, with the initial studies finding a negative attitude (e.g., the more time spent watching television, the more negative the attitude toward science) that has not been supported in recent replications. Other recent empirical studies have examined potential connections between different genres of television programming and viewer perceptions of science and specific scientific issues. For example, frequent viewing of religious TV programming has been linked with unfavorable attitudes toward scientific issues, frequent viewing of dramatic and comedic programming has been linked with support for agricultural biotechnology, and frequent viewing of science fiction programming has been linked with support for therapeutic cloning. Some research has also examined the audience effects of specific shows. The immensely popular TV show *CSI: Crime Scene Investigation*, for example, has received much scholarly attention (e.g., Ley et al. 2012) and has been linked to increases in viewers' awareness of and interest in forensic science and their belief in the reliability of DNA evidence.

The research summarized above focuses on the effects of science television on audiences in informal settings. Research, however, has also focused on the effects of science television in classroom settings. This body of work has had two main areas: experimental research exploring how science television content characteristics influence student learning, and case studies by educators and scientists evaluating and describing their use of science television (and fictional films) in their curriculum. Overall, these efforts have identified numerous positive outcomes from the pedagogical use of science television and films in the classroom. Some of the identified benefits include increasing student engagement, providing visual and enjoyable connections between scientific concepts and applications, establishing mental images about science, helping students better identify illustrations and violations of scientific principles, enhancing student interest in science by drawing connections to social issues, and highlighting the interdisciplinary nature and uncertainty of the scientific process. Additionally, this practice has also been observed to help teachers better understand students' preconceptions and attitudes toward scientific subjects.

In sum, this corpus of work demonstrates that television programming contributes to viewers' interest, identification, learning, and perceptions relative to science in both informal and formal settings. This point has been reached in several recently commissioned reports that synthesize the state of research related to informal science learning (e.g., Bell et al. 2009). Television, it seems, is likely to continue to play a major role in the ways that people learn about science, via both educational science programming for children and adults, and entertainment programming with narratives that involve science and scientists.

Keywords

Accountability; Common assessment; Diagnostic assessment; Formative assessment; Interim assessment; Measures; Summative assessment; Testing; Validity

A test is a way by which teachers can determine the extent to which students understand a topical area and can demonstrate such understanding. There is a growing abyss in education about testing practices and the purposes for which tests are being used. While there continues to be an emphasis on measuring student performance for the purposes of accountability, there also is a parallel emphasis that focuses more on understanding performance so that appropriate instructional steps can be identified. The distinction is between summative and formative assessments. Summative assessments are those that measure the result of a course, a chapter, or a unit of study. Formative assessments seek to identify students' learning weaknesses and strengths so that teachers can then determine what instructional steps are needed to address those needs (see Black and Wiliam 1998; Heritage 2010). The distinction also is between assessment *of* learning and assessment *for* learning (Stiggins 2005). The former measures what and how much learning has occurred. The latter seeks to identify what students have learned or not learned to inform instruction.

One helpful way to think about tests is to consider a pyramid (see Love et al. 2008). At the top of the pyramid are the summative assessments, those given primarily for accountability uses and administered annually. In many instances, these are high-stakes, standardized tests. At the bottom of the pyramid are classroom activities, teacher-made quizzes, projects, and portfolios, given daily or weekly. These activities can be teacher made or be provided as part of the textbook and curriculum.

Between the two extremes are benchmark and interim assessments that may be given quarterly to determine learning progress. Benchmark assessments are given at various intervals throughout a school year. They measure student performance against specified academic standards and explicit learning goals and are aligned to the sequence of the curricula (Herman et al. 2010). Such tests can be used for various purposes, including to inform instruction at the classroom, school, and district levels. Interim assessments (a) provide data about student knowledge and skills; (b) are administered at regular intervals throughout the school year; and (c) have results that are aggregated and compared across classrooms, schools, and districts (Goertz et al. 2009). Interim assessments can be used both for formative and summative purposes.

At the next level of the pyramid are formative and diagnostic assessments. These tests are administered several times a month to provide teachers and students with information about learning strengths and weaknesses. Formative assessment is not just a characteristic of the test per se. It is a process by which the assessment occurs (Bennett 2011). The purpose of such assessments is to improve the teaching and learning process by providing teachers with diagnostic data that can be used to adjust instruction to accommodate the learning needs of the students. The assessments are used at the classroom and individual student levels.

These tests form a continuum of relevance to instruction. The more removed a test is from instruction and the longer the duration from the instructional event, the less instructional validity there is for the assessment. The tighter the feedback loop between the assessment and the instruction, the more likely the test will be able to inform instructional practice.

Another characteristic of a test is whether it is a common assessment. Common assessments are administered in a systematic way across classrooms, schools, or even across districts to facilitate comparative analyses. State summative tests are considered common assessments, as are benchmarks and interim assessments. Common assessments may be developed within a district for course content areas where there are no standardized measures for the purpose of comparing the performance of different schools and classes. For example, in states where science is not included in their state accountability measures, districts may choose to develop common assessments for middle school science, biology, life sciences, or other courses so that educators can compare performance across classes or schools.

Textbooks: Impact on Curriculum

Mansoor Niaz
Department of Chemistry, Epistemology of Science Group, Universidad de Oriente, Cumaná, Estado Sucre, Venezuela

For as long as science has been a school subject, textbooks have been highly influential representations and interpretations of the curriculum to be taught. In most classrooms the impact of the textbook being used is very strong on both the intended and the implemented curriculums, and where the developers of the curriculum also generate the textbook, this impact is particularly striking.

The impact on implemented curriculum derives from the textbook very commonly being the only representation/interpretation of the intended curriculum that students use and often that the teacher uses. Although textbooks are not the only factor responsible for students' learning, in many parts of the world, they constitute the most important curriculum material. Reliance on textbooks is all the more important when teachers are teaching outside their own area of expertise, which is often the case at the middle school level.

The most striking examples of textbook impact on the intended curriculum are curriculum projects that have sought to develop an integrated package of curriculum, textbook, and other materials to support learner and teacher. This pattern was set by the very first of the science curriculum projects, the work of the Physical Sciences Study Committee (PSSC Physics) in the USA in the latter 1950s. PSSC Physics materials included a curriculum, a textbook, specially designed student laboratory equipment, films, and comprehensive teachers' guides to all these materials. In all of the many and varied contexts in which PSSC Physics was adopted, the textbook was the representation of the curriculum to be learned for all students and many teachers.

A current widely known curriculum project that has given serious attention to textbooks and their impact is Project 2061 being developed by the American Association for the Advancement of Science (AAAS 1990) and named for the next year in which Comet Halley will appear. Project 2061 has a focus on developing scientific literacy among students. It is particularly critical of current science textbooks. Typical textbooks, it argues, emphasize the learning of answers far more than the exploration of questions, memory at the expense of critical thought, unrelated items of information instead of understanding in context, and recitation over argument. Beyond the cognitive, Project 2061 analyses indicate that most textbooks do not encourage students to work together and share ideas.

Project 2061 has shown a particular concern for the production of high-quality curriculum materials. The central premise is that such materials should be judged primarily in terms of their likely contribution to the attainment of important and agreed-upon, specific learning goals (in their specific case, such as benchmarks and national standards). Its curriculum analysis procedure uses seven categories of criteria to determine the extent to which the instructional strategy of the teaching material is likely to facilitate students' learning of science:

- *Category I: Identifying and maintaining a sense of purpose*. Is the material understandable and motivating to students? Does each activity have a purpose and its relationship to other activities? Is there a logical or strategic sequence of activities, rather than a collection of activities?
- *Category II: Taking account of student ideas*. Does the material take into consideration the need for prerequisite knowledge and skills, alert teachers to commonly held student ideas (alternative conceptions), and assist teachers in identifying student ideas before introducing the scientific concepts?
- *Category III: Engaging students with relevant phenomena*. Does the material provide multiple and varied phenomena to support the benchmark idea? Does it provide students with firsthand experiences of phenomena?
- *Category IV: Developing and using scientific ideas*. Does the material introduce technical terms meaningfully in order to promote effective communication?
- *Category V: Promoting student thinking about phenomena, experiences, and knowledge*. Does the material include tasks and/or question sequences to guide student interpretation and reasoning about experiences with phenomena? Are students provided opportunities to check their own progress?
- *Category VI: Assessing progress*. Assuming a content match between the curriculum material and the benchmark, are assessment items included? Does the material assess understanding rather than responses that are trivial or based on memorized terms?
- *Category VII: Enhancing the science learning environment*. Does the material help teachers to create an environment that encourages student curiosity, rewards creativity, encourages a spirit of healthy questioning, and avoids dogmatism?

In a survey of 38 nations conducted as a part of the Third International Mathematics and Science Study (TIMSS), the relationship between science curriculum as a policy statement and classroom practice has been explored. In this context, according to Valverde et al. (2002), it is textbooks that are responsible for translating policy into pedagogy, intended into implemented, and are used consistently by both students and teachers in this way. TIMSS has used a curriculum model that distinguishes between curriculum as system goals (intended), curriculum as instruction (implemented), and curriculum as student achievement (attained). As already noted above, textbooks play a mediating role between the intended and the implemented curriculums. Based on this model, Valverde et al. (2002) have collected data from 630 mathematics and science textbooks from around the world. Some of the criteria used to evaluate the textbooks were proposed classroom activities, amount of content covered, content complexity, sequencing of content, and physical characteristics. Findings of the study showed that textbooks published in different countries exhibit substantial differences in presenting and structuring pedagogical situations that are related to grade level and subject matter. Furthermore, the study revealed a statistically significant relationship between textbook content and teachers' coverage of the topics promoted in textbooks, a further indicator of the substantial impact textbooks have on the implemented (and learned) curriculum.

Nature of Science

One of the features of most school science curricula and textbooks is consideration of "what is science," "what is the nature of science," and something whose equivalent is either rare or unknown in all other areas of the school curriculum. Although philosophers of science hold differing views of the nature of science, science educators have generally tried to present a consensus view with respect to how science works and how scientists do science. However, science education researchers and scholars of the history and philosophy of science have frequently been particularly critical of how textbooks misrepresent, truncate, and at times "distort" the scientific endeavor (views of science as a form of Baconian empiricism and simplistic and recipe-focused accounts of a "scientific method" are two common examples) (see, e.g., Kuhn (1970), pp. 137–138; although it is important to note that at times Kuhn also supported the traditional textbook presentation of science content, see Kuhn (1970), p. 165). As part of its concern with the quality of textbooks, Project 2061 has recommended the inclusion of the following ideas about the nature of science in the science curriculum and textbooks:

(a) The world is understandable.
(b) Scientific ideas are subject to change; change in knowledge is inevitable because new observations may challenge prevailing theories.
(c) Scientific knowledge is durable (e.g., Albert Einstein did not discard the Newtonian laws but rather showed them to be only an approximation).
(d) Science cannot provide complete answers to all questions.
(e) Scientific inquiry is difficult to describe as scientists differ as to how they investigate. In other words, there is no fixed set of steps that scientists always follow and no one path inevitably leads to scientific knowledge.
(f) Science is a blend of logic and imagination, namely, formulating and testing hypotheses to figure out how the world works, which is as creative as, for example, composing music.
(g) Science explains and predicts (e.g., a theory about the origins of human beings can be tested by new discoveries of humanlike fossils).
(h) Scientists always look for evidence in order to support their theories; however, interpretation of data can be biased, which requires the contribution of various scientists working on the same subject.
(i) Scientists disagree and are critical of the work of their colleagues and this facilitates progress in science.
(j) Scientific research is affected by the social and historic milieu in which the scientists work.

Niaz and Maza (2011) analyzed the presentation of nature of science in the introductory chapters of 75 US general chemistry textbooks. Some of the criteria for evaluation were the same as those used by Project 2061 (above). Very few textbooks presented the following ideas satisfactorily: the tentative nature of scientific theories; there is no universal step-by-step scientific method; observations are theory laden; scientific knowledge relies on observations, experimental evidence, rational arguments, creativity, and skepticism; scientific progress is characterized by competition between rival theories; different scientists can interpret the same experimental data differently; and scientific ideas are affected by their social and historical milieu. Interestingly, some of the textbooks analyzed referred to a wide range of specific issues in the development of science, such as the discovery of DNA; quantum theory; understanding heavenly bodies for 4,000 years; phlogiston theory and chemical revolution; Galileo, Copernicus, and the church; and Pauling, Sakharov, and nuclear weapons. These episodes from the history of science show the controversial nature of scientific progress.

Theories of Science, Assessing Understanding of

Seungho Maeng
Division of Science Education, Kangwon National University, Chuncheon, South Korea

Understanding theories of science has dual meanings depending on the perspectives one holds about what to understand about the theories. On the one hand, understanding a theory deals with understanding the science contents included in the theory. Thus, assessing understanding of theories is construed as the evaluation of how exactly students comprehend the content of a theory and/or interpret natural phenomena using the theory. On the other hand, understanding a theory deals with understanding conceptual and epistemic status of a theory in terms of the nature of science. Thus, the assessment of understanding theories of science is to examine what kind of idea students have on a theory, usually with no regard to the content or domain included in the theory.

Historically the first significant assessing instrument focused on understandings of scientific theories was ***Test on Understanding Science*** (TOUS, Cooley and Klopfer 1963) which had a branch of item groups to examine understanding about the method and aims of science. Although there have been some critics on TOUS, it has some meaningful elements related to theory development. Those are "communication among scientists, scientific societies, theories and models, controversies in science, generalities about scientific method, and unity and interdependence of the sciences."

Another assessing instrument which highly focused on the theories of science is the ***Conceptions of Scientific Theories Test*** (COST, Cotham and Smith 1981). COST sought to incorporate assessing items sensitive to alternative conceptions about the aspects of nature of science and sensitive to the conception with regard to the tentative and revisionary view of science. The tentativeness refers to inconclusiveness of knowledge claims in science and the revisionary view of science refers to revision of existing scientific knowledge in response to changing theoretical contexts. COST consists of 40 likert-scaled items with four subscales such as ontological implications of theories, testing of theories, generation of theories, and choice among competing theories. COST also contains four theoretical contexts for each subscale with a brief description of a scientific theory and some episodes from its history. Those contexts are Bohr's theory of the atom, Darwin's theory of evolution, Oparin's theory of abiogenesis, and the theory of plate tectonics. In addition to these four contexts, COST includes nontheoretical context which is related to general characteristics of scientific theories. The items following the short descriptions in each theoretical context for the subscales were designed to discriminate between two alternative conceptions organized around philosophic aspects of the theories of science. The categories of alternative conceptions for each subscale are realistic/instrumentalist for ontological implications of theories, inductive/inventive for generation of theories, tentative/conclusive for testing of theories, and objective/subjective for choices among competing theories.

Currently the most widely used assessing instrument about understanding of theories of science is the ***Views of Nature of Science*** (VNOS) Questionnaire (Lederman, Wade, & Bell, 1998; Lederman et al. 2002). As the name of VNOS means, the series of VNOSs (VNOS-A to VNOS-E) are assessment instruments to examine ideas on nature of science, which consist of 7–10 explicit and declarative tenets as the type of open-ended survey items with follow-up interviews. Among the survey items, VNOS contains tenets and questions which ask about the tentativeness in scientific theories and the difference between a theory and a law. While VNOS sought to elicit well-reasoned consensus lists between the responses to assessment items and the statements drawn from standard documents about nature of science, it probed learners' general beliefs or views about science and the theories of science not related to specific and actual contexts of science.

Current research on history and philosophy of science suggests that understanding the nature of science should be functional for the dimensions of reliability of scientific claims (Duschl and Grandy 2013). Thus, merely investigating the consensus of declarative tenets is not fully adequate for applying the consensus to personal or social decision making about the reliability of scientific claims or theories. Allchin (2011) proposed a frame of dimensions about how the reliability of science is achieved as knowledge develops, which he called ***Whole Science***. The Whole Science dimensions consist of 10 subcategories which are observations and reasoning, methods of investigation, history and creativity, the human context, culture, social interactions among scientists, cognitive processes, economics/funding, instrumentation and experimental practices, and communication and transmission of knowledge. From this point of view, the assessment of understanding theories of science also seeks for well-informed analysis about the factors that ensure the reliability of scientific claims and theories. Allchin (2011) also provided a prospective prototype of assessment for understanding of theories as well as nature of science, which he called ***KNOWS*** (Knowledge of the Nature of Whole Science).

From the view of naturalized philosophy of science, which focuses more on cognitive and social practices of actual scientists, the development of scientific theories is constructed not by a scientist's individual efforts but by the cognitive, epistemic, and social practices of communities of scientists (Duschl and Grandy 2013). Thus, the contexts of theory improvement and refinement show how scientists respond to new data, interpret them and build a model, and explain a phenomenon with a new theory. The deeper and broader a theory is over time by accounting for new more data, the higher are the advances of explanatory coherence of the theory. Therefore, assessing understanding of theories of science needs to scrutinize the level of sophistication in students' functional understanding of scientific practices from obtaining data through model building toward developing or refining a theory, so that it seeks for advancing the reliability of scientific claims that are drawn from the theory.

Overview

The Trends in International Mathematics and Science Study, TIMSS, is an international assessment of student achievement dedicated to improving teaching and learning in science and mathematics in the diverse array of countries that participate in TIMSS. TIMSS has reported on trends in student achievement in science and mathematics at the fourth and eighth grade every 4 years since 1995. TIMSS 2015 will be the sixth assessment, resulting in a 20-year trend line. Because TIMSS monitors achievement at regular intervals, it is a valuable tool for studying whether new or revised educational policies impact achievement. Sixty-three countries participated in the most recent TIMSS assessment in 2011.

At each grade, TIMSS reports on overall science achievement as well as reports achievement in major content domains (life science, physical science, and earth science at grade 4; biology, chemistry, physics, and earth science at grade 8) and in major cognitive domains (knowing, applying, and reasoning at both grades 4 and 8). In addition, results for each grade are reported as the percent of students achieving at or above four international benchmarks (advanced, high, medium, and low). In conjunction with these achievement data, TIMSS also collects an array of contextual data about curriculum, instruction, school resources, and students from curriculum specialists, school principals, science teachers, and the students themselves in each participating country. These data, collected through a series of background questionnaires, provide important context for understanding and interpreting the science achievement results and improving teaching and learning in science in the participating countries.

TIMSS Advanced, a companion assessment of TIMSS, assesses the advanced mathematics and physics achievement of students who are enrolled in pre-university advanced mathematics and physics courses in their final year of high school. TIMSS Advanced was originally assessed together with TIMSS in 1995 to provide participating countries with a comprehensive picture of their mathematics and science education across primary, middle, and upper secondary schools. However, TIMSS Advanced was not assessed again until 2008, when a number of countries expressed interest in an advanced assessment due the strong link between specialized STEM expertise and economic productivity. In 2015, TIMSS Advanced again will be administered in the same year as TIMSS so that countries once again can gain a comprehensive view of STEM education from primary school through the entry to university-level studies. Also, in 2015, countries will have the option to administer TIMSS Advanced to students enrolled in advanced mathematics and physics courses in their first year of post-secondary study.

Both TIMSS and TIMSS Advanced are projects of IEA (the International Association for the Evaluation of Educational Achievement). Headquartered in Amsterdam, IEA has been conducting international comparative studies of student educational achievement since 1959. TIMSS, TIMSS Advanced, and PIRLS are directed by IEA's TIMSS and PIRLS International Study Center at Boston College.

The TIMSS Science Framework

The TIMSS science assessment is based on a comprehensive assessment framework that is developed collaboratively with the participating countries (Mullis et al. 2009b). The assessment frameworks for each new TIMSS science assessment are updated from those used for the prior assessment. Updating the frameworks on a regular basis provides participating countries an opportunity to review and provide feedback based on changes in science curricula in their countries and enables the framework and assessment to evolve gradually over time, while still maintaining the coherence from assessment to assessment that is required for reporting trend data.

The TIMSS science assessment framework for TIMSS 2011 consists of a content dimension that specifies the subject matter domains to be assessed in science and a cognitive dimension specifying the cognitive domains – the skills and behaviors that are expected from students as they engage with the science content. At grade 4, three major content domains define the science content: *life science*, *physical science*, and *earth science*. At grade 8, four major content domains define the science content: *biology*, *chemistry*, *physics*, and *earth science*. At both grade 4 and grade 8, the cognitive dimension was defined by three domains based on what students are required to know and do when engaging with the various items included in the TIMSS 2011 assessment: *knowing*, *applying*, and *reasoning*. Table 1 shows the target percentages of testing time devoted to each of the science content and cognitive domains in the fourth- and eighth-grade assessments.

In addition to defining content and cognitive domains, the TIMSS 2011 science assessment framework recognizes the importance of the *science inquiry* in the teaching and learning of science and specifies that science inquiry should be assessed in TIMSS in the context of the TIMSS science content domains and drawing on the full range of skills and behaviors defined in the cognitive domains. Thus, assessment items addressing aspects of science inquiry are included within both the content and cognitive dimensions of the assessment framework.

Third International Mathematics and Science Study (TIMSS), Table 1 Target percentages of the TIMSS 2011 science assessment devoted to content and cognitive domains at the fourth and eighth grades

Fourth grade		
Content domains	**Percentages (%)**	
Life science	45	
Physical science	35	
Earth science	30	
Eighth grade		
Content domains	**Percentages**	
Biology	35	
Chemistry	20	
Physics	25	
Earth science	20	
Cognitive domains	**Percentages**	
	Fourth grade (%)	**Eighth grade (%)**
Knowing	40	35
Applying	40	35
Reasoning	20	30

The TIMSS 2011 assessment framework also includes a contextual framework that specifies the information to be collected via TIMSS background questionnaires. The 2011 contextual framework encompasses four broad categories of contextual factors that affect students' learning in science:

1. National and community contexts (including country demographics and economic resources, the organization and structure of country education systems, and the science curriculum)
2. School contexts (including school size, location, and characteristics of the student body; school organization for instruction; school climate for learning; professional development opportunities for teachers; school resources; and parental involvement in education)
3. Classroom contexts (including teacher education and development; teacher gender, age, and experience; class size, instructional time, and class composition; curriculum topics taught; availability and use of instructional materials and technology; types of instructional activities; and types and uses of assessments)
4. Student characteristics and attitudes (including student gender and language spoken, family immigration status and socioeconomic background, and student attitudes toward learning science)

Information about these contextual factors was collected via background questionnaires completed by national-level curriculum specialists, school principals, science teachers, and the students who were assessed in TIMSS 2011. National-level curriculum specialists also provided a written description of science education in their country to provide information about the national contexts that shape the content and organization of the science curriculum as well as political decision-making processes that impact science education. These national contexts are compiled in the *TIMSS 2011 Encyclopedia*, Vols. 1 and 2 (Mullis et al. 2012).

The TIMSS science framework currently is being reviewed, revised, and updated for TIMSS 2015 and will be available by October 2013 at http://timss.bc.edu.

The Development and Administration of the TIMSS Science Assessment

The assessment framework provides the blueprint for the development of each TIMSS assessment. In each new assessment, in order to report reliable trends in achievement, approximately 60 % of assessment items are retained from prior assessments, with 40 % newly developed items completing the assessment. The assessment consists of approximately half multiple-choice items and half constructed-response items.

For each new assessment, approximately twice as many new items are developed as are needed for the final assessment. Item development is a highly collaborative process. The development of new items is guided by a science Subject Matter Item Development Committee, which includes science experts from participating countries. In addition, representatives from participating countries produce items at an item-writing workshop. All items undergo a rigorous review process by subject matter experts before being assembled into field test *block*s, each of which is approximately 20 min in length. Field test blocks are reviewed by representatives from participating countries and then administered in the countries approximately 1 year prior to the administration of the final TIMSS science assessment. Based on the results of the field test, field test blocks containing new items are selected and combined with blocks of items retained from prior assessments to complete the final assessment. The 2011 TIMSS development process is described in detail at http://timssandpirls.bc.edu/methods/t-instrument.html.

Prior to the administration of the final assessment, the assessment blocks and background questionnaires are translated from English into the numerous different languages of the participating countries. A rigorous translation verification process is utilized to ensure comparability among translated instruments. The final assessments are administered to carefully drawn probability samples of students from the target populations of fourth- and eighth-grade students in each country. Each country is responsible for carrying out all aspects of data collection and scoring, using standardized procedures. The methods and procedures for sampling, translation, and assessment operations used in TIMSS 2011 are described in detail at http://timssandpirls.bc.edu/methods/index.html.

Analyzing and Reporting TIMSS Science Results

The TIMSS science achievement scales are designed to provide reliable measures of student achievement across the trend cycles of the TIMSS assessments, based on the metric established with the 1995 data. Student achievement is summarized using item response theory (IRT) scaling methods, and for more accurate estimation of results for subpopulations of students, the TIMSS scaling uses plausible-value technology. In addition to the overall scales used to estimate student achievement in each assessment and to measure trends over time, IRT scales also are created for each of the content and cognitive domains described in the TIMSS science assessment framework. In addition, to describe what student performance on the TIMSS science achievement scales mean in terms of students' science proficiency, a scale anchoring analysis is conducted to describe and interpret student achievement at the advanced, high, intermediate, and low international benchmarks. The methods and procedures for scaling and scale anchoring are described in detail at http://timssandpirls.bc.edu/methods/index.html.

A comprehensive report of results from each TIMSS science assessment is released in the year following the TIMSS administration. The *TIMSS 2011 International Results in Science* can be accessed at http://timss.bc.edu/data-release-2011/index.html. For each participating country, the 2011 report includes overall achievement results for fourth grade and eighth grade along with trends in achievement for countries that participated in previous TIMSS assessments. The report also presents achievement differences by gender and trends in achievement differences. In addition, results are reported in relation to international benchmarks and for each major content domain and cognitive domain, along with trends in achievement for each of those reporting categories. Finally, the report presents achievement results in relation to the extensive set of contextual factors surveyed with the background questionnaires.

TIMSS Advanced Physics

TIMSS Advanced physics assesses the physics achievement of students in the final year of secondary school who have taken courses in physics and is the only assessment that provides information about the achievement of these physics students in an international context. The most recent TIMSS Advanced physics assessment in 2008 was based on a framework developed in cooperation with the countries participating in TIMSS Advanced (Garden et al. 2006). As in the TIMSS science framework, the TIMSS Advanced physics framework consists of a content dimension that specifies the subject matter to be assessed in physics and a cognitive dimension specifying the cognitive skills and behaviors that are expected from students as they engage with the science content. The four major content domains are *mechanics*, *electricity and magnetism*, *heat and temperature*, and *atomic and nuclear physics*. The cognitive dimension is defined by the same three cognitive domains as in TIMSS science: knowing, applying, and reasoning. The TIMSS Advanced framework currently is being reviewed, revised, and updated for TIMSS 2015 and will be available by October 2013 at http://timss.bc.edu.

Methods and procedures for development, translation, sampling, administration, scoring, analysis, and reporting for TIMSS Advanced generally parallel those for TIMSS and are described in detail in the *TIMSS Advanced Technical Report* (Arora et al. 2009). The results for the most recent administration of TIMSS Advanced are reported in the *TIMSS Advanced 2008 International Report* (Mullis et al. 2009a).

Education for Sustainability

How can we prepare science teachers with professional knowledge and skills for ensuring that teaching and curricula meet the global challenges of the twenty-first century, among which learning to live sustainably on planet Earth is one of our most pressing concerns? Education for environmental, cultural, and economic sustainability has been a key focus of the United Nations for the past decade, underpinned by the Brundtland Report's advocacy of an "intergenerational conscience" which recognizes that meeting the needs of the present should not compromise the ability of future generations to meet their own needs (UNWCED 1987). The recent "Rio + 20" United Nations conference on sustainable development ratified this view.

But implementing education for sustainability is no easy task especially in science education. It involves much more than the traditional delivery and acquisition of objective scientific knowledge and skills. The Australian government (DEWHA 2010) adopted a definition of education for sustainability to guide curriculum designers nationwide that emphasizes the development of higher-level abilities essential to becoming an effective citizen and change agent:

- Ability to explore and evaluate contested and emerging issues
- Ability to deal with complexity and uncertainty
- Ability to take action as an individual and as part of community
- Ability to gather evidence and create solutions

Science education for sustainability brings together science education, values education, and citizenship education (including peace education) to focus critically on the interaction between the "Big Three": (i) *environmental issues*, such as human-induced climate change and loss of biodiversity associated with exploitation of natural resources; (ii) *sociocultural issues*, such as loss of indigenous knowledge systems that were developed through prolonged adaptation to living sustainably within the natural world; and (iii) *economic issues*, such as the implications for the natural and social world of economic models premised on producing prosperity via unlimited growth.

For students to learn meaningfully and collaboratively about these twenty-first-century sustainability issues, it is necessary that they develop higher-level cognitive and social abilities, including critical reflective thinking, cooperative decision-making, empathic and compassionate understanding of self and other, ethical awareness and values clarification, and commitment to personal and social action. The capacity of science teachers to prepare students with these higher-level abilities depends on teachers themselves having developed the same abilities.

Thus, the professional development of twenty-first-century science teachers calls for a more global perspective that takes science teaching well beyond the traditional (narrow) curriculum focus on *what* and *how* (or "pedagogical content knowledge") to embrace a humanistic perspective on the ethical responsibilities of science education (the curriculum *why*) and the unfolding personhood of the student as a future citizen in a democratic society (the curriculum *who*). For such a perspective, we turn to transformative learning theory.

Transformative Learning

Transformative learning theory has its roots in the work of Jack Mezirow in the field of adult and continuing education which came to prominence in the 1990s. Mezirow (1991) drew on philosophers such as John Dewey and Jürgen Habermas to reveal how our "meaning perspectives" are subject to epistemic, sociocultural, and psychological distortions that restrict the way we make sense of our experience of the world. Thus, we have limited ability to participate fully as creative, communicative, and self-determining agents in the processes of democracy.

For Mezirow, the key to transformative learning is to engage discursively with others in reflecting critically on the presuppositions underpinning our values and beliefs. Critical reflection emancipates us from our ideological prisons, thereby enhancing our conscious awareness of ourselves, others, and the worlds that we co-construct. For Mezirow, the role of transformative learning in adult education is to prepare citizens as critical self-reflective thinkers capable of contesting taken-for-granted social norms and making ethical judgments that lie at the heart of the process of democracy.

Over the past 20 years, Mezirow's ideas have been applied by many transformative educators to a range of adult education and training contexts such as higher education, the workplace, and the community. His theory of transformative learning has been enriched and become more nuanced by embracing nonrational modes of thinking in which emotions, intuition, mindfulness, and inspiration have an important part to play. Transformative learning theory has been coupled with theories of society, consciousness, wisdom, globalization, feminism, culture, and so on, to generate compelling aesthetic, spiritual, psychological, and ethical perspectives on the role of adult education in helping to create a more equitable, peaceful, diverse, and sustainable world (Taylor and Cranton 2012).

One of the uniquely powerful aspects of transformative learning is the focus on expanding conscious awareness of our situatedness in the world or, to put it more simply, our understanding of who we are and who we might yet become, as both individuals and social beings (Morrell and O'Connor 2002). Such a transformation entails developing a heightened consciousness of the relationship between our outer (material) and inner (nonmaterial) worlds. Transformative learning involves using cognitive, emotional, social, and (for some) spiritual "tools" to reconceptualize and reshape this relationship. Based on this perspective, transformative learning comprises five distinct but interconnected ways of knowing:

- *Cultural-self knowing* (self-realization) involves coming to understand our culturally situated selves, in particular how the (mostly invisible) premises underpinning our worldview – our shared values, beliefs, ideals, emotionality, and spirituality – give rise to our cultural identities and govern our habituated ways of being in, making sense of, and relating to our social and natural worlds.
- *Relational knowing* (opening to difference) involves learning to connect empathically and compassionately with our true (nonegoic) selves, our local community, the culturally different other, and the natural world.
- *Critical knowing* (political astuteness) involves coming to understand how and why (political, institutional, economic) power has structured historically our social realities by creating seemingly natural categories of class, race, gender, vocation, intelligence, etc., and how this mostly invisible power governs (especially distorts) our lifeworlds, our relationships with others, and our relationship with the natural world.
- *Visionary and ethical knowing* (over the horizon thinking) involves us in creative, inspirational, and discursive processes of idealizing, imagining, poeticizing, romanticizing, meditating on, and negotiating a collective vision of what a better world could be like and, importantly, what a better world should be like.

- *Knowing in action* (making a difference) involves consciously developing our capacity to help make the world a better place, committing to making a difference, and taking action locally while thinking globally.

Research as Transformative Learning

The question arises as to how to engage science teachers in transformative learning in order to prepare them with the higher-level abilities to pass on to their students so that they learn to participate individually and collectively in complex evidence- and ethics-based decision-making processes about living sustainably in an increasingly crisis-ridden and uncertain world buffeted by competing (economic, political, sociocultural) interests.

In recent years transformative learning theory has been instrumental in retheorizing postgraduate educational research, resulting in a model of "multi-paradigmatic research design" (Taylor et al. 2012). Building on developments in social science research over the past 30 years, this Kuhnian revolution has broken the stranglehold of (but not rejected) the traditional positivist paradigm wherein objective ways of knowing rule. For creative researchers the door has been opened to a range of innovative, exciting, and empowering epistemologies that enable research as transformative learning to flourish. These epistemologies derive from research paradigms, some of which are relatively new to science education.

The *interpretive* research paradigm offers a social constructivist perspective on the researcher's endeavor to develop deep, contextual, and emergent understanding of the culturally different other, together with a reflexive process of deepening his/her own culturally situated self-understanding. Ethnographic, autobiographical, and narrative methods are used to explore the lived experience of the researcher and his/her coparticipants. A powerful interpretive methodology used by researchers to excavate their life histories and recover lost cultural capital due to centuries of colonization by the Western modern worldview is auto-ethnography.

The *critical* research paradigm arms the researcher with an epistemology of ideology critique aimed at identifying sociocultural myths (made powerful by their invisibility) that structure social reality and contribute to perpetuating social injustice, cultural exclusion, inequity, racism, sexism, ageism, scientism, etc. A methodology of critical auto-ethnography enables the researcher to work toward decolonizing his/her own lifeworld, and ultimately the lifeworlds of students and/or colleagues, in a creative endeavor to enhance self-realization, identity, and free will as a prospective agent of social and structural reform.

The *postmodern* research paradigm brings a Janus-like (or two-faced) perspective to science education research. One face looks toward a philosophical deconstruction of the premises of all claims to secure, or foundational, knowledge (such as "scientism"), while the other face wears the smile of constructive playfulness. Postmodern researchers draw on the Arts for new methods of reasoning and modes of representation. Literary and artistic genres, such as fictive writing, poetry, ethnodramas, and imagery, embody innovative logics for researchers to make sense of and portray their nonrational experiences of the ineffability of their social and natural worlds.

Multi-paradigmatic research designs provide powerful ways of engaging researchers in transformative learning about the underlying premises of science education (Taylor 2013).

"Big picture" questions become accessible, as befits a science education endeavoring to respond to unprecedented global challenges:

- Whose human interests are being best served and whose are being excluded by current science curricula and pedagogies? And why?
- How can science education embrace authentically the popular ethos of "science for all" if it does not embrace the "sciences of all"?
- Why does the paradigm of Newtonian science, with its "clockwork" (reductionist, deterministic, linear, materialist) view of the universe, continue to prevail in physical science curricula? And in shaping postgraduate research designs?

- What are the distinctively different underlying premises of the "new sciences" of chaos theory, complexity theory, quantum theory, relativity theory, superstring theory, biocentrism, creative evolution, etc., and how might they contribute to a revitalized science education that aims to develop in students the higher-level cognitive and social abilities required for addressing the great moral and ethical challenges of the twenty-first century?
- How can a "socially responsible" science education counterbalance the triumphalism of modern science and technology (which are much celebrated on popular TV) with a "radical humility" born of a deep understanding of the well-documented harmful side effects of the seemingly benevolent use of science and technology to improve the human condition: global warming, natural resource depletion, loss of biocultural diversity, nuclear radiation contamination, unregulated genetic engineering, proliferation of weapons of mass destruction, etc.?
- What human values currently govern the selection (and exclusion) of science curriculum content and pedagogies, how well are they justified, what is their use by date, are there better alternatives, how are they being canvassed, and by whom?

Coda

As a form of professional development for science educators, transformative learning is inherently democratic and empowering as it makes visible and subject to critical scrutiny the (academic and political) decision-making process and premises that govern (past and future) curricula developments in science education. Transformative learning commits professional science educators to "making a difference" by having their voices heard in forums that shape future science curriculum policy. Transformative learning equips science education practitioners with advanced knowledge and skills to develop students' higher-level abilities for committing to act in ways that seek to promote the diversity of life on Earth.

Transposition Didactique

Andree Tiberghien[1] and Gérard Sensevy[2]
[1]National Centre for Scientific Research (CNRS), Université Lyon, Lyon, France
[2]School of Education, University of Western Brittany, Rennes, France

The concept of transposition didactique (didactic transposition) was first proposed by the French mathematics educator, Chevallard, in the 1980s, who first developed it in the context of mathematics education. To discuss it, let us start with a particular case. When the concept of force is listed in an official curriculum or is taught in high school, its meaning cannot be identical to the meaning of the concept of force in the physics community. From the perspective of didactic transposition, this difference is unavoidable.

To understand this claim we need to study how individuals or institutions understand and use an item of knowledge or, to approach it from another angle, the relationships that they construct with this knowledge. These relationships constitute the meaning of this knowledge constructed by the individuals or institutions. For example, if we take a group of engineers constructing a bridge, a group of physicists taking part in the construction of a space shuttle, a high school physics teacher, and a group of students, their ways of using the concept of force will not be the same. As a matter of fact, due to the different things that are at stake in the different situations, these individuals or groups will use the concept of force differently. Since, according to Chevallard (1989, 1991), the ways of using the concept of force are different, the concept necessarily has different meanings in each case, even if these meanings are compatible and may overlap.

When a country or a state develops a new curriculum or new standards, an official institution, most often the Ministry of Education, chooses groups of experts to design it. The members of these groups may belong to the institution itself or be nominated by it. Each group is in charge of a part of the curriculum, according to the disciplines taught in the country. In experimental sciences, the process might involve a single group or several groups depending on which disciplines are taught. In science, the curriculum is principally (perhaps even totally) designed with reference to the knowledge and practices of the scientific community. Sometimes, for example, when socio-scientific issues are included in the curriculum, the group can also use social knowledge and practices as references. The idea of didactic transposition makes explicit that there is an unavoidable difference/distance between the reference knowledge and practices and those involved in the curriculum or the standards.

This theoretical point of view therefore leads researchers to raise questions aiming to understand better how the transformation occurs and with what constraints. Two main steps of transposition are distinguished. The first step goes from the reference knowledge or practices to the curriculum. The second step focuses on the transposition from the curriculum to the classroom activity, which is mainly the responsibility of the teacher and of designers working from the official curriculum.

The Didactic Transposition from Scientific Knowledge to Official Curriculum or Standards

Institutions such as ministries of education are generally responsible for the step of transposition from scientific knowledge to official curriculum or standards. The products of this step are texts that present the knowledge to be taught. Note that here and in the following discussion, knowledge is used with a broad meaning that includes practices and epistemological aspects. These texts are usually structured according to the concepts, processes, or more recently societal uses of a discipline. This division into “objects of knowledge to be taught” is necessary and is different from those used in the scientific community. For example, the official curriculum in England for science at key stage 4 (14–16 years old, grades 10–11) (in its 2007 version) was divided into two main parts:

- How science works, with subdivisions: (1) data, evidence, theories, and explanations, (2) practical and enquiry skills, (3) communication skills, and (4) applications and implications of science.
- Breadth of science, with subdivisions: (1) organisms and health, (2) chemical and material behavior, (3) energy, electricity, and radiations, and (4) environment, earth, and universe. These divisions correspond more or less to the disciplines – life science, chemistry, physics, and earth science.

This division is not used in the activity of the scientific community. For example, in a typical published article, the methods, processes, and content are deeply related; similarly in laboratory activity, the researchers' practices integrate these two components. In contrast, in the curriculum, each part has autonomy; a given object of knowledge to be taught is developed for it in the text. Moreover, each part is developed as elements whose acquisition by the students has to be assessed. This corresponds to general characteristics of curricula or standards developed by Chevallard (1991). They are public texts identifying distinct objects of knowledge to be taught, the acquisition of which should be assessed. There are also three other characteristics: the knowledge to be taught is de-syncretized and its acquisition is sequential; it is depersonalized; and the sequence of students' acquisition of knowledge is planned.

De-syncretized knowledge: In the example of the official curriculum of England, in the part headed "How science works," one of the items is "how scientific data can be collected and analysed." Such an object of knowledge is not isolated in the practices of the scientific community; but, in the official curriculum, it is distinguished from other elements and becomes an item in the text of the curriculum. In other words, it is de-syncretized.

Depersonalized knowledge: The objects of knowledge are presented as independent of a person. This characteristic has been highlighted by educational researchers who discuss the role of history in science teaching. In the example presented above for England, this depersonalization is clearly done; the subheading is not "how scientists work" but "how science works."

Planned knowledge: The teaching of the objects of knowledge has to be planned. Moreover, at the level of a curriculum, this plan is implicitly supposed to be also the students' acquisition plan. This planning is also unavoidable. For example, the official curriculum is constructed at different levels from grade 1 to 12 (or 13 depending on the country); there is a planning according to the succession of grades. In addition, for each year the curriculum may propose a progression. The didactic transposition involves planning the sequence of the objects of knowledge; this planning can be more or less precise from case to case.

The Didactic Transposition from Official Curriculum or Standards to Teaching Practices

This transposition is up to the teachers and to the designers of teaching sequences or other teaching resources to the extent that they refer to the official curriculum. Of course teachers have many constraints to respect, such as allocated duration and school organization. However, this step of the transposition is crucial for students' outcomes. Nowadays, as we have already mentioned, most curricula involve practices, both scientific ones and, in some cases such as socio-scientific issues, societal ones. When practices are involved, the curricula specify objects of knowledge to be taught that include the type of teaching situations; this is not the case when science content knowledge is involved. In the latter case, the way these objects are introduced depends on the teaching strategies chosen by the teachers. They could be introduced using various strategies: traditional lecturing, problem solving in small groups with experiments or simulations, etc. In the case of practices as objects to be taught, the curriculum, more or less explicitly, specifies the types of teaching situations. For example, if the students should learn argumentation and not only the content of the arguments, the teacher should implement teaching situations where the students have to debate and produce arguments. Developing argumentation could also help students to learn how to argue and also the content of arguments. Similarly, introducing ideas about the nature of science can be made in diverse teaching situations such as discussing experimental results, designing experiments, constructing hypotheses, etc. These ideas can also be introduced together with new conceptual knowledge. In short, introducing diverse components of knowledge and scientific practices as objects to be taught makes teaching situations and their progression particularly complex to design. In the framework of didactic transposition, the teachers or the designers should carefully analyze the reference practices in order to choose among their components those that they want to teach and how they adapt them; thus, the unavoidable distance between the reference practices and those involved in teaching is recognized and analyzed. For example, the idea of authenticity sometimes proposed for enquiry teaching cannot lead to a simple reproduction of the practices of reference. The authenticity can only be partial.

The planning of the objects of knowledge is less complex when they are discretized and mainly content oriented. The teaching order is not always easy to choose, but the choices can be discussed; for example, voltage might be introduced first to characterize batteries, followed by current, or the reverse. However, when the objects of knowledge are components of practices rather distant from those of the students, such as scientific practices or even social debates, the planning is much more difficult. For example, the development of practices of debating in the science domain (which can include societal issues) can be associated with the development of conceptual understanding of other objects of knowledge or considered as a separate object of knowledge, and thus, additional teaching time is necessary. The introduction of practices to be taught constrains teachers to establish certain types of relationships with their students, for example, that different points of view should be accepted and taken into account in the classroom, that the dialogue between students is important, and so on. Hence, it may alter the didactic contract (contrat didactique) (Brousseau 1997) between the teacher and the students. Such changes in relationships cannot be introduced rapidly; the classroom practices take time to be modified. Planning involves delineating different elements of the knowledge to be taught at least for their introduction. For example, some components of energy might be associated with argumentation, whereas astronomy might be associated with the limits of science.

In sum, the didactic transposition is a theoretical tool to analyze and develop the official curriculum and also to implement the teaching practices.

Validity and Reliability of Science Assessments

Joan Herman
National Center for Research on Evaluation, Standards, and Student Testing, UCLA, Graduate School of Education and Information Studies, Los Angeles, CA, USA

Keywords

Accuracy and appropriateness of score inferences; Technical quality of assessment; Test quality; Validity

Validity is the overriding concept describing assessment quality. It expresses the extent to which an assessment measures what it is intended to measure and provides sound data for an intended decision-making purpose. As described below, reliability conveys the consistency of a measure and is necessary but not sufficient for adequate validity. Strong evidence of both validity and reliability is required for high-stakes uses of science assessments. While evidence requirements are reduced, both also are concerns for classroom assessment purposes.

Validity Defined

Modern measurement theory defines validity as the degree to which evidence and theory justify particular interpretations and uses of test scores (see AERA, APA, & NCME 2014). Validity is not a unitary property of a test but rather is an evidence-based judgment that requires a variety of evidence to evaluate the accuracy of score inferences and the appropriateness of score use for particular purposes. A test may have high degree of validity of one purpose but not another. For example, scores from a science test may have a high degree of validity for identifying scientifically gifted students but have a low degree of validity for diagnosing learning needs.

Reliability, as noted above, is a necessary but not sufficient requirement for validity. Reliability refers to the consistency and precision of the scores, the extent to which they provide constant estimates of some stable attribute, rather than error. If a bathroom scale is reliable, for example, it will give you the same result regardless of where or when you stand on it, unless you have actually gained or lost weight. In contrast, if the scale is not reliable, your measured weight may change at each weigh-in, regardless of whether your actual weight has changed and so the validity of the measure is compromised. At the same time, a measure can be reliable, but not valid. Consider your scale is perfectly reliable, but if its zero mark is 5 lb off, it will provide inaccurate information. So too with test scores, if they contain too much error or are unduly affected by factors unrelated to the construct being measured, they cannot be trusted to provide accurate inferences.

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

Validity Argument

Evaluating the validity of an assessment for a particular purpose involves laying out an argument that links student performance on an assessment to the specific interpretations, conclusions, and/or decision that will follow from the given purpose (see Kane 2006). The argument is composed of a series of claims that require substantiation to justify the use. While claims must be differentiated depending on the intended purpose, claims generally have many of the following criteria (see Herman & Choi 2010):

- **Alignment**: Science assessments should be aligned with meaningful learning goals that integrate science content and practices, including rigorous levels of cognitive demand. Historically, many science assessments have focused on lower-level facts and explanations at the expense of assessing students' ability to engage in inquiry, communicate, and apply their knowledge to solve problems.
- **Learning/instruction value**: Recent theory suggests the value of basing assessment development on a model of how learning is expected to develop so that results can be used to evaluate where students are relative to a progression of expected learning and to diagnose their learning needs. Assessments that are cognitively expansive, that is, that ask students to explain or organize their knowledge not only directly support student learning but have diagnostic utility in exposing student thinking and possible misconceptions.
- **Fairness**: A fair assessment provides all students the opportunity both to learn what is expected and to demonstrate what they know. A fair assessment does not contain construct-irrelevant elements that may unduly advantage or disadvantage some students, for example, unnecessary linguistic complexity in science item that may disadvantage English learners or low-ability readers.
- **Reliability and precision**: Reliability and precision indices provide estimates of the score consistency (see above). For constructed response tasks, the reliability of scoring as well as scores must be examined.
- **Transfer and generalizability**: Assessments sample student performance from a larger domain of knowledge and skills and scores are useful to the extent that they represent student capability in the broader domain, and not just how students do on this particular set of test scores.
- **Instructional sensitivity**: Any use of assessment to improve teaching and learning assumes that scores are influenced by effective instruction and engaged learning and are not simply a function of student ability.
- **Comparability**: Scores often are used to compare or rank students, teachers, or schools and/or to evaluate progress from year to year. To serve this purpose, scores must provide equivalent or interchangeable measures of the same construct. This is one important reason that test procedures are standardized – so that differences in test procedures, rather than student ability, do not unduly influence students' scores. Further, it does not make sense to judge student progress by directly comparing test performance in a chemistry class to that in the physics class – it is an apples and oranges comparison.
- **Consequences**: Research suggests that assessment serves a strong signaling function in communicating what is important to teach and learn and in modeling expected practice. Good assessment supports productive changes in teaching, learning, and equity.

Types of Evidence

The Standards for Educational and Psychological Testing lays out four sources of evidence for documenting validity claims. These include evidences based on:

- Analysis of test content, for example, expert review of the alignment between test content and intended learning goals or of the assessment's instructional/learning value
- Analysis of response processes, for example, think-aloud protocols to examine whether students actually engage in inquiry to solve science problems that are intended as inquiry measures

- Psychometric analysis of internal structure, for example, whether the psychometric structure of the test, such as its dimensionality, is consistent with the test blueprint and reliability and precision indices
- Evidence based on relationships to other indicators, for example, the extent to which test scores generalize to other, respected measures of the same construct or predict future, related performance
- Evidence based on consequences, for example, evidence substantiating that intended benefits of testing are realized, for example, that tests meant to improve science teaching and learning actually do so and the extent to which test-based decisions support subsequent success

Evaluating assessment validity starts with a clear definition of intended goals (constructs) and the purpose the test is intended to address and involves the integration of a variety of evidence supporting important claims and criteria (see Mislevy et al. 2002). The alignment of the test with intended learning goals is often a first issue that typically starts with expert review of test content during the test development process, may involve analysis of students' response processes during pilot testing, and is supported by psychometric analysis later in field testing or operational use of the test. Or another example, evaluation of fairness too starts with an expert review of test content to identify item characteristic or content that may unfairly advantage or disadvantage students from diverse subgroups, draws on psychometric analysis of differential item functioning, and is sensitive to the consistency of empirical relationships and consequential evidence for student subgroups. Test publishers and sponsors are responsible for providing validity evidence for their tests, and it should be found in the technical manual.

Validity and Classroom Assessment

While it is important that there be strong evidence of validity for tests that will have important consequences for students, teachers cannot be expected to develop such evidence for their classroom tests. Nonetheless, validity criteria provide important touchstones for teachers as they develop and use tests – for example, is the test aligned with and do the items well reflect the depth and breadth of intended science learning goals? Have students had the opportunity to learn what is being assessed? Is the test fair to all students? Will it provide value for instruction and learning? Is my scoring reliable – or were papers reviewed earlier scored differently than those scored later?

Values

Bulent Cavas
Department of Science Education, Faculty of
Education, Dokuz Eylul University, Izmir,
Turkey

Keywords

Ethic; Moral; Science education

It is clear from many studies that students' interest in science, mathematics, and technology declines as grade levels increase. Another alarming issue is recruitment of students for STEM-related careers. According to the ROSE Project results, extremely few girls wish to become scientists, and even for boys, the percentage is low. Even in Europe, only about 50 % of boys gave a positive response to the question: "I would like to get a job in technology," but very few girls indicated that they would like to pursue such a career option (Sjøberg and Schreiner 2010). These kinds of results from project reports highlight the urgent need for more effective action on the teaching and learning of science in schools (Cavas 2012).

A critical aspect of science education is the values of science education. A value can be defined as individual belief on a moral or ethical issue. Values have major influence on a person's behavior and attitude and serve as broad guidelines in all situations (Business dictionary 2013). In most science education curricula, the aim is not only to produce scientists but also to empower all citizens with the knowledge, skills, and values they need to live and work successfully in an increasingly technological-knowledge-based society (Tang 2013; Character Development Forum 2013). The latter in particular requires the valuation of science. The values in science, however, are not so different from values in general: valuing objectivity, accuracy, precision, pursuit of truth, and problem-solving; valuing human significance, the protection of human life, and balancing safety and risk; valuing intellectual honesty and academic honesty; valuing courage and humility; and valuing decision making and willingness to suspend judgment. More scientific-oriented values include valuing logic, evidence, and verification and valuing integrity, diligence, persistence, curiosity, open-mindedness, critical evaluation of alternatives, and imagination (Character Development Forum 2013).

There are also some concerns about negative values in science education: misuse of science and hidden values. The negative values in science education might have an important impact on a students' science achievement. Negative values, like a disrespectful interaction between a teacher and student, treatment of student opinions in a disrespectful way, and "right answer" syndrome, may be harmful to young students who are easily influenced. Students influenced by negative values in science classroom often have problem to achieve science courses and negative attitudes toward science.

Values and Indigenous Knowledge

Dawn Sutherland
Research Office, Canada Research Chair in Indigenous Science Education, The University of Winnipeg, Winnipeg, MB, Canada

Keywords

Science education in the non-west

A fundamental attribute of Indigenous Knowledge is that it is place based (Cajete 2000); therefore, the values tied to much of the knowledge are also place specific. However, Indigenous people also share commonalities in their

Indigenous ways of understanding how to live. The commonalities are discussed in the following paragraphs.

The term "coming-to-know" or "coming-to-knowing" is used to describe the process of developing understandings in Indigenous Knowledge (Cajete 2000; Peat 1994). The term means to live properly in ones community and in nature, which includes the "action of living in harmony with the natural environment for the sake of the community's survival" (Aikenhead and Michell 2011, p. 69). "Coming-to-know" reflects the idea that understanding is a life-long journey, or process, or quest for knowledge (Cajete 2000). Learning, from an Indigenous perspective, is an experience that seeks balance in mental, spiritual, emotional, and physical ways.

The importance placed on life-long, balanced, and experiential learning in Indigenous cultures influences what is valued by Indigenous societies. Elders pursue "wisdom-in-action as lifelong learning and as advice for a community's survival" (Maryboy et al. 2006, p. 9). Indigenous wisdom is intimately related to human action based on natural laws. Some have described this as the relational attribute of Indigenous Knowledge (Aikenhead and Michell 2011), where everything in nature, including humans, enjoys equal status and humility is a cherished value. The relational attribute of Indigenous Knowledge also includes the value of respect.

In addition to values associated with the relational attribute, the values inherent in Indigenous Knowledge have been described in terms of competencies that reflect an ability to survive in a real-world context (Barnhardt and Kawagley 2005). The competencies valued by Indigenous society would be those associated with providing for your family and community such as hunting, fishing, and preparing hide.

Values and Learning Science

Deborah Corrigan
Faculty of Education, Monash University,
Clayton, VIC, Australia

Keywords

Creativity; Curiosity; Empiricism; Open-mindedness; Parsimony; Rational thinking; Skepticism; Values

Halstead (1996) has provided a definition of values that places them as life-guiding principles (see also "Curriculum and Values"). In learning any discipline, including science, there are certain rules or paradigms that must be followed, and consequently any discipline is underpinned by values. Many of these values are discussed in "Curriculum and Values." When learning science, students need to be aware of these values and their significance when learning science and differences with values in other disciplines they are learning. For example, rational thinking in science and mathematics may be partly similar whereas empiricism gives science one of its unique values and qualities.

The inclusion of Nature of Science as a fundamental part of learning science means that the values that underpin science are often more explicit in terms of learning than they are in many other disciplines such as mathematics. However while the articulation of such values may be explicit when focusing on the Nature of Science, how teachers interpret such values and promote their development within science classrooms is often less obvious. For example, where are the opportunities for students to develop an understanding of creativity and parsimony in the science classroom? In providing some definition around values that are essential components of learning science, teachers may be able to encourage students to gain an understanding of how these values underpin science. Some definitions of values central to science and therefore science learning that are often not explicitly considered in learning science are now provided.

Parsimony

When there are competing explanations (hypotheses, models, systems, etc.), the simplest explanation, model, or system that accounts for most of the data is accepted for use.

Note: The term "parsimony" is derived from the Latin lex parsimoniae which broadly translates as the law of parsimony, law of economy, or law of succinctness. In more recent times, the phrase Ockam's razor has been used to describe this value of science. The razor is a principle that suggests we should tend towards the simplest explanation until such simplicity of explanation can be substituted for greater explanatory power. Its (the razor's) value lies in the justification of deciding between the competing explanations. Such justifications need to also take account of the plausibility, fruitfulness, and robustness of such explanations.

Curiosity

Curiosity relates not only to the questioning but also to consideration of the wonder and mystery that is aroused when attempting to provide explanations for phenomena that occur in the natural world.

Creativity

Creativity, particularly in thinking, is characterized by its apparent lack of connection to other ideas. Processes such as "random thoughts," "thinking outside the box," "guesses," and "intuition" are often attributes of creativity. In attempts to promote the creative process, it is important to not place parameters around thinking.

Open-Mindedness

Open-mindedness means being receptive to the alternative and different ideas and opinions presented by others. It is also attributable to looking at data in alternative ways.

Rational Thinking

Rational thinking or rationality describes the cognitive process of reason, how one thought links to another. Rationality is different from logic in that it focuses on the notion of reason as a type of thought. Logic, on the other hand, is a process that attempts to describe the norms and rules by which reasoning operates and in this way can attempt to teach orderly thinking. Logic is one type of rational thinking. For example, rational thinking would include such things as skipping steps, working backwards, and drawing diagrams, which are not part of logic.

Empiricism

Empiricism relates to knowledge that is derived from sensory experience (and includes direct and indirect observation). In this sense, it provides an alternative view to rationalism on the processes of knowledge creation, as rationalism is based on reason or thought. The power of these two seemingly opposing theories on knowledge creation is in recognizing their differences and making judgements based on the differences.

Skepticism

Skepticism relates to a general attitude of doubt or questioning of knowledge, opinions, and beliefs presented as facts or claims that are made. Skepticism in science is often seen in the practice of subjecting beliefs and claims to scientific investigation (and further scientific investigation) in order to supporting their reliability.

This list of values is not complete. It focuses on only some of the epistemic and sociological dimensions of values of science. Providing such definitions of fundamental values gives learners of science an opportunity to appreciate the attributes of science as a powerful way of knowing and acting. Other values such as interdependence (on other scientists and their research) and community practice also need to be fostered when students learn science.

Values and Western Science Knowledge

Gürol Irzik
Faculty of Arts and Social Sciences, Sabanci University, Istanbul, Turkey

The central question regarding the relationship between science and values is whether science is value-free or not. The doctrine of value-freedom, which should be understood as an ideal rather than a reality, is based on a categorical fact-value judgment distinction, according to which no value judgments can be derived from facts. It then states that the business of science is to discover facts about the world, not to pass any value judgments; that science is neutral with respect to social, political, and moral values and therefore can serve any such values; and that scientific theories and claims should be accepted or rejected on empirical-evidential grounds, not on social, political, moral, and religious considerations (Lacey 1999). The ideal of value-free science, an early formulation of which is owed to Bacon and Galileo, dates back to the great Scientific Revolution in Europe in the sixteenth and seventeenth centuries and remains especially popular among scientists today.

Contemporary versions of the doctrine of value-freedom distinguish between epistemic and non-epistemic (social, political, economic, moral, religious, and personal) values and recognize the role of the former in scientific inquiry. Epistemic values typically include truth, quantitative accuracy, testability, explanatory power, fruitfulness, unification, internal and external consistency, simplicity, and the like, though currently there exists no consensus about this list. For example, social constructivists and instrumentalists shun truth, feminist philosophers of science prefer novelty (as opposed to external consistency), ontological heterogeneity (as opposed to unification), complexity (as opposed to simplicity), and applicability as important epistemic values (Longino 1996). Epistemic values also function as criteria for theory choice: other things being equal, a theory which exhibits an epistemic value is better than another which lacks it. In the light of the distinction between epistemic and non-epistemic values, the doctrine of value-free science can be formulated more accurately: non-epistemic values should play no role in scientific inquiry; any “outside” interference with the workings of science has devastating effects on scientific progress and objectivity, as exemplified by the Galileo and Lysenko affairs.

As stated, the ideal of value-freedom does not do justice to the role of non-epistemic values. To begin with, the sustained pursuit of science by whole communities of scientists in a society itself reflects a positive value orientation to science: scientific investigation of the world is considered to be a worthwhile enterprise in that society because it is believed to yield reliable knowledge. This valuing of science is not epistemic, but social (Douglas 2009). Clearly, epistemic values contribute to the production of such knowledge. But so do some non-epistemic values. To see this, we must note that science is not just an epistemic system of thought and activity, but is at the same time an institution with its own social and ethical values and norms, which refer to certain attitudes scientists are expected to adopt and display in their interactions with fellow scientists as well as in carrying out their scientific activities. These include Mertonian norms of universalism (scientific claims should be evaluated according to preestablished objective criteria so that characteristics of scientists such as ethnic origin, nationality, religion, class, and gender are rendered irrelevant), organized skepticism (scientists should subject every claim to logical and empirical scrutiny on the basis of clearly specified procedures that involve scientific reasoning, testability, and methodology), and disinterestedness (scientists should evaluate and report their findings independently of whether they serve their personal or national interests, ideologies, and the like). Also among the non-epistemic values already present in the institution of science are intellectual honesty or integrity (scientists should not fabricate, distort, or suppress data), respect for research subjects and the environment (scientists should treat human and animal subjects with respect and dignity and avoid causing harm to the environment), freedom (e.g., scientists should be free to pursue any research, subject to certain constraints, as implied by the previous two values), and openness (scientists should be open to free and critical discussion and to share ideas, data, and techniques and be willing to change their opinion when presented with good reasons) (Resnik 2007). That these ethical and social values (with the possible exception of respect) function to produce reliable and objective knowledge needs no argument.

Non-epistemic values play a direct role in the choice of scientific problems and research programs as well. For example, the search for cures and more effective treatment of diseases, techniques of better crop yield, and more efficient means of energy production may no doubt be motivated by intellectual curiosity, but they also reflect the value of human life and of the reality of a competitive economy. It is a well-known fact that scientific research costs money and that, therefore, the direction of research is influenced greatly by funding decisions. The role of such ethical, social, and economic values in science is widely acknowledged and deemed acceptable even by the defenders of the doctrine of value-freedom. In short, not all influences of non-epistemic values on science are necessarily damaging to the progress, reliability, and objectivity of science.

Science is, to varying degrees, value laden in its social organization, language, methods, and even theories. Women and ethnic minorities are often excluded, underrepresented, or marginalized in scientific institutions. Such terms and phrases as “adaptation” and “survival of the fittest” in biology are laden with positive value (Graham 1981). Feminist scientists and philosophers have documented sexism and androcentrism in experimental design in medical sciences and theories about sexual reproduction, menstruation, and heart disease (Kourany 2010). To the extent that non-epistemic values cause bias in science and jeopardize the objectivity of its findings, these cases can be interpreted as a strong reason for protecting the ideal of value-freedom. They invite revising the institutional structure of science, methods, and theories of science rather than rejecting the ideal of value-freedom.

The crucial question is whether non-epistemic values have any legitimate place in accepting or rejecting scientific theories. The demand that theories be accepted or rejected on the basis of evidence and scientific reasoning seems unobjectionable, and proponents of the ideal of value-freedom claim that the intrusion of any non-epistemic value in this context would destroy the whole stature of science, turning it into a battlefield of societal forces. Critics argue that since no amount of evidence can verify a theory completely, the scientist must decide whether the evidence at hand is strong enough to warrant the acceptance of the theory in question. But this decision will depend on weighing the pros and cons of making a mistake, i.e., accepting a false theory or rejecting a true one. This weighing would typically involve considering, among other things, the ethical and social consequences of one's decision, which would then amount to a value judgment (Rudner 1953). Hence, the argument goes, non-epistemic values necessarily play a role even in the context of theory acceptance and rejection, but this would not make science less objective if scientists explicitly state the non-epistemic value considerations they employ in their decisions. If anything, it would make science more objective by opening up such considerations for public discussion.

A similar conclusion is reached through the argument from underdetermination. Theories are often underdetermined by evidence at hand, and since a collection of data counts as evidence for or against a theory only relative to certain background assumptions, a change in the latter amounts to a change in the evidential relations (Longino 1990). As an example, consider the phenomenon of stellar parallax predicted by the Copernican theory. Seventeenth-century astronomical observations failed to detect any such phenomenon. Whether this counts as a disconfirmation of the Copernican theory or not depends on the background estimation of the distance between the star and the Earth. No doubt, background assumptions cannot be chosen arbitrarily, but sometimes it so happens that even mobilizing non-evidential epistemic values such as fruitfulness, explanatory power, and the like is of no help. This creates some space for scientists to pick those background assumptions that are in line with the social, political, ethical, or whatever values they favor, at least until new evidence kicks in (Anderson 2011). In this way, non-epistemic values may play a role in theory acceptance and rejection.

If the ideal of value-free inquiry is flawed, what is to replace it? A promising alternative is "social value management," which welcomes non-epistemic values into science, provided they are all publicly subjected to rigorous critical scrutiny by taking into account all perspectives (Longino 2002).

So far the discussion has focused on whether and, if so, how non-epistemic values influence science. It should be noted that their influence runs in the other direction as well. Just as societal values enter into science, science impinges on social, political, ethical, and religious values in various ways. To give a few striking examples, the Copernican revolution caused an upheaval about the place of human beings in the universe. Findings in the fields of physics, geology, paleontology, and evolutionary biology regarding the age of the Earth and the origin of humans clash with certain religious interpretations of sacred texts, questioning deeply held beliefs about what it is to be a human being. Environmental science teaches the value of respect for the natural world by showing how fragile our biosphere is, a knowledge that has implications regarding patterns of production and consumption. To the extent that science drives medical technologies (e.g., think about gene therapy, genetic enhancement, and cloning), it raises all sorts of questions about their regulation, how their benefits will be distributed in society, and who will pay for them, not to mention questions about the limits of human capabilities, the meaning of life and death, and what it means to lose loved ones especially if human cloning is allowed one day.

Values in Science

Levent Cavas
Division of Biochemistry, Faculty of Science,
Department of Chemistry, Dokuz Eylül
University, İzmir, Turkey

Science is a combination of testable and certifiable, well-accepted, reliable knowledge about the physical world. Science has many epistemic values such that science should be conducted by scientists using systematic, validated, and well-accepted research methods (Allchin 1998; Allchin 2012). Scientific epistemic values include simplicity of concepts and heuristic testability, accuracy, precision, reliability, and generality (Allchin 2012). Scientific values involve a preference for the *simplicity of concepts* over complexity (Allchin 2012). Scientific conjecture must be testable in some way. Testing must involve *accuracy* and *precision*, measured values must be proximate to reference values, and measurement must be reproducible. *Reliability* suggests that the repetition of experiments should yield the same results (Allchin 2012). It is important that *generalizations* can be drawn from results. Moreover, scientific values include *ethics* given that science can never be disassociated from society and culture (Merton 1973; Allchin 1998; Allchin 2012).

Visitor Studies

John Falk
Center for Research on Lifelong STEM
Learning, Oregon State University,
Corvallis, OR, USA

Although there is no uniformly accepted definition of visitor studies, it can be described as encompassing the broad range of research investigations conducted in order to better understand the behaviors, attitudes, interests, motivations, and learning of individuals who visit informal/free-choice educational settings such as museums, parks, nature centers, zoos, and aquaria. Another name often used as a synonym for visitor studies is audience research.

Consistent with a lack of agreed upon definitions, there are equally no agreed upon goals or parameters defining what should or should not be included as falling within the purview of visitor studies, though some ideas have been put forward. For example, the American Association of Museums' Standing Committee on Audience Research and Evaluation has suggested a particularly narrow scope for visitor studies saying that it refers to "the process of systematically obtaining knowledge from and about museum visitors, actual and potential, for the purpose of increasing and utilizing such knowledge in the planning and execution of those activities that relate to the public" (CARE 2012).

Taking an evaluation perspective, Bitgood (1988) asserted that visitor studies involves four fundamental assumptions:

1. *Visitor advocacy is the primary mission*: That input from visitors should play a major role in the design of both exhibitions and programs; the assumption being that traditionally this has not been the case.
2. *Multidisciplinary view*: That visitor studies is a devise for including a mix of viewpoints and expertise by b1ringing together specialists from exhibition design, education, visitor services, marketing, recreation, and evaluation.
3. *Formal evaluation*: That visitor studies represents a technique for answering questions about the effectiveness and efficacy of exhibitions and programs.
4. *Scientific*: The visitor studies approach utilizes a scientific model of collecting information about visitors and a scientific model of theory building borrowed from disciplines like psychology, sociology, education, and marketing to formulate empirically based principles of visitor behavior and learning.

Similar themes can be found in the definition proposed by the Visitor Studies Association (VSA), a professional organization dedicated to visitor studies. The VSA argues that visitor studies is an "interdisciplinary study of human experiences within informal learning environments. The systematic collection and analysis of information or data to inform decisions about interpretive exhibits and programs" (VSA 2012). They go onto say that visitor studies must always meet three criteria:

- Visitor studies follows rigorous research methods that adhere to the standards of the social sciences.
- Visitor studies draws from and contributes to the theory and practice of social science.
- Visitor studies is designed to improve the practices of learning in informal environments.

These three criteria are probably more aspirational than descriptive of the current state of visitor studies as there are numerous examples of studies, including published works, that fail to meet one or more of these criteria.

Brief History of Visitor Studies

Historically the vast majority of visitor studies research has been evaluative in nature, and most of the individuals calling themselves visitor studies professionals have been evaluators. Much of the original visitor studies research though could be classified as falling within the domain of basic research. With ever-increasing frequency in the past decades, this is again true. The number of published visitor studies research, as opposed to evaluation, investigation has grown by roughly 500 % over the past quarter century (Falk et al. 2012). Systematic, empirical investigation of visitors to informal/free-choice settings began roughly 100 years ago. Some of the earliest known visitor studies research by Eugene Robinson (1928) and his student Arthur Melton (1935) focused on visitors' behaviors and fatigue surrounding their viewing of art museum exhibits. However, it was not until the late 1960s and 1970s that visitor studies research began in earnest.

Early investigators and important exemplars of their works include Harris Shettel (1968), Chan Screven (1969), Roger Miles (Miles and Tout 1978), Minda Borun (1977), John Falk (Falk et al. 1978), and Robert Wolf (Wolf and Tymitz 1979). Starting in this period, the focus of visitor studies began shifting strongly from questions designed to develop generalizable understandings of visitors within informal settings to more evaluative questions related to assessing the efficacy of exhibitions and programs. It was also during this period that the first qualitative methodologies began appearing within visitor studies, originally as part of evaluation studies. This approach was initially quite controversial in the field and was considered by some as lacking the rigor and value of traditional quantitative, hypothesis testing approaches.

Although the quantitative-qualitative debate did not completely disappear during the 1980s and 1990s, the ranks of investigators conducting visitor studies grew considerably as did the number of methodologies employed. An ever-growing list of researchers began to investigate the behavior and learning of visitors across multiple settings, but increasingly the venue for these investigations was science-rich settings. Notable in this group of new investigators and some key examples of their work were individuals like Steve Bitgood (Bitgood and Patterson 1995), Judy Diamond (1986), Ross Loomis (1987), Beverly Serrell (1998), John Koran (Koran et al. 1988), Lynn Dierking (Dierking and Falk 1994), Gaea Leinhardt (Leinhardt et al. 2002), Paulette McManus (1987), Léonie Rennie (Rennie and McClafferty 1995), and Ben Gammon (1999). Although most of the individuals above could be considered basic researchers, the boundaries between research and evaluation became increasingly blurred in this period. Table 1 summarizes the contributions of these early researchers.

During the first dozen years of the twenty-first century, research has continued to expand to include many more investigators and a much wider diversity of topics and approaches. Historically published studies were scattered across a wide range of journals leaving individuals interested in this topic to their own wiles to find relevant research. Beginning around the turn of the new century, several new journals and/or sections of established journals were established specifically for this kind of investigation. Three particularly noteworthy examples include the journal *Visitor Studies*, the special section *Learning in Everyday Environments* of *Science Education* and the *International Journal of Science Education, Part B: Communication and Public Engagement*.

Current and Future Trends

Visitor studies remains a new and emerging field. Widely accepted paradigms and venues for publication remain an issue. Research of every variety is currently conducted representing a wide diversity of theoretical perspectives, with every imaginable type of methodology and data collection strategy utilized. At the same time, there continues not only to be work along the entire evaluation to research continuum but a widespread confusion amongst both researchers and practitioners about where the boundaries between these different forms of investigation lie, or even whether a distinction should be made. At one level this is typical of a young and emerging field still trying to find its center. It could be argued that this lack of focus is a good and healthy thing since it encourages broad thinking and multiple points of view. Alternatively, there are those who believe it is time for the field to determine a dependable suite of models, frameworks, and consistent metrics that can serve as an intellectual foundation on which to build future research and understanding.

Like many areas of the social sciences in the twenty-first century, there exist considerable tensions amongst investigators with differing paradigmatic perspectives. Individuals with more cognitivist leanings look askance at those who approach problems from a sociological or sociocultural perspective. The tensions between quantitative and qualitative researchers remain; though most investigators publicly express tolerance for diverse methodologies. And lurking in background of these more philosophical concerns lie the tensions within the community between those who believe that the goal of visitors studies should primarily be evaluative, directed toward short-term improvements in the quality of exhibitions, programs, and practices and those who are more theory driven and who are less concerned about immediate usability. Though not totally, these two camps roughly divide

Visitor Studies, Table 1 Summary of key historic works in visitor studies

Reference	Purpose	Methodology	Key finding(s)
Robinson (1928)	Research	Quantitative	Series of studies of art museum visitors, both in museums and in laboratory setting. Robinson found that size of the object or picture, its position on the wall, and the density of objects or pictures were all important factors in determining visitor attention
Melton (1935)	Research	Quantitative	Melton also focused on art objects in museums. He found that every object competes with other objects and that position/location of art objects influenced visitor attention
Shettel (1968)	Evaluation	Quantitative	Focused on criteria for judging exhibit quality using quantitative measures like "attracting power" and "holding power"
Screven (1969)	Evaluation	Review	Outlines front-end, formative, remedial, and summative evaluation and provides overview of techniques for designing and implementing these evaluations
Miles and Tout (1978)	Evaluation	Quantitative	Pioneering UK study of the "Human Biology" exhibition at the Natural History Museum; also a description of the new approach to exhibition design
Borun (1977)	Evaluation	Quantitative	A pioneering pilot study of museum effectiveness using a range of measures
Falket al. (1978)	Research	Quantitative	Investigation of how learning on school fieldtrips is influenced by a child's prior familiarity with the physical setting
Wolf and Tymitz (1979)	Evaluation	Qualitative	One of the first qualitative/descriptive evaluation studies of visitors
Bitgood and Patterson (1995)	Research/ evaluation	Review	Summary of research on exhibit design and its influence on visitor behavior; summarizes key points
Diamond (1986)	Research	Qualitative	Documented the influence of children on the viewing behaviors of family groups and the importance of parent–child interactions
Loomis (1987)	Evaluation	Review	Handbook of techniques and approaches for designing and implementing exhibition evaluation
Serrell (1998)	Research/ evaluation	Quantitative	Meta-study of dozens of visitor tracking and timing studies to determine generalizations about dwell time in exhibitions; most visitors view less than half of the elements in most museums' exhibitions
McManus (1987)	Research	Qualitative	Detailed investigation of visitor conversations. Although conversations were influenced by exhibit labels, they also tended to be quite focused on personal interests and concerns
Koran et al. (1988)	Research	Quantitative	Research showing that visitors are strongly influenced by observing the behaviors of other visitors, which they often try to emulate
Dierking and Falk (1994)	Research	Review	Broad review of the family behavior and learning literature; summarizes key points
Leinhardt et al. (2002)	Research	Qualitative	A summary of a collection of studies of visitors to museums utilizing a sociocultural framework
Rennie and McClafferty (1995)	Research	Review	Synthesis of research about learning in interactive science-related museums that concludes that visits do provide valuable motivational opportunities and generally impact student learning
Gammon (1999)	Evaluation	Review	Summary of research on exhibit design and its influence on visitor learning and behavior; summarizes key points

along professional lines with the former camp dominated by those who work primarily within or consult for informal institutions such as museums, science centers, zoos, and natural parks and the latter camp dominated by university academics housed in schools of education or psychology departments. Although it is too early to know whether the end result will be a fission into two distinct camps or some hybrid between the two, it is probably reasonable to predict that these tensions will ultimately need to be directly resolved.

The other trend that is likely to have a long-term impact on visitor studies is the growing pressure to minimize the distinctions between learning in and out of school (e.g., Falk and Dierking 2010; Stocklmayer et al. 2010). As the boundaries between formal and informal/free-choice learning diminish, so too will the boundaries between what constitutes the learning and behaviors of "visitors" and "students," as well as the theories and frameworks that currently divide those who investigate formal and informal settings. That is not to say that there are no differences between learning experiences in these settings. The importance of the physical and sociocultural context means that the unique affordances of experiences in settings like museums, zoos, nature centers, and the like will always require the need for methods and approaches that are specially tailored to these settings. However, it is quite likely that increasingly the distinct underlying theories and questions that currently separate visitor studies investigators from, for example, those who investigate learning in school classrooms, will become ever more blurred, if not largely disappear. The bottom line is that in the future, there will be an inexorable trend toward seeing learning as not rigidly bounded by time or setting. This will undoubtedly impact the direction of visitor studies as a field as well as those who conduct research under this umbrella.

Visualization and the Learning of Science

John K. Gilbert
King's College London, University of Reading,
London, UK

Keywords

Levels of representation; Meta-visual capability; Multiple representation; Representation

Representation, Visualization, and Models

In general terms, a representation is anything that recalls an entity to mind for either the verbal description or the actual portrayal of it. Visualizations are a major subset of representations, consisting of those that are actually perceived by the eye ("external representations") or imagined in the mind ("internal representations"). Although still a matter of controversy, the only representations that are not usually classified as visualizations are words, whether spoken or written.

The goal of science is to produce explanations of the world as experienced. A model is a representation of a phenomenon in the world as experienced that is produced to enable specific types of explanations of it to be created (e.g., what causes it?). A model can be a representation of a material entity (e.g., the heart), an abstraction treated as if it were a material entity (e.g., energy), a system (e.g., a railway network), an event (e.g., an athletics meeting), or a process (e.g., an industrial chemical plant) (Gilbert and Boulter 2000). In short, models are an essential ingredient of all thinking and have a central role in scientific methodology. The visualization of models enables them to be thought about and to be manipulated and their explanatory capabilities explored. Given their importance, it is not surprising that a wide variety of modes, or types, of representation have been devised and used in science education.

The Modes and Codes of Visualization

Visualizations, as external representations, can be grouped into four broad modes – the material, the visual, the symbolic, the gestural – for all of which sight is the main medium of access. Each of these is characterized by its capacity to emphasize particular aspects of the models it is used to depict. Each mode will depict, in some way and to some extent, the entities of which a model is thought to consist, the angular relation between those entities (i.e., the distribution of those entities in three dimensions), and the distances between them and, in many cases, time and causality. This characterization is not a simple process, for each of these broad modes has spawned sub-modes in which the representational emphasis is somewhat different. Taking the four broad modes in turn:

The Material Mode

This mode consists of solid materials (e.g., metals, wood, plastics) used to create a representation of the three-dimensional structure of a model. As the result can be explored by touch, the mode is widely used in the initial phases of a scientific enquiry and throughout all phases of science education. The mode is very versatile, for example, in chemistry, the “ball-and-stick” genre can represent 3D crystal structures; in physics, the “blown-up” genre can represent the structure of electrical devices; and in biology, the “cut-away” genre can be used to depict the layout of organs in the body of an animal.

The advent of the large memory store personal computer has lead to the development of programs which generate virtual versions of material mode visualizations. The 3D nature of the original is indicated by visual clues, e.g., shading to show relative distance. While these virtual visualizations have the great advantage of being very easy to access at any time, the lack of the tactile aspect does limit their value to some extent.

The Visual Mode

The visual mode exists in many sub-modes, collectively known as “diagrams.” The most commonly used taxonomy of diagrams divides them into three groupings: “iconic diagrams,” in which both the entities in the parent model and all their spatial relations are retained (e.g., pictures, line drawings); “schematic diagrams,” in which the entities are reduced to abstract symbols but their spatial relations are retained (e.g., linguistic trees, Venn diagrams); “charts and graphs,” in which the entities and their spatial relations are all replaced by abstract concepts, e.g., line graphs and pie charts. In practice, these groupings are not adhered to diagrams in textbooks often consisting of mixtures of them. Diagrams are widely used to augment text in science education; however, students must become acquainted with their “codes of representation,” i.e., the way that they depict the elements of the model, for this to be successful.

The Gestural Mode

Parts of the body, typically including movements of the hands and arms, are used to visualize a model, most often almost unconsciously during direct interpersonal communication, e.g., when a teacher is talking to a class. Because it is invariably accompanied by speech, the preeminent mode of communication, the gestural mode of visualization is underappreciated in the lexicon of representation and hence has been under-researched. The gestural mode is of very great value to the hard of hearing.

The Symbolic Mode

The symbolic mode is the most abstract of all the modes of visualization, for in it both the entities constituting a model and their spatial relations and specific behaviors are reduced to single letters or groups of letters. The consequent reduction in demands made on a person’s memory capacity enables them to be readily manipulated relative to each of other, such that the imagination to be exercised.

There are two main symbolic modes used in science and hence in science education: the mathematical equation and the chemical equation. Both of them are attended by demanding codes of representation, and hence school students find them difficult to master. However, both are vital ingredients in the advanced study and practice of science, and so the attainment of mastery in both of them is a key indicator of success in pre-professional science education.

Multiple Representations

As discussed above, the various modes of visualization support to varying extents the representation of the several aspects of a given model. It has been found to be educationally valuable to use combinations of them when wishing to support the acquisition of effective and comprehensive learning of a given model. This is known as “multimedia learning” (Mayer 2002), for which three claims have been made. First, by presenting information in different modes, the likelihood of students understanding the core message through one of them is increased. Second, by presenting information in different modes, the likelihood of students being able to transfer it to different contexts is increased, for they do not associate the information with a particular mode. Third, by presenting information in different ways, the ability of students to actively construct knowledge is supported, this being a general goal of all education, including science education.

However, perhaps the main value of multiple representations lies in their use during progression through a course of study. Such a progression involves students acquiring an understanding of scientific explanations of greater depth. It has been found useful to represent this greater depth in terms of "levels of explanation."

Levels of Representation

The notion of a "level of representation" was first used in chemical education. Progression in the understanding of a chemical phenomenon is modelled (Gilbert and Treagust 2009) as moving from the macro level, to the sub-micro level, to the symbolic level, defined as:

- The macro level. Pure samples of a substance (an element, compound, or mixture) displaying the chosen chemical phenomenon in an exemplary way are prepared and the empirical properties that define it are assessed. The representation of these, say in the form of a table, together with the pure substance, constitute the macro level of understanding of it.
- The sub-micro level. A model is created of the entities on which the phenomenon is thought to rely (i.e., atoms, ions, molecules, free radicals). This model can include that of the bonding electrons within/between the entities, leading to conjectures about their shape. This model is then externally represented (e.g., in the material and /or the visual mode) and used to predict not only its existing properties but also those that should exist if the physical conditions were changed. The validity of these predictions is then tested empirically.
- The symbolic mode. At the symbolic level, the model of the sub-micro level is simplified. Thus, molar quantities of atoms are represented by signs (e.g., O), the use of superscripts used to show any electrical charges (e.g., O^{2-}) and suffixes used to show the physical state of species (e.g., $O_{(s)}$). The simplified representations of all the species involved in a reaction are then written as a chemical equation, such that matter is conserved, e.g.,

$$2Mg_{(S)} + O_{2(g)} \rightarrow 2Mg_{(s)}{}^{2+} + 2O_{(s)}{}^{2-}$$

This approach has been adopted for and extended for biological phenomena (Treagust and Tsui 2013), thus:

- The macro level. Here the larger-scale structures of a biological phenomenon are visible to the naked eye.
- The cellular level. Structures at this level are only visible under a light or electron microscope.
- The sub-microscopic level. Here the chemical species that constitute the cellular level are represented, e.g., DNA.
- The symbolic level. Here simplified versions of the sub-microscopic level are used in a quantitative way, e.g., to represent genotypes and metabolic pathways.

A similar treatment for phenomena that fall within the purview of physics is awaited.

Full explanations of phenomena of scientific interest thus involve all the levels of representation. These will use a wide range of modes of representation, implying that the successful scientist, and hence also the high-achieving science student, will need to understand and be able to use the codes of representation for every mode. Possessing this competence implies that a person not only has a detailed knowledge of all the modes and their codes but is able also to reflect on how that knowledge may be used and on the nature of the tasks to which it can be applied and to the ways in which this may be done. This capability may therefore be termed meta-representational competence.

The Demonstration of Meta-representational Competence

To demonstrate full meta-representational competence, a person:

- Should know and be able to confidently use the codes of representation for all the four major modes of visualization, being aware of the scope and limitations of the ways in which they represent entities and relationships in any given model. This primary requirement is made more complex because, in addition to generic descriptors of a mode, there are usually many sub-modes each with subtly different capacities, for example, "ball-and-stick," "space-filling," and "skeleton," versions of material models used for molecules in chemistry.
- Be able to use different visualizations in order to demonstrate the relationship between each of the levels of representation for a given phenomenon. For example, in respect to the function of the liver: to use a material model to show the position of the liver in the body, to use a different material model to show the cellular structures of the liver, to use yet a different material model to show the structure of the components of the liver, and to use a diagram to show the metabolic pathway by means of which the liver functions.
- Be able to "translate" the visualization facilitated by one mode into that made by another mode. For example, to show the relation between a material visualization of the composition of a crystalline chemical and that given by a two-dimensional diagram of it.
- Be able to construct a visualization within any one of the modes that is relevant to the requirements of the model. The "liver example" above would be such a case.
- Be able to use visualizations in order to solve problems that have not previously been encountered. For example, to represent the technique of hydrocarbon extraction known as "fracking" and to explore the possible consequences of it for geological stability in a given location.

Little if any effort is currently made to systematically develop meta-visual competence in either science students or their teachers. That both are needed is shown by research evidence that:

- Students are able to produce a visualization at the macro level but are unable to do so for the same phenomenon at the sub-micro or symbolic levels.
- Students find it difficult to "translate" the symbolic visualization for a phenomenon into the corresponding sub-micro one and vice versa.
- Students find it difficult to "translate" a given visualization between the sub-modes of a given mode.

The first step in making provision for such development must be to establish what is entailed and how it might be facilitated.

The Development of Meta-visual Competence

From a study of undergraduate chemists, Kozma and Russell (2005) identified five distinct stages – what they called levels – in the development of meta-visual competence. In summary, and adopting the word "phase" for them to avoid confusion over the meaning of the word "level," these are that in:

- Phase 1, students visualized a physical phenomenon solely as an iconic depiction of the original.
- Phase 2, students included some symbolic elements in such an iconic depiction.
- Phase 3, students included far more symbolic elements in their depiction, but these were often not scientifically accurate.
- Phase 4, students only used symbolic elements in producing a visualization and always did so correctly, being also able to transform a given visualization into one in another mode.
- Phase 5, students were able to use one or more appropriate and symbolically accurate visualizations to explain the relationship between the entities present in the phenomenon and the behavior they show, also being able to justify any such claims they make.

A student progressing from Phase 1 to Phase 5 will have undergone a major process of conceptual development both in terms of ontology and of epistemology. This development can be supported by teaching in which:

- Explicit use is made of several modes of visualization in discussing a given topic, relating their use systematically to the levels of representation used in that topic.
- The introduction of those visualizations starts from the one that is both the simplest and the most iconic and progresses to the one that is the most comprehensive and most symbolic, explaining the appropriate codes of visualization as the sequence is followed.
- The differences between the visualizations is emphasized by the use of sharp edges, distinct shapes, shading, and color.
- Use is made of stereodiagrams to enhance students capacity to understand the 3D nature of a model (if that is relevant) from a 2D visualization of it.
- The skills of reflection and rotation are systematically exploited.

Indeed, these and other strategies should also be included in teacher development programs.

Teacher Development for Meta-visual Competence

The general principles of good practice for teacher education programs, whether preservice or in-service (Gilbert 2010), certainly apply in designing and providing professional development activities on the theme of visualization. These activities could readily serve two functions: the development of the teachers' own capability and the demonstration of how these themes can be incorporated into schemes of work for students. The activities should thus:

- Be philosophically and practically congruent with the intended purpose. This criterion can be met in three ways. First, have the teachers develop visualizations for use in their own teaching. Second, have them analyze the design and intended use of the many visualizations that are included in the textbooks issued to students. Third, have them explore the teaching potential of the many computer software packages for the generation of visualizations that are available.
- Recognize that learning, including that of teachers, is a social activity. An organization of activities such that they lead to an atmosphere of "critical support" among participants working in small groups will enable them to see both that they share many of the same challenges and that they can cooperatively arrive at solutions to them.
- Enable activities to be spaced such that reflection on what has been learned can occur. One way of doing this is to have participants develop visualizations that are to be used with classes before the next teacher education meeting, to evaluate their implementation, and to report back at that meeting.
- Monitor the consequences of the professional development activities for the evolution of classroom practice. This can be expensive in terms of expert counselling but the impact is likely to be substantial.
- Require participants to engage in action research. The process of developing meta-visual capability is likely to be a lengthy one such that the taking of small steps and evaluating their significance is the soundest way forward.

In the course of such activities, myriad small changes should be sought to overcome what is known about shortcomings in teachers' knowledge and skills. Thus teachers should be encouraged to:

- Adopt the correct terminology for the field.
- Use appropriate modes of visualization, not only the iconic form.
- Use visualizations throughout a topic and not just during its introduction.
- Explain when changing the mode of visualization being used why this is being done.
- Only use personally developed visualizations when they have been prepared and considered before their use in a class.
- Develop their pedagogic content knowledge about the use of visualization in general.

The Assessment of Visual Capability

There is clearly a need for instruments that, severally or collectively, assess students' progress on the road to meta-visual competence. Although many partial instruments have been produced for more narrowly conceived research purposes, typically concerned with the skills of "rotation" and "reflection," it will only be when the development of meta-visual capability is placed as a central commitment of science education that comprehensive, teacher-friendly, packages will be developed.

Department of Education in Science and Technology, Technion – Israel Institute of Technology, Haifa, Israel

Keywords

Blogs; Search engines; User-generated content

The Internet has increasingly become the main source for science-related information for Western societies (National Science Board 2014). Web 2.0 was coined to describe the second generation of the World Wide Web that shifted from passively viewing content from static web pages to a focus on users' ability to interact, collaborate, generate, and share information online. Web 2.0 includes wikis (e.g., Wikipedia), blogs (e.g., ScienceBlogs), podcasts (e.g., RadioLab), video sharing (e.g., Khan Academy on YouTube), massive open online courses (e.g., Coursera), social networking sites (e.g., Facebook), and many other applications. Web 2.0 digital and interactive technologies have enabled nontechnical citizens to become consumers as well as producers of science content by creating, changing, linking, remixing, and disseminating information on a global scale at relatively low cost.

Web 2.0 provides opportunities for eliciting public engagement with science in informal environments and students' engagement with science within formal K–12 and higher education environments, as well as unique affordances for educational research.

Although the traditional digital divide between people with and without access to the Internet has declined, a second-level digital divide has emerged involving what people do with the Internet, and it is becoming wider. This divide may relate to actual and perceived web skills and is correlated with demographics such as gender, educational background, and age. "Digital natives," for example, the generation born after 1982, have been immersed in an environment of digital technologies for their entire lives and are said on average to have better understanding of its value and application to their lives. The daily interactions of digital native students increasingly involve information and communication technologies (ICT), but their in-school learning have been found to be technologically impoverished or use controlling technologies to restrict Internet use. These students are increasingly turning to the Internet to complete educational assignments, regardless of whether the assignments are intended to involve Internet use.

The evaluation of information sources is a critical subskill for any complex task that involves learning from multiple digital sources. Web users must critically evaluate diverse and sometimes contradictory sources of information. This situation shifts the burden of information evaluation to the reader, since web-based

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

information may lack reliability due to the absence of a professional gatekeeper (e.g., editor). However, research has shown that users do not usually make the effort to appropriately evaluate the quality of information obtained on the web and the quality of its source. Luckily, evaluation skills are amenable to improvement through instruction. Beyond their contribution to the effectiveness of inquiry learning in science, these skills may be even more important for successful lifelong learning and making real-world decisions (Wiley et al. 2009).

One of the hallmarks of Web 2.0 is the introduction of new capacities for information seeking, sharing, and aggregating. Research on science students' information seeking has involved assigned tasks, like using digital libraries, or plagiarism prevention, rather than self-generated search tasks. However, new data mining and analysis tools can now document trends in science-related web searches. In 2006, Google launched Google Trends. This public web tool tabulates how often a particular search term has been entered into the Google search engine versus the total search volume across time periods, various regions, and languages. Data on online searches, which reflect a conscious effort to acquire information, have been used to study trends in health, economics, and science information seeking. Studies measuring public interests in science have found that searches for general and well-established science terms were strongly linked to the academic calendar, meaning that the trigger for the search was probably the education system.

On the other hand, searches for concepts related to ad hoc events (e.g., Nobel Prize announcements) and current concerns were better aligned with media coverage. Web searches on nanotechnology indicated that the public was mostly interested in future directions but was less interested in policy and regulation. However, significant differences in search behavior have been found depending on the wording of the search query. Studies demonstrated cases of discrepancies between the science topic people search for online, specific areas suggested to them by a personalized search engines and what people ultimately find. This is important, since search results may shape users' perceptions, knowledge, and discourse about emerging technologies (Brossard and Scheufele 2013).

Ask-A-Scientist sites are aimed at providing students and the general public direct access to legitimate scientific knowledge in an accessible manner. One project called Madsci, for example, enables a direct exchange between scientists and students. Analysis of usage demonstrates a surprising dominance of female contributions among K–12 students, whereas offline situations are commonly characterized by a greater interest in science among males. This female enthusiasm was observed in different countries and had no correlation to the level of equality in those countries. This may indicate that the Internet as a free-choice science-learning environment plays a potentially empowering and democratic role. However, an analysis of 10 years' worth of data revealed that girls' interest in submitting questions to scientists dropped all over the world as they grew older, and the stereotypically gendered science interests persist in this environment as well (Baram-Tsabari et al. 2009).

Social networks have increasingly become a channel for distributing and publicly debating scientific information. The microblogging social network Twitter has been used in schools to provide instant feedback tool during class, as a means of triggering in-class discussion and a technology-based strategy to support informal learning beyond the classroom. Educational use of social networking sites may involve the replacement of common online learning management systems (e.g., Moodle) by private Facebook groups specifically created for classroom communication. Examples include enhancing students' participation in an introductory chemistry laboratory course or knowledge sharing in a history course where students uploaded profiles of relevant historical figures.

Reader comments to online news articles is another way in which Web 2.0 capabilities have begun to transform web activity from being passive to being more active, through creating content in the virtual world. This is a great opportunity for public engagement with science, where citizens can now add their voices to published content, as well as repost, up-vote, or use various other means of adding social information to the original content. In recent years, reader comments about science online media coverage have been used to learn about the concerns, sources of information, and knowledge of participants in discussions about socio-scientific issues, such as animal experimentation, nanotechnology and climate change. It was found that the most fruitful discussions within comments were initiated in the discussion threads themselves, rather than in the science news articles, indicating that the audience participation now plays a role as a "growth medium" in which seeds flourish through reader contributions. On the other hand, the effects of online incivility in reader comments have been found to effect the perception of risk toward science-related issues.

The changing nature of the web as well as the changing nature of "classrooms" where learning can take place across physical and cyber spaces in and out of school provides twenty-first-century learners with an array of choices for the topic and location of their learning experiences.

Wikis

Vanessa L. Peters
Center for Technology in Learning, SRI International, Menlo Park, CA, USA

Background

A wiki is a collaborative website that allows users to add, delete, and edit content via the Web browser on a networked computer. What distinguishes wikis from other programs, such as word processing software, is that the documents remain available for ongoing editing by those who have membership to the wiki. Wiki membership can be of any size – from small groups and classrooms, to schools, communities, and the entire world. Wikipedia, the well-known online encyclopedia, popularized both wiki technology and the idea of collaborative writing. Wikis are primarily used for the co-construction of text-based documents, which are referred to as wiki pages. Wikis can also include other types of media; even the most basic and freely available wiki software enables users to embed videos, links, and images within the wiki. Certain commercial wikis, such as those used in business and industry, have increased functionality including group calendars, advanced search capabilities, and content streaming.

Wikis are suited for all levels of education, including formal K-12 classrooms, higher education, and informal learning settings. They serve many educational purposes. Teachers have used them as a platform for content management, a repository for class projects, and as a forum for group discussion. Wikis are easy to learn and require little or no training to be used productively, a factor that has contributed to their widespread usage among educators. Wikis support the ongoing reflection and refinement of ideas by maintaining an archive of students' contributions and edits. The publication of student work, even when limited to their peers, legitimizes their contributions within the wider class community. The co-writing of wiki pages can also lead to important transferable skills, including problem solving, communication, decision-making, and teamwork.

Wikis in Science Education

Wikis can be a valuable tool for creating knowledge resources for science education. When editing content, students make decisions about the ideas and information that have been contributed by their peers. In doing so, they may engage in negotiation and consensus making, processes that are important for learning and foundational to theories of social constructivism. The collaborative component of wikis makes it possible for all students to contribute their ideas and perspectives. The growing collection of resources that students co-create and share comes to represent the collective knowledge of the class. For this reason, wikis are suitable for knowledge communities, where students rely on the knowledge and contributions of their peers for their science learning. In addition, the ability to include hyperlinks, either to external websites or to links within the parent wiki, can support students in making connections between the ideas and information that are contained within the wiki pages.

One of the challenges of using wikis for science education involves the measurement and assessment of student contributions. Wikis include detailed history logs that keep track of the moment-to-moment edits made to wiki pages. These history logs are typically voluminous and complex and are difficult to use and make sense of without extensive analyses. Educational researchers have developed both sophisticated technological tools and simple metrics for assessing the quality of students' wiki contributions, as well as measurements of their collaborative efforts. The challenge of developing valid and reliable assessment instruments is ongoing, including efforts to develop practical tools for K-12 science teachers that can be used for assessing student performance.

Wikis are used in both formal and informal science learning environments. The Informal Science Education Evidence Wiki provides summaries of research on informal Science, Technology, Engineering, and Math (STEM) education and provides a forum for public discussion about informal science learning. Wikispaces has been used extensively by science educators at all levels and is popular for providing a free and accessible wiki space that includes teacher-controlled permissions for content and file viewing. Regardless of the educational context, wikis can contribute to science leaning in a number of important ways. Collaborative wiki writing supports scientific literacy, the acquisition of disciplinary content, and the development of twenty-first century skills. Wikis are also a valuable educational resource for helping learners of all ages to become informed consumers and producers of science.

Worldview

William W. Cobern
The Mallinson Institute for Science Education,
Western Michigan University, Kalamazoo,
MI, USA

Worldview provides a nonrational foundation for thought, emotion, and behavior. Worldview provides a person with presuppositions about what the world is really like and what constitutes valid and important knowledge about the world. It is, according to Kearney, "culturally organized macrothought: those dynamically inter-related basic assumptions [i.e., presuppositions] of a people that determine much of their behavior and decision making, as well as organizing much of their body of symbolic creations. . . and ethnophilosophy" (1984, p. 1). Worldview is thus about metaphysical levels *antecedent* to specific views that a person holds about natural phenomena, whether one calls those views commonsense theories, alternative frameworks, misconceptions, or valid science. A worldview is dynamic colocation of mostly implicit fundamental presuppositions on which these conceptions of reality are grounded. Because worldview is an exhaustive concept that far exceeds the realm of science for all but the most extreme scientistic believers, it is problematic to speak of a *scientific* worldview. Scientific ideas can be grounded in many worldview variations. Scientists have come to their work from very different worldviews. There is not one worldview that is required for scientific thinking or for valuing science. A scientifically *compatible* worldview is thus a more accurate and useful construction for the vast majority of persons. This construction puts emphasis on the integration of scientific thinking with other powerful ways of thinking that are important to people. It guards against the twin problems of scientistic and antiscientific thinking.

Writing and Science Learning

Brian Hand
University of Iowa, Iowa, USA

Keywords

Criteria for writing; Knowledge bases; Writing-to-learn

Writing has been used in every classroom in every country since the time schooling began. Students have been asked to copy notes from the board, record their experiments, and complete assignments for eons. The major role of all of this writing was for the students to have a record of what was being said and what they understood. The function of writing was to produce a product – there was only a limited focus on the process. It was not until the mid-1970s that the idea that writing was both a process and a product began to emerge. The idea that writing was more than just a record of work or talk written down, something that could help students learn, focused research on understanding how this was possible.

The shift in thinking about writing occurred around the time that there was beginning to be a shift in how science was taught. Much of what had been the focus of the 1960s and 1970s in science was based on behavioral learning, that is, students were provided with information and skills that they were required to give back or perform. There was the added restriction in some countries that curriculum and students' progress were based on the stages of development theory derived from Piaget, with the central premise that students were unable to advance their cognitive work until they had reached particular ages. The focus of science teaching was much more on the product, not the process.

Process and Product

If writing is not simply a product but a process, then the question becomes as follows: What is the process? What is actually happening during the process of the construction of the text? Is the process a series of steps, that is, a set of behaviors? Can the process of writing be simply a matter of mastering a series of steps? Or is it a cognitive process? That is, is the process of writing something that is internal to every individual? These two different perspectives have led to an ongoing debate between contrasting positions – the "learn-to-write" position and the "writing-to-learn" position.

The initial research on writing occurred during the 1980s. This involved a great deal of focus on establishing the steps that were required to complete a writing task. If writing is more than talk written down, how is the process of writing achieved? In understanding that the end goal of writing is a product – a completed piece of writing – how does an individual plan and complete the process? Do they have a series of steps to complete? This was the focus of much of the work in the 1980s. Research was done that was centered around understanding what the necessary steps an individual had to complete were. This resulted in a focus on the issues related to genres or particular types of writing, what the structures of the genres are that a writer has to put in place for success, and what the writer has to know to be successful in terms of being able to write in different genres (persuasive writing, narrative writing, expository writing, argumentative writing, information writing, etc.).

This led to the work of Halliday and Martin (1993) whose book has very much guided the "learn-to-write" movement in science education. For these researchers, there was a very strong push to have students learn the structure of the genres before doing science. For example, they believed that for students to learn from science, they had to know the structure of the laboratory report before they could use it for inquiry activities in the classroom. Many researchers have adopted this important position, that is, you first have to teach the structure of the genre (e.g., laboratory report) before the students can use it. For students to have success in the laboratory, they have to be able to complete the traditional format of hypothesis, data, results, and conclusions.

This position is still the focus of what happens in many science classrooms today. That is, the value of writing is framed around having the correct structure and ensuring that this structure is completed. However, this raises questions such as the following: What does it mean to learn using this approach? How does completing a genre actually produce successful learning? Is the learning achieved in the actual writing or in completing the structure? For example, is writing the laboratory report itself where the learning occurs, that is, making sure that the hypothesis is connected to the data, to the results, and to the conclusion, the crucial component of the learning? Or is the learning gained in filling in each of these sections?

Many teachers of science spend the first week or so of each year making sure that the students know the "scientific method" and know how to write up their laboratory reports. It is believed that ensuring that this structure is firmly in place will enable students to learn science better – the position of the learn-to-write movement. The results of many studies have shown that there are roughly an equal number of positive gains as negative consequences using this particular orientation.

Shifting the Focus

In trying to explain how learning does occur through writing, Bereiter and Scardamalia (1987) put forward a model that highlighted that there are in fact two knowledge bases that need to be engaged with in writing – the rhetorical knowledge base and the content knowledge base. In terms of rhetorical knowledge, each author has to know what the requirements of the structure of the genre (complete sentences, paragraphs, etc.) as well as the purpose of the genre (to inform, informational essay; to persuade, argumentative report; etc.). The content knowledge base encompasses what needs to be actually described using the rhetorical knowledge base. That is, if a student is asked to write about force and motion, then he/she has to make decisions about the particular aspects of force and motion he/she is going to use – straight line motion, speed, velocity, acceleration, etc.

Bereiter and Scardamalia argued that each author will only be able to operate one knowledge base at a time – they are either using the rhetorical knowledge base and then moving to the content knowledge base or vice versa. There is a constant movement back and forth between these two knowledge bases.

Bereiter and Scardamalia highlighted two critical caveats with their model. The first was that there would be constant motion back and forth between these knowledge bases until the task was finished. Each individual would be using one knowledge base, for example, the rhetorical knowledge base, before moving to the other knowledge base in completing the writing task. The second is that there are two different outcomes of the writing process – knowledge telling and knowledge transformation. They believe that there are two major functions involved as the outcome of the writing process. Knowledge telling is where the emphasis is on recall of information – recalling what information you have stored and telling the reader what it is that you know. There is acknowledgement that there is no change to the knowledge the writer is describing.

In one sense this form of writing can be considered as a memory dump. The knowledge transformation process however is very different to the knowledge-telling process. In this process what the individual knows is changed or transformed by the actual process of writing about it. It is through the writing process itself that the knowledge is transformed. This was an important breakthrough in terms of understanding the value of writing – knowledge is not transformed before writing it down; it is transformed through the writing process. As the individual completes a writing task that goes beyond simply telling, then they are going through a process where what they know is being transformed by engaging in the process of writing itself.

This critical breakthrough was important in framing an argument that moved writing away from a procedural view of a planning and production process to engaging more with the idea that writing was in fact an epistemological tool. Through the process of writing, an individual can come to know more about the topic than they did before they started. That is, writing is much more than a process of thinking about what to write, shaping the sentence, and then writing the sentence. Writing became a process that in the moment of writing, there is thinking and that as a result of the writing, more thinking occurs. As one puts pen to paper (or now we would say, fingers to the keyboard), the outcome of the previous text will generate different thinking to that that was occurring before the text was constructed. If you think about any example where as you were writing you became excited because suddenly there were new ideas flowing from your "pen," then you have a very stark example of this process. A situation in which you are going in one direction and suddenly as you are writing, there are many new ideas emerging as if from nowhere is a very clear example of writing as an epistemological tool.

Improving Our Understanding of the Process

As with any theory put forward to explain a phenomenon, there is always some disagreement which then leads to advancement of ideas. This was the case in the writing research community. A model put forward by Galbraith (1999) helped generate a richer understanding of the writing process. One of the disagreements with the previous model put forward by Bereiter and Scardamalia was around the idea that the knowledge transformation process did not build new knowledge but rather only transformed what already existed – the process, Galbraith argued, did not in fact lead to knowledge that was new and different to that which previously existed.

Galbraith agreed with the idea that there are two different knowledge bases that need to be engaged with when writing, but he argued that there was a dialectic or dialogue between these that is continuous and not dependent upon being in one or the other knowledge base. His argument was that it is through this dialectic, this continuous interaction, that text gets built. Importantly, the dialectic produces new and different links with the knowledge that currently exists, so that it is in fact constituted in a different way, resulting in new knowledge. The links between points within the web of stored knowledge are generated in new ways, and hence, what is constructed is different to that which previously existed. This newly constituted knowledge allows the individual to come to know the topic/idea in a different way than before. That is, writing is an epistemological tool.

This was a really critical shift for researchers because this meant that the idea of writing was not just to demonstrate what an individual knows but rather to see each writing task as a learning task. All the writing tasks that students engage with, apart from straight note-taking which is nothing more than copying exactly what is written down somewhere else (notes from the board, copying a summary from a textbook, etc.), become learning tasks. The view of researchers of writing tasks shifted from being about the production of some finite product to understanding that the process of production in itself is part of the learning process. This means that not only are the assigned writing tasks within a topic learning tasks, but when extended response questions are used on a test, these become writing-to-learn tasks as well. That is, even while they are completing a writing task as part of an examination, individuals are going through a learning process.

Shifting from “Fuzziness”

The final piece of theory that has been guiding the writing-to-learn movement in trying to understand how writing is an epistemological tool is the work of Klein (1999). In explaining how writing is a learning process, he posited that there are a number of different positions. These ranged from the concept of genre, that is, learners have to understand the structure of the writing task (genre) to be able to use it as described above, to what he termed “backward and forward searching.”

Backward searching resembles the planning phase described in the early studies of writing in that he argued that learners have a plan for completing the task. By continually referring back to the plan as he/she moves through each part of the plan, the learner is able to complete the task. However, the point of construction of the text is where the learner will search forward to continue to complete the writing of the sentence, paragraph, and/or whole text. It is this interaction between completing the plan (backward searching) and continually having to go forward in the construction of the text (forward searching) where learning occurs. The planning process does not imply there is planned text prior to writing but rather there is a plan in what needs to be completed.

The goal of this interactive process of backward and forward searching is to move from fuzzy understanding to an understanding of the canonical forms of science knowledge. For Klein it is this second-generation cognitive psychology position of fuzziness that is the driver of the epistemological gains made through writing.

As a learner writes, they will shift from being fuzzy about the idea toward the first-generation cognitive psychology position of canonical knowledge, that is, toward what is the recognizable science knowledge. This in essence is what is meant by writing as an epistemological tool – through writing the learner is able to shift from being fuzzy about the concepts being studied to a place where they know or understand the ideas being studied.

Conditions for Using Writing

As the view of writing shifted from production to process to understanding that writing is an epistemological tool, then there was a push to determine what the critical criteria were in helping to maximize the learning outcomes. There has been much work done on framing some critical elements that learners need to be aware of or are required to engage with in using writing as a learning tool. These elements include audience, writing type, topic, purpose, and method of production. These are discussed below:

Audience – learners constantly have to write to the teacher as the audience for their writing. The problem with this is that they are playing the game of giving the teacher back what he or she wants to see. This can include bold words from the text or the words highlighted by the teacher as well as ensuring the complex explanation used in the textbook is part of the written product. The trouble with this is that instead of being placed in a position of explaining the ideas, the learner merely repeats what has previously been given to them. By choosing an audience other than the teacher, the demands on the learner shift, particularly when the audience is their peers or a younger group. Students need to be placed in a position where they are forced to break down the "big" scientific words in order for the audience to understand what they are trying to explain. By asking learners to write to a real audience who will participate in scoring their work, the learner is placed in a position to have to explain the science words to himself/herself as well as the audience, hence encouraging a much richer engagement with the topic.

Writing type – traditionally, learners are required to write using a small number of different writing types within the science classroom. These include laboratory reports, chapter summaries, notes from the board, and an occasional creative essay about, say, a day in the life of a red blood cell. When instead learners are asked to write using nontraditional writing types such as letters to the editor, travel brochures, creative stories, etc., they have to deal with issues that focus on both the rhetorical demands of the writing type and the need to correctly explain the science concepts. These different types are not about fictional science, but about having to explain to others the scientifically correct concepts in ways that require the learner to break these ideas down and consider them in contexts other than the science classroom.

Topic – commonly, science is taught via the teacher breaking the ideas down and laying out a linear path to understanding, with the Internet that every learner will be able to put the pieces together correctly. Very rarely are learners provided with the "big idea[s]" of the topic – somehow it seems it is supposed to be obvious to everyone. However, there is a need to use writing tasks that are centered on asking students to focus on the conceptual frame of the topic. It is through having to explain the "big idea [s]" of the topic that the students will attach meaning to all the content of that idea. Thus, writing tasks should focus on what is the framing concept of the topic under study.

Purpose – there are many purposes for using writing within the science classroom. These include the following: at the start of the topic in order to determine what students know, in the middle of the topic to provide opportunities for learners to gather their thoughts together, or at the end of the topic to demonstrate what they have constructed as the conceptual frame of the topic. Building on the idea that each writing activity is a learning opportunity, the purpose of the learning itself can shift depending on the timing of the writing opportunity.

Method of text production – given the changes in the use of technology in schools, then the construction of the written text can shift from the more traditional pen to paper to any of a range of electronic platforms. This shift also has consequences for how a learner constructs the text they write because the ease in which they can change text, shift text, or cut out text is a very different writing process than the traditional method of construction. The method of text production also refers to the idea that a text can be constructed in other ways apart from an individual endeavor. For example, is the construction a group effort? Or do individuals contribute to part of a text? These are decisions that have to be taken into consideration when framing a writing task.

The above elements can be used to frame different writing tasks for any learning situation. The particular combination of these elements is determined by the context of the situation and the learners that are to undertake the task. However, results to date indicate that much benefit is gained in using these critical elements to help in constructing the writing tasks.

Students' Understanding of Writing

In a secondary reanalysis of a series of qualitative studies over a 10-year period, McDermott and Hand (2010) showed that students are very aware of the benefits of using these writing-to-learn approaches within classrooms. That reanalysis highlighted that students identified three characteristics of the writing task that were beneficial – writing to a different audience, the opportunity to do multiple drafts, and the opportunity to receive real feedback. Importantly, students were aware that while these writing tasks are time-consuming and difficult, they were getting learning benefit from completing the tasks, particularly because these tasks required them to think more about the topic. They were very aware that having to deconstruct science terms for their audience was beneficial for their learning. Having to break down such ideas as "photosynthesis" into its component parts for younger students means that the author really has to understand what these component parts are, rather than simply feeding back to the teacher the term itself.

In another secondary analysis, Gunel et al. (2007) were able to show that there are statistically significant performance advantages for students on tests when they are involved in writing approaches in the science classrooms. The analysis also showed that students' test performance was significantly boosted when they were required to answer conceptual questions or extended response questions.

Importantly, these results showed that not only do writing-to-learn approaches improve students' understanding of content/concepts, it also enhances students' understanding of why and how there was benefit for them. By using such approaches, we can generate a greater involvement for students and hence increase their chances for success.

Future Directions

Currently, there are a number of different directions being taken by research on writing-to-learn approaches. These include two very promising areas of work. The first is on science argumentation while the second is centered on multimodal representation. Both of these research ideas extend writing-to-learn approaches beyond what has been seen as the more traditional ideas of writing.

Science argumentation is now being recognized as a central practice of science. It is how science knowledge is advanced. As such this raises critical questions about how we can use writing as a critical learning tool in the building of students' knowledge of argument and science at the same time. This shifts the focus from using writing-to-learn approaches for engaging with already defined ideas to working with students to use writing as a learning tool in understanding how science knowledge is constructed. How can we use writing as a means to help students learn about questions, claims, and evidence and the relationship between these as a means to building understanding of the science itself? Given the shift in some recently released national science curricula to a great deal of emphasis being placed on the argumentative practices of science as central to the advancement of science, such questions become critical.

The second area of focus is broadening the use of writing to focus on how to embed multimodal representations as a critical part of the language. This focus places emphasis on broadening the idea of language to move beyond just writing. Given the shift in how technology is being used in classrooms, we need to explore how writing and other modes of representation can help students learn science. Writing is the "glue" that helps students move between representational modes, but as yet we have not explored the best ways to incorporate all these modes, how students engage with the modes, and the best ways to represent science ideas from the student perspective in terms of different writing opportunities. This research holds much potential for advancing how we can help all students learn.

Wildlife centers; Zoological parks; Zoos

Zoos are collections of animals displayed in designed settings, typically open to the public. The earliest zoos were private menageries designed to demonstrate the wealth and influence of royalty. Some served as “libraries” of living things of great educational value to the scholarly elite, though many were merely meant for the amusement of those permitted access. Over time, the mission of modern zoological parks has evolved to a current focus on conservation, education, scientific research, and recreation. The emphasis on the conservation and educational mission of zoos in particular has led to a change in the way the zoo experience is presented to guests. Modern zoos take very seriously their role as conservation centers that inspire guests to take an active role in protecting wildlife and wild habitats (Myers et al. 2004).

Historically, learning at the zoo primarily meant transfer of knowledge from expert to guest, by acquisition of facts and figures about the animals on exhibit. More recently, zoo educators have begun focusing on how the learner experiences the zoo and its educational programming in an effort to ensure that the zoo experience has a positive impact on learners’ attitudes and behaviors related to wildlife conservation (Myers et al. 2004).

The World Association of Zoos and Aquariums reports that global zoo and aquarium attendance tops 700 million visitors annually. Because of their ubiquity and popularity, zoos can claim to be key settings designed to support science learning by people across the life span. Research has shown that the general public value zoos as places where children develop and strengthen connections to nature and where families make discoveries and learn about science together (Fraser and Sickler 2008). Zoo experiences are uniquely positioned to inspire guests to become interested in science, to ask questions about what they observe, and to reflect on the world around them and how they can learn more about it. Zoo educational programming often encourages guests to become active participants in science learning and, in so doing, inspires guests to view themselves as life-long science learners.

Subject matter that visitors encounter through their zoo experiences include conservation, animal behavior, animal husbandry, environmental

science, research methods and equipment, analytic tools of mathematics and engineering, natural and engineered habitats, veterinary science, ecology, and more. The types of engagement that are encouraged in visitors include appreciation, respect, empathy, awareness, conserving, activism, and stewardship. The educational programs offered range from guided tours to classes, camps and clubs, remote field trips and web-based courses, internship opportunities, conferences and workshops, citizen science projects, outreach visits, and travel, among other programs. Audiences are varied; many zoos offer specialized programming from early childhood through adulthood.

Efforts to refine the educational focus of zoos and the work of their staff have been developing in earnest over the past 20+ years. Collaborations with conservation groups and universities have multiplied; educational experiments have been funded; best practices are being identified and shared; increasing numbers of zoological facilities are investing significantly in evaluation efforts; research on the educational impact of zoos is building on what have been identified as critical features of learning in other informal science settings. The nature of working with living collections, however, makes the setting unique and research on zoo-based education will take its own direction as more studies are undertaken.

The issues attendant with measuring outcomes in other informal settings apply to zoos as well, but recent research points to the effectiveness of zoos (and aquaria) for learning and engagement (Fraser and Sickler 2008). For example, research has shown that interactivity by and with animals encourages caring (Myers et al. 2004). Introducing mathematics activities in zoo programming allows zoo staff to engage visitors in some of the work of animal scientists and demonstrated to teachers that zoos are an ideal setting for introducing and reinforcing students' math skills. Ongoing studies are examining the impact of a zoo visit on guests, using a variety of indicators (Dierking et al. 2002).

Many zoo guests may simply seek an outdoor stroll with family and a chance to observe interesting creatures. Zoo professionals see opportunities to help visitors stop and notice, reflect and wonder, and become aware of their connections with nature and of the work of zoos themselves. The ultimate goal of zoo-based education is to inspire guests to develop attitudes and behaviors that support wildlife and habitat conservation.
