Preface

This is the first English language Encyclopedia of Science Education to be published and, as far as I have been able to determine, the first Encyclopedia of Science Education in any language.

But "being the first" does not mean "this is needed." So why an *Encyclopedia* of Science Education? This was literally my immediate reaction when Harmen van Paradijs, then Springer's science education editor, first asked me some years ago if I would create and edit an Encyclopedia of Science Education for Springer. After all, quite comprehensive handbooks of Science Education had been a common feature of our research world for two decades: The USA-based National Association for Research in Science Teaching (NARST) initiated the first (in 1993, edited by Dorothy Gabel). At the time Harmen spoke with me, there were two current well-known handbooks, one endorsed by NARST (edited by Sandra Abell and Norman Lederman) and the other published by Kluwer (now Springer, edited by Barry Fraser and Kenneth Tobin), and the second (and current) editions of each of these were both already well underway. Two of the eventual seven volumes in the regionally focused series of handbooks of Science Education research published by Sense had by then been completed. And the journal *Studies in Science Education*, a journal primarily devoted to reviews of science education research, was then in its 45th year. Clearly, an encyclopedia was not justified if it was to be just another form of handbook.

Why *This* Encyclopedia of Science Education?

In general terms, an encyclopedia ought to be different from a handbook, given both the format of large numbers of separate contributions ordered alphabetically (rather than single-/joint-authored major reviews of broad topics) and the ways this differing format invites different approaches to synthesizing research findings and future directions.

I spent some time considering the question of why *this* Encyclopedia of Science Education before deciding I had answers acceptable to me and so agreed to Harmen's invitation. Arriving at my answers involved exploring two things: whether I believed science education warranted an encyclopedia and how such a publication could be sufficiently different to anything currently in existence so as to attract me to accepting the major commitment that the creation and editing would involve.

Commonly, encyclopedias are defined as something of the form of "a comprehensive reference work – book or set of books – containing extensive information on all branches of knowledge or on one particular branch of knowledge, usually arranged alphabetically." The issue as to whether or not science education deserves such a publication is, as I see it, easily settled. As an English language label to describe an area of research and teaching, "Science Education" essentially emerged for the first time in the very early 1960s. This was in particular response to the proliferation of a range of evaluation types of studies of the then new and large-scale US science curriculum projects. It was at this time, for example, that the first named Professors of Science Education were appointed (first in USA, then in Australia). Thus, the discipline is, by this name, only about half a century old. Yet, science education has developed rapidly and remarkably. Fensham's 2004 book *Defining an Identity: Science Education as a Field of Research* (Kluwer) alone would make a convincing case in the powerful presentation of data and analyses that he gives to support the proposition that science education does indeed have the status of a distinct "field of research." Many other observations are also convincing about this status of science education; for example, there are now at least eight specifically science education journals included in the highly selective Thomson Reuters (formerly ISI) Web of Knowledge database and several others such as *Science Communication* and *Science and Society*, in which science education researchers are among those who publish. This is considerably more than for any other specialist school curriculum area.

So I became comfortable with the notion that science education as a research field warranted an encyclopedia. And then, I saw that something of substantial potential worth and quite different to what currently existed could be attempted – in short, I would attempt to have research authors and research traditions from beyond the dominating anglophone/English language research world represented in the encyclopedia. That is, I would take "comprehensive," perhaps the central characteristic of an encyclopedia, to include recruiting authors from around the globe and attempting to identify and include relevant non-English language constructs and literatures and perspectives – while being clear at all times that this was to be a solely English language publication.

Some researchers have previously pointed to the sharp contrast between the nature of causality that science itself seeks and the nature of causality that it is feasible to seek in science education. In simple terms, causality in science seeks to be singular and absolute, while causality in science education is necessarily multiple and relative (e.g., both *context* – including the content that is the focus of the teaching/learning/curriculum/assessment – and *time* are very often determining causal variables in our research even though they are often treated as issues that can somehow be ignored or "controlled"). Too often, science education research and practice seeks some form of absolute and constant causality that cannot be attained.

One central aspect of the multiple causality that is inherent to [science] education research is that some fundamental issues are conceptualised quite differently in different sociohistorical-cultural contexts. That is, for some issues, the beginning points of even thinking about how to investigate aspects of causality are in sociohistorical-cultural contexts different to, for example, my own. A quite widely recognised example of this, an example that is also frequently only understood at the most superficial level in the anglophone world, is the way in which the range of issues the anglophone world gathers together under the broad concern of "how do we decide what content to teach and how to teach this?" are conceptualised in parts of continental Europe (see the entries *Bildung* and *Didaktik* in this encyclopedia). The issue I saw as "being of substantial potential worth and quite different to what currently existed" that I have attempted to include in this encyclopedia is that of alternative ways of conceptualising central issues in science education that, for those of us who are monolingual, are currently unavailable.

The Processes of Generating the [Changing] List of Entries

I first began by recruiting a number of outstanding science education scholars to work with me as an Editorial Board, with each of them having particular expertise in one of a range of broad areas (Assessment, Curriculum, Nature of Science, Teaching, Learning, etc.). All are from the anglophone world of science education research – I had a further strategy to broaden the range of entries and authors (see below).

The Editorial Board had one face-to-face meeting immediately prior to the 2010 conference of the National Association for Research in Science Teaching. This was supported by Springer with costs and with both secretarial and intellectual support. Prior to that meeting, I generated a first draft of possible entries by (a) using the indexes of the two Handbooks of Science Education that were in print then and (b) working through the complete contents to that time of the review journal *Studies in Science Education*. We (the Editorial Board) then spent most of our one meeting working through this list, revising and adding and deleting entries and sometimes suggesting authors. We also agreed on the ways we would divide up the work involved in seeking authors and editing entries. Although it was never intended that the final publication would involve separate sections, the allocation of responsibilities by section was to enable the best use of the outstanding expertise involved on the Editorial Board.

Entries relating to Assessment and Evaluation were the responsibility of Audrey Champagne, Curriculum – Robin Millar, Intersections with Other Substantive Areas – Justin Dillon (resigned March 2011; I took over these entries), Learning – the late Phil Scott and me (because of the extremely large number of entries here, Phil and I intended to share responsibility; on Phil's tragically early death in July 2011, I took over all entries in this area), Nature of Science – Rick Duschl; Science Education in Out-of-School Contexts – Léonie Rennie, Socio-Cultural Dimensions of Science Education – Bill Cobern, Teacher Education/Teacher Development – John Loughran, Teaching – John Wallace, Technology-Enhanced Learning – Doris Jorde, replaced by Jim Slotta in January 2012.

Over the next several months, the list of proposed entries was further developed and expanded to include notional length (either short [up to ~1,000 words], medium [~1,200–1,500], long [~1,500–4,000] or essay [~5,000]) and an outline of a sentence or two about the intent of the entry. These two added features were to enable invited authors to be more informed about the task. The list of entries has remained a changing phenomenon right to the point of production. I am very grateful to all members of the Editorial Board for the wholehearted and insightful ways they engaged with this uncertain process of developing what the encyclopedia would contain and for which we were continuously working out for ourselves how to approach this central task.

Our approaches to expanding the entries and authors to embrace ideas and people from beyond the anglophone world involved my creation of an Advisory Board of science education academics. These were scholars who knew well the English language literature in their specialty, who knew well the literature in their first language, and who knew the ways research was conceptualised in their own culture. The invitations I sent out early in 2011 explained the embracing of ideas and people beyond the anglophone world I wanted to include in the encyclopedia. I included the list of entries as it then stood and described what I was inviting them to undertake as considering the list of proposed encyclopedia entries with the task of identifying

(i) Potential authors from beyond anglophone contexts for entries proposed by the Editorial Board.
(ii) Issues (potential entries) that do not appear in this list of entries generated by the Editorial Board that are of importance to the traditions/literatures with which the Advisory Board member is familiar.
(iii) Entries that are on the list for which the perspectives of the Advisory Board member's tradition/literature are different from the perspectives of the anglophone traditions and literatures and different in significant ways – that is, in ways whose elaboration will help inform and enhance the English language/anglophone perspectives.

Those who agreed to be involved and their countries are Jens Dolin (Denmark), Reinders Duit (Germany), Mansoor Niaz (Venezuela), Masakata Ogawa (Japan), Roser Pintó (Spain), Marissa Rollnick (South Africa), Jinwoon Song (Republic of Korea), Fatih Taşar (Turkey), Andrée Tiberghien (France), Benny Yung (Hong Kong SAR, People's Republic of China).

As with the Editorial Board, I am extremely grateful for the considerable time and expertise that these members of the Advisory Board have given to the production of the encyclopedia.

The Nature of the Final Entries

In this first edition of the Encyclopedia of Science Education, there are 383 substantive entries and another 1793 entries that are only cross-references (e.g., there is an entry *Accommodation in Piagetian Theory* that is only a cross-reference – see "Piagetian Theory" – because Accommodation as advanced by Piaget is discussed in detail in *Piagetian Theory*). These entries have involved 353 different authors, and the authors plus Advisory Board members plus Editorial Board members have come from 36 different countries.

Some entries are of considerable length and cover all of a major field (e.g., *Piagetian Theory*), and others, by the specific circumstance of related entries, are quite brief (e.g., *Meaningful learning* is only about 140 words because this construct and the way it has been conceptualised in science education is considered at some length in the entry *Ausubelian Theory of Learning*; therefore, *Meaningful learning* is cross-referenced to *Ausubelian Theory of Learning* rather than all relevant material being repeated in each entry).

The intended audience for this encyclopedia is, put simply, beginning researchers – either research students (and so "beginning" in the conventional sense) or existing researchers who are exploring an area beyond their current expertise (and so "beginning" only in terms of the focus of the entry they seek). Clearly then, the expectation of all involved in the production of these volumes is that readers will always be sampling the specific parts that reflect their needs at the time and following cross-references as appropriate to further explore their immediate needs. It is very hard to imagine this work being read in the sequential manner of conventional books.

Acknowledgements

It is appropriate for me to repeat here what is written above – both the Editorial Board and the Advisory Board have given a very great deal by way of commitment and expertise to the production of this encyclopedia.

While all members of both Boards have been absolutely central to the development of this encyclopedia, I have used two members of the Editorial Board more than all others as sources of advice and as sounding boards for my thinking – my two Australian friends and colleagues Léonie Rennie and John Loughran. I am especially grateful to them for their unfailing and immediate willingness to help in a variety of ways and with a huge range of thoughts and concerns. John also has my sincere thanks for the ways he has happily and very helpfully responded to my innumerable verbal queries delivered (usually) very early in the morning as he sat in his Dean's office trying to do uninterrupted work only to have me rush in and ask about my latest encyclopedia concern.

I also wish to specifically acknowledge the contributions of the late Phil Scott. Phil and I had been colleagues and friends since his first year at the University of Leeds (which coincided with a period of sabbatical leave I spent at Leeds). Initially, as he and I worked together on the development of entries related to Learning, I could not have asked for a more expert and congenial colleague – just as Phil was, unfailingly, with all. Then, after his sudden death, I invited those authors he had suggested in ways that made it clear that the suggestion of the author was Phil's, not mine. The response was almost

ubiquitously remarkable. It was not that people said "yes" (as they almost always did); it was that they were genuinely touched by it being Phil's idea to involve them. The warmth felt towards this wonderful man shone through over and over again.

Access programmes

In most countries access to tertiary STEM (science, technology, engineering, and mathematics) study is restricted to those who attend schools that offer prerequisite preparation, predominantly in mathematics, the main gatekeeping requirement to STEM study in almost all contexts around the world. This restriction leads to either a shortage or a lack of diversity among STEM students, as these schools usually serve the middle and upper socioeconomic groups in any population. In developing countries this pattern is exaggerated even further to the extent that students of first-year undergraduate science classes are often drawn from just a few schools in the whole country. For example, in 1999/2000, 65–75 % of students admitted to two of Ghana's most prestigious universities were drawn from only 50 out of the 500 plus secondary schools in that country. To address this problem, many countries institute special programs known as access programs to increase the number and diversity of students in these programs. This is an attempt to break the vicious circle in science education, illustrated in Fig. 1 below (Rollnick 2010, p. 13). Access programs generally intervene in the cycle both by providing greater numbers of school leavers into the system and by improving throughput at university.

Access programs serve different clientele depending on the country context. In developed countries access program students would most likely be mature adults making late decisions to enter tertiary education or ethnic minorities. Both groups may have been excluded from mathematics and science in secondary school. In developing countries those students able to enter higher education in science tend to come from a few elite schools, while the more able students from the majority of schools are not able to gain access.

Access programs differ in their structures but in most cases increase the duration of the undergraduate program. Figure 2 below summarizes the most common models assuming a 3-year undergraduate degree (Rollnick 2010, p. 17). Four-year degrees would be similar with an additional year.

The first two models are the most common and the least transformative in their orientation but can be further classified according to whether the

2+2	Two year Access programme		Senior years of main degree	
Complete restructuring	Year 1	Year 2	Year 3	Year 4

institution directly offers the program or whether it is outsourced. A study of various initiatives internationally led to the characterization shown in Fig. 3 (Rollnick 2010, p. 46).

"Inreach" in Fig. 3 refers to programs aimed at getting students from underrepresented communities into programs such as summer schools and adult access programs. These may be offered by the university itself or outsourced. Flexible programs are described as those that involve adjustments to the HE delivery, structure, or administration and include cooperation between different types of institutions, open learning, and part-time provision. Systemic initiatives are large scale, commonly at the school level, aiming to improve access by improving the school system as a whole.

Within these categories, the type of support that is provided is categorized as follows:

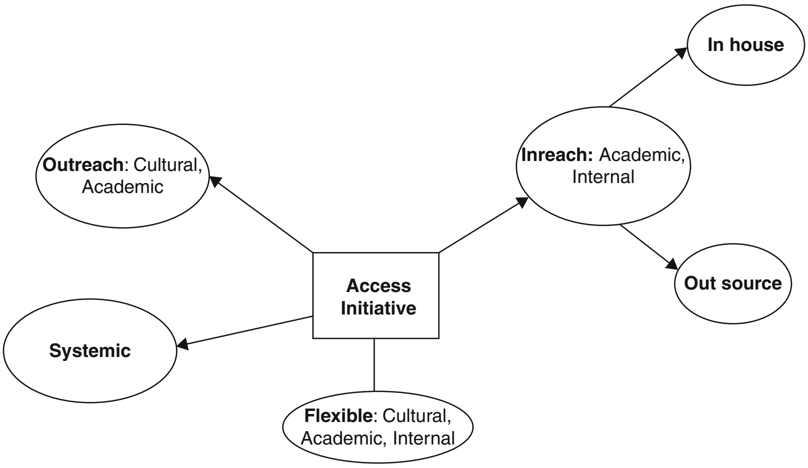
- Academic: Support aimed directly at assistance or offering of relevant content
- Cultural: Support aimed at providing broader epistemological access (see below)
- Internal: Support provided either through an extended curriculum or add-on support

Table 1 below shows how the different types of support differ between developed and developing countries using Southern Africa as an example.

As can be seen, programs are commonly outsourced in developed countries while universities in Southern African countries feel the need to take institutional control of the programs, probably to ensure that students exiting the access programs enroll in their institutions.

Accounts of the purposes of the programs differ but common elements are:

- The development and provision of quality SET education, particularly for students from disadvantaged backgrounds
- Delivery of SET education for meaningful employment for all
- Provision of alternative access routes to students who may not otherwise have had the opportunity to participate in tertiary study
- Increasing the pool of competent STEM graduates



Access of Historically Excluded Groups to Tertiary STEM Education, Fig. 3 Categorization of access programs (Adapted from Osborne 2003)

Access of Historically Excluded Groups to Tertiary STEM Education, Table 1 Comparison of types of support in developed and developing countries

Types/characteristics	Developed countries	Southern Africa

Flexible	6	2
Inreach in-house	9	36
Inreach outsource	6	3
Outreach	25	3
Total	50	45

- Provision of the STEM-specific and more general skills and knowledge for success at tertiary study
- Providing outcomes relating to more than content alone – for example, ability to communicate, problem solve, and work as part of a team
- Increasing the knowledge base and confidence of students in STEM fields

Program Ideologies

The mode of operation and success of the program depends on the ideology associated with the access courses. These ideologies would be closely linked to ideologies of admission, as those in access programs are those who do not gain direct admission.

Brennan (1989) outlines four ideologies of admissions:

1. Relation of admissions to the reputation of institutions: The ability to attract good students is a sign of the institution's quality and is thus easily linked to the performance of the school leavers admitted.
2. Emphasis on equity: The concern is with fair competition for places, so admission to higher education becomes an award for diligence. Nonstandard routes into higher education other than access programs are suspect because they allow admission through unfair means.
3. The social engineering approach: Like the equity approach, it is concerned about equality of opportunity but wishes to level the playing fields by recognizing that some applicants are disadvantaged. Concern is about the social composition of the cohorts admitted.
4. The "shortage-of-students" approach: This arises when universities have difficulty filling places with conventionally qualified students.

A useful concept to describe the essential nature of access work has been provided by Morrow (1994) who coined the term "epistemological access" to the university. Essentially the term describes the extent of access to the culture of the institution. This relates to working to make students excel rather than avoid failure. It highlights the importance of making the program part of the academic enterprise, rather than isolating it.

This issue goes to the heart of epistemological access – students need to become part of the community of practice.

Grayson (1996) translates epistemological access into pedagogy as follows:

- Reasoning and practical skills must be taught explicitly.
- Learning must be rooted in specific content.
- Thinking and reasoning skills needed for science must be identified and explicitly taught.
- Disciplines should be broadly integrated.
- Teaching and learning are interactive.
- Content should be restricted in scope and covered in depth so as to promote conceptual understanding.

Relationship to Higher Education Policy

Richardson (2000) has designed a model of institutional adaptation to student diversity, shown in Fig. 4 (Rollnick 2010, p. 32).

Richardson (2000) suggests that when an institution is put under pressure to accommodate diversity, they initially respond by behaving in a reactive fashion (Stage 1), emphasizing recruitment and admissions and providing extrinsic support such as financial aid, without the deeper support structures needed to retain nontraditional students. Such reactive strategies are of necessity shallow and result in a revolving door admissions policy.

When these strategies fail, the institution becomes more strategic (Stage 2) and responds by trying to change the students in such a way that they provide a better fit for the institution. Stage 2 is characterized by outreach, transition programs, and the use of mentors who have already been successfully socialized into the institution's culture. The improved socialization in the institution may result in improved retention, leaving the institution satisfied that they have successfully managed a transformation process.

Stage 3 strategies, which require the institution to adapt its practices to take account of a changing student population, can only take place in the context of transformative state policies combined with committed institutional leaders. Stage 3 strategies are characterized by a change in culture of the university resulting in new curricula (or curricula adjusted to changing demands in the outside societies) and new pedagogies.

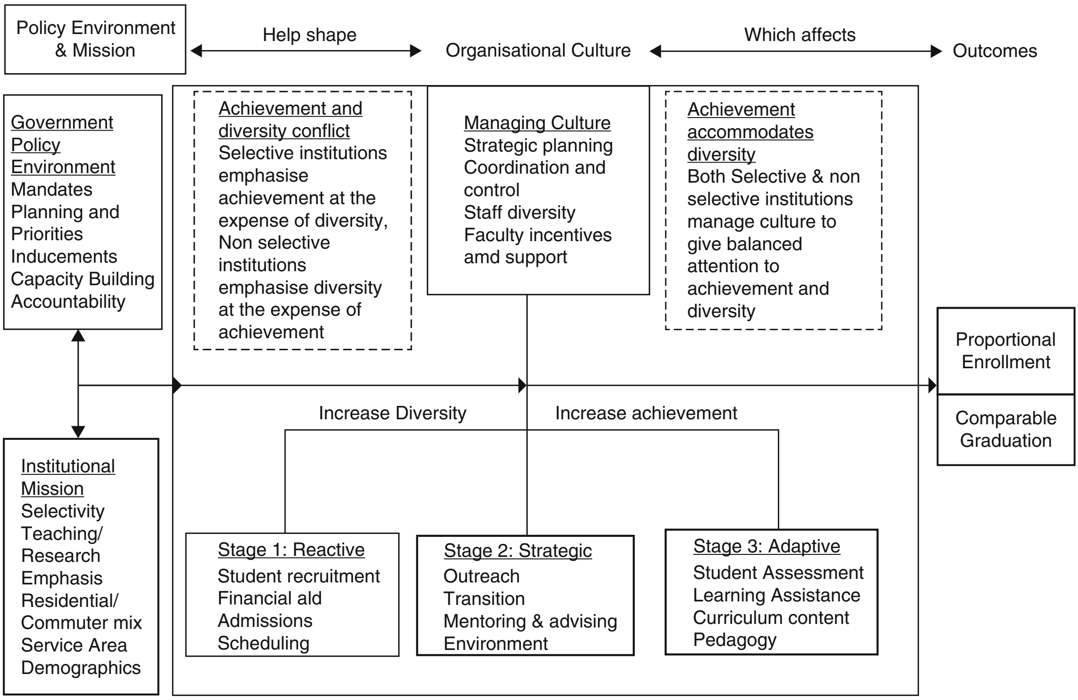
In countries where change is slower, it is easier for institutions without a long history to achieve this transformation. So traditional elite institutions would experience more difficulty in adapting in this way. However in a society where rapid social changes have taken place, state policies exert pressure on the institutions to change.

Richardson cites various characteristics of effective programs in the hard sciences and medicine:

- Provide students with more time to master the same material
- Use socialization experiences primarily to contribute to academic objectives rather than as ways of protecting the student from the campus environment
- Involve academic staff members in curricular reform to articulate access programs with those involving advanced work
- Emphasize changes in pedagogy to increase student success rates

Grayson (1996) outlines six different areas in which access students experience difficulties:

- Background knowledge: Mainly mathematics and language, but also general knowledge gained from living in an inquiring environment
- Attitudes: Rote learning, accepting knowledge without question
- Behaviors: Failure to do homework and preparation, failure to seek help, poor time management, lack of punctuality, meeting deadlines, becoming dependent on the lecturer, not studying with peers
- Cognitive skills: Logical reasoning, critical analysis, interpretation, and abstract representations
- Practical skills: Lack of experience in laboratory
- Metacognitive skills: Monitoring own thinking/understanding, studying effectively, responding to particular demands of a task,



Access of Historically Excluded Groups to Tertiary STEM Education, Fig. 4 Model of institutions adaptation to student diversity

making unrealistic assessment of requirements and own performance

The above shows that the difficulties are only partially cognitive and intimately associated with epistemological access to the university as outlined previously. Recognition of this has had an impact on the content of the curriculum in most access courses. Most courses have the following elements: discipline-specific courses, mathematics, language support, life skills, and computer skills.

The importance of mathematics as a gatekeeping course for most science studies needs to be recognized. As mentioned above where these are absent, they frequently require extra attention and carry no credit when taken at university.

Language support takes many forms at different institutions. More superficial approaches consider the required program to target technical English, while others recognize the deeper issue of changing discourse and communicative competence. Most programs recognize the need to integrate the language support into the teaching of the discipline-specific subjects.

In addition to purely academic skills, many programs address what could be termed "para-academic" skills to enable students to succeed and survive tertiary study. These skills address students' needs for assistance with metacognitive skills, behaviors, and attitudes as outlined by Grayson above. Some institutions offer these skills in a separate course or through counseling services as well as integrating them into the teaching of the courses.

Accommodation in Assessment

May M. H. Cheng
Department of Curriculum and Instruction, The Hong Kong Institute of Education, Hong Kong, China

Keywords

Effectiveness of accommodations in assessment; English language learners

The purpose of accommodation is to allow students to best demonstrate their development, understanding, and achievement. There is, however, a lack of consistency in the design, development, and provision of accommodation which is a controversial issue. The types of accommodation adopted include extended time such as time and a half, double time, or unlimited time; small group/individual assessment to reduce distraction to other test takers; providing test directions such as interpretation for students taking tests not in their first language or for English language learners (ELLs); test items read aloud or interpreted; and student sign response for those students having difficulty expressing themselves in writing. Further, there are accommodations in settings such that the environment setup is changed, which is a common practice for students who are easily distracted. Many of these accommodations are not limited to science but are also common in other subject areas.

Considerations of accommodation in assessment in science are recent. Other studies aim to identify the effectiveness of the various measures for accommodations in assessment. Effectiveness is measured or represented in a number of ways including student satisfaction, test score validity, and verifying scores from accommodated tests to see whether they measure the same attributes as the unaccommodated tests.

Acculturation

Glen Aikenhead
Aboriginal Education Research Centre, University of Saskatchewan, Saskatoon, SK, Canada

Acculturation is a concept borrowed from cultural anthropology and applied to education (Eisenhart 2001; Aikenhead 1996), in which teaching-learning is understood as cultural transmission-acquisition and meaningful learning is assumed. Within cultural anthropology, science has been described as a cultural entity (an ordered system of meaning and symbols, in terms of which social interaction takes place;

according to Geertz 1973). As a subculture of Euro-American cultures, Eurocentric science (ES) can be distinguished from other cultural ways of rationally and empirically describing and explaining the physical world (Aikenhead and Ogawa 2007).

Accordingly, conventional science education seeks to transmit the culture of ES to students so they can conceptualize, talk, value, and behave scientifically – being scientific. Two extreme reactions can result. Science-oriented students are eager to be identified with being scientific because their worldviews tend to harmonize with a worldview endemic to ES conveyed by school science (e.g., they often embrace a mathematical idealization of the physical world). The way these students' experience the cultural transmission-acquisition of ES is called ▶ *enculturation*, in which being scientific enhances their everyday world. However, for non-science-oriented students whose worldviews are discordant with a worldview endemic to ES in varying degrees, the school is attempting to get them to comply with being scientific and to significantly change or add to their self-identities and everyday thinking, more or less. This is a transmission-acquisition experience called ▶ *assimilation* (Aikenhead 1996). Most non-science-oriented students resist assimilation successfully.

Between the extremes of enculturation and assimilation lies the transmission-acquisition experience of *acculturation*: the selected modification of one's currently held ideas and customs under the influence of another culture (Aikenhead 1996). An ideal goal of school science acculturation is to have students master and critique ES without, in the process, diminishing their own worldviews, self-identities, and culturally constructed ways of knowing the physical world.

When participating in acculturation, a non-science-oriented student most often changes a concept or belief, or adds new ones, to their understanding of the physical world. A key phrase in the definition of acculturation is "selected modification," because selections can be made either in an explicit, informed, autonomous way or in an implicit, uninformed, pressured way. The former is called *autonomous acculturation* (Aikenhead 1996), while the latter could be seen as *coercive acculturation*.

Examples will help clarify these categories of acculturation. A non-science-oriented student experiencing autonomous acculturation makes a decision in a fairly deliberate way to adapt from the culture of ES attractive aspects of being scientific. For instance, a non-science-oriented student takes on sufficient aspects of being scientific to become more critical of science-related advertisement claims. Another example is non-science-oriented American Indian students adding the scientific concept of disease to their Indigenous understanding of poor health (i.e., the imbalance among the physical, mental, emotional, and spiritual dimensions of humans) because they anticipate gaining power by addressing ill health from two cultural perspectives. In both examples, students autonomously appropriated knowledge from the culture of ES. Their decisions were guided by intellectual independence.

On the other hand, selections can happen under mild coercion, that is, made subconsciously or without full cognizance of the consequences. Intellectual independence is mostly absent. An example of coercive acculturation is a situation in which reductionist and/or mechanistic metaphors in ES replace a student's holistic and/or aesthetic images of nature and thereby causing angst for the student. Another example is an isolated American Indian community purchasing a satellite dish, only to discover that the next generation of children has become fluent in English at the expense of their native tongue and therefore losing a critical aspect of their culture. In other words, the community has experienced coercive acculturation into mainstream American culture by the community's selection of a technology without understanding the consequences. If instead of offering satellite dishes, the dominant society implemented residential schools harmful to American Indians or refused to include American Indian perspectives in school science courses, that act would be assimilation.

The line between coercive acculturation and assimilation is a vague one. On the one hand, coercive acculturation is associated with inadvertent action by educators who perhaps have not critically considered how their policies or teaching indoctrinate non-science-oriented students and how these students risk unconsciously altering their self-identities or worldviews without the benefit of considering the consequences. On the other hand, assimilation is associated with actions by educators who achieve their *intended* consequences of indoctrination.

The degree to which non-science-oriented students actually incorporate being scientific into their self-identities and everyday subcultures reflects the degree to which acculturation has taken place (Aikenhead and Jegede 1999). Such students can be empowered to draw upon the culture of ES in appropriate situations, such as working at a job or profession, judging a -science-related personal or social issue, participating in a science-related event, or making sense of one's own community or society increasingly influenced by ES.

The process of acculturation, however, does *not* apply to those non-science-oriented students who are able to acquire enough content from the culture of ES to pass science courses but without understanding that content in any meaningful way, in other words, without integrating aspects of the culture of ES into their self-identities or everyday world. Those students tend to avoid any of the cultural transmission-acquisition processes related to science education. The process these students follow has been labeled "playing Fatima's rules" (Aikenhead 1996), and the "rules" comprise various strategies of resistance against any attempt to enculturate, acculturate, or assimilate these students.

Achievement Differences and Gender

Lara Perez-Felkner
College of Education, Florida State University,
Tallahassee, FL, USA

Achievement Differences and Gender

It has been asserted that achievement differences in certain fields – the sciences in particular – can be explained by innate differences in boys' and girls' ability, specifically their representation among those with the highest ability in mathematics. Although some research evidence supports this hypothesis, scholars have also argued against this claim. For example, a meta-analysis of US state assessments found that female and male 2nd through 11th grade students did not significantly differ in mathematics performance, but limitations in these data did not allow for analyses of the areas in which extant research finds that gender differences may be more likely to emerge – complex problem solving and advanced mathematics (Hyde et al. 2008). If not ability, what does explain variation in male and female secondary school students' selection into scientific disciplines, in postsecondary and beyond?

Importantly, extensive research suggests that gendered differences are most likely shaped more strongly by social, psychological, and cultural forces rather than biology. Recent research shows cross-national variation in sex segregation of career fields as well as in the level of gender differences in students' performance on mathematics assessments. Importantly, differences in science achievement and choice of career pursuits in these fields appear to develop over time.

Socialization begins early in life, including messages girls and boys receive about what careers are appropriate for them. Notably, US girls perform as well as US boys in mathematics and science in elementary and early secondary school on the National Assessment of Educational Progress (NAEP). Male students have been found to slightly outperform females on these tests at the end of high school, particularly on advanced curriculum. One hypothesis for the emergence of this gap could be that males are simply stronger in advanced mathematics and science than females.

But another pattern emerges in secondary school that suggests a different causal path. It is in secondary school that students can choose which courses to take, and females may be less inclined to pursue areas that are not associated with female success. Indeed, males have been found to enroll in more advanced secondary school physics courses than females. Notably, of those students who completed the most advanced mathematics and science courses and went on to major in the most male-dominated sciences – physical sciences, engineering, mathematics, and computer sciences (PEMC) – there is a negative association between female gender and tenth grade perceptions of their mathematics ability on their chances of selecting these majors instead of other college majors – controlling for mathematics ability and other potentially confounding factors (Perez-Felkner et al. 2012). This finding corresponds with research on career task values. When children internalize their society's expectations for their career-related achievement, they may in turn devalue and turn away from tasks related to areas in which their group is not expected to perform well (e.g., mathematics for girls) (Eccles 2011). It may be that gender differences in scientific career achievement can be explained by these social psychological differences in female and male students' orientations to mathematics and science.

Keywords

Achievement levels; Advanced International Benchmark; High International Benchmark; Intermediate International Benchmark; Low International Benchmark; TIMSS

Achievement levels are performance standards describing what students who achieve a given level on a scale typically know and can do. They refer to academic achievement providing a context for interpreting students' scores on different assessments. Each achievement level description reveals a picture across a broad range of performance levels with corresponding details related to the framework. They are cumulative, students performing at one of the superior levels also displaying the competencies associated with the lower levels.

For example, Trends in International Mathematics and Science Study (TIMSS) utilizes scale anchoring procedure to summarize and describe achievement at four points on the mathematics and science scales – Advanced International Benchmark (625), High International Benchmark (550), Intermediate International Benchmark (475), and Low International Benchmark (400). The first step was to identify those students scoring at each cut point followed by determining which particular items anchored at each of these benchmarks. To determine which items students at each benchmark are most likely to answer successfully, the percent correct for those students was calculated for each item. The delineation of sets of items that students at each international benchmark are very likely to answer correctly and that discriminate between adjacent anchor points takes into consideration the percentage of students at a particular benchmark correctly answering an item and the percentage of students scoring at the next lower benchmark who correctly answer an item. The experts based on the items' descriptions within each benchmark elaborated the descriptors according to the frameworks. The result is a summary of the international learning outcomes in terms of acquiring skills and knowledge reflecting demonstrably different accomplishments by students reaching each successively higher benchmark.

Action and Science Learning

Gérard Sensevy
School of Education, University of Western
Brittany, Rennes, France

The Actional Turn in the Sciences of Culture

We argue that an actional turn is currently taking place across all the social and human sciences – the "sciences of culture." By "actional turn," we mean the fact that each studied phenomenon is seen through practice, as a practice.

For example, Science is studied “in action” (Latour 1987), in a research process which privileges Science “in the making” over “ready-made” Science.

In Educational Sciences, in particular Science Education Research, this conception has two major consequences. The first one refers to the fact that, in order to understand Education, one has to understand two fundamental actions, the teaching action and the learning action, both in their conceptual structure and their empirical unfolding here and now. The second consequence rests on the same logic and refers to the knowledge ontology within the educational process. This knowledge is not seen as a thing, but as a praxeology (Chevallard and Sensevy 2014): a praxis (a practical action) and a logos (a body of discourse) related to this action. Knowledge is seen as a living organism, and the researcher’s work consists of understanding the life of knowledge (Tiberghien et al. 2009) from the sphere in which it has been shaped in scientists’ practice to the settings where it is transmitted, as it is enacted and embodied in student’s and teacher’s practices.

What Kind of Action?

We argue that acknowledging this actional turn in Science Education Research is a point of departure that enables the educational process to be conceptualized in a different manner. In this way, the Joint Action Theory in Didactics (Sensevy 2012; Ligozat 2011; Tiberghien and Malkoun 2009; Venturini and Amade-Escot 2013) conceives the educational action as a specific kind of joint action, in which the teacher’s action and the student’s action are deeply interrelated through the growing of common knowledge.

It is important to note that the Joint Action Theory in Didactics (JATD) does not see these actions as symmetrical. In particular the teacher’s work consists of managing learning situations in which the current student’s strategic system of action (the didactic contract) may enable him/her to deal with the emerging symbolic structure of the knowledge in the problem at play (the didactic milieu), so that the student may endorse the specific thought style (Fleck 1981; Sensevy et al. 2008) that this knowledge embeds. In that way, in JATD, the art and the science of teaching could be seen as a way of monitoring the relationship between the student’s work and the milieu.

The Didactic Joint Action: What Methodological Consequences?

Such an “actional ontology” of the didactic action entails some consequences from a methodological viewpoint. Among them, it is important to emphasize the following idea. If didactic joint action is conceived as a fundamental dialogic action between the teacher and the student through the piece of knowledge at play in the didactic activity, the research method needs to document this specific relationship. That is to say that a prominent place is given to the study film (Tiberghien and Sensevy 2012), which enables the researcher to describe and understand the relational tridimensional patterns that links the knowledge growing, the student’s action, and the teacher’s action. Such study films constitute the central component of what one may call hybrid text-pictures systems (Sensevy et al. 2013) in which different kinds of “pictures” (e.g., systems of photograms) and different kind of “texts” (comments, content analysis, statistical analysis, etc.) are thought of in mutual annotation and as specific to these systems. One of the major features of a hybrid text-picture system is that it puts in relation different scale levels, from the briefest transactional moment to the longest duration teaching-learning process. Some of these hybrid text-pictures systems may be considered as practical exemplars (Kuhn 2012) and, according to Hacking (in Kuhn 2012), be seen as “shared examples” in Kuhn’s essential perspective.

Cooperative Engineering: Research as a Joint Action

In the first three parts of this entry, we have focused on didactic joint action, which refers to knowledge transactions between the teacher and the student.

As we previously argued, this “actional turn stance” stemmed from a more general conception pervading through the sciences of culture. Within such an actional conception, the very process of research itself may be modified. In particular, a prominent place has to be given to design-based research according to the fact that the sciences of culture are in part engineering sciences, sciences of the artificial, which help modify human practices in order to make them achieve new ends for a better life. The consequences of such a viewpoint for science education may lie in the development of a specific form of design-based research, cooperative engineering (Sensevy et al. 2013), which can be characterized by the common definition of educational ends between teachers and researchers, and by their common proposal and test of work hypotheses relating to the students’ learning. This teacher-researcher joint action does not erase the differences between teachers and researchers. On the contrary, it asks for a common grasp of consciousness of these differences. But it rests also on the sharing of a common stance, that of an engineer of the educational action, an engineer of the culture.

Activity theory

What Is Activity Theory?

Activity theory represents the application of principles of human development and learning from the Russian psychologist Lev Vygotsky and his contemporary interpreters such as Yrjö Engeström (1987) and Michael Cole (1996). While this ensures that activity theory enjoys a rich albeit evolving philosophical grounding, it also confronts science educators with challenges when appropriating it into their classrooms. Activity theory is not a monolithic template or a well-bounded set of research techniques that one can quickly extract from a textbook and reassemble for use. Rather, it is better considered a spectrum of ideas – without achieving complete consensus among researchers – that are located within the sociocultural learning tradition. Its unfamiliarity to those trained in Western psychology may have resulted in either indifference to activity theory or its use in ways that some experts would deem as unorthodox if not erroneous. While this state of affairs is understandably confusing for educators, activity theory can offer those following Vygotsky's method of research a number of guidelines for organizing science teaching–learning that are respectful of how people learn and collaborate in tandem with cultural artifacts/tools. Together with its potential for addressing long-standing theoretical and practical dilemmas in science education research, this framework has already found resonance among those from the Learning Sciences, computer sciences, and organizational and workplace learning communities.

Within the field of science education, one has to realize that the sociocultural tradition in learning has only gained acceptance over the last 15–20 years. Placing issues of language, social interactions, and culture and history in the foreground, advocates here downplay the emphasis on achieving and assessing visible outcomes of learning where intelligence is believed to be housed within the mind. This sea change regarding the origins and development of learning as processual or transactive during activity rather than solely biological was sparked by the appearance of Vygotsky's writings in English. Activity theory can thus be said to be the most sophisticated and interdisciplinary elaboration of Vygotskian thought for education currently, which itself draws upon dialectical-materialist underpinnings in Marxism. Remembering its long intellectual heritage enables one to quickly appreciate its ontological and epistemological assumptions as well as generate applications of activity theory that are more faithful to its practice-oriented, transformatory stance. Two ideas in dialectical materialism are acknowledged as salient in activity theory:

(A) **The reciprocal relationship between acting in the world and being transformed psychologically and sociologically by this very process**.

Being within, relating to, and acting on the material world, that is, when pursuing the conditions for life, human agents are simultaneously transformed at the level of the individual (the creation of consciousness [i.e., learning], personality) and at the level of the collective (the beginning of division of labor in society). On the one hand, it affirms that there is no escape from a materialist account of learning; without the prior concrete world of experience, there would be no knowledge to grasp or exhibit. As some have put it, there is no knowledge without praxis. The Cartesian rift between mind and body (and other dualisms) is thus healed through an activity theoretic perspective. On the other hand, there is another dialectical relationship; through their labor individuals serve both individual and collective needs; indeed labor creates the very conditions for society to function just as social institutions open up opportunities for individuals to contribute and sustain themselves in diverse ways. Unlike how other creatures usually interact with nature in a direct, stimulus–response manner, humankind manages or mediates these relationships of self and others through created and ever-changing tools and practices to satisfy human needs. It is argued that all higher psychological functions such as motivation, identity, and sensemaking are irrefutably mediated by interactions with others and shared artifacts (e.g., language) – learning as a sociocultural process precedes biological development as Vygotsky maintained. Individual learning therefore contributes towards expanding knowledge in/for others at the same time as established knowledge enables any newcomer to appropriate these through instruction without necessarily rediscovering this wisdom de novo.

Because not everyone contributes in the same manner in/to society, a division of labor therefore exists. The totality of these societal activities (from which activity theory properly derives its nomenclature), however, serves in part to reproduce as well as be the engine for change in the world. And because these social practices form the basis of culture that individuals can orient towards, participate in, and perhaps depart over the course of time, the adjective "cultural-historical" is properly attached to activity theory (i.e., the popular acronym "CHAT") to underscore their explanatory significance. Psychology has traditionally eschewed matters of culture and history in accounting for learning but activity theory instead conflates them as it is felt that mental processes are utterly dependent on the former. This again affirms the materialist-dialectical core of activity theory; change in any aspect of the material world or social practices and mutual changes in human functioning and cognition will ensue. Hence, when studying skilled actions, activity theorists pay careful attention to expertise occurring within a specific environment that they regard as ontologically indistinguishable although kept separate for analytical purposes by necessity. Rather than just privileging the actions of human agents, activity theorists prefer to scrutinize that particular societal activity as a whole and then interrogate these subsets of activity through various ways: what is happening or being changed there, by whom, through what means, and for what (historical) purposes. This close as well as practical approach towards understanding learning in a complex world (e.g., through interlinking levels of individual/collective) is a distinguishing feature of activity theory.

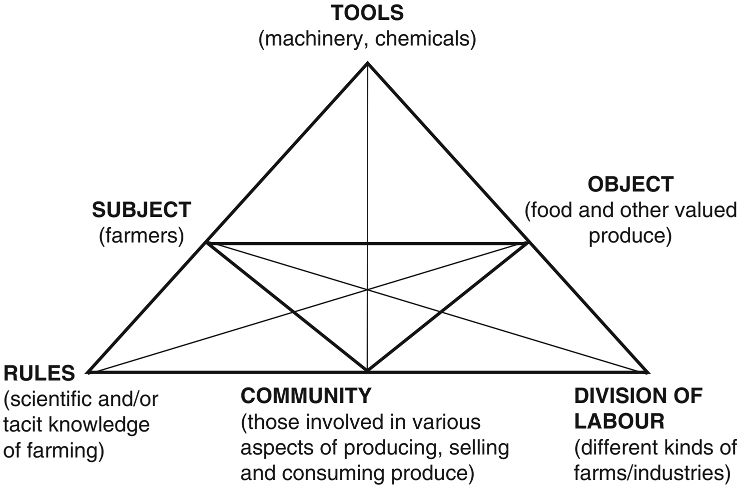
(B) **The transformation of the world should be a primary activity, not its mere contemplation**.

This is an extension of the former point; it is not sufficient to merely describe or philosophize about the world at the level of ideas. Instead, one has to participate with others (e.g., to describe, critique, explain, expose power) to author one's context in a life-affirming, creative, and humane sense (Roth 2010). The material world will pose all sorts of resistance to our desires (we cannot fly like birds), but this does not hold true for social phenomenon, which is amenable to human intervention/change that gave rise to it in the first place. True to its Marxist roots, activity theory is distinguished from other theories of learning in its problem-solving, expansive, and improvement-seeking nature that have been used to critique many situations and processes both in and out of school (Langemeyer and Nissen 2011). This has provided activity theory with intrinsic appeal as both a theory of instruction and a model of learning, not only for those concerned with social justice and equity agendas. A hypothetical example might serve to tie the two aforementioned key ideas in dialectical materialism: Annotated lesson plans have recently been recommended as an ideal vehicle for building a shared knowledge base for school improvement. When a teacher is motivated to submit something towards the pool of lesson plans (i.e., a knowledge product), not only does her school department benefit in enlarging the pedagogical repertoires for the collective to tap upon, but student learning (and school climate) also improves, which is the raison d'être for teachers. Identifying any obstacles together with the enablers in the overall system can provide leverage to sustain this virtuous cycle of innovative activity. Knowledge (better seen as a verb or process) in the activity system of schooling thus increases as the lesson plans are continuously revised by individual teachers engaging with different classroom/school settings and subject areas. Better yet, when students are jointly engaged in learning with teachers such as during aspects of Assessment for Learning, the joint transformation of their lifeworlds in the zone of proximal development is made manifest – does it really matter who is doing the teaching–learning now when everyone benefits?

How Can We Describe and Use Activity Theory?

Research in activity theory has fallen into two main thrusts: (1) a method and a methodology to research human psychology during engagement in everyday activities and (2) a practical intervention method for redesigning work conditions in organizations including that of schools. There are finer distinctions and a specialized vocabulary available too; the object (that part of the world to be changed) of activity is that which motivates participation in the activity system to produce an outcome. It makes no sense to speak of activity without an object for people would not undertake any actions or efforts to change the object in the first instance; they are mutually constitutive. While these actions that serve the object(s) are conscious behaviors, there is another lower level of activity that can be described – operations – which are unconscious processes (without any connotations of psychoanalysis). These three important hierarchical levels – activity, actions, and operations – are dialectically linked, just as an object is linked in a similar way to its subject (i.e., human agents). A classic example here was provided by Vygotsky's student A. N. Leontiev who spoke about the primeval collective hunt; hunters and beaters are united by a common object (to obtain food) even as they perform different and distributed actions during activity.

A more recent but highly influential heuristic known as the activity triangle has similarly proven to be an easy entry point into activity theory as seen in Fig. 1 below. Building on the fundamental concept of mediation, the subject focuses on the object using certain tools (both real and symbolic). This part of the activity system is characterized by production, whereas during consumption, exchange, and distribution, other moments/elements are brought to bear such as the rules,



Activity Theory and Science Learning, Fig. 1 A depiction of an activity system – the fundamental unit of analysis – using agriculture as an exemplar. Farmers (subject) plant crops using machinery and chemicals (tools) to produce food and other valued produce (object). This process follows scientific and/or tacit knowledge of farming (rules) and articulates with those involved in production/exchange/consumption practices such as salespersons, irrigation experts, and restaurateurs, etc. (community). No single farmer can/might produce everything and is thus reliant on others for equipment, building materials, seeds, and so forth (division of labor) community, and the division of labor. Important to note is that they are again all dialectically linked; while we can focus on a single moment in the activity system, one should recall that the others are always residing in the background.

The activity triangle has achieved an iconic status although approaching activity theory this way is not without some pitfalls. For example, it tends to emphasize the synchronic rather than diachronic aspects of activity just as it has tempted some to be indiscriminate in identifying the various moments in an activity system that exist in a parts–whole relationship. These problems are partly due to the subtlety in defining "activity"; the English language is unable to differentiate the German/Russian understanding of societal activity or work (*Tätigkeit*/*deyatel' nost*) from mere effort, being engaged or busy, which is known as *Aktivität*/*aktivnost*. Hence, educators are frequently puzzled over the most appropriate level of analytical focus – the national system (i.e., schooling), the school/district, or the classroom/groups of students – because all three "activity systems" are amply represented in the literature, sometimes even within a single manuscript.

Besides the three hierarchical levels of activity and the different moments in an activity system, another fruitful concept is the idea of contradictions. These are frequently described as inner contradictions and are not to be confused with issues, conflicts, or problems of a superficial nature. Contradictions per se do *not* cause change; instead, they act as both resources and products of human agency during transformations of activity systems (i.e., when the object is changed). These dilemmas that are cultural-historical in origin exist at the collective/societal level and appear in four kinds. For instance, schools undergoing STEM reforms might encounter a lack of resources (a primary contradiction), learning mismatches between learners and teachers (secondary contradiction), unrealistic policy mandates coming from external authorities (tertiary contradiction), and possibly graduating students ill-prepared for science-related careers (quaternary contradiction). Presently, one reads about third generation (at least two interacting activity systems, tensions, dialogue, etc.) and fourth generation activity theory (inclusion of emotions, identity, ethics) although there is no firm consensus on their characteristics. What perhaps can be agreed is that activity theory tries to explain how sensemaking and development occur at the intersection of people acting in and on their sociomaterial environments.

Activity Theory and Science Education

In general, activity theory has been commended for its ability to handle issues of contexts, complexity, power and politics, identity and emotions, and the rapidity of educational change among others. Yet, the inroads into science education have been patchy without any person, group, or research program who can be consistently associated with this framework save for a select few such as Wolff-Michael Roth (2010). Science educators would find interest in some of the advantages of using activity theory in the discipline that are summarized below (see Roth et al. 2009).

1. To understand tool mediation in teaching and learning

   Most studies in this category have examined the use of computers and software as mediators of science learning, including the role of contradictions in the activity system. The use of psychological/thinking tools such as scientific representations has also been an area of interest. And treating science as practice in the new STEM standards in the United States finds much alignment with understanding activity as equivalent to the production, consumption, and exchange of knowledge.

2. To make visible normally invisible structures, processes, relations, and configurations

   It is the intent of educators here to provide accounts of learning that are more inclusive, to understand how schooling in society mediates individual learning. Urban science education or those initiatives that advocate science for all or with science–technology–society emphases immediately come to mind. Important but less invoked themes of race, class, and gender that play over different timescales for learners are now salient. This is the strength of activity theory when it draws culture and history into our explanations of learning.

3. To investigate issues concerning a larger system or across systems

   Even though the focus of analysis has often been the single activity system, activity theory allows researchers to zoom in and out, to make linkages between nested and overlapping activity systems (i.e., boundary objects) and give greater breadth and depth to analyses. For example, science teachers are impacted by district and societal demands and the forces of globalization even though classrooms might seem like rather isolated activity systems to many.

4. To rethink and empower science learning

   Squarely within its transformative stance, past research in this category has shifted attributing (dis)ability in purely personal terms to incorporate the sociocultural dimensions as well. Research in science education here has studied informal learning environments (e.g., environmental groups) where deep motivation and surprising levels of science expertise are displayed among students that have been written off by formal institutions.

5. To create structures and collaborations to facilitate change

   Notable here is the vast amount of work done on coteaching and cogenerative dialogs in urban science education where activity theory is used as a theory for praxis and theory of praxis. Stakeholders in environmental or workplace disputes have also been brought together using this framework to good effect because it allows for multi-voicedness in uncovering the contradictions and the heterogeneous forms the object of activity might assume.

Ongoing Difficulties with Activity Theory

One persistent dispute concerns the unit of analysis in activity theory. If we assume that activities are properly those that sustain human society, then the unit of analysis that Vygotsky championed tends towards larger, more encompassing categories such as schooling, agriculture, law, and so on. It is definitely not at the level of the individual which classical psychology has favored. Be that as it may, this has not prevented the examination of classrooms or curricula programs using activity theory to unpack the systemic contradictions there or to pinpoint specific individuals as the subject of activity. Similarly, identifying the elements or moments within the activity triangle has been seen as problematic because these are believed to be dialectical in nature thereby impossible to analyze or comprehend as stand-alone entities. Again, such a purist stance has not been consistently applied; individual elements within the triangle have been the topic of past research. In short, activity theory has philosophical underpinnings that are not easily understood (e.g., privileging knowledge as process), and thus it sometimes seems too encompassing to the point of being vague as well as too specific on other occasions with claims made that are unsupportable by the data. However, it is now increasingly accepted that micro-level phenomenon feed and support macro-level events which themselves offer affordances for the emergence of new or existing structures – both levels are analytically productive as what Vygotsky had proposed although declaring one’s theoretical commitments here is needed.

Contradictions have also long been irresistible as an explanatory variable when accounting for problems and resistance to change in activity theoretic research. Yet, fidelity to these being an inner, systemic contradiction which the use and exchange value of all objects exemplify is not often adhered. The final candidate for why activity theory is so frequently misunderstood is most likely its inherent dialectical structure; learning changes from being largely attributable to individual qualities or accomplishments to being a social, collective venture. A dialectical perspective likewise suggests a needed corrective against a form of smugness in sociocultural research – our interpretations of the social world are but works in progress, by-products of a particular age and place and of fallible human beings. Certainly, this lack of closure and certitude in taking a dialectical stance will be frustrating to many.

Overall Assessment of Activity Theory in Science Learning

What are science educators to make of activity theory? It has been claimed to be able to overcome dichotomies that have plagued education such as individual/collective, body/mind, intra-/inter-psychological, and so forth. While these goals are still being worked out, at the very minimum it sensitizes us to view learning as an ongoing orchestration of people and cultural artifacts in practices (activity systems) where the past and the present are intertwined. It also inspires us to see the potential for human(e) development when societal contradictions are surfaced, critiqued, and overcome. This is an exciting but extremely difficult endeavor; human learning is multidimensional and complex, which science educators have overwhelmingly theorized at the level of the individual learner. Activity theorists will therefore continue to plod on in their research long after where Vygotsky had left off.

Adaptive Assessment

Elena Papanastasiou
University of Nicosia, Nicosia, Cyprus

Adaptive Testing

Adaptive assessment can be defined as any type of assessment that is tailored specifically to each examinee, based on their performance on previous items on the assessment. Most adaptive assessments are based on the theories and advances of Item Response Theory (IRT). More specifically, in IRT the examinee ability estimates, as well as item characteristics such as the item difficulty, are placed on the same continuum. This allows for the administration of items that are matched to the estimated ability level (θ), of each examinee, at each point of the assessment. Therefore, adaptive assessments allow for the administration of items that are targeted to the ability level (or trait level) of each examinee, which enables the estimation of more accurate examinee ability estimates. For example, if an examinee responds correctly to item 1, their estimated ability will increase, so the second item that will be administered will be of higher difficulty than the first item. If the examinee responds incorrectly to item 2, the examinee's estimated ability will drop slightly, so the third item that will be administered will have a level of difficulty in between the difficulty levels of items 1 and 2. By administering more items that are specifically targeted to each examinee's ability, a more accurate ability estimate is achieved.

Adaptive assessments come in contrast to linear, nonadaptive assessments where all examinees respond to the same or equivalent forms of a test in a predetermined order. One problem with nonadaptive assessments is that the majority of the items administered are targeted to examinees in the middle of the ability continuum. Therefore, linear tests typically include a large number of items of average difficulty and few items of lower and of higher difficulty. This creates problems for the accurate estimation of examinees at the extremes of the ability continuum, as low ability examinees will find the items at the middle of the ability continuum too difficult, whereas high ability examinees will find such items too easy. Consequently, nonadaptive assessments tend to provide little information for high-achieving and low-achieving examinees, the ability estimates of whom therefore include large amounts of measurement error.

Some of the advantages of adaptive assessments are those of increased measurement accuracy for examinees at all ranges of the ability continuum and item efficiency since fewer items are needed to reach the same level of accuracy as with linear tests. Additional advantages of adaptive assessments when they are administered electronically are those of immediate scoring and reporting and more frequent test administrations.

Some disadvantages of adaptive assessments include (a) the considerable initial costs of creating and calibrating large item pools that are needed for such assessments, (b) the inability of the examinees to go back and change their answers on most adaptive assessments which can create anxiety and frustration to some examinees, as well as (c) the security issues related to the compromise of the item pool due to the overexposure of some items.

Adaptive assessments can take various forms, based on their degree of adaptivity. Fully adaptive assessments are those where every item is matched to the examinee ability estimate with the only goal of increasing the amount of information on each examinee's ability. Other types of adaptive assessments administer groups of items together, as a testlet, and are called multistage adaptive tests. In other cases, due to various content constraints and problems with the overexposure of certain items, the assessments are called Barely Adaptive Assessments. For most types of adaptive assessments, due to the extensive computations that are required, they are typically administered on a computer and are frequently called Computerized Adaptive Tests (CAT).

Affect in Learning Science

Steve Alsop
Faculty of Education, York University, Toronto,
ON, Canada

Keywords

Affect; Content; Learning; Pedagogy

Introduction

In the current era of education where there is so much emphasis on cognitive educational outcomes and accountability, it can be difficult to recognize the importance of affect in learning science. Today, much of the public debate about and rationale for education sees the very basis of that education being best captured by accounts of instructional efficiencies, curriculum statements, lesson plans, and public records of pupils' performance. This is at best only a partial picture, and in such an era, we need to be vigilante in reminding ourselves of this. What is abundantly clear from research and practice is that affect has considerable influence over what happens in the classroom. Some emotions (such as joy, happiness, pleasure, delight, thrill, zeal, and gladness) act to potentially enhance learning and optimize student enjoyment and achievement, while other emotions (such as sorrow, boredom, sadness, distress, regret, gloom, misery, and grief) can close down concentration, deaden curiosity, and insight and in so doing can suppress learning. The affective and emotional encounters and relationships that we develop within pedagogies and with knowledge are profoundly and deeply important. Indeed, some would go as far as to say that they actually make science education possible (Alsop 2005).

Such an assertion is not really controversial. After all, there is overwhelming evidence from a diversity of academic fields and professional practices that teaching and learning are complex, both individually and particularly in their interactions. The focus here is on the mutually constitutive nature of cognition and affect. This may seem a small point; however, it is a shift in perspective with far-reaching consequences. In recognizing the importance of affect in knowing and knowledge, we start to dispel the view that science and science education is, can be, or ought to be based on reason alone. There is a long associated history, of course, in which affect is framed as mainly undesirable, as a potential obstacle to enlightened, objective thought (especially in science). In departing from this history and holding onto the importance of affect, we open up profound questions of objectivity and subjectivities, questions that more often than not accompany popular Western narratives of mind and body duality. There are legitimate arguments that such a departure leads one to a history of science that is more consistent with the practices of sciences than history often seeks to represent.

Affect has become represented by so many diverse theories and methodologies: Darwinism, Jamesian, cognitive and socio-constructive, phenomenological, neurological, psychoanalytical, and many other perspectives as well. These each bring languages, analytical categories, modes, and methods of explorations. In the history of science education, we have been drawn to a particular personal psychological perspective and have placed sustained attention on explorations of the construct of attitudes toward science. This significant and thoughtful body of work is the subject of another entry; so it is mentioned only in passing here.

Affect in Science Education

Studies of attitudes toward science have now been joined by a growing number of studies that adopt more situated perspectives in which affect is studied within particular contexts and settings. Such studies accentuate the situated nature of affect, stressing that emotions are always grounded in personal, social and cultural contexts. Of course, studies of attitudes are themselves set within particular contexts and times, and they often reference these within their methods. Today, attention is more commonly placed on studying learning embedded within identified and identifiable science education environments, such as school classrooms and laboratories. Studies of affect in science education (a term that is used here to denote these studies) are theoretically wide ranging and empirically diverse. Some researchers, for instance, attend to particular motivational constructs including self-efficacy, interest, task value, and achievement goals. These constructs have established definitions and lineage within particular educational learning theories. They have become firmly associated with enhanced learning outcomes. In particular educational settings, researchers explore the mediatory and moderating effects of such constructs with an overarching goal of better understanding how and why some instructional practices and approaches might be more efficacious than others. Here, for instance, emphasis could be placed on personal and environmental interactions as represented by interactions between intrinsic and extrinsic motivations (see Bonney et al. 2005).

Other researchers focus on specific instructional practices and processes. In these cases, affect is evoked as a vital consideration in understanding the relative advantages (or disadvantages) of some pedagogies – such as "hands-on" laboratory or practical work, animal dissections, inquiry-based learning, drama and role play, computer-based learning, and science field trips as well as many out-of-school activities. In particular instructional contexts, studies of pupils' emotions, and conceptual understandings employ a diversity of methods but are unified in stressing the importance of positive affect for deeper, more meaningful, and longer-lasting learning. Studies deploy a wide range of different measurements as a means to comment on the effectiveness (or otherwise) of instructional practices and innovations. Studies of free-choice learning and learning within informal contexts – to give very high profile examples – consistently highlight the importance of affect for learning. Indeed, affective considerations such as "interest," "curiosity," and "fun" are now widely assumed as an essential part of lifelong learning encounters with science.

There is a literature in science education in which affect is conceived more as an outcome rather than, or as well as, a process. In such cases, the goal of a learning encounter might be evaluated predominately in affective terms (such as building a positive relationship with science). Learning encounters with science can be seen in emotional developmental terms, using constructs such as Emotional Intelligence (EI), Emotional Quotient (EQ), or emotional well-being. EI and EQ are both associated with best selling popular texts, and there are a series of widely available standardized EI and EQ tests. Although these constructs remain controversial, in some educational jurisdictions, they can be appealing (particularly within associated discussions of character education and civic education).

Perrier and Nsengiyumva (2003) study of affect has a distinctive outcome focus of therapeutically reclaiming a sense of self as an "affective being." Set within the context of post-genocide Rwanda and extreme trauma, these pedagogues turn to inquiry-based science as a means to open up channels of communication, play, and joy. The predictability and safety of gathering biology and physics data offer a platform (they persuasively demonstrate) to restore and build learner's self-actualization and relationships with others. As the authors' note of their practice, "the most important goal, indeed, is not the quality of the scientific message or the pedagogy: the most important is whether the activities contribute to an actualization of the being" (p. 1123). Although this study was conducted nearly a decade ago, this account remains a powerful example of the potentially far-reaching emotional effects of science education.

Affect of Science Education

In the examples above, emphasis has been placed mainly on the socio-psychological; the focus has been on individuals within particular educational contexts and practices. There are a modest number of studies in which affect is framed more as a sociocultural or poststructural construction with particular social, cultural, and political origins. With this orientation, affect is represented as constitutive with particular cultures and social practices (including language, institutions, social relationships, behaviors, and histories). Research attention is drawn to analyzing these co-constructed educational cultural practices with their associated emotionalities.

Zembylas (2004, p. 301) in a 3-year ethnographic study of an elementary classroom, for example, draws attention to how a teacher's performance of emotional labor is an important aspect of science teaching. Teachers' emotional labor and their emotional metaphors function, in part, in creating inspiring cultures for teaching and learning. The teacher is willing to embrace "suffering" in the form of emotional labor because of seemingly "gratifying" emotional rewards. This study highlights teachers' agency in creating and maintaining socio-emotional cultures.

Orlander and Wichram (2011) study exposes some deep rifts between learners' lived emotional experiences and some of the sociocultural academic traditions of school-based science education. The focus here is adolescents' reactions to calf-eye dissections and sex education. The authors persuasively cast this as an instance in which learners' bodily reactions are central to meaning making in science. It also highlights the emotionally lively nature of some aspects of science education and raises questions of what emotionality is desirable or indeed, undesirable within science education practices.

Cultural and poststructural studies of affect raise significant socio-political questions concerning the emotional rules governing science classroom behavior and underpinning power relations that these rules support. For some time, feminist and postcolonial scholars have drawn attention to the politics of affect, exposing the legacies of Western patriarchal thought and institutional practices. Different authors theorize the political motivations that reinforce the seemingly undesirable nature of some emotions and the worldviews that this presupposes and actively supports. This raises a number of questions for science education, including whose emotionality gets to count in our practices? How? Why? What are the shorter-term and longer-term implications of more dominant emotional traditions for different groups of learners? Are practices in science education failing students because of the particular emotional (or emotion less) forms of knowing that are stressed in teaching? These questions are presently largely under-researched and call for much greater attention in the future.

Affect in Learning Science

As with all attempts to describe learning and education, there are associated theoretical and methodological conundrums. Our narratives of learning are at best partial and serve to illuminate particular aspects whilst leaving others underdeveloped. We make our way in the world through telling stories and these stories also make our worlds. Our primary story in science education is cognition, and we record and rightly celebrate the conceptual performances of learners. Yet there is a clear evidence base that affect and cognition are inseparable and mutually constitutive.

This entry has drawn attention to three broadly different orientations to the study of affect and learning science: attitudes toward science, affect in science education, and affect of science education. These orientations are not offered here as distinctive or categorical, but as illustrative and carry with them an invitation to explore how they might, or might not, be connected. While pupils' attitudes toward science have been widely documented (often and for many decades presenting worrying trends of decline) there is an open question as to how to best respond. Different authors, quite understandably, offer a wide variety of suggestions and these often make reference to changes in teaching and learning practices. As such, they assume a connection at some level between attitudes and situated experiences. However, much research suggests that individual dispositions and situated experience are very different. Attitudes can develop more slowly; perhaps over a longer period of time, while lived emotional experiences can be short lived, episodic, transitory and more immediate. In a recent study, for instance, Abraham (2009) records an increase in short-term engagement during practical lessons but this does not translate into longer-term changes in students' interest. One of his recommendations is that researchers need to develop much more realistic understandings of the potential affective benefits of practical work. Indeed, much evidence now suggests that the construct attitudes toward science and more situated studies of affect in science education are not as closely related as is often assumed. For instance, much research paints such a gloomy picture of students' declining attitudes to science and this is a source of legitimate concern. However, this research cannot be simply extrapolated to conclude that students are regularly having problematic emotional experiences in science lessons. Most science teachers, I am sure, spend considerable time seeking to make their lessons emotionally engaging and enticing.

Similar arguments can be made concerning sociocultural studies of affect (affect of science education). While the emotional natures of our practices remain largely under-researched, these natures raise a number of questions of how they might (or might not) influence learner's situated experiences and their general dispositions and attitudes toward science. It remains an open question, for instance, as to how ways of feeling that are legitimized and de-legitimized by classroom practices impact (or not) students' lived classroom experiences. Orlander and Wickram (2011) previously mentioned study serves to demonstrate that dominant cultural traditions can be quite different to pupils' actual educational experiences. The relationship between what teachers intend students to learn and what they do learn is both dynamic and complex. Exploration of the nature and consequence of possible connections between attitudes toward science, affect in science education, and affect of science education requires greater attention in the future.

Studies of affect also present their own methodological conundrums. The ephemeral, fleeting and episodic nature of situated affect makes it challenging to quantify. Perhaps this is one reason why it is often absent from high profile discussions of school and pupil performance. It now seems like a cliché to say that the ways in which we measure learning influences how learning is both publically and privately conceived and valued. In science education, we have clearly been drawn more to some approaches in the study of affect rather than others. There is an open question of why personal psychological studies have been so appealing and seem so influential in policy and curriculum reforms. The politics of why and how we speak for science education is important.

There has been a sustained interest in a "theory of content" in science education. This is based largely on an assumption that particular content might be best taught and learned in particular ways and in particular social and environmental contexts and settings. Few would disagree that some science content is more provocative and once encountered can arouse intense reactions and equate to particular political allegiances. Other content can, of course, be much more anodyne, dry, and mundane, and this poses its own set of educational dilemmas. Over the past few decades, increasing attention has been placed on socio-scientific issues that are themselves now readily associated with heightened emotions (sometimes grief and loss with apocalyptic dimensions). Global warming and climate change is one such example. Other examples include nanotechnologies, genetically modified foods, and nuclear power and weaponry. Encountering science and technology in these areas raises axiomatic questions of affect and learning. To use a distinction drawn by Bruno Latour, encountering "matters of concern" is likely to be very different than encountering "matters of fact" – a distinction that raises some important pedagogical questions for science education. Traditionally, we have tended to associate difficult knowledge with conceptual demands rather than emotional demands. The emotive power of content still remains largely unexplored. More recently, Maria Puig de la Bellacasa has encouraged us to move beyond facts and concerns to reflect on "matters of care" in techno-science and ask: "Who cares?" "Why ought we care?" "How ought we care?" Reactions to climate change, for instance, raise questions of the importance of understanding the science involved but also, perhaps even more importantly, recognizing why, how, where, and with whom we should, or might, care. Although "pedagogies of care" have been a topic of sustained attention in education, they have yet to develop as a major theme of interest in science education and as such offer an intriguing topic for future research.

Recognizing the constitutive nature of cognition and affect (in contrast to more dualistic orientations) raises profound questions central to any considerations of science teaching and learning. As science educators, our pedagogies are at their heart an invitation to invite others into our worlds and experience a subject that has occupied our minds and emotions for such a long time. This invitation carries with it an open prospect of encountering the wonderment, delight, hopes, challenges, and possibilities of seeing the world and ourselves in different ways. Studies of affect hold the potential to simulate a new body of research with fresh insights into the teaching and learning of science. This can have far-reaching implications for practice and this seems even more pressing in an era of truly global concerns.

Introduction

Nations all over the world are recognizing the importance of preparing their students to be literate and proficient in science, technology, engineering, and mathematics (STEM) fields so their citizens can navigate the modern world and participate productively in the workforce. For students in kindergarten through high school, the formal school day and classroom teachers are at the forefront of the effort not only to increase the number of children and youth who have access to STEM learning opportunities but to do so in an equitable manner that will reach and equip a diverse group representative of the nation's population. But because children spend less than 20 % of their waking hours in school, out of school-time experiences such as afterschool programs – and the institutions and people who provide them – need to be essential partners in this effort. Both the additional time offered by afterschool programs and the opportunity are needed to diversify the ways that students experience STEM learning.

"Afterschool" is defined here as programs which provide an array of safe, supervised, and structured activities for children and youth that are intentionally designed to encourage learning and social development outside of the typical school day. Programs generally operate during the hours immediately following school dismissal; however, they also include activities that occur before school, on weekends, over school breaks, and during the summer. They may be located at a school or off-site, but the programs that show more impact on the participants are usually aligned with the school day (Afterschool Alliance 2011). A common element across these programs is an engaging, hands-on learning approach and less formal environment that aims to feel different from school. Afterschool programs are different from some of the other informal science education (ISE) environments in that they are usually much more structured and sit at the junction of the school day and a truly free-choice learning environment.

In the United States, afterschool programs present a significant potential for young people to engage in STEM education programs – 8.5 million children participate in afterschool programs and structured, comprehensive afterschool programs provide an average of 14.5 hours of programming per week for the participants. Children from populations traditionally underrepresented in STEM fields are more likely to participate than others (Afterschool Alliance 2009) – 24 % of African-American, 21 % of Hispanic, and 16 % of Native American children attend afterschool programs, compared to the national average of 15 %. Girls attend afterschool programs in equal numbers to boys. The afterschool setting thus presents an opportunity to reach the very populations we need to bring into the STEM pipeline through experiences that supplement and complement the school day.

Why STEM in Afterschool?

Afterschool programs have traditionally been very strong on targeting and delivering youth development outcomes. Public support for this setting has also been traditionally based on keeping children and youth safe and providing them with enriching experiences that contribute to the development of the whole child. However, modern afterschool programs do much more than keep kids safe and are strong learning environments that provide a wide array of engaging activities. Many of them have embraced STEM programming and pride themselves on providing engaging hands-on learning opportunities that complement the school day and get young people excited and knowledgeable about STEM topics and careers.

National youth organizations in the United States such as 4-H, Girls Inc., and Girl Scouts and a few other strong state and local afterschool providers have been offering STEM education programs for many decades. However, over just the past 5 years, the general afterschool field has come to enthusiastically embrace STEM programming and is deepening its commitment to offering STEM learning opportunities. Afterschool programs are strategic partners to engage in STEM education – they provide an environment that is free of many of the constraints of the school day and is structured yet flexible. Children and youth can engage in STEM learning and projects in this setting without fear of academic failure. Afterschool programs are characterized by a focus on project-based learning, relevance to real life, and exposure to STEM career options. Thus young people in these programs can meet and interact with adults working in STEM fields; be encouraged to appreciate the relevance of STEM topics and fields to their daily lives and global problems through hands-on projects; and come to understand that persistence in the face of failure is crucial for being an effective STEM professional. It is also a setting where technology and engineering education can occur as they are often not included in school curricula.

Among students who are fortunate enough to have access to afterschool enrichment opportunities, the benefits of afterschool programs in general are well documented, showing positive impacts on both academic and behavioral development. A review of evaluations of afterschool programs in 2011 showed that attending high-quality STEM afterschool programs yields STEM-specific benefits that can be organized under three broad categories: improved attitudes toward STEM fields and careers, increased STEM knowledge and skills, and higher likelihood of graduating high school and pursuing a STEM career.

Supporting STEM in Afterschool

The US Department of Education’s 21st Century Community Learning Centers program is the largest exclusive federal funding stream for afterschool programs (at approximately $1B as of 2013), but many other federal agencies also allocate small pots of funds for supporting various aspects of afterschool programming. While only a small portion of these public monies are applied toward afterschool STEM programming, corporate and philanthropic foundations have recognized the potential of this space for STEM education and have begun investing in it as well.

To enable growth and support for STEM in afterschool, infrastructure is being assembled at a rapid pace. In addition to supports and technical assistance that go along with federal funding streams, system-level intermediaries funded by private philanthropic foundations are working to increase the quality and availability of afterschool programs and STEM learning opportunities within such programs.

Statewide Afterschool Networks operating in 42 states (as of 2013) are increasingly becoming the brokers to advocate for and coordinate afterschool STEM learning efforts in their states. Similarly, *Every Hour Counts* is a partnership of intermediary organizations dedicated to increasing the availability of high-quality afterschool programs by building citywide afterschool systems. Both these networks follow a model of advocating for policy changes at the state and local levels while working to build capacity at the practitioner level.

To aid with the capacity building and professional development needs, strategic partnerships are being formed to bridge the learning that happens within the traditional school day and in afterschool programs. Examples of systemic partnerships include those with school districts, science centers and museums, federal science agencies, and businesses and corporations. This type of alignment and reinforcement of learning will be especially critical as the nation moves toward adoption of a common set of national standards (the Next Generation Science Standards), which will require STEM education to go beyond content knowledge and embrace contextualized modes of learning.

Challenges

However, several challenges remain. Although afterschool programs are increasingly being recognized as important partners in STEM education, much of the dialogue about STEM education improvement centers around what traditional schools can do. The education reforms that are unfolding also mainly target the school day, and hence most public policy initiatives and public dollars target formal schooling as well. As children and youth spend less than 20% of their waking hours in school, it is critical that there is movement away from a model of placing the entire burden on schools and toward a model of a learning "ecosystem" that includes all relevant partners and has appropriate funding streams attached to it.

The range of STEM offerings in afterschool programs varies from one-off science activities to yearlong projects. Consequently the range of reported outcomes for afterschool STEM programs and the language used to describe them also vary greatly. There is a need to define an ISE outcome framework for afterschool that takes advantage of its strengths and clearly defines how it is responding to the national need around STEM education. A challenge for the field is to document and demonstrate the ways in which children's deepening STEM learning and engagement develops and is made possible (and possibly is more inclusive, including of children who do not succeed in school science) *because* of the strong youth development contexts in which the teaching and learning take place. That is, rather than choosing between youth development and STEM learning, it is imperative that the field identify ways of showing how they interrelate and indeed advance one another in the context of the broad reach and audience of the afterschool student population.

There have been efforts to define meaningful outcomes for ISE: the National Science Foundation released a *Framework for Evaluating Impacts of Informal Science Education Projects* in 2008 that defined impact categories (Friedman 2008); the National Research Council's 2009 report, *Learning Science in Informal Environments*, described six strands of science learning in informal environments (National Research Council 2009). Most recently, the Afterschool Alliance conducted a Delphi study (Afterschool Alliance 2013) that asked expert practitioners, policymakers, and funders to define an appropriate set of outcomes and indicators of learning for afterschool STEM. A challenge is how to take these studies and design assessments that do not change the social and cultural tenor of the afterschool space but reveal the ways in which the skills students are developing go hand in hand with the kinds of understandings traditionally associated with schools such as conceptual knowledge.

Afterschool programs have emerged as strong partners in STEM education improvement efforts. Policy initiatives and appropriate resource allocation would allow them to go the next step and become an essential part of the STEM learning ecology.

Agency and Knowledge

Gérard Sensevy[1] and Andree Tiberghien[2]
[1]School of Education, University of Western Brittany, Rennes, France
[2]National Centre for Scientific Research (CNRS), Université Lyon, Lyon, France

An Agentive and Social Conception of Knowledge

What is the meaning of knowledge? We think that any educational endeavor rests on a conception of what knowledge is. This conception may be explicit or tacit, but we argue that it shapes the way educational processes unfold and the conception in turn is shaped by these educational processes.

In this short entry, we propose an agentive conception of knowledge. What does it mean? We consider knowledge as a power of acting. In that conception, learning a piece of knowledge means becoming able to act in a specific new way. This definition does not imply any normative conception of knowledge. For example, a person who learns a science formula by rote and without understanding has gained a power of action. If someone asks her to recite this formula, she will be able to do it and she will be able to do something she was unable to do before she learned by rote. One may argue that that is a poor conception of science education, in that the learned capacity is not very strong. But it suffices to find an educative situation, in a given institution, in which “reciting” is the right thing to do, to convince oneself that, in this setting, the person who recites the formula accurately fulfills the local educational obligations. Of course, it will be possible to find educational settings in which knowing a formula only by rote will not be sufficient. One can even think of educational settings in which rote learning will not be necessary. But we claim that in each case, knowledge, as a power of action, is shaped by the institutional setting in which it is used.

This leads us to a definition of knowledge. Knowledge is a power of acting in a specific situation, within a given institution. This conception of knowledge is both agentive and social. It is agentive, in that it sees that knowledge through the possibilities of acting it enables human beings to undertake. It is social, in that it relates these possibilities of acting to the way the social structure in which knowledge is acquired considers them.

Transmission of Knowledge in Joint Action Theory in Didactics

Conceiving knowledge as a power of acting in a specific situation, within a given institution, gives us an ontology of knowledge, both social and agentive. But such a definition has to be worked out in order to be productive. In the Joint Action Theory in Didactics, the transmission of knowledge is conceived of as a knowledge building, which is viewed in a specific dialectic between two concepts of the theory, the contract and the milieu.

The relation between the teacher and the student is considered as a transaction in which the object is based on knowledge. In this transaction the teacher's intention is to teach knowledge and the student's intention is to learn knowledge, and a problem is at play. Here "problem" corresponds to what is at stake in the transaction and thus is not limited to its usual meaning.

The didactic contract can be seen as the previous knowledge system against the background of which the teacher and the student deal with the problem at play. This knowledge system has been developed in the prior joint actions between the teacher and the student. It is both epistemic (e.g., the way of resolving a given problem or a particular concept as it has been figured out in the didactic joint action) and transactional (grounded on a system of reciprocal expectations between the teacher and the student). The contract then can be seen as a system of rules structuring the didactic action and, more generally, as the strategic systems used by the teacher and the student to deal with the problem at play in the transaction.

The didactic milieu (Sensevy 2012) is the actual material and symbolic structure of the problem at play, which the teacher and the student have to deal with in order to solve this problem. At the outset of the interaction, most of time, the milieu is not identical for the teacher and the student, depending on their understanding of the problem. The milieu can be described as the set of symbolic forms that the didactic experience transforms in an epistemic system, through the didactic contract.

In this perspective, what we call didactic equilibration refers to the way contract and milieu are related in the didactic activity. One can delineate two main patterns of didactic equilibration. According to the first pattern, the milieu is used by the teacher mainly as a way of reenacting a piece of knowledge already encountered by the student. We termed this structure a contract-driven equilibration. According to the second pattern, the contract is used by the teacher as a way of organizing the student's inquiry in the milieu so that he/she is able to solve the problem on his/her own. We term this structure a milieu-driven equilibration.

This theoretical conception enables us to come back to the issue of agency and knowledge. We assert that didactic activity has to be carried out in institutional settings in which the power of acting that the knowledge bestows is acquired through an equilibration form in which the conceptual priority is given to a milieu-driven equilibration. In that, the student's power of acting is strongly related to the teacher's capacity to enable the student to use accurately the didactic contract meanings and to accept to work in a certain kind of epistemic uncertainty to explore the milieu. The result of this equilibration work will be the growing of the student's epistemic agency.

Let us give a short example of such an epistemic agency.

An Example in Mechanics

The chosen example (Tiberghien et al. 2009) comes from a mechanics teaching sequence at high school level (grade 11) after the introduction of the inertia principle and Newton's first and second laws. One of the activities to carry out in small groups (two students) proposed the situation where a student, standing up on the ground, pushes horizontally on a vertical wall. The question was "By using the laws of mechanics, say if the forces that are exerted on the student compensate for each other or if they do not compensate for each other. Indicate the law(s) to which you refer to answer." To solve this problem the students had to make the experience, and they have an available text, given by the teacher during a previous session, with the laws of mechanics.

The two students working in group who were observed and videotaped showed two ways of seeing the situation and solving the problem; they instantaneously disagree and gave different arguments (A, the first student; L, the second student; T, the teacher):

1. A: no.
2. L: yes.
1. A: no because you do not feel the force of the ground but you feel the force of the wall.
2. L: but look at me I am going to tell you something it is [L is looking for something in his file].
3. A: no you do not feel the force no.
1. L takes the sheet and read the Inertial principle. [. . .] L calls T and T arrives.
1. L (to T): in the inertia principle, there is a condition that says that if the velocity of the inertia center is null, then (. . .) the forces compensate for each other.
   T leaves the group [. . .]
2. L: in fact you are like that there is there is/last year we saw the inertia principle it was er the forces they compensate for each other either the object it did not move like here the forces compensate for each other or there is a uniform rectilinear motion then that is if the vector is constant that is in the same direction same length [. . .] (L reads and shows the statement with his finger) if the velocity of the inertia center of a system is a constant vector, then the sum of the forces exerted on the system is null; here the constant vector is null.
3. A: but it means that in fact all the forces there remains the force of the Earth only.
4. L: no even not/all the forces they canceled.
5. A: pouff wait I have to read the summary again (10s) indeed but I am not sure; I wonder if there is not a force that does not get canceled.

For the two students, the contract-milieu relations are not the same when solving the problem.

Student L looks for the text of the principles and uses it; his strategy starts by raising a physics principle; he then checks it with the teacher if he can apply it. Then, the starting point (the problem statement, the studied situation of pushing a wall that he experiences, etc.) of his inquiry strategy is elements of the milieu and his strategy development is based on the contract (text of the laws, calling the teacher, etc.). In this case the use of contract (as the knowledge system developed in the prior joint action between the teacher and the student) is motivated by the milieu that orients the contract. In other terms, the didactic equilibration process is milieu driven.

Student A uses his perception and puts in question the physics principle. His relationship with physics knowledge leads him to use his own perception as a solution more certain than a physics principle. Consequently he does not use the available elements of milieu. His strategy development is directly associated to what he personally knows, as a previous system of knowledge which would enable him to answer the question. In this case it is the contract that orients his activity. The didactic equilibration process is contract driven.

Concluding Remarks

This example enables us to underline a critical point. In our mind, epistemic agency is not a “here and now” achievement. Even though it can be acknowledged in a specific problem solving, this performance depends on a long-duration inquiry process, in which students are enabled to acquire a scientific thought style (Fleck 1981; Sensevy et al. 2008), that one may consider as an epistemic activity in which the current system of knowledge (the contract) has always to be redesigned by the elements of the problem at stake (the milieu). This long-time process needs a specific methodology to be documented (Tiberghien and Sensevy 2012).

Alienation

Christopher Emdin
Department of Mathematics, Science and
Technology, Teachers College, Columbia
University, New York, NY, USA

Characteristics

Alienation is as a sociopsychological construct broadly defined as the state of being/feeling disengaged, disempowered, and isolated from people and/or the local contexts where one is embedded (Lukes 1978; Calabrese 1987). Its symptoms are both individual and collective and are manifested in unique ways by those who have been positioned, or position themselves as, the Other. To be the Other is to be outside of an established norm, and being outside of an established norm results in the development of a bevy of emotions which result in "the distancing of people from experiencing a crystallized totality both in the social world and in the self" (Kalekin-Fishman 1998, p. 6).

In science education, where teaching is often focused on the meeting of arbitrary benchmarks of science skills, and learning is assessed based on the ability of the student to memorize information, alienation is one of the chief means through which a large number of youth underachieve in science. This is the case because school science lends itself to the creation of spaces where there are constant clashes between science, school science, and the ways of knowing and being of students in classrooms. In urban science education, where socioeconomically deprived urban youth of color populate classrooms, alienation from science is a pervasive issue. In these classrooms, alienation is closely correlated to Durkheim's term anomie, which he describes as a mismatch between individual/group norms and larger societal norms (Durkheim 1915).

In urban classrooms, larger societal norms reflect a White, middle-class experience (Bourdieu and Passeron 1977) that is markedly different from the experiences of urban youth. In urban science classrooms, "the dominant cultural ideals of mainstream White society and Eurocentric science…are incommensurable with the beliefs and values of African American students" (Seiler 2001). This incommensurability is exacerbated by the physical structures of school and science such as textbooks, scripted curriculum, and laboratories that do not reflect the culture of students. When textbooks do not have images of Black and Brown scientists, curriculum does not create a space for students to express their inherent need to question, and cultural dispositions that align to orality, impromptu expression, verve, and movement are not considered in the teaching of science, youth of color are alienated from the discipline just by entering into the classroom (Emdin 2010).

While the larger structures of traditional science classroom alienate urban youth just because they happen to be in those physical spaces, alienation is even more deeply expressed because of the constant efforts to extract/invalidate urban youth culture in teaching and assessments. For example, when students are given academic grades in science based partly on "good" behavior or "academic potential," they may be inadvertently judged based on the extent to which their expressions of culture are aligned to a Eurocentric ideal or the extent to which they are able to hide this culture. This process equates to an attempt to wipe out of the customs and the understandings of a population to the extent that consciousness of oneself within a context (in this case the science classroom) is a negating activity. In other words, they are commended or viewed as more scientific for not being themselves or for being closest to what is perceived to be a White male scientist ideal (Emdin 2011).

Finally, one cannot understand alienation without having some understanding of affiliation. Affiliation, which is the state of being connected to, or feeling the connections between, self and others, is a significant component of making youth feel like a part of the science classroom. It is also one of the major ways of being within communities who are not well represented in science. For these populations, there is strength in acknowledging their unique culture, and feelings of contentment, satisfaction, belonging, and togetherness are developed as they communicate with each other. Each of the emotions generated through affiliation stand in contrast to powerlessness, meaninglessness, normlessness, cultural estrangement, self-estrangement, and social isolation that Seeman (1959) suggests are the result of alienation. If youth develop these emotions within science classrooms, they will not see themselves as scientists.

Alignment of Assessment

There are research studies which look into the alignment of assessment and instruction and assessment and content standards. These alignment studies provide data to guide decisions on assessment, standards, and instruction. Based on the findings of these alignment studies, decisions for changes can be made on course level, e.g., related to course content, course objectives, and assessment tasks. The data may also inform educators to make decisions to align instruction or the curriculum for targeted learning outcomes.

Different methods are employed to study alignment including Webb methodology, Achieve methodology, and Surveys of Enacted

Curriculum (SEC) methodology. These methods have all been adopted in the United States. Webb methodology was developed by Webb in 1997 when he compared alignment with content focus, articulation across grades and ages, equity and fairness, pedagogical applications, and systems applicability. Achieve methodology involves both qualitative and quantitative comparisons of assessment with standards. The SEC alignment methodology allows comparisons across schools, districts, or states.

Other methods to study alignment include eliciting assessment beliefs, observing assessment practices, and reflecting on assessment events. Having gathered these data, the researcher may subsequently compare the data collected relating to assessment with data relating to instruction or classroom teaching. There are studies which investigate alignment for vulnerable populations including students with disabilities, preschool children, individual students, and classroom teachers.

Alternative Conceptions and Intuitive Rules

Ruth Stavy and Dina Tirosh

Keywords

Conceptual change

A major thrust in science education research has been the study of students' conceptions and reasoning. Many have pointed out the persistence of misconceptions, naïve conceptions, alternative conceptions, intuitive conceptions, and preconceptions. Studies have covered a wide range of subject areas in physics, in chemistry, and in biology (Thijs and van den Berg 1995).

In view of the large volume of documented instances of alternative conceptions and reasoning, a theoretical framework with explanatory and predictive power seemed to be in order. While most of the previously mentioned studies adapted a content-oriented perspective of alternative conceptions, another approach is suggested by the intuitive rules theory. The intuitive rules theory takes a task-oriented standpoint, addressing the impact of specific task characteristics on learners' responses to scientific tasks (Stavy and Tirosh 2000). The main claim of this theory is that students tend to provide similar, intuitive responses to various scientific and daily tasks that share some external features. The intuitive rules theory offers four major intuitive rules. Two of these rules (*more A–more B*; and *same A–same B*) are identified in students' reactions to comparison tasks, and two (*Everything can be divided* and *Everything comes to an end*) are manifested in students' responses to processes of successive division. Here we refer briefly to the two comparison rules, whose impact can be seen in students' responses to a wide variety of situations.

Responses of the type *more A–more B* are observed in many comparison tasks, including classic Piagetian conservation tasks (e.g., conservation of weight, volume, matter), tasks related to intensive quantities (density, temperature, concentration), and other tasks (e.g., free fall). In all these tasks, relationships between two objects (or two systems) that differ in a salient quantity A are described ($A_1 > A_2$). The student is then asked to compare the two objects (or systems) with respect to another quantity, B ($B_1 = B_2$ or $B_1 < B_2$). It was observed that a substantial number of students responded incorrectly according to the rule *more A* (the salient quantity)–*more B* (the quantity in question), claiming that $B_1 > B_2$. We suggest that students' responses are determined by the specific, external characteristics of the task, which activate the intuitive rule *more A–More B*. This tendency is evident in a wide range of ages. For instance, even university students tend to incorrectly predict that a heavy box will hit the ground before a light one. This response is in line with the intuitive rule *more A* (heavier)–*more B* (faster).

Responses of the type "*same A–same B*" are observed in many comparison tasks. In all of them the two objects or systems to be compared are equal in respect to one quantity A ($A_1 = A_1$) and this equality is salient. Yet, these objects or systems differ in another quantity B (B_1 is not equal to B_2). A common incorrect response to these tasks, regardless of the content domain, is $B_1 = B_1$ because $A_1 = A_1$. Megged (in Stavy and Tirosh 2000), for instance, found that when middle school students were presented with two vials containing equal amounts of water and one of these vials was heated, the students tended to incorrectly claim that *same A* (water)–*same B* (volume of water).

The intuitive rules, which account for many incorrect responses to science tasks, have a predictive power. That is, one could predict how a student will respond to a given task on the basis of external, specific features of the task and a small number of intuitive rules. Moreover, the rules seem to be universal to affect students' responses regardless of culture.

Various instructional methods have been employed in science education for overcoming intuitive interference including teaching by analogy, conflict teaching, calling attention to relevant variables, raising students' awareness of the role of intuition in their thinking processes, and experiencing practical activities. Recently, cognitive psychology (e.g., reaction time) and neuroscience methodologies (e.g., fMRI) are employed to study the reasoning mechanisms related to intuitive rules (Stavy et al. 2006). The insight to be gained from employing these methods could lead to a deeper understanding of students' difficulties and their reasoning processes and eventually to improve science education.

Setting the Scene

The discovery of students' alternative conceptions constitutes one of the major landmarks of science education. No longer is it sufficient to study only "effective methods," or general learning processes. Instead, the field came to understand that students had particular and resilient ideas about various scientific domains, which strongly affect learning.

Few doubt this constructivist presumption today. However, there is still much debate about how to construe these phenomena. As a result, there is also debate concerning how one should best pursue good instruction in the light of alternative conceptions. P-prims theory offers a carefully articulated and systematic approach to understanding the nature of students' naïve ideas, their origins, and their role in coming to understand science concepts deeply.

P-prims theory is part of a broader approach, called "Knowledge in Pieces" (KiP), to understanding the nature of students' intuitive ideas and their role in learning. P-prims theory deals with intuitive preconceptions per se, and other parts of KiP (e.g., the "coordination class" model) deal with the nature of expert concepts. Kindred approaches to KiP include Minstell's "facets" and Linn's "knowledge integration." Here, I use "the theory theory" and the basic idea of "misconceptions" to represent competing perspectives.

The Basic Idea

P-prims theory aims to explain student alternative conceptions as stemming from bits of intuitive knowledge that contribute to our intuitive "sense of mechanism," that is, what kinds of occurrences are natural and to be expected. P-prims express regularities, like scientific principles, except that there are many more p-prims than scientific principles, and there are other significant differences, described below.

"P-prim" stands for "phenomenological primitive." "Phenomenological" means that p-prims are usually evident in our everyday experience. One just sees situations in terms of them. As a consequence, what happens in a situation is regarded as natural if a p-prim applies, or surprising otherwise. "Phenomenological" also suggests that p-prims are encoded in ways other than in words, as images or kinesthetic schemes. "Primitive" means to imply that people cannot, in general, analyze or justify their p-prims. Part of this follows from the fact that they are not encoded in language. In contrast, the words "force equals mass times acceleration" provides a clear top-level analysis of Newton's laws, but the same cannot be done for p-prims (except by us, as analysts). Similarly, while Newton's laws can be argued for, explained, and even supported by empirical results, one cannot do those things for p-prims. P-prims are simply evoked by situations either directly or as a result of deliberately attending to other aspects of a surprising situation that might render it more comprehensible than our first impressions.

I will not discuss other aspects of p-prims theory, such as (1) how we describe a p-prim's contextuality – when it applies and when it does not – and (2) how they develop, as a result of sorting experience toward deeper principles.

P-prims theory maintains that there are hundreds or thousands of p-prims. That is, our personal search for ultimate explanation of the world does not result in only a few general principles. No p-prims are as deep and complicated as Newton's laws. So, we simply must have many of them to "cover" the array of experiences that we have.

In contrast to p-prims, the "theory theory" view maintains that intuitive knowledge comes down to just a few core principles. Some advocates of the theory theory even describe intuitive theories as "remarkably articulate," suggesting a close connection to language, which is explicitly denied by p-prims theory. The theory theory also contends that intuitive principles, in addition to being few, are substantially coherent. That is, they are embedded in a rich web of relations that mutually constrain all the pieces. P-prims theory maintains that p-prims, for the most part, have independent developmental histories and remain, at best, loosely interconnected.

Examples

Since there are many p-prims, there is no definitive list of them. However, we illustrate with some informative examples.

Ohm's P-Prim. Ohm's p-prim is one of the most powerful and important p-prims. It specifies that many causal situations can be understood as an "agent" acting against some kind of "resistance" to achieve some particular "result." People are prototypical agents that exert effort toward particular results. We "work harder" (e.g., push harder) in order to obtain greater result (which may be that an object moves either faster or farther). Various intervening "resistances," such as friction or the object's size, can moderate our efforts. Ohm's p-prim applies to intellectual effort, such as working harder to achieve a higher grade in school. In inanimate situations, agency may be attributed to elements of situations that have the capacity to make things happen. A rapidly moving object, for example, may be construed as an agent, or a battery might exert a kind of "effort" called "voltage."

In contrast to the misconceptions perspective, p-prims recognize the ecological validity of intuitive ideas. It is not strange that we have ideas that fit particular situations (throwing harder to have a ball travel faster). Such ideas are "entrenched" because they are excellent ideas. They simply work well for many situations in the real world. However, p-prims are not yet the complex, general, and articulated ideas of professional science.

P-prims research has found many reuses of intuitive ideas in learning science. Ohm's law in electricity is comprehensible to novices precisely because it is an obvious situation that is governed by Ohm's p-prim. Similarly, although Ohm's p-prim contradicts $F = ma$ in some situations, in other situations (e.g., those involving small objects moving through a viscous fluid, which involves Stokes' law friction) Ohm's p-prim is entirely consistent with Newton, and it is likely to be used for rapid reasoning, then, even by experts. The problem with Ohm's p-prim is not its incorrectness, but its vague contextuality. Students are prone to apply Ohm's p-prim where it should not apply, and they do not know that deeper principles can often replace and improve Ohm's p-prim even in circumstances where it does apply.

The fact of productive engagement of p-prims in learning science cannot be overemphasized. Misconceptions views uniformly characterize intuitive ideas as false and in need of replacement. Similarly, theory theory views uniformly describe naïve theories as in need of replacement. As a consequence, misconceptions and theory theory views are effectively "blank slate" theories of learning or, worse, views holding that the slate must be wiped clean before real scientific ideas can be developed. In contrast, p-prims theory sees many productive roles for p-prims, achieved through modifying them, adjusting their contextuality, combining them, and reorganizing them.

Abstract Balance and *Equilibration.* Balance is a powerful intuitive principle. When people view a balance scale, its behavior is intuitively comprehensible as a system that has a natural "balanced" position. According to the abstract balance p-prim, a balanced system can be disturbed and put "out of balance." If the disturbance is then removed, the system just returns to its natural state; it *equilibrates.* This conceptualization is a misconception to the extent that Newtonian mechanics requires a force or torque to drive equilibration; intuitively, return to balance just happens and needs no other explanation.

No putative naïve theories of physics recognize either abstract balance or other important balancing p-prims. Such ideas have been found particularly helpful, not surprisingly, in understanding thermal phenomena such as temperature equilibration. It is conjectured that balancing p-prims also help with understanding conservation laws, such as conservation of energy.

Carrying. One can easily imagine very young children recognizing that carried things just "go with" their carrier. A baby goes with the carrying parent. A toy in a child's red wagon just goes along wherever the wagon goes. A true physics explanation of these situations is simply too complicated for children, or even for most college students. So, the carrying p-prim is about as good an understanding of these situations as early physics learners can achieve.

Dropped Objects Fall. As with carrying, it is hard to imagine even very young children not noticing that when one drops an object, it falls (straight down). This p-prim, like others, fails as science because of contextuality. People do not notice that the "straight down" aspect only happens when the dropper is not moving. Yet, dropping from rest is so much more important and frequent in a young child's world that it should not be surprising that separate principles are not developed for moving drops.

Channeling, *Blocking.* The channeling p-prim recognizes that trains just follow their tracks and balls just follow along in a tube in which they move. Like equilibration of a balance scale, forces are not needed. Blocking is the very important phenomenon, observed every day, that sturdy objects simply support things put on them; they block falling. These situations are, again, somewhat complicated to analyze from a Newtonian point of view, so students often appeal to the relevant p-prims when asked about blocking or channeling situations.

Competitive Advantage

P-prims as a theory of intuitive knowledge have a number of advantages, compared to competitors. Here are a few:

Strong constructivism. Tracking the positive value of p-prims in learning science (Ohm's p-prim works for electrical circuits; balancing p-prims evolve into understanding conservation laws) distinguishes this view from the uniformly negative view of intuitive ideas in the misconceptions or theory theory views. So learning, when it happens, is easier to account for with p-prims.

Coverage. The theory view selects, without good rationale, the effects of certain p-prims (or combinations of p-prims) *in certain situations* (*not* where they work well) to "knight" as part of a "core theory," and it ignores many other p-prims. This is particularly problematic when naïvely less important p-prims grow substantially in importance when they enter into learning real science.

Tracking Learning at Fine Grain Sizes. The task of understanding how learning happens in sequences of student thinking is much easier to handle in p-prims theory. The theory theory marks one end of a wide spectrum as "the naïve theory," and the other as "the normative theory," but what happens in between requires more detail. P-prims' growing or fading in importance or combining with other ideas can track learning much more precisely. Recent p-prims work has been particularly rich in tracking moment-by-moment learning.

Implications for Learning and Instruction

Here is a short list of implications of p-prims theory concerning instruction, and some opportunities it may afford with future work:

Pools of Productive Resources. As we learn more about the p-prims students have, we come to understand better a pool of very helpful resources for instruction. Misconceptions or naïve theories that are "just wrong" cannot help us in this way.

A Fine-Grained Approach to Instructional Design. The latest p-prims work shows in detail how moment-by-moment learning can happen. As such, it is a lens that can be used to understand and refine instructional sequences.

Deep Learning Just Takes Time. The change from the naïve state to scientific understanding is unequivocally complicated when viewed at the grain size of p-prims. Recognizing this, many instructional approaches may simply be grandly overoptimistic. Experiments that try to squeeze down known-to-be-effective instruction to shorter interventions suggest that this may be impossible.

Learning in Many Contexts. P-prims are highly contextualized. It is almost certain that one cannot learn scientific ideas without sampling a wide range of contexts that employ the same scientific ideas, but are construed very differently from an intuitive point of view – and conversely!

Handling Diversity. The set of p-prims students may have and levels of confidence concerning particular ones may vary a lot from student to student. Recent p-prims-based work has allowed us to see these differences and to understand why they can lead to success or failure of instructional treatments.

Coaching Students Metaconceptually. A significant part of understanding the *nature of science* might well be understanding the distinctive properties of students' own intuitive knowledge and how it changes to become genuine science. It may be that this is far more important to students' learning than understanding "what scientists do."

Alternative conceptions; Alternative conceptions movement; Alternative conceptual frameworks; Alternative frameworks; Implicit knowledge elements; Intuitive theories; Knowledge in pieces; Misconceptions; Personal constructivism; P-prims; Preconceptions; Cognition; Conceptual change

There are a great many studies into learners' ideas in science topics, focusing on learners at different levels of the education system (Duit 2009; Taber 2009). These studies reveal that learners often present ideas relating to science topics which are at odds with the target knowledge set out in the curriculum. These ideas have been described using a wide range of terms, including misconceptions, preconceptions, alternative conceptions, alternative frameworks, alternative conceptual frameworks, intuitive theories, and mini-theories. Sometimes particular authors distinguish between meanings for some of these terms, but usage varies across the literature so often the different labels are, in effect, broad synonyms (Taber 2014).

Interest in students' ideas came to prominence in science education in the 1980s when a considerable research program (sometimes labeled the "Alternative Conceptions Movement") developed around eliciting such ideas. The theoretical perspective that informed much of this work was personal constructivism, which considered knowledge to be developed iteratively within the minds of individual learners (Driver 1989; Gilbert and Watts 1983). Teachers were seen as being able to support and scaffold learning, but learning itself was considered an act of personal construction of knowledge. From this perspective, the notion (inherent in much discourse around teaching) that knowledge could somehow be “transferred” or copied from teachers and textbooks to learners in a straightforward way is untenable. The learners’ prior knowledge and beliefs were recognized as providing the conceptual resources for interpreting teaching, and studies showed that students commonly held informal ideas about science concepts and topics that were inconsistent with the target knowledge set out in the curriculum.

The constructivist perspective was influenced by a range of thinkers including Jean Piaget, George Kelly, David Ausubel, Jerome Bruner, and Lev Vygotsky. The personal constructivist perspective and the research programs it informed have been significantly criticized from various standpoints, although robust defenses against these different criticisms have also been offered, and the constructivist perspective continues to be widely adopted in science education (Taber 2009). However, it has become clear that it is important to distinguish between constructivism as a theory of learning (which is widely accepted) and constructivism as a wider epistemological stance (which is sometimes characterized as inconsistent with the epistemology of science). Those adopting a personal constructivist perspective have had to acknowledge an increasing focus on the importance of cultural and social influences on learning, with some commentators seeing social constructivist perspectives as contrary to (rather than complementary with or able to be accommodated within) personal constructivism.

The initial motivation for research in this area was the claim that students commonly held alternative ideas inconsistent with the science to be learned that were tenacious and which would impede the learning of canonical scientific concepts. It was widely argued that it was important to diagnose learners’ alternative conceptions in a topic before teaching and then to explicitly challenge them. Ideally learners would be presented with activities, demonstrations, and opportunities for dialogue that would allow them to recognize the superiority of the scientific concepts and models presented in the classroom to their own alternative conceptions. All aspects of this argument have been subject to criticism and counter claims. In particular, there have been debates about the key issues of the nature of learners’ ideas about scientific topics and the significance of alternative conceptions for subsequent learning.

Some initial characterizations of learners’ alternative conceptions were that these were of the form of personal theories to which learners were strongly committed. However, critics argued that learners’ ideas were more akin to “fragments” of knowledge, often of very limited ranges of application, and readily disregarded. Some argued that giving attention to “alternative conceptions” in teaching would seem to give them more status and was likely to reinforce rather than challenge them, whereas such ideas were otherwise likely to be readily abandoned when scientific knowledge was authoritatively and persuasively presented in teaching. The empirical evidence suggests that neither view is generally correct. The range of results reported in diverse studies suggests that learners’ ideas about scientific topics are actually quite diverse in nature, as might be expected when considered as knowledge “under development” (Taber 2009, 2014).

Some ideas have been found to be widely applied across broad ranges of application and to be retained despite teaching designed to explicitly challenge them. Two examples would be the idea that a moving object must be subject to a force (sometimes referred to as the impetus framework or F-v thinking), and the idea that chemical reactions occur so that atoms can fill up their outer electron shells (the octet alternative conceptual framework). These ideas seem to become well established, to be linked to explicit principles (and so can be seen to form the core of a framework of related conceptions), to be applied consistently and across diverse contexts, and to be largely retained despite teaching of the scientific models. These ideas have been reported across many different educational contexts.

However, not all of the reported alternative conceptions have these features, and some of the ideas reported in studies are more labile (as learners are not strongly committed to them) and do indeed seem to be better characterized as knowledge fragments. Clearly such characterizations are important in considering potential implications for teaching. Where students hold fanciful and weakly committed ideas about science topics, then these are likely to have limited influence on learning of target knowledge, and there is limited value in spending time devising teaching strategies that take them into account. However, it is known that an idea like the impetus framework is highly intuitive to many learners and often tends to be retained after school and even college instruction. Research also suggests that even when students learn to answer regular classroom exercises correctly from the scientific model, they may still apply their alternative intuitive ideas when facing a problem that cannot be solved by standard algorithmic approaches, or when asked a question set in an everyday context, or when facing real-life problems beyond the classroom.

Moreover, even apparently persuasive demonstrations that seem to convince students that their alternative conceptions are wrong may only dominate their thinking over short periods before they revert to their longer-established ways of thinking. For example, students who initially assume that current must decrease at each lamp in a series circuit are often found to change their minds once they have seen their predictions of lamp brightness and ammeter readings are wrong. However, after some weeks have passed the students are likely to revert to their original view and may actually "recall" the demonstration as having shown that lamp brightness or ammeter readings did indeed diminish around the circuit.

An important theme for research concerns the origins of students' alternative conceptions. A number of possibilities have been suggested, although in reality there will be interactions between these and many alternative conceptions cannot be understood to have a single distinct origin. One potential influence is genetic, in that our genetic inheritance provides the framework within which we can develop. Although it seems unlikely that specific ideas are coded in our genes, it does seem that we have genetically directed predispositions to perceive the world in particular ways. One well-known example is the ability of neonates to recognize faces (i.e., the general pattern of a face, not specific faces) suggesting this ability is innate. The ability to identify a face in what William James referred to as the "great blooming, buzzing confusion" a newborn baby experiences clearly has value but leads to people readily recognizing faces in all kinds of inappropriate places – so a vague resemblance to faces in images of the surfaces of the moon and mars is taken by some as evidence that aliens have deliberately sculptured faces there.

The importance of the cognitive apparatus responsible for recognizing familiar patterns in perception has been emphasized in an approach to thinking about students' ideas referred to as knowledge in pieces (Hammer 1996). In this approach (championed by Andrea diSessa and David Hammer among others), the importance of implicit knowledge elements not open to direct introspection is emphasized as the basis for intuitive understanding of the world. Certain patterns recognized as recurring in experience become so familiar that we come to see them as natural and part of how the world works. These implicit knowledge elements (sometimes called p-prims or phenomenological primitives) act as basic cognitive resources that are recruited to make sense of diverse phenomena. This processing is preconscious, so the individual is not aware of the p-prim, just the outcome of its application.

The knowledge in pieces perspective emphasizes how many ideas elicited from students which might be labeled as alternative conceptions may not be established ideas, but rather could be constructions undertaken in response to a researcher's questions offering a new (and perhaps transient) nexus drawing upon the more stable underlying knowledge elements. An example might be a research participant explaining the seasons in terms of the earth's distance from the sun, drawing upon a more general intuition that effects are greater closer to the source. However, even if many elicited conceptions begin in this way, once such conceptions are made explicit (e.g., verbalized or built into a mental image or simulation), they may often become incorporated into the individual's explicit knowledge base, i.e., coming to believe that summer is the time when the earth is closer to the sun in its orbit. The common alternative conception that objects will only continue to move when acted upon by a force does not match scientific understanding, but actually fits most people's experience of moving objects. Given its constant reinforcement in everyday life, it is not surprising that this has been found to be an especially tenacious alternative conception.

Although many of our formal conceptions of the world may begin as applications of intuitive knowledge elements (what Vygotsky called spontaneous conceptions), a key feature of human learning is the role of culture, and in particular language, that allows us to learn vicariously from the experiences of others. For such learning to be more than rote learning, it needs to be interpreted in terms of our existing stock of conceptual resources – with the inherent risk of misinterpretation. Nonetheless, formal learning of "academic" concepts allows us to learn vastly more than is possible if we relied on our spontaneous concepts alone. Unfortunately, many of the ideas with currency in popular discourse are themselves inconsistent with scientific concepts, and so "folk theories" may act as sources of individuals' alternative conceptions.

Language is the key mediator of meaning between individuals, although inevitably communication is imperfect. Sometimes language has been considered to influence the development of alternative conceptions such as when a technical term has associations from everyday life that do not match the scientific meaning (e.g., particles, electron spin), or when it is used metaphorically (plant "food") or is misleading (e.g., neutralization of an acid with a base does not always lead to a neutral product as students may assume is implied by the term).

Teaching may itself be the source of students' alternative conceptions. This may be either because students do not realize when such teaching devices as analogy, models, metaphors, and anthropomorphisms are being used to help make the unfamiliar familiar and so take these representations too literally or because alternative conceptions are taught. The common alternative conception about chemical reactions being driven by atoms seeking to fill their shells is clearly not based on students' direct experiences of atoms and therefore seems to be based on the interpretation of teaching which either presents inadequate models or offers ambiguous descriptions that students then misinterpret in terms of their intuitions of the world. Research has shown that some alternative conceptions in this particular topic area are found widely among trainee school teachers suggesting that some alternative conceptions are being directly taught to new generations of learners by their teachers.

Research to understand the nature and characteristics of students' conceptions continues because understanding the precise nature and status of different types of reported conceptions is important in understanding how conceptual change may be best brought about, e.g., by directly challenging student conceptions, by ignoring them and simply teaching the canonical ideas, or by seeing learners' conceptions as useful (or necessary) starting points that need to be modified over time through a multistage conceptual trajectory. Each of these approaches is likely to be most sensible in some cases and counterproductive in others. Research into implicit knowledge elements such as p-prims may even lead to strategies to recruit the most helpful intuitions in learning particular concepts. So where much early research on alternative conceptions was concerned with cataloguing the range of ideas presented by learners, current research in this area is closely linked to models of conceptual change and designing appropriate strategies for teaching different curriculum topics.

Analogies in Science

Richard Coll

Saweni, Lautoka, Fiji Islands

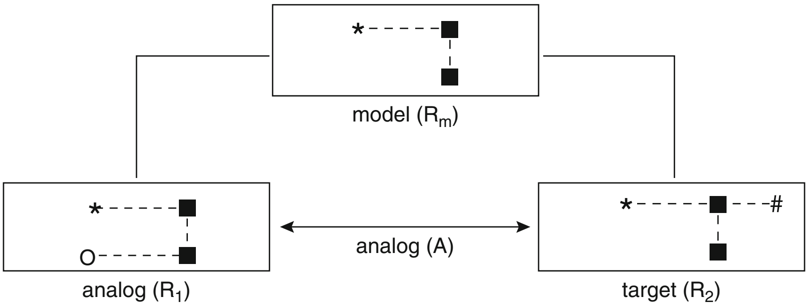
Keywords

Analog; Analogies; Scientists; Target

Analogies help scientists and everyday people make sense of the natural phenomena that surround them. We have an everyday object, event, or story that is well understood – this is called an analog, and a science concept to which it is compared called the target. Links – called mappings – are then made between the analog and the target. Mappings can be positive, ways in which the target is like the analog; negative, ways in which the target is not like the analog; and neutral, when it is not clear whether the target is or is not like the analog.

A visualization of mapping by Duit (1991) shows there may be identical features in parts of the analog (R1) and target (R2); the model (Rm) then represents similarity – with analogy (A) representing the relation between analog and target (Fig. 1).

To illustrate, we might compare a model of the atom with the solar system and map shared and unshared attributes: the sun and nucleus, the electrons and planets, and the sun is large – the nucleus is small, electrons travel much faster than planets.



Analogies in Science, Fig. 1 Duit's model for analogical transfer by mapping (This material is reproduced from Duit, R., 1991, Science Education, 75(6): p. 650, with permission of John Wiley & Sons, Inc)

The use of analogy works because it makes the unfamiliar (i.e., what we are trying to explain/teach) familiar by drawing on what the student already knows. We do need to make sure the analogy is interesting and familiar, and both the shared and unshared attributes need to be discussed. We also must point out where the analogy breaks down, lest students think the analog and target have things in common that they do not.

Keywords

Analog; Analogies; Metaphors; Models

It can be argued that all language is itself a metaphor, the "conduit metaphor" (Reddy 1979), such that meanings are contained in words and linguistic expressions are containers which are sent to somebody. A range of types of "containers" can be used. While a simile is merely a decorative addition to a statement, e.g., "as dead as a doornail," a metaphor is an attempt to understand something about which little is understood (the "primary subject") by considering it to be the same as something that is much better known (the "secondary subject"), e.g., "the sun (primary subject) is a furnace (secondary subject)." In so doing, the understanding of the secondary subject is also altered by an interaction of meaning: in this case it becomes possible to think of the furnace as life-giving.

The very readable book *Metaphors We Live By* (Lakoff and Johnson 1981) argues that metaphors are central to thinking and hence to communication, for they are the tools with which we conceive of, and hence experience, the world. They point out that metaphors can be grouped into categories, each of which is manifest with a particular resonance in a given culture. Typical categories are the "orientational," relating to positions in space relative to a person, e.g., "having full control of events is up" and "having no control is down," and the "ontological," where an abstraction is given the status of an object, e.g., "inflation is an entity." To be of any value, the characteristics of the secondary source must be known in detail. That said, a secondary source that is of great value is one that is drawn from a field of endeavor very different from that of the primary source. Metaphors do not identify exact equivalences; thus, there are attributes of a furnace that the sun does not have, e.g., a furnace uses oxygen, the sun does not. A metaphor seems promising where the secondary source has a number of important attributes that might be useful in understanding the primary source, and the relationship is explored to yield an analogy. In an analogy, the primary source is said to be like the secondary source to some extent, but not identical to it. The important issues are the identification of those attributes that are similar and the estimation of the degree of similarity.

Hesse (1966) separated the attributes of any secondary source into three types. Positive analogues are where some similarity seems likely, e.g., "the sun produces both heat and light as does a furnace"; negative analogues are where no similarity seems possible, e.g., "the thermal output of the sun cannot be controlled as can that of a furnace," while neutral analogues are attributes of the secondary source that may, or may not, be useful in understanding the primary source, e.g., “the sun may or may not consume its fuel.” Neutral analogues are valuable in that they direct research attention to the attributes in question. The conceptualization of the degree of similarity between a primary and a secondary source in respect of a given positive analogue is still taking place. “Structure mapping theory” (Gentner 1983) is a useful approach using an analogy of “distance” to discuss the issue. In it, a “near” analogy is one that is readily perceived, while a “far” analogue requires more adaption of ideas before the relationship becomes apparent.

The readiness with which metaphor and analogy can be used by an individual will depend both on the width of the spectrum of domains of knowledge with which they are acquainted in any detail and on their capability to evaluate the status and degree of similarity of attributes. These capabilities are manifest in the creation and use of models.

The world as experienced, as initially encountered, is a bewildering complex of objects and events. In order to make sense, to be able to think about it, humans (and probably other species) isolate and simplify specific aspects of it: models are produced. In the broadest sense, a model is therefore a simplified representation of any object, system of objects, events involving systems, or ideas about any of these, which is initially produced for a specific purpose. Mental models are ontological entities created in the mind and are vital to all thinking (Johnson-Laird 1983). Science, being centrally concerned with producing explanations of the world as experienced, places an especial value on models, for these are used to produce the predictions which are a defining aspect of scientific methodology. The creation of all models involves the identification of metaphors and hence on the drawing of analogies; being human creations, a distinct culture has evolved around them.

It is in the nature of science that once a mental model has been created in the mind of an individual, an attempt is made to express it to others. This expression can be carried out using gestures, materials, words, visuals (e.g., in pictures, diagrams, or graphs), symbols and equations, or a combination of these (Gilbert et al. 2000). It does seem that the translation in both directions between a mental model and an associated expressed model can involve some change: perfect communication is probably impossible. Each of these modes of representation relates to a given mental model in a precise way: each has a specific code of representational capability. Attempts to comprehensively communicate any mental model may therefore require the use of several modes of representation.

A mental model is expressed into the public arena by the creator(s) as a suggestion about the nature, structure, and mechanisms of the world as experienced. This suggested model is then subjected to tests by the science community and is then either discarded, amended, or accepted as a consensus model of some value. This valuation may continue for any number of years, ranging from a few (e.g., Pauling’s triple strand model for DNA) to very many (Aristotle’s model for motion). Eventually, in most cases, a given model is superseded for research purposes but is retained as an historical model because of its capability to provide adequate explanations of some phenomena that are now seen to be unproblematic. Metaphors, analogies, and models play key roles in science. Examples are Harvey’s metaphor of “the heart is a pump,” based on extensive knowledge of water pumps in mines, and Bohr’s metaphor of “the atom is a planetary system,” based on the standard model of the solar system, both of which advanced thinking considerably in their respective fields when they were proposed. The central role of science education of introducing students to science ensures that the major models produced by science are taught. These are usually historical models, originally proposed in a simplified form, and, having come to rest in the school curriculum, dwell there unchallenged for many years. For models that are particularly intellectually challenging, teaching models, based on metaphors that will be more readily comprehended by students, are devised.

Finally, in addition to transmitting established models, teachers themselves develop metaphors, and hence analogies and models, of their work. For example, they may see themselves as "captains of a ship," "entertainers," "facilitators of learning," and "assessors of learning." Professional development can involve causing science teachers to reconsider the significance of their chosen metaphor(s) of teaching.

Introduction

Science education research studies have shown that analogies, when well designed, can support students' science learning. Well-designed science analogies can help students build conceptual bridges between what they already know and what they are setting out to learn. This entry explains what analogies are, how analogies support learning, and what form analogies should take to be effective. A research-based model for designing effective analogies is described: It provides guidelines for the use of analogies in science classrooms, textbooks, software programs, and Internet sites.

Science Education and Analogies

Analogies have often played an important role in scientific discoveries, not as proof, but as inspiration. Analogies have also played an important role in explaining those discoveries. Ernest Rutherford, for example, used an analogy when describing his experiment which led to the modern model of the nuclear atom. Rutherford had bombarded a metal foil with charged particles, and some of them bounced back. Rutherford said: "It was almost as incredible as if you fired a 15-in. shell at a piece of tissue paper and it came back and hit you.... I had the idea of an atom with a minute massive center, carrying a charge."

Science teachers, like scientists, frequently use analogies to explain concepts to students. The analogies serve as initial models, or simple representations, of science concepts. The teachers frequently preface their explanations with expressions, such as, "It's just like," "Just as," "Similarly," and "Likewise." These expressions are all ways of saying to students, "Let me give you an analogy." The students use these analogies to support their learning, and they often construct their own analogies. Constructing their own analogies helps students to take an active role in their learning.

Analogies are double-edged swords: They can foster understanding, but they can also lead to misconceptions. Effective analogy use fosters understanding and avoids misconceptions (Duit et al. 2001). In order to use analogies effectively, it is important to understand what analogies are, how they can support learning, and what kind of analogies are particularly effective.

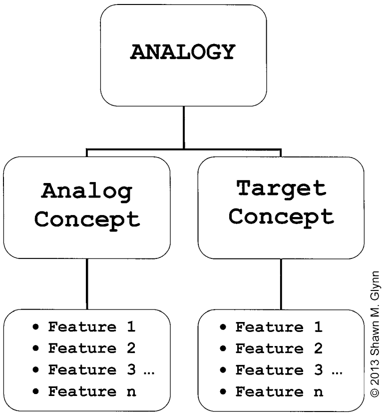
Analogy Defined

An analogy is a comparison of the similarities of two concepts. The more familiar concept is called the analog and the less familiar one the target. Both the analog and the target have features (also called attributes). If the analog and the target share similar features, an analogy can be drawn between them. A systematic comparison, verbally or visually, between the features of the analog and target is called a mapping. A conceptual representation of an analogy, with its constituent parts, appears in Fig. 1.

Analogical reasoning can occur between conceptual domains and within a conceptual domain. Between the domains of physics and biology, for example, an analogy can be drawn between a camera (with its lens, aperture, and microchip sensor) and the human eye (with its lens, pupil, and retina). Within the domain of physics, for example, an analogy can be drawn between a water system (with its pipes, pump, and pressure) and an electric circuit (with its wires, battery, and voltage).

How Analogies Support Science Learning

The analogies used in classrooms, textbooks, software programs, and Internet sites should be designed to promote elaboration, the cognitive process of constructing relations between what is already known and what is new. Elaboration can be activated by questions, objectives, personal examples, and other strategies, but analogies seem to be particularly appropriate because they can provide the rich, familiar contexts that successful elaboration requires. Elaboration is essential to ensure that students' science learning is meaningful rather than rote.



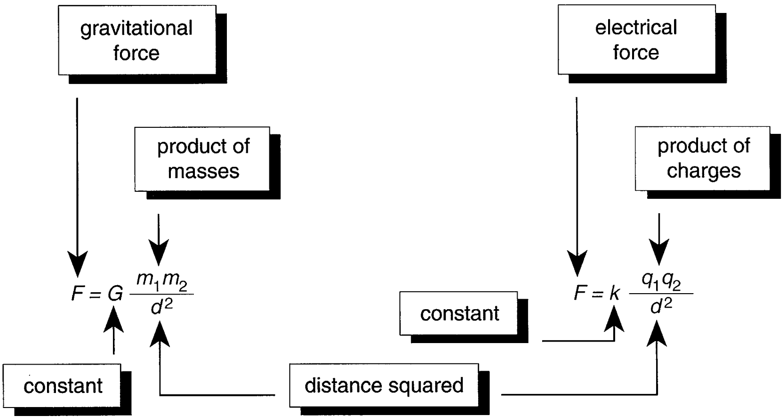
Analogies, Role in Science Learning, Fig. 1 A conceptual representation of an analogy

In a constructivist learning framework, students learn progressions of increasingly sophisticated mental models of science concepts. Often, these concepts represent complex, hard-to-visualize systems with interacting parts: An atom, a cell, photosynthesis, an electric circuit, and an ecosystem are all examples. Often, such concepts are introduced to students when they are about 10 years of age and then refined in subsequent grades, technical schools, and college. Familiar analogs (e.g., a factory) often serve as early mental models that students can use to form limited, but meaningful, understandings of complex target concepts (e.g., a cell). The analogy paves the way for the expansion of the target concept.

It is important to ensure that all students are familiar with the analog concept in order for it to be effective. Teachers should explain to students what an analogy is. Teachers should also encourage students to construct their own analogies and to keep in mind the limitations of analogies.

Highly Effective Science Analogies

In research studies, the effect of analogies has been inconsistent: Sometimes analogies increase learning and sometimes not. This inconsistency has been due to weak operational definitions of analogies, to constructions of analogies that have failed to map analog features systematically onto target



© 2013 Shawn M. Glynn

Analogies, Role in Science Learning, Fig. 2 An analogy between two inverse-square laws: Newton's law of gravitation and Coulomb's law of electrical force

features, and to analogies that have not capitalized on visual imagery. Instructional analogies are sometimes limited to simple assertions, such as "Mitochondria are the powerhouses of the cell," without explaining the analogy. These assertions, or simple analogies, do not provide the instructional scaffolding that many learners need, particularly in the initial stages of learning a concept.

A much better mechanism for providing instructional scaffolding is an elaborate analogy: "In an elaborate analogy, analog features are systematically mapped onto target features, verbal and imagery processes are active, and these processes mutually support one another" (Glynn and Takahashi 1998, p. 1130). Elaborate analogies provide a rich, situated context for learning. By systematically mapping verbal and visual features of analog concepts onto those of target concepts, analogies can facilitate the cognitive process of elaboration. Elaborate analogies have been found to increase students' learning of target concepts and their interest in the concepts (Paris and Glynn 2004).

An Example of an Elaborate Analogy

Joseph Priestly was thinking analogically when he proposed a law of electrical force. Priestly was familiar with Newton's law of universal gravitation, which holds that the gravitational force between any two bodies is inversely proportional to the square of the distance between them. Priestly speculated, correctly as it turned out, that the electrical force between two charges is also inversely proportional to the square of their distance.

Charles Coulomb experimentally confirmed the law of electrical force, and the law was named after him. The analogy between Newton's law of universal gravitation and Coulomb's law of electrical force is mapped out in Fig. 2. In Newton's law, the gravitational force between two objects is proportional to the product of their masses and inversely proportional to the square of the distance between those two objects. Newton's law contains a constant, G, which is the universal gravitational constant.

In Coulomb's law, the electrical force between any two objects has a similar inverse-square relationship with distance. When objects or charged particles are small in relation to the distance between them, then the electrical force is proportional to the product of the charges and inversely proportional to the square of the distance between the charged particles. Coulomb's law also has a proportionality constant, k.

So, Newton's law of gravitation is analogous to Coulomb's law of electrical force. Both are inverse-square laws, and both have constants. But, although the laws are similar, there are important differences between them. For example, m represents the mass of an object, and q represents the charge of a particle. And, although both laws have constants, the G in Newton's law is a very small number, whereas the k in Coulomb's law is a very large number. Yet another difference is that gravitational force only attracts, while electrical force attracts when charges are different but repels when they are similar.

Teaching-With-Analogies Model

The Teaching-With-Analogies Model (Glynn 1995, 2007) is based on cognitive task analyses of how analogies are used effectively in lessons, textbooks, software, and Internet sites. In both formal experiments and classroom settings, the use of the model has been found to increase students' learning and interest in science concepts.

The Teaching-With-Analogies Model includes six steps. When applied to the analogy between Newton's law of gravitational force and Coulomb's law of electrical force, these steps are:

1. Introduce the target concept, Coulomb's law, to students.
2. Remind students of what they know of the analog concept, Newton's law.
3. Identify relevant features of Coulomb's and Newton's laws.
4. Connect (map) the similar features of the laws.
5. Indicate where the analogy between the laws breaks down.
6. Draw conclusions about the laws.

The analogy between the laws breaks down because the Newton's law G is a relatively small number and the Coulomb's law k is a relatively large number. This means that the gravitational force between, say, two 1-kg masses is tiny, whereas the electrical force between two 1-C charges is comparatively large. An important conclusion to draw is that gravity plays a more important role than electricity at planetary levels, but electricity plays a more important role than gravity at atomic and molecular levels.

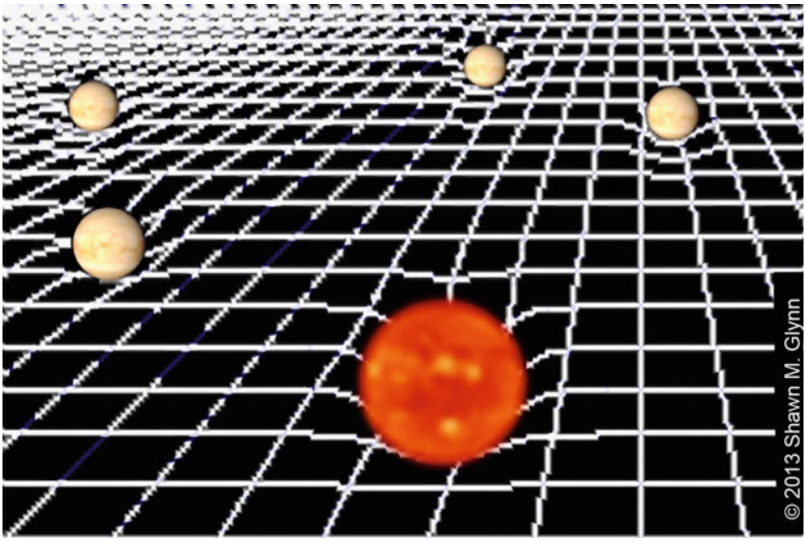
The Teaching-With-Analogies Model implies that teachers should try to select analogs that share many similar features with the target concept. In general, the more features shared, the better the analogy. Another implication is that teachers should verify that students have not formed misconceptions. One way to do this is to ask focused questions about features that are not shared between the analog and the target concept.

When teachers show students how to use the Teaching-With-Analogies Model, it becomes a Learning-With-Analogies Model (Glynn 1995, 2007), and the students can use its steps as guides when constructing analogies of their own (e.g., a heart is like a force pump, a kidney is like a waste filter, and a pulsar is like a lighthouse). Students are naturally inclined to generate analogies when learning science, but the analogies will be of higher quality if the students are taught how to systematically generate them. Sometimes these analogies are even more meaningful than those provided by teachers because the students draw on their own knowledge to construct them. Constructing analogies also helps students take a more independent approach to learning.

An analogy drawn between a concept covered earlier in a course (e.g., Newton's law of gravitational force) and one covered later (e.g., Coulomb's law of electrical force) is particularly effective because the earlier concept is familiar to every student. The previously discussed concept, however, should be reviewed to refresh students' memories.

An analogy can also foster students' transition to a new conceptualization of a previously taught concept. For example, as Newton conceptualized it, gravity is a linearly directed force: Objects with mass exert this attractive force. This conceptualization works well most of the time, and that is the reason it is still taught and frequently used. A better conceptualization, however, is that developed by Einstein: Gravity is a consequence of the shape of the universe. In this conceptualization, objects with mass alter the curvature of space-time, the 4-dimensional "fabric" of the universe. In Einstein's general theory of relativity, differential field equations describe how the shape of space-time depends on the amount of matter or energy in a region of space.

Because it is difficult to visualize 4-dimensional space-time, a 3-dimensional rubber sheet analogy is often used (see Fig. 3). Space-time is viewed as a sheet of rubber, stretched flat when there is no matter present.



Analogies, Role in Science Learning, Fig. 3 A rubber sheet analogy of space-time

If a massive object like a star is placed on this rubber sheet, the object pushes down into the sheet creating a cuplike depression. Less massive objects, like planets, create smaller depressions. An object like an asteroid traveling nearby the star would not pass the star in a straight line; the path would curve, as if the asteroid were rolling along the depression in the rubber sheet. If an asteroid were in the right position, going just the right speed, it might remain in the depression and orbit around the star.

The rubber sheet analogy helps students to draw important conclusions about space-time and Einstein's theory of general relativity. The curvature of space-time is responsible for gravity. Gravity is strong where space-time is curved and absent where it is flat. Although helpful in conceptualizing space-time, the rubber sheet analogy – like all analogies – breaks down. For example, the analogy is 3-dimensional rather than 4-dimensional, focusing on the spatial feature of space-time and ignoring the temporal feature.

Summary

Well-designed analogies are pedagogical tools that can support students' science learning. The steps in the Teaching-With-Analogies Model describe how to design effective analogies for use in classrooms, textbooks, software programs, and Internet sites. Well-designed analogies can help students understand many kinds of science concepts, including those with hard-to-visualize systems of interacting parts.

Externalizing Internal Mental Representations

Over the past two decades, consistent research findings have shown that a variety of external representations used by science teachers, science teacher educators, and science education researchers can lead to successful student learning outcomes. These external representations include analogies, metaphors, and models and model-based learning which have the effect of helping teachers and students externalize their internal mental representations providing avenues for discussion and more focused learning (see for example, Aubusson et al. 2006; Khine and Saleh 2011). This short entry deals with analogies as one form of external representation that is introduced by science teachers and used effectively with both elementary and secondary students when they learn a variety of science concepts.

Need for a Guide to Help Science Teachers Use Analogies Effectively

In science lessons, both teachers and students generate analogies, and sometimes these work well and sometimes they do not. Research has shown that analogies require explanation and analysis if they are to effectively contribute to students' science learning. Consequently, if analogies are to be used most effectively by science teachers, then a carefully planned teaching strategy is required that makes the analogies relevant to as many students as possible. As the vast majority of science teachers have no formal training in the use of analogies, it is not surprising that analogies used in teaching and learning are less effective than they could be.

In working with a group of science teachers who were interested in improving their teaching with analogies, Treagust et al. (1998) initially used an existing analogy-teaching model which was modified and adopted by teachers who taught a grade 10 optics class on refraction. The findings from this optics study and other studies led to the development of an approach called the FAR guide for teaching science with analogies, the letters being the three phases of the teaching strategy – focus–action–reflection (Treagust et al. 1998). This instructional strategy was designed to help teachers maximize the benefits and minimize the constraints of analogies when they arise in classroom discourse or in textbooks.

In the **focus** phase from his or her experience, the teacher decides whether or not the (1) *concept* is difficult, unfamiliar, or abstract, (2) what ideas about the topic that the *students* already know, and (3) whether or not the *analog* to be used is familiar to the students.

In the **action** phase, the teacher presents the analogy by (1) discussing those features of the analog and the science concept that are *alike*, drawing similarities between them and then (2) discussing those aspects where the analog is *unlike* the science concept.

In the **reflection** phase, the teacher and students discuss the analogy and *conclude* whether or not the analogy was clear and useful or confusing. Finally, the teacher reflects on the effectiveness of the analogy and whether or not *improvements* to the analogy should be made in light of outcomes.

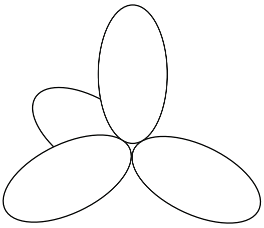
The phases of the FAR guide have become second nature to those teachers who become familiar with them, and these phases have been usefully applied to teaching and learning science concepts with analogies. A wide range of analogies for use in physics, chemistry, and biology lessons using the FAR guide is presented in Harrison and Coll (2008). One of these

49 analogies – balloon analogy for chemical bonds and molecular shapes – is presented below as a prototypical example.

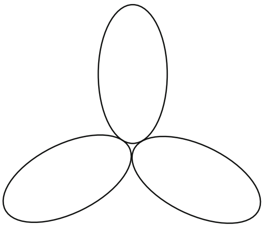
Balloon Analogy for Chemical Bonds and Molecular Shapes Using Focus–Action–Reflection (FAR Guide)

For this grade 11 chemistry lesson, the topic being taught is the forces between nuclei and electrons which result in the formation of covalent bonds that are electrostatic in nature. The repulsion forces between electron pairs around a central nucleus produce linear, trigonal planar, and tetrahedral molecules in, for example, ethyne, ethene, and methane, respectively. The teacher demonstrates the repulsion between adjacent electron pairs by means of four elliptical balloons inflated to their maximum with their stems tied together. The pneumatic pressure of four balloons forces them into a tetrahedral shape, and when one balloon is burst, the remaining three take up a trigonal planar shape. When a second balloon is burst, the two remaining become roughly linear (see Figs. 1, 2 and 3). Teachers can use this balloon model as an advance organizer for the lesson. This analogy works best once the valence shell electron pair repulsion (VSEPR) rules have been described which predict the shape of individual molecules based upon the extent of electron-pair electrostatic repulsion. Teachers typically use this demonstration along side other external representations such as space-filling and ball-and-stick models of molecules.

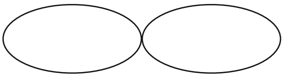
The FAR guide has been implemented with both secondary and elementary students. For example, Sickel and Friedrichsen (2012) engaged students (grade 9–12) in a predator–prey simulation to teach natural selection. The authors noted that, after using the FAR guide, classroom discussion was guided in a more purposeful way and that students had a more coherent understanding of biological processes and mechanisms. In a study with elementary students (grades 1–4) studying a variety of science topics, Smith and Abell (2008) noted that after implementing the FAR guide, teachers reported increased confidence and enthusiasm for teaching the topics and were more aware of the need for students to be familiar with the analog so that they could identify similarities and differences.



Analogies: Uses in Teaching, Fig. 1 Four balloons tied together form a tetrahedral shape



Analogies: Uses in Teaching, Fig. 2 Three balloons tied together (one is burst) form a planar shape



Analogies: Uses in Teaching, Fig. 3 Two balloons (another one burst) form a linear shape

Using Analogies to Engender Interest, Motivation and Conceptual Change

There is much potential for analogies to be used in the science classroom to not only improve conceptual understanding and engender conceptual change but also enhance student interest and motivation. Introducing analogies into science lessons and using them to achieve both conceptual and affective outcomes are consistent with many researchers who argue for a unity between the cognitive and emotional dimensions of learning. Similarly, children's and young people's thinking often involves visual imagery; by using their imagination, analogies used in the science classroom can create additional interest in the lessons. As noted above, researchers have reported that students enjoy lessons in which analogies were used to learn science concepts. Also teachers have exhibited enthusiasm and were animated when using analogies in their teaching. An excellent example of how analogies engender interest and motivation in science conceptualization is the interview with a student named Dana in the optics lessons reported by Harrison in Harrison and Coll (2008). Essentially, Dana's responses to questions about the optics lessons went from disinterested to enthusiastic and knowledgeable once the analogy was evoked. Thus, while the evidence is scant, there appears to be a prima facie case to investigate the relationship between learning and teaching with analogies and students' interest and enthusiasm for science.

Concluding Comments

The teachers who trialed this instructional strategy in their classrooms helped to refine the FAR guide to a point where it can enhance student understanding of the science concepts explained using analogies. Both teachers and researchers have reported viable learning outcomes with this approach. Provided teachers spend time negotiating each analog's familiarity and establishing the analogy's similarities and differences with their students, analogies can be powerful and motivating learning tools. The FAR guide does more than just establish analog familiarity and ensure valid shared and unshared mapping; it encourages teachers to regularly self-evaluate their teaching, and this should result in enhanced teaching and learning of science. Furthermore, when teachers use analogies effectively in their lessons, the opportunities for enhanced student interest and motivation are increased.

Aquaria

Steve Yalowitz
Institute of Learning Innovation, Annapolis,
MD, USA

Introduction

An aquarium, or aquaria in plural form, is a site that offers visitors the chance to view water- and land-based animals (either marine or freshwater) in a museum-like environment; they include a variety of species including fish, amphibians, reptiles, and mammals; they include tanks, hands-on exhibits, interactives, educational programs, and sometimes touch experiences. Much of a person's learning during their lifetime happens outside of formal learning environments such as schools and universities, as documented by the National Research Council (USA) in

Learning Science in Informal Environments: People, Places, and Pursuits. Free-choice learning at places like museums, zoos, and aquariums is learning that is self-motivated, lifelong, and personally guided by an individual's personal needs and interests. While the exact definition of a public aquarium can be debated, it is estimated there are somewhere between 125 and 150 public aquaria worldwide; around 75 of these are in the United States alone (source: Wikipedia, "public aquarium").

History and Educational Opportunities in Aquaria

While people have kept fish indoors and on display dating back to the Roman Empire, public aquaria are roughly 150 years old starting with the first public aquarium opening in the London Zoo in 1853. The Association of Zoos and Aquariums (AZA) estimates that the 225 aquaria and zoos accredited by AZA account for more than 175 million visits worldwide; the largest aquaria attract more than two million visitors a year. Much of what motivates people to visit these institutions is viewing live animals they would not normally get to see, and this offers a unique opportunity for aquaria to connect and engage with visitors through exhibits, programs, and live animal "touch" experiences and increasingly through web- and mobile-based experiences.

Learning in Aquaria

Most public aquaria consider themselves to be informal science learning institutions and have education departments that work with local school groups or whole education systems, providing materials before, during, or after field trips to complement and enhance the visit itself. The learning that occurs during field trips typically focuses on cognitive information tied directly to the school curricula for that particular grade. However, the majority of aquaria visitors come outside of field trips, and learning for these visitors tends to be more open-ended, visitor driven, and more of a combination of cognitive, affective, social, and other types of learning than exclusively cognitive learning. In fact, visitor learning is influenced most by individual visitors' interests, prior experiences, knowledge, and motivations for visiting. Regardless of who someone is, what visitors learn in aquaria tends to be focused on the animals, although visitors often learn about the animals' habitats and human impact on animals and the ocean.

Learning About Conservation-Related Issues

In the past decade, there has been a noticeable shift from zoos and aquaria exhibiting animals to including messages about conserving animals and their habitats; including conservation messages is now common in institutional mission statements. As a result, research is being conducted about how a visit impacts visitors' conservation-related attitudes, beliefs, and behaviors (Yalowitz 2004). Recent studies have looked at the cumulative impact of visits across aquaria and zoo visits, including the *Why Zoos and Aquariums Matter* study (Falk et al. 2007), finding that aquaria and zoo visitors bring a higher-than-expected knowledge about basic ecological concepts, experience a stronger connection to nature as a result of their visit, have their values and attitudes reinforced, are prompted to reconsider their role in environmental problems, and can see themselves as part of the solution. While this is good news to aquaria and zoos, the *Assessing Public Awareness, Attitudes, and Actions: America and the Ocean* study found that the public still had only a marginal understanding of how oceans work, their relative importance, and the challenges we face in keeping oceans healthy. However, this study found that certain audiences, like teens and "tweens" aged 10–12 years, had a higher level of awareness about ocean-related issues compared to adults.

Learning About Climate Change

Studies at informal science education venues have shown that science-based institutions such as aquaria have visitors who are more aware of and knowledgeable about climate change compared to the general public. A supplemental round of funding by the National Oceanic and Atmospheric Administration (NOAA) in 2009 specifically supported aquaria and zoos communicating about climate change; one project is designed to build a shared community where zoos and aquariums can share information about interpreting climate change (see www.climateinterpreter.org). Aquaria are also starting to categorize visitors based on the well-known Global Warming's Six Americas Study to gauge whether aquarium visitors have different attitudes from the general public regarding climate change. One recently released publication discusses recent approaches and research for specifically communicating climate change in zoos and aquariums (Grajal and Goldman 2012).

Summary

In summary, aquaria have had a long history first as attractions and then as educational institutions who can effectively communicate science content about animals and their place in the world. As aquaria make the shift to stressing the importance of protecting animals, their habitats, and encouraging environmental stewardship, they have great potential to not only communicate science concepts and issues but empower visitors to take care of the world in which they live.

Links

Association of Science and Technology Centers (ASTC) – represents science-based visitor-based organizations, such as science museums, science centers, natural history museums, zoos, aquaria, and the like.

Association of Zoos and Aquariums (AZA) – international association representing zoos and aquaria, with a particular focus on education.

ClimateInterpreter.org – a site for the zoo and aquarium community to share about how to most effectively communicate climate change to the public.

Informalscience.org – a repository of evaluation and research reports, many focusing on learning and education; one can search evaluation reports by "aquarium."

NOAA Ocean Education Grants for AZA Aquariums: FY09 – a series of grants "to support education projects designed to engage the public in activities that increase ocean and/or climate literacy and the adoption of a stewardship ethic."

The Ocean Project (TOP) – a nonprofit that "advances ocean conservation in partnership with zoos, aquariums, and museums around the world."

Argumentation in Science Education

Argumentation may be conceptualized in a range of ways, at least two of which are relevant for science education: first, argumentation as justification, or the evaluation of knowledge claims in the light of available evidence, and, second, argumentation as persuasion of an audience (Erduran and Jiménez-Aleixandre 2008). Argumentation plays a central role in the building of explanations, models, and theories, as scientists use arguments to relate the evidence they select to justify the claims they reach through use of warrants (Toulmin 1958). In science education, argumentation studies can be framed in two complementary approaches: on the one hand a theoretical approach – grounded in epistemology – about appropriation of scientific practices, that is, epistemic practices associated with producing, communicating, and evaluating knowledge in science, and on the other hand a policy approach (central, for instance, to the Program for Indicators of Student Assessment, PISA) emphasizing the development of scientific competences, in particular the ability of using scientific evidence to draw and communicate conclusions and of identifying the assumptions, evidence, and reasoning behind conclusions. The rationales for argumentation in science education draw also from other fields, such as language sciences, psychology, and science studies. Rather than being a one-way relationship, argumentation studies and science education have the potential to inform these perspectives, leading to fruitful interactions.

It is not easy to disentangle the influences of these fields, as sometimes they are combined, as happens with science studies, highlighting the importance of discourse in the construction of scientific knowledge, and language studies. Not all linguistic interactions should be considered as argumentative, but only those concerning the process of contrasting two or more views or meanings and of negotiating a solution. From discursive interactions, the ones that can be regarded as argumentative are those involving, for instance, formulating claims, supporting them with evidence, or evaluating arguments. On the other hand, argumentation in science education is not just a linguistic activity, but requires drawing from the relevant knowledge, selecting appropriate sources, and analyzing it by means of particular skills. Developmental psychology has examined, for instance, the epistemological and cognitive prerequisites for engaging in argumentation. A developmental pattern of epistemic cognition is reviewed by Garcia-Mila and Andersen (in Erduran and Jiménez-Aleixandre 2008). There is also a perspective viewing argumentation as a psychosocial practice embedded in institutional, historical, and cultural contexts (Muller-Mirza and Perret-Clermont 2009), a view combining developmental, social, and sociocultural approaches.

A key feature of argumentation, according to Osborne, MacPherson, Patterson, and Szu (in Khine 2012), is the role of criticism in the construction of knowledge. The implication would be that learners should be provided with opportunities to engage in critique and evaluation. About the contributions of argumentation to science learning, Tiberghien (in Erduran and Jiménez-Aleixandre 2008) summarizes the place of argumentation in science education in terms of three goals: acquiring knowledge about nature of science, developing citizenship, and developing higher-order thinking skills.

Jiménez-Aleixandre and Erduran (in Erduran and Jiménez-Aleixandre 2008) propose that argumentation may support the following: (a) the access to the cognitive and metacognitive processes characterizing expert performance, (b) the development of communicative competences and critical thinking, (c) scientific literacy, (d) the enculturation into the practices of scientific culture, and (e) the development of reasoning.

Research on Argumentation in Science Education

Research on argumentation in science education is a relatively recent phenomenon, beginning in the 1990s. Early studies concentrated on exploration of whether or not argumentation took place in science classrooms, often with a negative outcome in terms of children's inability to formulate sound arguments. A large number of studies focused on students' argumentation (Kelly and Takao 2002). In time, the focus shifted to the study of quality of argumentation and methodological approaches to the study of argumentation in science classroom. More recently work has been dedicated to the design of learning environments and professional development programs to support the implementation of argumentation in everyday classrooms. The emphasis in argumentation studies has varied in the work of researchers from different parts of the world. A distinctive feature of argumentation studies in Europe and in general of the attention given to argumentation throughout Europe in the last decade is its connection to the development of competences. In particular, argumentation is framed in the development of scientific competence in light of the PISA framework. In other parts of the world, for instance, in the United States, argumentation is framed in scientific practices. A great deal of research has been done in relation to argumentation in the context of socio-scientific issues (SSI). In relation to these issues, science is involved in a social debate, typically concerning personal or political decision-making related to health or environmental controversies. The notion of SSI is grounded on previous approaches as science, technology, and society or science-based social issues. While all socio-scientific issues are scientific, it needs also to be acknowledged that the controversies, either in the classroom or in society, have sometimes a stronger ethical component, while in other cases students need to appeal primarily to scientific explanations.

There have been numerous research and development initiatives across the world to integrate information and communication technologies (ICT) in argumentation studies. A key rationale for the choice of argument and argumentation as a genre in ICT has been based on the notion that learning activities should confront cognition and its foundations. In this sense, substantial amount of research has been dedicated to how best to scaffold argumentative processes ranging from generating to justification of claims. Research in the context of teaching and learning with tools such as scientific visualization tools, databases, data collection and analysis tools, computer-based simulations, and modeling tools has been widespread. Another trend in the use of ICT in argumentation research has been the contextualization of argumentation in scientific inquiry processes. ICT tools can provide a graphical platform in which participants may collaboratively construct an argument (on one computer or on different computers in asynchronous mode) or participate in synchronous discussions. The argumentative map produced during the construction or during the discussion is an artifact that participants can exploit in further activities, as opposed to face-to-face discussions from which students cannot "physically" extract previous outcomes.

A significant line of work in argumentation relies on models of professional development based on Lee Shulman' notion of teachers' "pedagogical content knowledge" as outlined by Zohar (in Erduran and Jiménez-Aleixandre 2008). Other approaches to teacher education have extended the work of educational psychologists such as Deanna Kuhn in application to science education. In the context of argumentation, advocates for effective professional development have argued that the teaching of argumentation requires a model of pedagogy that is based on knowledge construction as opposed to knowledge transmission. Teachers' enculturation into new models of pedagogy to support argumentation requires systematic and long-term professional development.

Toulmin's Model for Analyzing Arguments

Toulmin's Argument Pattern (TAP) is a model or scheme for analyzing arguments that was developed by Stephen Toulmin (1958) in his book *The Uses of Argument* (updated in a second edition in 2003). Toulmin's model is intended for the purposes of describing argumentation in practice and of studying argumentation as it is practiced in the natural languages and therefore away from the schemes of formal logic. This practical nature makes it a useful tool in order to analyze discourse in situations where new knowledge is being generated, as science laboratories or classrooms. Formal logic frameworks, while being adequate for analyzing established knowledge, may be less fit for those other fluid, ill-defined contexts. According to Toulmin, TAP represents a "practical" or "substantial" argument instead of a theoretical argument in the form of premises to conclusions.

The focus of Toulmin's model is on the function of arguments in order to justify claims, placing the validity of an argument in the coherence of its justification. In this approach a justification of a statement or set of statements is characterized as an argument to support a stated claim. He proposes to move away from the logic-mathematical model of arguments and to draw on the jurisprudential model, using it as an analogy. His goal was to elaborate a tool of analysis more sophisticated than the model consisting of minor premise, major premise, and conclusion. Toulmin suggests that the examination of the form of arguments from different fields (e.g., law, science, and politics) yields a common pattern consisting of six elements or components, claim, data, warrants, backings, qualifiers, and rebuttals, which are discussed below. This scheme is known as Toulmin's Argument Pattern or TAP.

TAP embodies some points about arguments and reasoning, as, for instance, (a) that arguments involve not only supporting points of view but also attacking them, (b) that conclusions drawn from reasoning may be qualified, or (c) that standards of reasoning can be field dependent. As Hitchcock and Verheij point out, in the introduction to a special issue of the journal *Argumentation* in 2005 devoted to the influence of Toulmin's layout of arguments, each of these points is illustrated by Toulmin's layout: for instance, rebuttals illustrate point (a), qualifier point (b), and warrant and backing point (c).

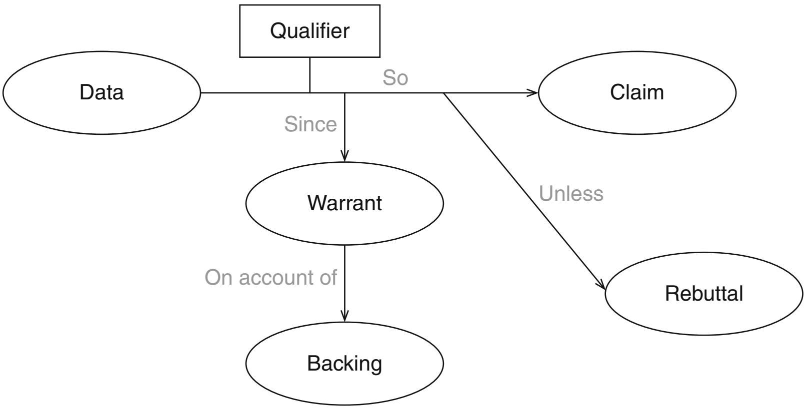
Components of Toulmin's Argument Pattern

In Toulmin's scheme, an argument, or in other words the result of coordinating an explanation with the evidence supporting it, has three essential components, in his own terms the first skeleton of a pattern: claim (C), data (D), and warrant (W). There are three components that account for other features of arguments: backing (B), modal qualifiers (Q), and rebuttals (R). Besides Toulmin's original characterization, some modifications of the components in science education literature are presented:

Claim: the statement, knowledge claim, or conclusion that has to be supported or disproved (in science, explanations seeking to interpret natural phenomena constitute a relevant sort of claim).

Data: observations, facts, or experiments that are appealed to as a foundation for the claim or, in more general terms, that are used in order to evaluate a claim. In science education the term *evidence* has been used in some argumentation contexts: it should be noted that is not fully interchangeable with *datum*. In other analyses data and warrants are collapsed under the term *evidence*.

Warrant: a statement that relates the claim to the data, in order to show that, taking these data as



Argumentation, Fig. 1 Toulmin's Argument Pattern (Toulmin 1958)

a starting point, the step to the claim or conclusion is a legitimate one. In science education the terms *justification* and *reasoning* have also been used instead of warrant.

Backing: generalizations making explicit the body of knowledge or experience relied on to establish the authority or trustworthiness of the warrants. In science education they may be, for instance, appeals to theories, and the term *background knowledge* has sometimes been used.

Modal qualifiers: indicate the strength conferred by the warrant and express the grade of certainty or uncertainty of an argument, for instance, "probably," "for sure," and "it depends."

Conditions for rebuttal: for Toulmin, they acknowledge the restrictions or exceptions to a claim. However, in analyses of argumentative contexts where a confrontation between two opposite explanations exists, a *rebuttal* means a criticism of the evidence of the opponent, as discussed in detail in Erduran's chapter in Erduran and Jiménez-Aleixandre (2008).

Toulmin also proposed a graphical representation for the relationships among these components that is reproduced in Fig. 1.

For Toulmin, some components of arguments are the same, while others differ across fields of inquiry. He termed the elements that are similar across fields as being field-invariant features of arguments, whereas those that differed were called field-dependent features. Data, claims, warrants, backings, rebuttals, and qualifiers are field invariant, while "what counts" as data, warrant, or backing are field dependent. Thus, appeals to justify claims used to craft historical explanations would not necessarily be the same kind of appeals used to support claims for causal or statistical-probabilistic explanations. The flexibility of Toulmin's model to function in both field-dependent and field-invariant contexts provides an advantage for understanding and evaluating the students' arguments in science classrooms.

Toulmin's Argument Pattern in Science Education

Toulmin's Argument Pattern (TAP) has been applied in science education in numerous ways. It has influenced the conceptualization of argumentation in science education theory, practice, and policy. Though not acknowledged explicitly, there are examples of curricular policy documents from around the world that have incorporated some of the notions and terminology embedded in the TAP framework, for instance, the Program for International Student Assessment (PISA), which emphasizes the role of evidence in the reaching of conclusions. Jiménez-Aleixandre and Erduran (in Erduran and Jiménez-Aleixandre 2008) discuss examples of steering documents and standards from different countries that incorporate ideas from Toulmin's model.

TAP has been used extensively as an analytical tool in the study of argumentation in the science classroom. As summarized by Erduran (in Erduran and Jiménez-Aleixandre 2008), apart from its methodological use, TAP has been used as a framework for understanding the nature of scientific reasoning, as a theoretical tool and representation, and as an indicator of problem-solving in expert-novice studies. In situating argumentation as a particular type of communicative interaction, Rigotti and Greco Morasso (in Muller-Mirza and Perret-Clermont 2009) propose a model that draws on the discursive nature of Toulmin's framework and may be useful for arguments in socio-scientific contexts.

Despite its various adaptations and uses, Toulmin's work has received much criticism within the science education community. A primary criticism has centered on the issue of difficulty in capturing dialogic argumentation. It has been argued that Toulmin's scheme is a model of rationale discourse adequate primarily for a monologue, although the inclusion of the modal qualifier can be conceived as the introduction of an element of dialogue. Richard Duschl (in Erduran and Jiménez-Aleixandre 2008) advocates that the focus of argumentation analysis should be on epistemic criteria and that TAP is not effective for the purposes of the clarification of "what counts" as claim, data, warrant, and backing or, in other words, the field-dependent dimensions of arguments. Duschl proposes Douglas Walton's reasoning schemes as an alternative to analyze dialectical exchanges in science classrooms. Further methodological difficulties have been described by other researchers, as, for instance, that organizing student discourse into Toulmin's argument components required careful attention to the contextualized use of language. Kelly and Takao (2002) discuss the ambiguity of Toulmin's categorical system, pointing out that in the context of actual arguments, claims may serve as data in more complex chains of reasoning, as is the case in written arguments. A second criticism raised by these authors is that Toulmin's approach does not consider the relative epistemic status of knowledge claims. In order to address these shortcomings, Kelly and Takao developed an analytic framework focused on the epistemic level of propositions within an argument and how they are connected within and across levels.

Apart from research-based applications of TAP in science education, there are examples of work where TAP has been used to inform the production of resources for teaching and learning as well as professional development of science teachers. For example, TAP has been used to structure the students' writing of arguments and the design of training programs for teachers. The adaptation of TAP as a structure and a process of argumentation has also yielded understanding of the hierarchy of pedagogical strategies that underlie effective teaching of argumentation (Zohar in Erduran and Jiménez-Aleixandre 2008).

Future Perspectives

Despite wealth of research in classroom-based research on argumentation since the mid-1990s, reviews suggest that the territory remains ripe for numerous lines of work in the future. An aspect of argumentation research that has not been addressed sufficiently in the literature is the relationship between disciplinary content or conceptual knowledge and argument structures and processes. There is also little work dedicated to the exploration of students' and teachers' perceptions of argumentation. Likewise, developmental trajectories of teachers in learning argumentation in a longitudinal fashion are virtually nonexistent. Future studies could build on investigations on the cultural or contextual factors that impact teachers' and learners' argumentation in science classrooms. The study of emotions, gender, and power relations in relation to argumentation is virtually inexistent in science education research. While acknowledging the potential of argumentation to engage students in scientific practices, McDonald and Kelly (in Khine 2012) point out the limitations of an increasingly specific focus on argumentation in student discourse, for instance, narrow focus on one type of discourse and analytic limitations in terms of understanding the quality of students' classroom science discourse. They suggest scientific sensemaking as a broader perspective on science discourse practices that would be more productive to support both science teaching and learning and science education research. This perspective may be one future direction for the integration of argumentation studies in broader frames. A fruitful new territory for argumentation research could draw from "science studies" – the interdisciplinary studies on science with implications for science education.

Argumentation Environments

Camillia Matuk
Graduate School of Education, University of
California, Berkeley, Berkeley, CA, USA

Definition

Argumentation environments are computer-based systems that engage and support learners in constructive and collaborative activities around argumentation, such as creating, editing, communicating, interpreting, and/or critiquing arguments. Scientific argumentation, as a process of building upon or refuting claims based on empirical evidence to arrive at agreed-upon scientific conclusions, challenges learners in that it requires both conceptual understanding of relevant content knowledge and mastery over various problem-solving and social skills. As such, argumentation environments typically consist of technology-based tools integrated into extended face-to-face or computer-supported activities for K-16 students and designed to address the dual pedagogical goals of helping students learn the practices of scientific argumentation (learning to argue), as well as the content knowledge necessary for engaging in those practices (arguing to learn) (Scheuer et al. 2010).

Features of Argumentation Environments

Two kinds of argumentation environments may be distinguished. Discussion-oriented argumentation environments emphasize the use of arguments in collaborative dialogue among peers, whereas argument modeling environments support the creation of arguments, often by piecing together primitives and testing these against an underlying model. Whether a system is discussion- or modeling-oriented has large impacts on the possible kinds of learner interactions, automated analyses, and feedback that can be generated. However, any one system may feature characteristics of both categories. Generally, although to varying extents, the tools within argumentation environments focus on scaffolding idea generation; information seeking; text planning, structuring, and linearizing; argument expansion, elaboration, and evaluation; and collaboration and debate. The manners by which these scaffolds are manifested reflect designers' pedagogical goals and theoretical perspectives on argumentation (Clark et al. 2007). Nevertheless, argumentation environments typically include several features in common (Hilton 2010): (1) contextualizing representations, (2) access to relevant content information, (3) support for communication and collaboration, (4) argument representations, (5) socio-cognitive structures, and (6) metacognitive supports.

(1) *Contextualizing representations* embed argumentation in an overarching activity, helping learners realize the relevance of argumentation and motivating them to apply their knowledge and skills in meaningful ways. Students are either presented with or allowed to explore representations such as narrative, images, video, and other interactive media. These serve to establish a problem scenario and prompt students to develop solutions, in which they must take on particular perspectives, seek information, and justify and communicate their claims.

(2) *Access to relevant content information* helps reduce learners' cognitive load when engaged in constructing and communicating arguments. Through explorable content-rich representations, students may access student-generated or curriculum author-generated databases of information from which they may gather information to help establish a perspective on a given topic and to use as evidence in support or refute of claims in their arguments. These databases may be contained such that students explore it without leaving the environment, or else they may be provided access to external resources, such as the World Wide Web. Often, tools associated with these information databases support information processing tasks, such as gathering, documenting, and sorting information, as well as managing sources of that information. These tools allow students to create and maintain intermediate representations toward preparing final arguments. For example, some tools may allow open-ended note-taking, list creation, or direct annotation on an information source. Such tools may furthermore support cognitive actions such as sorting, grouping, and tagging individual information entries, that together help students prepare to formally present their ideas.

(3) *Support for communication and collaboration* generally consists of shared spaces with tools to promote social interactions and to encourage learners building and negotiating joint understandings. These supports often afford the co-construction of artifacts, including knowledge repositories, intermediate representations, as well as text and diagrams of final agreed-upon arguments. They may also offer platforms on which learners can review, critique, and debate each other's points of view.

Environments differ in the degree to which the computer mediates learners' interactions. For example, certain systems have embedded support for such communication and collaboration and thus allow interactions among spatially or temporally separated individuals via an entirely virtual space. In these cases, tools may permit synchronous and/or asynchronous communication among students via real-time chat applications or archived discussion forums. Other environments support only single-user interaction, but may instead promote face-to-face interactions within groups of students sharing the same computer station, or among individuals via a group projection system. Still other systems may support individual learners through student-to-computer interaction.

(4) *Argument representations* are the ways by which arguments are presented to learners. By offering visual ways to externalize ideas as learners formulate or review the structure of their arguments, they allow learners to recognize, through visual inspection, the relations between elements as well as any missing components of their arguments. Argument representations vary in appearance, often taking the form of text containers, linear or threaded discussions, matrices, or node-link graphs. They may also vary in the manners by which learners are able to interact them. For example, some representations may be individually or collaboratively constructed and may scaffold the construction of particular argumentative structures by limiting, requiring, or allowing learners to create any number and particular kinds of elements and relations between them. Other representations may be system generated and provide learners with artifacts for inspection, reflection, and critique. Certain systems

display argument representations as part of a linear series of activities, whereas others support the simultaneous use of multiple representations. Argument representations tend to reflect the particular conceptual primitives that make up an argument (e.g., hypothesis, data, evidence) and which differ depending on designers' underlying theoretical perspectives.

(5) *Sociocultural design* involves specifying and guiding sequences of activities to maximize the success of interactions among learners, as well as the quality of learners' resulting arguments. For example, some environments orchestrate social interactions by distributing roles in which learners must take on particular perspectives and tasks. Other systems group learners based on personal characteristics (e.g., gender, prior knowledge) or on their similar or opposing views determined from learners' responses to previous items. Still other systems moderate learner discussions in various ways, such as by seeding discussions with predetermined topics.

(6) *Metacognitive supports* encourage learners to monitor and reflect upon their understanding and on the quality of their own and of others' contributions. Supports may include visual or numeric displays that give learners information on group dynamics. These may include participation metrics in terms of interactions had with others and of contributions made or requiring attention by themselves and others during joint tasks. They may also include displays of socio-cognitive information in terms of levels of certainty and agreement among group members. Metacognitive supports may also involve various kinds of feedback, either generated by a human moderator or by the system itself. For example, learners may receive adaptive feedback on the quality of their contributions based on automated analyses of their submitted work, or generic text prompts to reflect upon the state of their understanding and to make decisions about the information they may require to further refine their ideas.

Assessment and Feedback

The technological capacities of computer-based argumentation environments offer various ways to assess and understand how people learn through argumentation and how such systems can support them (Scheuer et al. 2012). These techniques vary in sophistication depending on the nature of the objects of assessment, whether these consist of learners' natural language contributions or entries in tightly constrained input fields. Generally, analyses of argumentation focus on identifying the content and patterns of learners' discussions in order to characterize how learners communicate with one another. From archived interactions within a system, for example, researchers can count and categorize the kinds of exchanges that occur between learners in terms of their argumentative functions (e.g., claims, warrants, evidence). Machine learning and artificial intelligence techniques can also be used to automatically identify patterns in the structure of learner-generated arguments and to evaluate their quality in terms of their positive attributes (e.g., evidence-backed claims, logical chain of reasoning) or negative ones (e.g., irrelevant contributions, lack of responsiveness). By then relating these measures to assessments of learners' content understanding and other interactions in the environment, researchers may gain a sense of how conceptual learning and argumentation skills develop over time as a result of learners' interactions in the environment. Results from these automated analyses may then be used to generate various forms of feedback (formative, summative) at different times (immediate, on-demand), from different sources (human moderator or system generated), and in various modes (text messages, colored highlighting). Automated feedback may either be sent to teachers to inform them on how to guide subsequent activities, or it may be delivered directly to the learner.

Implications for Learning

There are several educational benefits of learning through argumentation that features of argumentation environments, such as scaffolded role play, co-constructed artifacts, and dynamic argument visualizations, aim to support (Andriessen 2006). For instance, learners not only become familiar with various argumentative structures, but by engaging in key processes of argumentation such as elaborating, reasoning, and reflecting upon ideas, students achieve deeper understandings of those ideas. Furthermore, by participating in argumentation, students develop their sense of social awareness and their skills in collaborating with others. At the same time, practice in argumentation helps students become better at arguing, and thus, more competent members of knowledge-based professional communities.

Online argumentation environments can furthermore support specific twenty-first century skills. They develop learners' adaptability to changing information and contexts by scaffolding investigations into unfamiliar topics and distributing roles that give learners practice taking on perspectives different than their own. They also develop complex communication skills by providing learners with tools that orchestrate productive interactions with their peers and that scaffold them articulating their ideas. Argumentation environments furthermore support non-routine problem-solving by helping learners seek patterns and explore alternative perspectives as they evaluate and integrate large amounts of seemingly disparate information. They support self-management and self-development by providing students with tools for monitoring and reflecting upon their own and their peers' contributions. Finally, these environments develop learners' systems thinking skills in that arguments are themselves systems of functional components; thus, scaffolding tools in argumentation environments help students consider how various pieces of information fit together to form a coherent whole.

Research shows impacts of argumentation environments on students learning to argue. Indeed, depending on how they are designed and used, the scaffolding features in argumentation environments have the potential to support students' developing argumentation skills that equal or exceed what is observed in oral argumentation. At the same time, another research suggests that students better manage their argumentation activities face-to-face than mediated by a computer. Designers thus strive to create learner-centered environments that maintain the benefits of face-to-face interaction while capitalizing on the advantages of technology for providing adaptive instruction and for relieving the burden on teachers to provide individualized support to large classrooms of students during open-ended science inquiry activities.

Software Architecture and Technology

A number of free and proprietary software exist that have been explicitly designed to support argumentation in educational science inquiry settings (e.g., as opposed to argumentation in the legal, political, or social sciences domains). Currently, most of these argumentation environments are built upon unique software architectures that are independent of prior technology developments. They use two primary formats to save and exchange data between systems: state based and action based, each of which offers different affordances for automated analysis and feedback. Other domain-general software tools, such as wikis, blogs, forums, and diagramming tools, have been appropriated to support argumentation in educational science inquiry settings.

Asian Ancestry

Mijung Kim
University of Victoria, Victoria, Canada

In traditional Asian cultures, especially the Confucius tradition in East Asian countries, teachers were regarded as exemplary persons with knowledge, life experiences, wisdom, and compassion toward the world. Teachers were highly respected by the members of community; thus, their teaching and contributions to the community were influential and well accepted. Teacher-student relationship was built based on respect, trust, and care for each other. The traditional ways of knowing are based on the Confucian understanding of teaching and bringing up the younger generation to become good human beings with knowledge and wisdom (Hall and Ames 1987). Education was valued and teachers' status was high. Even though most educational traditions and practices have changed in response to modern societal changes, education is still highly valued and emphasized in Asian cultures.

Asian countries were rapidly industrialized and globalized in the nineteenth and twentieth centuries, adapting and transforming modernized education models from Western societies such as school subjects, school systems, curriculum, etc., into their local situations. In many Asian countries, schools use the same national curriculum which is authorized by the government. In junior and senior high schools, science is taught by science teachers who specialized in science and science education (specifically biology, chemistry, physics, and earth science).

Elementary science is taught mostly by teachers who specialized in elementary education, not specifically in science.

One of the current fundamental issues faced by teachers and students in Asian countries is the assessment system. In many countries, there are exam systems to evaluate students' knowledge and skills for university entrance. Such assessments have resulted in content-based curriculum and teaching practice in public schools (Kim et al. 2013) and also caused the emergence of problematic private education involving private tutoring and cramming for exams.

Despite the high level of student achievement in international assessments in science (e.g., TIMMS, PISA), exam-focused education in Asian countries has caused concern about students' creativity, inquiry skills, and attitudes toward science (Bybee and McCrae 2011). Recognizing this concern, many countries have started to recognize the importance of critical thinking, creativity, and problem-solving skills for the twenty-first-century learners and have attempted to innovate science curriculum and teaching practice with inquiry focus (Kim et al. 2013).

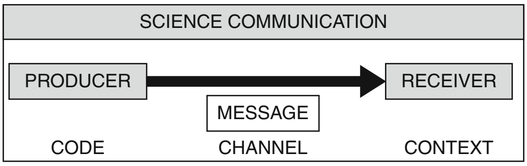
Assessing Science Communication: An Overview of the Literature

Alandeon W. Oliveira
University at Albany, State University of
New York, Albany, NY, USA

Introduction

The literature on assessment of science communication in classroom settings is vast and focused on a broad range of communicative behaviors, including talking, writing, reading, and listening. One useful way of understanding this literature is in terms of a message transmission model (see Fig. 1) wherein teachers and students take turns playing the roles of producers and receivers of a science message. A message (scientific information) is produced in a linguistic code (e.g., the English language) and transmitted via a particular channel (oral or visual) through the performance of communicative acts (e.g., utterances or texts) in a given context (e.g., whole-class discussion, lab write-up, written test). From this perspective, science communication entails production as well as reception of a scientific message. Much of the existing research has focused on the assessment (formal and informal) of one or more of these different dimensions of science communication.



Assessing Science Communication: An Overview of the Literature, Fig. 1 Message transmission model of science communication

Communicative Production of Science

The primary focus of this literature is the assessment of student-written production of science. Various studies have examined the use of writing templates to scaffold student-written communication in the context of science inquiry activities. The Science Writing Heuristic (SWH) is one such tool that has been used widely. Theoretically, the SWH represents a bridge between more personal, expressive forms of writing and the recognized form of the genre, the scientific laboratory report, which represents canonical patterns of presenting results, most especially the link between claims and evidence.

The SWH guides student-written communication through the provision of a series of prompts (What are my questions? What did I do? What did I see? What can I claim? How do I know? How have my ideas changed?). Keys et al. (1999) describe how the use of SWH in an eighth grade earth science class improves several aspects of student-written communication in science lab reports, including evidence-based reasoning, nature of science, and metacognition.

Considerably less attention has been given to the assessment of teacher production of science messages (both oral and written). One exception is a recent study by Glass and Oliveira (2014) who assess the communicative practices of five elementary teachers faced with the task of orally delivering a science text of relatively high linguistic complexity. Assessment of teacher oral production was conducted quantitatively through the combined use of two computer programs to measure relative linguistic complexity of both speech and text: the Simple Concordance Program SCP4.9 and the vocabulary profiler Classic-VP English v.3. This computer-based assessment revealed that oral discussions had an increased percentage of less sophisticated words (everyday parlance) and reduced use of more sophisticated vocabulary (academic terms) than found in the science books. In other words, teachers resorted to accommodation (i.e., provision of simplified linguistic input) in order to promote student comprehension (i.e., reception) of the textual contents of children's science books.

Lastly, some research has also been conducted on science curriculum developers' communicative production of written messages, particularly in science textbooks. Catley et al. (2010) point out that noncladogenic diagrams (ambiguous evolutionary depictions that place organisms in a linear progression rather than nested sets) in biology textbooks and popular science articles miscommunicate macroevolution as a process of biological change that is both anagenic (an entire species directly evolving into another rather than splitting or branching into two) and teleological (purpose or need driven). This research highlights the potential for visual miscommunication of science in curricular materials at the secondary and college levels.

Communicative Reception of Science

Research on the receptive end of science classroom communication has been primarily focused on the assessment of student reading, often underscoring students' difficulties in making sense of expository science texts written in the scientific genre. Norris and Phillips (1994) report that high school students tend to disregard hedges (tentative expressions such as probably, possibly, approximately, and occasionally) when reading popular science texts from the media and are generally unable to interpret those hedges as signals of tentativeness and inconclusiveness. In addition to ascribing higher certainty to the text than originally intended by the author, many students also misunderstand the epistemic status of written statements in popular science reports, often confusing justifications with evidence and conclusions.

Several studies have also examined students' reception of graphical or visual messages from curricular materials (e.g., pictorial representations in science books). This research shows that poorly designed images can lead to misunderstanding and confusion in picture-based science communication, regardless of topic or grade level. Colin et al. (2002) describe secondary students' difficulties in interpreting textbook images of optical phenomena (diffuse reflection, Young's principle of interference, converging lenses, Romer's discovery of the finite speed of light, and colors), including a tendency to ascribe a realistic status to light rays (represented by arrows), a story-like view of optical phenomena due to the classical left-to-right orientation of textbook illustrations, and mistaking colored lights for paints.

Conclusion

In sum, the existing literature highlights the multifaceted and diverse nature of science classroom communication. Communicative assessment can focus specifically on the production or reception of varied types of messages (speech, texts, visual images, etc.) by varied parties (science instructors, learners, curriculum writers, etc.) and take place in many types of contexts (classroom discussions, silent text reading, visual inspection of curricular images, etc.). Careful and reflective consideration should be given to these different aspects or dimensions in effort aimed at assessing the quality of communication in science classroom settings.

Assessing Students at the Margins

Jerome M. Shaw
Education Department, University of California - Santa Cruz, Santa Cruz, CA, USA

Assessing students at the margins can refer to either or both nonmainstream *students* or nonmainstream *settings*. The former might be females, students of color, or students from a language background other than English. For science education, nonmainstream settings include contexts such as museums and community-based programs.

Regardless of the particular student population or context, fairness in the assessment process is key. The *Standards for Educational and Psychological Testing* (AERA et al. 1999) describe fairness as encompassing lack of bias, equitable treatment, equality in outcomes, and opportunity to learn. The latter notion is further conceptualized by Pullin and Haertel (2008) to include the content taught and educational resources as well as classroom processes. Attention to these issues is important for all students; it is even more so for nonmainstream students who are often misrepresented or underserved by the assessment process.

From an assessment design perspective (Shaw 2005), the use of bias review panels and the approach known as universal test design (Thompson et al. 2002) aim to remove potential barriers and biases, while an assessment is being developed. For example, consider students whose native or primary language is different from that of the test, known as English learners (ELs) in the USA. Eliminating complex language that is irrelevant to the content being assessed can make assessment items more accessible to such students, thus improving the accuracy of the information provided by the assessment. With respect to assessment delivery, accommodations such as longer time and use of bilingual glossaries have been shown to increase fairness for ELs without advantaging them over native English-speaking peers (Abedi et al. 2004).

In many cases, the above strategies are coming to be seen as mainstream approaches for assessing students at the margins. They are readily applicable to school-based assessments, be they teacher-developed or large-scale external. Yet science learning is not confined to the four walls of a classroom. Assessment in nonmainstream settings offers interesting challenges and opportunities. In such settings comparability may be less of a concern such that standardization has less importance. Grasping what students have learned and are able to do is still worth knowing.

Fusco and Barton's (2001) work with a community-based science program offers insights to assessment in settings at the margins. Their efforts focused on performance assessment, which they saw as "an excellent resource to help create a participatory and inclusive practice of science that draws more closely and critically from the culture and practices of young people" (Fusco and Barton 2001, p. 352). This vision of fairness redefines marginalization through student advocacy, agency, and empowerment. Such "learner relevant assessment" strives to improve learning through critically incorporating student knowledge and background into all phases of the process.

Learner relevant assessment calls for an expanded definition of opportunity to learn and its consideration of what is taught as well as how. It draws on the notion of "culturally relevant pedagogy" and its propositions of students' academic success, cultural competence, and critical consciousness (Ladson-Billings 1995). Learner relevant assessment connects also to the concept of "cultural validity" (Solana-Flores and Nelson-Barber 2001), the effectiveness with which assessment addresses the socio-cultural influences that shape student thinking and the ways in which students make sense of items and respond to them (p. 555).

Learner relevant assessment envisions a process of assessment influenced by nonmainstream students' "daily lives, the assets they bring to [assessment] practices," along with "the possibility of a co-opted [assessment process] that would be respectful of who they are and are becoming" (Rahm 2010, p. 4). This is what assessing students at the margins is truly about.

Assessment Framework

Gabriela Noveanu
Curriculum, Institute for Educational Sciences,
Bucharest, Romania

Keywords

Assessment framework; NAEP; PISA; TIMSS

Assessment frameworks are guides for the design of the assessment. These portray the structure of the assessed curricula providing a context for discussing the purpose of the assessment and what it is trying to measure.

Trends in International Mathematics and Science Study (TIMSS) framework include mathematics, science, and contextual frameworks. There are defined mathematics or science content domains covered by the assessment at fourth and eighth grades. Each topic area belonging to a content domain is presented as a list of objectives written in terms of student understandings or abilities that items are designed to elicit. There are also defined three cognitive domains – knowing, applying, and reasoning, at both fourth and eighth grades, mathematics and science. The understandings and abilities required to engage in scientific inquiry are included within the two dimensions of the assessment framework – the content and cognitive dimensions. Contextual framework identifies the major characteristics of the educational and social contexts that will be research for improving student learning (Mullis et al. 2009).

Programme for International Student Assessment (PISA) framework presents reading, mathematics, science, and questionnaires frameworks. The concepts of *reading literacy*, *mathematical literacy*, and *scientific literacy* are described in terms of the skills students need to acquire, the processes that need to be performed, and the contexts in which knowledge and skills are applied. Accessing and retrieving information, forming a broad general understanding of the text, interpreting it, reflecting on its contents, and reflecting on its form and features are considered key aspects in demonstrating the students' proficiency in reading. Mathematical literacy is assessed in relation to mathematics contents defined mainly in terms of four overarching ideas (quantity, space and shape, change and relationships, and uncertainty) and to processes (the use of mathematical language, modeling, and problem-solving skills) in five situations (personal, educational, occupational, public, and scientific). The assessment of scientific literacy is designed in relation to scientific knowledge or concepts related to science in life and health, science in Earth and environment, and science in technology. It also targets the following processes: acquire, interpret, and act upon evidence. PISA questionnaire framework presents the information to be collected at four different levels: the educational system as a whole, the school level, the instructional setting, and the student level. It presents also some dimensions for the analyzing the policy relevance of the data (OECD 2010).

The National Assessment of Educational Progress (NAEP) framework encapsulates a range of subject-specific content and thinking skills appropriate for the testing of three grade levels – 4, 8, and 12 (http://nces.ed.gov). In addition, NAEP framework contains details about the design of the context questionnaires addressed to school, teacher, and student that helps to understand student achievement in context. The framework serves for revising curricula and also could serve as model for measuring the skills in innovative ways.

Assessment of Doing Science

Bronwen Cowie
Wilf Malcolm Institute of Educational Research,
Faculty of Education, The University of Waikato,
Hamilton, New Zealand

Keywords

Curriculum; ICTs; Laboratory Work; Representation; Summative

This contribution examines assessment practices associated with the "doing of science." All assessments are predicated on assumptions about *what* knowledge is of value and *how* this knowledge might be developed and made visible. Hence this contribution begins by reviewing developments in the goals for science education and then considers how assessment practices associated with the goals of "doing science" have played out in different ways for different purposes at the different levels of the education system (international, national, and classroom). Issues associated with the equity and inclusion, the situated and social nature of learning, and the use of information and communication technologies are also addressed.

What Is Involved in Doing Science? A Focus on Expansive Curriculum Goals

Hands-on and practical tasks are widely recognized as a distinctive feature of school science, but the nature of these activities along with understandings of what is involved in doing science has changed over time. The interrelated nature of curriculum, pedagogy, and assessment has meant that shifts in curriculum goals have required innovation in both pedagogy and assessment. It is no longer sufficient that teachers monitor student conduct of a teacher-prescribed confirmatory experiment or even the development of student investigative skills per se. Curriculum, pedagogy, and assessment need to combine to develop students as citizens who are willing, able, and sensitive to occasions when they could take science-informed actions in their homes and communities. Students need to appreciate how scientists generate, legitimate, and communicate science and to meet the demands of the "knowledge society" they need to develop the capacity to be lifelong learners of science. Given that assessment is a key message system for according value within schools, any assessment of students "doing" science needs to encompass and attend to the full breadth of these learning outcomes.

Research has highlighted the value of pedagogies that explicitly focus on the development of student argumentation, modeling and scientific reasoning capabilities, and the affordances of units that are grounded in socio-scientific or local issues and that offer students with opportunities to participate in science inquiry. The implementation of these pedagogical approaches has required analysis of the nature of the learning outcomes aimed for, what performances would indicate proficiency in a given outcome, and what kinds of tasks would develop and require the desired learning outcomes. The new pedagogies have demanded and afforded new opportunities for student assessment to make visible what students know and can do.

Who Is Assessing and Why?

A consensus is emerging that better assessments need to be developed to capture and communicate the breadth of student learning across all levels of the educational system. International organizations such as the OECD and UNESCO, national and state governments, and schools, teachers, students, parents, school communities, and employers are all important stakeholders in and audiences for the assessment of student achievements in the doing of science, albeit for different reasons and consequences. While the assessment needs at each of these levels are not the same, it is desirable that assessments at the different levels come together to support a common set of learning goals, rather than working at cross-purposes. A balance needs to be achieved between formative assessment, where the intention is to support and enhance teaching and learning, and summative assessment that sums up and reports on student achievement at a particular point of time for accountability and certification purposes.

Internationally the PISA has been influential in directing attention to scientific literacy as a key outcome for science education (OECD 2013). It has contributed to developments in the assessment of student science capabilities through the use of context-based assessment items and the assessment of student knowledge and attitudes. In 2006 and 2009, PISA pilot-tested the computer-based assessment of science (CBAS), designed to measure science knowledge and inquiry processes. Combined, these developments have been important through a wash-back onto national priorities and practices and, subsequently, onto classroom teaching and student learning.

At the national level, countries around the world have moved to include learning outcomes to do with inquiry and scientific practices in their assessment for system accountability and student qualification programs. Policy and practice reviews to date suggest that the nature and level of specification of outcomes from practical and inquiry learning are variable within and across the years of schooling and across country settings. There is no clear evidence for what level might be optimal in terms of supporting valid, reliable, and productive teacher and student assessment practices. Current concerns at the national level in many countries revolve around the potential for assessments designed for system accountability to restrict curriculum time spent on science at the primary school level and to narrow the science curriculum at all levels of schooling to material that can readily be tested through paper-and-pencil-type tasks. In the USA and UK, there is evidence that this is limiting student opportunities to experience the practical data/knowledge generating and testing aspects of science.

At the classroom level, researchers are continuing to find that teacher instruction and assessment at the beginning, throughout and at the end of practical and inquiry tasks, are often restricted to conceptual outcomes. From their actions it seems that teachers assume that student understanding of links between concepts and theories and of science-specific ways of generating, validating, and reasoning with and representing evidence will emerge from their observations of phenomena, and so they miss opportunities for formative assessment to support students to make these connections.

Student involvement in the assessment of their progress through self-assessment is important from an assessment point of view as a means for fostering student learning capacity and autonomy. It is essential within student-directed inquiry. Additionally, student involvement in the assessment process through peer assessment is important from an assessment point of view as a source of timely and focused feedback. It is congruent with students having opportunities to engage in and gain expertise in argumentation, reasoning, and modeling as part of explaining and justifying their science ideas to others. Collaboration and critique are important aspects of how scientists work and central to many current pedagogical innovations. However, a collective focus poses a challenge for assessors once the goal moves beyond supporting learning (formative assessment) to documenting for others what science an individual knows and can do (summative assessment). This matter is one that requires further exploration given the “social turn” in understandings of learning and the strength of research evidence and wide policy recognition that all assessments should, and can, support teaching and learning in some way.

Very little attention has been paid to parents and school communities as stakeholders for assessment beyond their being an audience for information on individual student achievement or school-aggregated information. Curriculum aspirations that include students being able to continue learning science and take science-related actions in their everyday lives, coupled with proposals that community linkages can support the engagement in science of disenfranchised student groups, suggest that this is an area in need of development.

The How of Assessment of "Doing Science"

The assessment of students' doing of science is challenging and has been made more complex as the goals for science education have expanded to include student participation in inquiry, modeling, argumentation, and so on. Recognition of the situated social nature of learning and its links to the transformation of identity has added further complexity. Some of the key challenges and practices include those related to the relative merits and practicality of direct and indirect assessment of student practical/inquiry competencies, of holistic or component assessment of student inquiry capabilities, of individual or student group practices, and of the use of multiple modes and means (Harlen 1999; Hodson 1992). At the same time, research is emerging that suggests information and communication technologies; the development of learning progressions for particular topics and for inquiry practices has the potential to help policy makers, curriculum developers, and teachers meet these challenges.

Debate exists about the relative merits and practicality of direct and indirect assessment of student practical/inquiry practices, skills, and orientations (Reiss et al. 2012). With direct assessment student practical and inquiry skills are assessed by teacher observation of students as they engage in an investigative task. With indirect assessments student competency in terms of a specific or generic skill is *inferred* from their reports of the work they have undertaken or via pencil and paper test questions. Several studies have found differences in student performance in practical investigations, depending on whether a direct assessment mode or a written assessment mode is used. It has suggested that written tasks elicit evidence of what students *know* about practical work/inquiry and how it should, in principle, be undertaken rather than on their competency in terms of actually being able to *do* practical work themselves. Typically, direct assessment is advocated as it captures both the process and the product of student learning.

With regard to high-stakes summative assessment, including assessment exit qualification purposes, different countries use different combinations and forms of direct and indirect assessment. Tasks used in direct assessment can be teacher or externally designed, supervised, graded and the grades moderated, to various degrees. Often the awarding body provides a bank of tasks and of exemplars of student responses at different levels of achievement to support teacher grading. In some contexts direct assessment data is collected on one occasion; in other contexts it is collected over a range of tasks, contexts, and topics. In the UK, for example, the collection of data is loosely controlled by the teacher and can be undertaken by a group, but the analysis and communication of results are done individually under test-like conditions.

Given the influence of high-stakes assessment on curriculum and pedagogy, it might be expected that the inclusion of inquiry and practical work in high-stakes assessment would promote and enhance the teaching and learning of these aspects. In contrast, studies are emerging that indicate the tendency to train students to do investigations has had the effect of conflating the teaching, learning, and assessment of investigations. Research has identified that teachers can narrow their practice of formative assessment to ensuring students comply with criteria required for the award of external qualifications credits. It also appears that to yield good marks within the full range of possible scores, teachers tend to select investigations that they are familiar with which then restricts the pool of investigations students experience and limits their involvement in investigations they develop for themselves. The issues to do with the reliability of teacher judgments and of teachers teaching to the assessment have also been identified, raising questions about the validity and reliability of student results. A counterargument is that such teaching to an assessment is only problematic when an assessment task is limited in its expectations of students; otherwise teacher scaffolding would be seen as part of enhancing the alignment of pedagogy and assessment with desired student performances.

Outside formal summative assessment, teacher classroom assessment practices tend to span a continuum of integration with teaching and learning from more formal and planned to embedded and on the fly. Ongoing informal teacher formative assessment via interaction generates information on student learning that is generated and used in the same context to provide feedback on student learning. The use of interaction coupled with curriculum-embedded assessment tasks, including the collection of student workbooks, where the information is used formatively has been found to effectively support student learning as teachers scaffold and guide student inquiry. Although contested, there is some evidence that teachers can accumulate evidence through these means that can then be revisited to make a summative judgment about student achievement that takes account how and what they have learned.

Task design is a key aspect of instruction and assessment. Sociocultural views of learning and assessment, which are currently exerting a substantial influence in science education and assessment research, recognize the situated social and cultural nature of learning and its expression or demonstration. From this perspective, student practical work and inquiry processes and products cannot be evaluated in isolation from the context of production where this context includes the task format, topic, and other resources in the assessment setting although the extent to which these contextual and content-related elements influence student performance is still a matter of debate. There is considerable research support for the use of authentic situations and real-life contexts as part of teaching and formal assessment but student familiarity/lack of familiarity with a context and its meaning in their community and culture can be a source of bias. Suggestions to address these matters include finding contexts likely to be unfamiliar to all students and the compilation of a portfolio of student work across the range of contexts students encounter in class. Other suggestions are to use different contexts for different topics and to incorporate more contexts by assessing smaller, specific aspects of an inquiry. Counter to many of these suggestions, research has demonstrated the key contribution of content knowledge in student practical work and inquiry with little evidence of the generalizability of skills assessments across science subjects. In addition, there is some evidence suggesting that the conduct of an investigation is largely a holistic task and breaking it down into separate skills might misrepresent the essence of the process, which requires the integration of a variety of skills and ideas and thus of student capabilities. These matters of context familiarity and presentation are of particular importance when test results are used to determine students' further study or career options.

Context-based performance assessments can support students to demonstrate abilities in scientific inquiry by requiring them to interact in various social groupings and use a variety of communicative modes. However, this aspect of performance assessments can be affected by student cultural norms. For example, some communities do not socialize their children to making public displays of achievement such as those valued in schools; others place an obligation on the more knowledgeable person to share their knowledge, irrespective of their ages, while still others value the production of a high-quality physical product.

Advocates of performance assessment argue that it provides students with more flexibility and options for expressing what they know and can do and recommend it as a means for accommodating student diversity and addressing issues of equity and inclusion. However, contextualized summative tasks come with reading and representation interpretation demands for student understanding of the context and what is required of them. Students, particularly, those whose first language is not English can find it difficult to make sense of a task and express what they know quickly and easily when a written response is required. Opportunities to edit or to display their knowledge in less language-embedded tasks can be of benefit to these students as can curriculum-embedded performance assessments that are subsequently aggregated to produce a summative assessment of student learning.

Modern digital and information and communication technologies present new possibilities and new challenges for teaching, learning, and assessment through the variety of means they afford for investigating phenomena; for generating, analyzing, and representing data; for working collaboratively; and for the communication of ideas to an audience. The ability to capture student inputs permits collecting evidence of processes such as problem-solving strategy use as reflected by information accessed and selected, numbers of attempts, approximation to solutions, and time allocation. Recent developments include the trialing of adaptive testing, including knowledge and skills diagnosis, the provision of immediate feedback to teachers and students accompanied by scaffolding for improvement, and the potential for accommodations for special populations.

Technology-based simulation tasks can support students to design and conduct experiments, including them being able to quickly and efficiently pose and answer a series of "what if" questions as they change different variables. Findings can be graphed or represented in a variety of ways prior to students reaching a conclusion and writing a final response. Because simulations use multiple modalities and representations, evidence is emerging that students with diverse language and experiential backgrounds may have better opportunities to demonstrate their knowledge than are possible in text-laden print tasks. Students can use video, digital photographs, and audio to document and provide commentary on their own learning journeys.

A number of research groups are exploring the viability of web- and simulation-based units that incorporate tools for curriculum-embedded student reflection and self-assessment, teacher formative feedback and task customization, and end-of-unit summative assessment, with some groups seeking to develop systems where these final assessments have the technical quality required to be part of a state accountability system. A learning management system can generate embedded assessments for teachers and students that indicate the level of additional help students may need and classify students into groups for tailored follow-on off-line reflection activities, which further guide students to use scientific discourse. Since many new media tend to be inherently social, but most existing assessment systems are fundamentally individualized, their use introduces clear tensions and challenges making newly salient questions such as the following: Is it ever possible to gauge individual contributions to fully participatory activities? On the other hand, some scholars are arguing that eventually evidenced centered design combined with modern technologies has the potential to support "seamless" collection of multiple pieces of evidence embedded in ongoing work through an assessment system that would seem so natural students would not realize that it had even occurred.

Assessment involves the making of judgment about the status of student learning against some referent. A number of jurisdictions have developed standard-based criteria to be used to judge student acquisition of a particular level of accomplishment in the different aspects of the inquiry process. Similar criteria/rubrics are being developed to assist teachers in making decisions about and providing support for student scientific argumentation, modeling, and reasoning. Researchers with an interest in learning progressions, initially focused on content areas such as the nature of matter and evolution, are now turning to investigate the development of student competency in inquiry practices as these might be activated, developed, and expressed over a variety of contexts. To date these researchers have taken the grain size of a learning progression to be a single aspect of inquiry, such as mechanistic reasoning, modeling, and coherence seeking, while acknowledging that progress in one aspect of inquiry may be inextricably linked to progress in others. This work can be expected to have substantial implications for large-scale and classroom assessment of students doing science in terms of teacher expectations for and guidance of student learning and for student monitoring and action on their own learning progress.

Where and When to Assess the Doing of Science

The current imperative that school science prepares students to use and continue to learn science throughout their lives poses a substantial challenge to the robust assessment of students doing science. This challenge relates to how student knowledge construction, critique, and use over time and out of the classroom/school and into their future might be captured and documented. Implicitly it requires that assessment tasks, like learning tasks, have value, meaning, and traction beyond the classroom. Grounding assessment tasks in a real-life context, as discussed above, goes someway towards addressing this issue. So too do attempts to require students to show that they can apply their skills, knowledge, and understanding in "unfamiliar contexts." Other options for addressing this challenge include students demonstrating or presenting what they know and can do to an audience beyond the teacher, and sometimes beyond the rest of the class. This could involve students writing storybooks for younger children which they then read to younger students; students preparing posters or constructing local environmental impact statements which are publically displayed and/or sent to interested members of the community; a class preparing and presenting what has been learned to a school assembly to which their families are invited; or staging a mock public debate for which they collect and marshal evidence to support a point of view. In these instances students need to focus on the demands and indicators of success of real-life audiences. Optimally, students' sharing and demonstration of knowing result in learning and/or action of benefit to others. In the case of the last two examples, parents gain a more direct insight into what their child knows and is capable of. In yet other studies students have been involved in community-based projects in which, although student learning is often still assessed via conventional means, evidence of what has been learned is embedded in the class contribution to the community. Examples of this type of instruction and assessment tend to revolve around environmental issues such as water monitoring.

Concluding Comments

Assessment practices are part of a multilayered interactive system in which curriculum, pedagogy, and student and societal expectations and experiences all exert an influence. What it means to do science has expanded from a focus on practical skills to science-informed action. New pedagogical approaches in support of these goals are being developed. The challenge remains to develop assessment at all levels of the system that will complement these expanded goals and help make the learning process and what has been learned visible to learners and other interested stakeholders.

Assessment of Knowing and Doing Science

Audrey B. Champagne
University at Albany, State University of
New York, Albany, NY, USA

The essential function assessment serves is the measurement of students' science knowledge and abilities at a moment in time. Data from the measurement answer the question: What do students know and what are they able to do? The simplicity of the question belies the challenges posed when interpreting data that answer the question.

What do students know? The breadth of scientific knowledge and differences in the depth to which it can be known contribute to the complexity of possible answers. The PISA 2009 Assessment Framework distinguishes two categories of science knowledge, knowing of science and knowing about science. Knowledge of science includes knowing the fundamental concepts, principles, laws, and theories of the physical, life, and Earth and space sciences. Knowledge about science includes knowing the modes of inquiry, philosophical perspectives, and history of the natural sciences. Because the development and practice of the natural sciences is closely aligned with technology and engineering, knowing of and knowing about technology and engineering are components of science knowledge included in assessment. The breadth and diversity of science knowledge contributes to the complexity of answers to the question, what do students know.

Depth of knowledge is also confounding factor. In the literature of science education, a distinction is made between just knowing something, a principle for instance, and understanding it. However, the essential characteristics on which the distinction is based are seldom described. Because depth of knowledge is weakly conceptualized, the nature of the empirical evidence from which valid conclusions regarding depth of knowledge can be made is difficult to describe. Consequently, interpretation of data describing what students know is challenged by knowing the depth to which students know it.

What are students able to do? Skills, abilities, and practices are generic terms used to answer this question. Science skills, abilities, and practices are extensive in number and related to diverse activities including the design and conduct of inquiries; the construction of science explanations and arguments, and the reasoning modes applied in the natural sciences. The breadth and diversity of science skills, abilities, and practices contributes to the complexity of answers to the question.

While claims are made that certain assessment tasks are exclusive measures of what students know and others exclusively measure what students can do, in fact, every assessment task measures both knowing and doing. Students' knowledge, skills, abilities, and practices are inferred from observations of actions or products of action. The action may be as simple as penciling in the circle next to the correct response to a factual question, such as how many bones are in the human body. Even simple tasks such as demonstrating knowledge of a fact require generic skills including reading and following directions. More challenging tasks such as writing an explanation of an observation require generic skills, science knowledge, and science-specific abilities. If the action, writing, produces an explanation that has the characteristics of a scientific explanation, we infer that the student knows the characteristics of scientific explanations and has the ability to apply that knowledge to write an explanation. The explanation is also evidence of the student's knowledge of the science principles relevant to the phenomena observed and the student's ability to apply that knowledge appropriately. Generally the appropriate application of science principles is considered evidence that the principle is understood rather than just known.

The breadth and complexity of scientific knowledge and abilities and their interaction make interpretation of data that answer the question what do students know and what are they able to do challenging. This challenge is particularly relevant when attempting to compare data from different assessments. Absent detailed information about the knowledge and abilities measured comparisons may be spurious.

Assessment of Knowing Engineering and Technology and Doing Engineering and Technology: Overview

Edys Quellmalz
WestEd, Redwood City, CA, USA

Keywords

Assessment; Concepts; Engineering; Practices; Technology

A variety of meanings have been associated with the terms engineering and technology. The definitions for this entry are based on numerous documents produced by USA sets of experts. The National Academy of Engineering report, *Standards for K-12 Engineering Education?* (NAE 2010), surveyed standard documents in engineering, technology, science, and mathematics to identify common engineering concepts and skills. The National Assessment Governing Board supported the development of the *Technology and Engineering Literacy (TEL) Framework for the 2014 National Assessment of Educational Progress*. The National Research Council of the National Academies has published the *Framework for K-12 Science Education*, which, along with a draft *Next Generation Science Standards*, integrates engineering ideas and practices with those in science (NRC 2012; Achieve 2012). Definitions of engineering and technology can be culled from these frameworks and standards developed by national engineering and science organizations, as well as from standards for engineering and technology for state, national, and international assessments.

The definitions of engineering and technology are the starting points for developing assessments of understanding them. Similarly, conceptualizations of the engineering design process are the starting point for developing assessments of engineering practices that both use and produce technologies. This entry begins with a summary of prominent conceptualizations of engineering and technology and the practices of applying them. The definitions are followed by descriptions of an assessment design framework that can be used to develop and analyze assessments of engineering and technology. Descriptions of some potential types of assessment tasks and items to test understanding and application of engineering and technology are provided.

Definitions of Engineering and Technology

Engineering is defined as a systematic and iterative approach to designing objects, processes, and systems to meet human needs and wants. *Technology* is defined as any modification of the natural or designed world developed to fulfill human needs or desires. Technologies, therefore, are products and processes resulting from application of engineering design processes. Technologies also often function as tools and processes used to support engineering design. In most reports that set forth frameworks or standards for engineering, technology, and science, the three domains are described as related by their focus on systems in the real world, yet different in the roles that the disciplines play in understanding and modifying the world. Engineering and technology often apply science knowledge to meet human needs and desires.

Sources of Conceptualizations of Engineering and Technology

Standards for K-12 Engineering Education?

The purpose of the National Academy of Engineering report was to survey contemporary frameworks, standards, and practices in engineering to determine if a national set of engineering standards could be proposed (NAE 2010). The report summarized key ideas of engineering and recommended that engineering concepts and processes should be integrated into and linked with contemporary frameworks and standards in science, technology, mathematics, and other disciplines. The report identified a set of the most commonly cited core engineering concepts. The central engineering construct was "design" – understanding and doing it. Other important concepts included understanding constraints, understanding systems, and optimization. Central skills included modeling, system thinking, and analysis. In addition, the report emphasized the importance of understanding the relationship of engineering and society and the connections among engineering, technology, science, and mathematics.

Technology and Engineering Literacy (TEL) Framework for the 2014 National Assessment of Educational Progress

The TEL framework is unique in its focus on assessing the interrelationships of engineering and technology. In the framework, technology and engineering literacy is defined as the capacity to use, understand, and evaluate technology as well as to understand technological principles and strategies needed to develop solutions and achieve goals (NAGB 2010). The framework lays out three areas of technology and engineering literacy, the types of thinking and reasoning practices that students should be able to demonstrate, and the contexts in which technologies occur. Three main assessment areas are specified: Design and Systems, Information and Communication Technology, and Technology and Society. Within Design and Systems, three subareas of essential knowledge and skills are identified: nature of technology, engineering design, system thinking, and maintenance and troubleshooting.

Principles for the nature of technology expand the scope of common conceptualizations of technology beyond computers and the internet. The broader view includes every way people manipulate the natural environment to satisfy needs and wants. Therefore, technology includes all the various devices and systems that people make to fulfill some function. The framework lays out key principles for the nature of technology: (1) technology is constrained by the laws of nature; (2) scientists examine what exists in nature and engineers modify natural materials to meet human needs and wants; (3) technological development involves creative thinking; (4) technologies developed for one purpose may be adapted for other purposes; (5) science, technology, engineering, and mathematics and other disciplines are naturally supportive; (6) the pace of technological change has been increasing; and (7) tools help people to do things efficiently, accurately, and safely. The framework then lays out assessment targets for the nature of technology for grades 4, 8, and 12.

The engineering design subarea in the TEL framework is described as an iterative, systematic process for solving problems. These processes are among the practices of engineering. The process begins with stating a need or want and identifying the criteria and constraints of the challenge. Then, potential solutions are explored referencing relevant scientific and technical information. Potential solutions are compared, and models and prototypes are constructed, tested, and evaluated to see how they meet the criteria and constraints of the problem. Two additional components of Design and Systems are system thinking and maintenance and troubleshooting. System thinking is a way of thinking about devices and situations so as to better understand interactions among system components, root causes of problems, and the consequences of various solutions. Maintenance and troubleshooting is the set of methods used to prevent technological devices and systems from breaking down and to diagnose and fix them when they fail. For each of these Design and Systems components, assessment targets for grades 4, 8, and 12 are presented.

The framework also specifies components, principles, and assessment targets for grades 4, 8, and 12 for the pervasive technology area of Information and Communication Technology (ICT). ICT is presented as a separate assessment area within technology and engineering literacy because of the central place ICT plays in learning and functioning in school, the workplace, and daily living. ICT sub areas to assess include understanding and use of technologies for (1) construction and exchange of ideas and solutions, (2) information research, (3) investigation of problems, (4) acknowledgment of ideas and information, and (5) selection and use of digital tools. Assessment targets for ICT at grades 4, 8, and 12 are presented.

The assessment area of Technology and Society addresses the effects that technology has on society and on the natural world and the sort of ethical questions that arise from those effects. The area is further divided into interaction of technology and humans, effects on the natural world, effects on the world of information and knowledge, and ethics, equity, and responsibility. Assessment targets for grades 4, 8, and 12 are presented.

The TEL framework also describes three crosscutting practices: understanding technological principles, developing solutions and achieving goals, and communicating and collaborating. The framework provides numerous examples of how these practices apply to the Design and Systems, ICT, and Technology and Society areas.

Framework for K-12 Science Education and the Draft Next Generation Science Standards

The framework includes engineering and technology as they relate to applications of science (NRC 2012; Achieve 2012). Engineering is used to mean engagement in a systematic design practice to achieve solutions to particular human problems. Technology is used to include all types of human-made systems and processes. Two core engineering ideas are specified. The first is engineering design – how engineers solve problems. The second core idea is understanding the links among engineering, technology, science, and society. Engineering design is subdivided into three components: (1) defining and delimiting a problem, (2) developing possible solutions, and (3) optimizing the design solution. Links among engineering, technology, science, and society are partitioned into (1) interdependence of science, engineering, and technology and (2) the influence of engineering, technology, and science on society and the natural world. The framework describes grade band end points for each of the three components.

The framework also describes the key practices that scientists use as they investigate and build models and theories about the world and the key engineering practices that engineers use as they design and build systems. Science and engineering practices include asking questions and defining problems; developing and using models; planning and carrying out investigations; analyzing and interpreting data; using mathematics, information and computer technology, and computational thinking; constructing explanations and designing solutions; and engaging in argument from evidence. The framework describes grade band end points for these practices.

The draft *Next Generation Science Standards* provide more specific guidance for assessing engineering design that produces and uses technology. Performance expectations are presented for the engineering design components. The performance expectations integrate the engineering core ideas with cross-cutting concepts such as systems and models and cause and effect and also with science and engineering practices.

Each of the frameworks and standards described above can serve as resources for specifying the engineering and technology concepts and practices to assess. In the following section, the use of a systematic assessment design framework is presented to support the selection or development of assessments.

Assessment Design

The focus of this entry in the encyclopedia is on methods for assessing understanding of engineering and technology and the practices for applying the engineering design process and the technologies that both can support the design processes and are a result of them.

Assessment Purposes

The selection or development of assessments will depend on the purposes of the assessments and the planned interpretations of the data. An assessment may be intended to provide diagnostic feedback and be used in a formative way to allow adjustments during instruction to improve performance. Or, assessments may be intended to provide summative information about proficiency levels of knowledge and skills following courses or projects.

Formative Assessments

Assessments intended as formative feedback for students and teachers about progress on learning outcomes can be embedded throughout learning activities in extended projects. The more extended the project, the more opportunities will be available to build in ongoing assessments and to adjust instruction. Ideally, the design of both the learning activities and assessments would occur simultaneously, stimulating iterative cross-checking that the learning activities are designed to directly promote all the specified engineering and technology knowledge and practices, that systematic assessments of progress on all these targets are planned, and that provisions for scaffolding and instructional adjustments can be made.

Learning progressions may guide the sequence of assessments within learning activities and be linked to types of common misconceptions or ineffective problem-solving and inquiry strategies. Careful analyses from embedded formative assessments of the unfolding conceptual and problem-solving development planned throughout a project can allow in-depth attention to problem-solving practices ranging from design and prototyping to communication of solutions. Assessments of the particular engineering and technology knowledge and strategies can be made “just in time” as students are applying the concepts and in the process of engaging in the practices. Extended engineering projects offer opportunities to assess more knowledge and practices, more often, and in more depth.

Summative Assessment

An assessment may be intended to serve a summative purpose to report on the status of proficiency at a point in time. Summative assessments may be administered at the end of a project or course or at end points such as units or project phases. These purposes will have implications for the criteria used to select, design, or interpret assessments.

Evidence-Centered Assessment Design

A useful framework for understanding the structure and functions of assessments is evidence-centered assessment design (Mislevy et al. 2004). Evidence-centered design is intended to structure an assessment argument. The argument begins with the claim that specified knowledge or skills have been learned. Evidence to support the claim comes from the types of questions or tasks that will elicit observations and performances of the targeted knowledge or skills. Summaries of performances, typically in the form of scores to be reported and interpreted, then are used as evidence to complete the argument. Therefore, evidence-centered assessment design tightly links the targeted knowledge and skills (student model), with assessment tasks and items to elicit evidence of these targets (task models), with specifications of how the evidence will be scored and analyzed to report proficiencies (evidence model). The evidence-centered assessment design framework can be used to analyze and evaluate existing assessments of the knowledge or practices targeted or to guide the systematic development of new ones.

The essential first step will be to settle on the definitions of engineering and technology – the specific knowledge about them and practices to be tested. These knowledge and practice targets would become the first component of the student model. A second component of the student model would be the cognitive demands or levels of reasoning required. Cognitive demands could range from identifying definitions and examples of the concepts and practices to analyzing descriptions of the technology and engineering concepts and practices in a project as it unfolds to evaluating others' use of the technologies and engineering design practices.

The engineering design process creates plans for developing solutions. Solutions may be tangible artifacts or technologies, such as digital devices or farm machinery. Solutions may also be new or improved technological processes such as more efficient manufacturing procedures or pharmaceutical clinical trials. These solutions are *technologies* that have been developed to address needs in areas of the designed world such as medicine, agriculture, energy, transportation, manufacturing, and construction. ICT projects may set goals to be achieved by use of multimedia resources. Students tend to think of technology in terms of computers and digital technologies, not in terms of the artifacts and solutions engineered in the many other areas of the designed world. Students are expected to understand that there are technologies in all these areas, from pills, plows, plugs, planes, and pinions to pickup trucks. Specifications of the knowledge to be tested will need to decide what students need to understand about the engineering processes, the role of technologies in them, and the technology products. Statements of what the student needs to know and the level of reasoning for showing it will become the assessment targets of the student model.

The task model(s) for an assessment specifies the kinds of contexts, problems, and items that would elicit evidence that the students understood the engineering design and technology ideas and concepts and could use them to solve problems and achieve goals. Simple items could ask for students to identify concepts and components of an engineering design project and the technologies used and produced. Descriptions of needs addressed by an engineering project producing solutions could include questions to determine that students understood that the solutions, whether new tools or new processes, are technologies. At stages in the design process, students could respond to questions and post work samples to demonstrate that they were able to apply the design concepts and processes.

Types of embedded assessment tasks and questions can vary. Conventional question formats can be inserted to check for basic knowledge. Tasks that ask students to document their work in progress may include entries in design notebooks and periodic submissions of interim material such as sketches, prototypes, pilot test data, and presentations.

Tasks and items can be designed around scenarios presenting engineering design problems and/or ICT goals in a range of applied contexts. The overarching problem could be to select and construct engineering processes to use in attempting to solve the problem. Within tasks could be inserted questions about the appropriate supporting technological tools to use and about the resulting solution as a technological advance.

The SimScientists program at WestEd has developed simulation-based models of systems to assess understanding and use of science and engineering practices (Quellmalz et al. 2012b; http://simscientists.org). As shown in Fig. 1, a scenario was developed in which students are working to establish a sustainable research center in Antarctica. By harnessing available sunlight and wind, scientists at the station are able to generate electricity, which can be used for the electrolysis of water, which in turn results in the production of hydrogen gas. The simulation-based assessments have been designed to assess core ideas about atoms and molecules, changes in state, properties of matter, and the science practices of designing and conducting investigations. The scenario could be adapted to also assess engineering and technology by augmenting the scenario with sets of tasks about the design, testing, and troubleshooting for an energy production, conversion, and storage system that contributes to a sustainable research center.

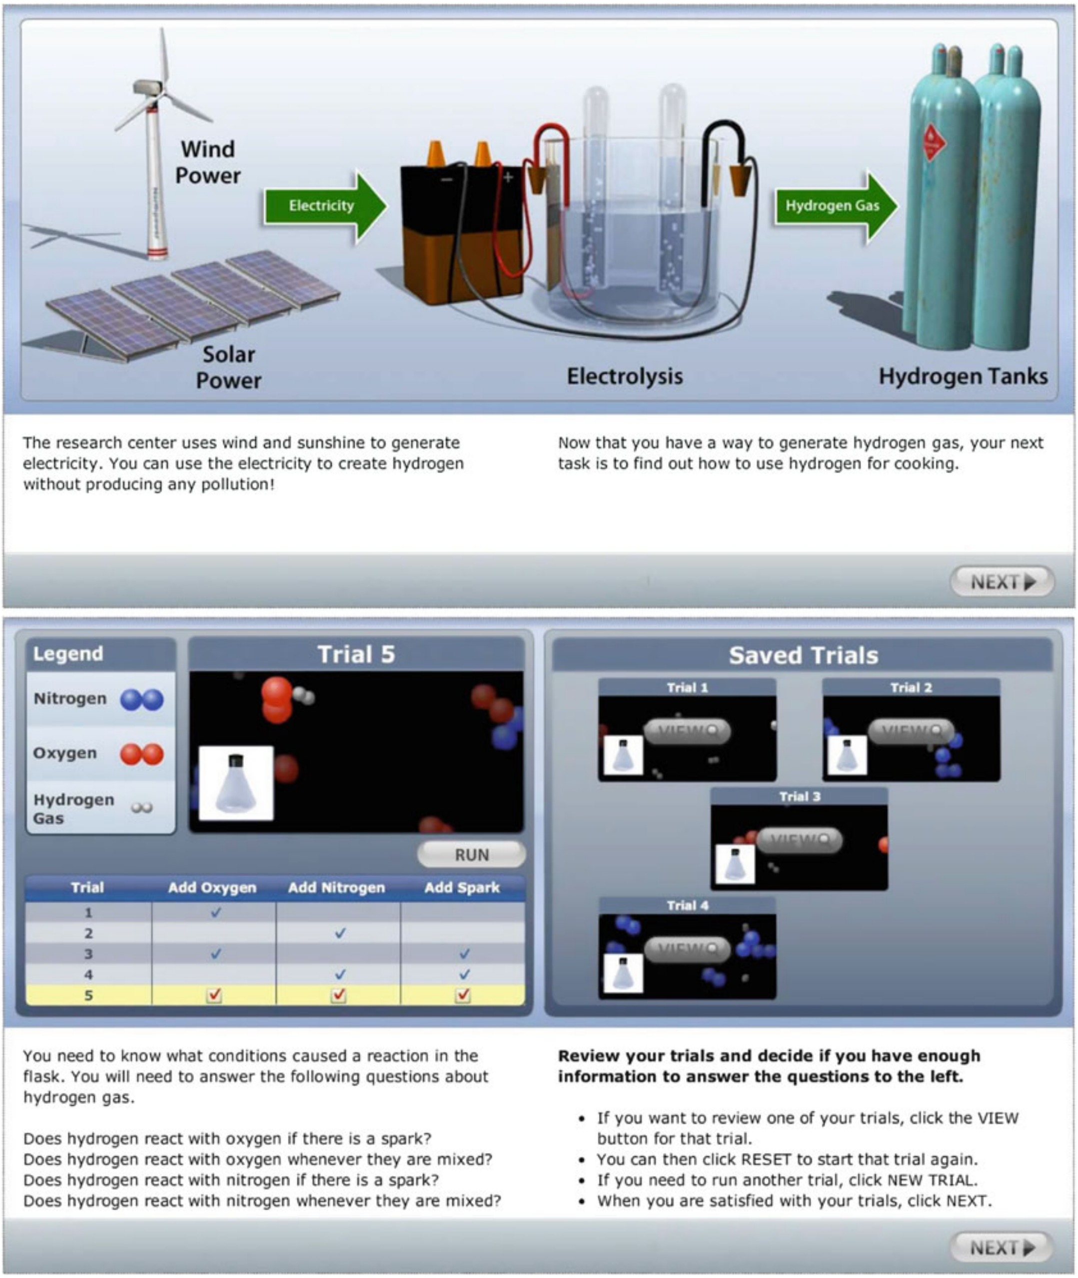
As foundational computer models of systems, natural and man-made, are developed, they can support the development of tasks to assess engineering, technology, and science concepts and practices and also to assess twenty-first-century skills such as communication and collaboration (Quellmalz et al. 2012a). For example, students could be asked to construct descriptions for the Antarctic Research Center Board for a proposed sustainable energy plan or to critique if solutions proposed by others meet the design constraints. A virtual collaborator could be queried to seek relevant information about the trade-offs of alternative sustainable energy treatments.

Final project artifacts and presentations can be used in summative assessments of specific engineering projects or performance assessment events. Rubrics for evaluation of the performances, artifacts, and exhibitions should go through standard assessment development procedures and technical quality screening for reliability and validity (AERA/APA/NCME 1999). Project-specific reports should interpret evidence on all targeted knowledge and practices. Postings of portfolios of final projects and explanations of how they meet criteria can serve as examples of successful performance.

Summative assessments of student learning should carefully align tasks and items in existing or newly developed measures with all the knowledge and practices claimed to be benefitted by prior learning activities. A custom-made summative assessment for a particular project or curriculum should provide an alignment document describing the links between the assessment tasks and items and the targeted engineering and technology standards. Studies of the technical quality (reliability and validity) of these project-specific summative assessments should be conducted and documented (AERA/APA/NCME 1999).

Design of Large-Scale, Cross-Program Summative Assessments of Engineering and Technology

Claims for the effects of multiple engineering and technology programs on learning will need to carefully align the scope of the claims to the scope of the learning outcomes. One approach is to analyze program effects on learning by examining performance on separate tests of engineering and technology. Existing large-scale assessments in the separate disciplines, such as district, state, or national tests, will only be aligned with some of the intended outcomes in one discipline, let alone in multiple disciplines. A large-scale technological literacy or science test, for example, will test a broader range of content than any one engineering or technology program would claim to affect. Moreover, problem-solving and design practices do not tend to be well measured by conventional item formats prevalent on most large-scale tests. A specific program, curriculum, or project can compare student performance on targeted



The research center uses wind and sunshine to generate electricity. You can use the electricity to create hydrogen without producing any pollution!

Now that you have a way to generate hydrogen gas, your next task is to find out how to use hydrogen for cooking.

Trial	Add Oxygen	Add Nitrogen	Add Spark

Assessment of Knowing Engineering and Technology and Doing Engineering and Technology: Overview, Fig. 1 SimScientists simulation-based assessment

standards to results of an entire math, science, engineering, or technology test, or to subsets of items within each test that are directly aligned with the targeted knowledge and practices. The more closely aligned program-specific engineering and technology targets are with subsets of items within a large-scale science, engineering, or technology test, the more likely program effects will be detected by analyses of performance on these aligned item clusters.

Preferably, large-scale, summative assessments would be especially designed to measure engineering and technology learning within applied problems and contexts. Scenario-based assessment tasks could set up relevant, applied, real-world challenges. For instance, students could be asked to address design problems related to the use of wind turbines in an urban area. Task and question sets related to the scenarios would tap key concepts and practices for engineering and technology. Students could be asked to design a study about amounts of wind or sunlight in different areas of the city, to compare the benefits of alternative wind turbine designs, to evaluate environmental effects such as dangers to birds, and to then analyze and report the data.

The evidence model for an assessment would involve determining what kind of scoring and reporting would convey that the student understands the engineering and technology conceptual targets and their application in applied problems. Scoring rubrics are commonly developed to evaluate these variable and open-ended performances and artifacts. The rubrics for specific assignments should derive from more broadly accepted criteria in the field for the quality of work as indicated by its appropriateness, breadth, and depth. The challenge is to develop criteria that relate to general quality features, but that can be clearly applied to the specific project's problem. The rubrics should be usable by students as well as teachers. Practice using the rubrics and checking that multiple users apply them consistently are fundamental elements of sound assessment practice. Moreover, in a balanced assessment system, criteria for rubrics for classroom-level, project-specific activities would be criteria also applied in summative performance assessments. Therefore, criteria would apply to effective use of engineering and technology concepts and practices, rather than to unique information about the design of a bus or an airplane wing. Monitoring and recording formative progress assessments is recommended for comparing project-specific performance on assessment targets to performance on summative measures. Specific reports about the conceptual and practice assessment targets would be needed.

The assessment selection or development process can use the framework of evidence-centered assessment design framework to guide analyses of existing tasks and items or to guide the development of new, appropriate tasks and items. The framework would ask if the knowledge to be tested and practices are clearly specified (student model) and if the tasks and items will provide evidence of conceptual understanding and application, perhaps in a range of applied areas such as ICT, agriculture, medicine, and manufacturing (task model). The framework would also ask if the scoring and reporting clearly allowed decisions to be made about whether the understanding of the targeted concepts of engineering and technology and the use of the practices are sufficiently strong (evidence model). The decisions could then be used as formative assessments that would diagnostically inform further instruction or as summative assessments to support a proficiency report. The key to sound assessment is that the assessment argument is clear and supported.

Curriculum, Institute for Educational Sciences,
Bucharest, Romania

Keywords

Assessment specifications; NAEP; PISA; TIMSS

Assessment specifications refer to the design of a plan that is used to develop the assessment indicating the main features to be covered. They identify the topics and skills to be tested and the emphasis given to each category. Also, they document the student population to be assessed, test booklets' design, question types, constructed-responses scoring, and achievement reporting and provide samples of items. The released examples from previous cycles are offered to illustrate how the learning acquisitions are measured and also to present a range of response formats and coding and scoring features. The role of the specifications is to provide a foundation of terms, processes, and procedures so that all involved with the development or consumption of assessment results may operate from a common understanding. They represent the first step to take for constructing the assessment being continually reviewed and modified to reflect the current state of knowledge.

For example, Programme for International Student Assessment (PISA) 2009 is administered to 15-year-olds. The specifications include information about the tested domains in that cycle – reading is the major domain and mathematics and science are minor domains. For the paper-based assessment, there are 37 reading units comprising 131 cognitive items, 18 mathematics units with a total of 34 items, and 18 science units with 53 items. The item formats are either selected response multiple choice or constructed response. The items are organized in units around a common stimulus – passage text, table, graph, or diagram setting out a real-life situation. Items have to be developed with respect to the major framework variables defined for each tested domain – text type variable, text format variable, situation variable, and aspect variable (for the reading domain); competency and content category (mathematics domain); and competency and knowledge type (science domain) – and have to represent a wide range of difficulties. Their distribution across categories is also provided. The items are allocated to 13 clusters (seven reading clusters, three mathematics clusters, and three science clusters). The items are assembled in 13 standard test booklets; each booklet is composed of four clusters according to a rotated test design, each cluster representing 30 min of testing time. Each student is randomly assigned 1 of the 13 booklets administered in each country. Student responses in all participating countries and economies are scored following certain procedures. The coding scheme is developed to enable markers to code the student responses in a consistent and reliable manner. Codes are applied to test items, either automatically capturing the alternative chosen by the student for a multiple-choice item or by an expert judge selecting a code that best describes the response given by a student to an item that requires a constructed response. The dichotomous scoring provides full credit or no credit. Partial-credit scoring is used for some of the more complex constructed-response items. Such items scored polytomously receive full-credit score, one or more partial-credit scores, or no-credit score. The code, of either type, is then converted to a score for the item. The students' scores are represented on a common achievement scale using item response theory methods that provide an overall picture of the assessment results for each country (OECD 2012).

Trends in International Mathematics and Science Study (TIMSS) assesses the mathematics and science achievement of students in their fourth and eighth years of formal schooling. The assessment specifications identify the content and cognitive domains for the TIMSS fourth- and eighth-grade assessments and their percentages in the testing time for both mathematics and science. The entire assessment pool of items at each grade level is packed into a set of 14 achievement booklets, each item appearing in two booklets. There are 28 item blocks: 14 mathematics blocks and 14 science blocks. Each block groups approximately 10–14 items at the fourth grade and 12–18 items at the eighth grade. The assessment time is established to 72 min for fourth grade and 90 min for eighth grade. Two-item formats are employed: multiple choice and constructed response. The format that best enables students to demonstrate their proficiency determines the choice of item format. The students' responses at constructed-response items are scored using the scoring guide. In the scoring guide the essential features of appropriate and complete responses are described. The focus is on evidence of the type of the cognitive process the question assesses. Each descriptor is accompanied by examples of partially correct and fully correct responses and incorrect answers. Each multiple-choice question is worth one score point. Constructed-response questions are generally worth one or two score points. Reporting scales are available for each content and cognitive domain in mathematics and science at each grade level (Mullis et al. 2009).

Assessment to Inform Science Education

Ellen B. Mandinach
WestEd, Evaluation Research Program,
Washington, DC, USA

Keywords

Accountability; Data-driven decision making; Formative assessment; Proximal formative assessment; Summative assessment; Validity

Assessment in science education, like other disciplines, is evolving into measures designed so that they can be used to inform instruction and learning, not be used just for accountability purposes. It is essential that instruction and assessment be linked and form a feedback loop in which assessment results inform instructional decisions, but the assessments must be closely aligned to the instructional objectives in order for this to happen. The tighter the feedback loop, the more instructionally relevant the data become. The longer the delay, the less useful the data will be for instructional purposes. For example, state accountability testing often occurs in the spring and results are delivered to educators for the following academic year. There are two major issues here. First the test may not be sufficiently aligned to the educational objectives. Second, the duration between testing and delivery of the results may render the data less than useful. Such data are referred to as autopsy or dead-on-arrival data. What may differ for science, as opposed to content areas such as English language arts and mathematics, is that science is not always tested for state accountability purposes. There still may be summative science assessments, but just not for high-stakes purposes.

Another issue centers around the issue of validity. Validity is often seen as a property of the assessment; that is, does the assessment measure what it purports to measure? Another view is that validity resides in the interpretation made on the results. Assessments used for accountability may be designed to provide an estimate of how well students have mastered a particular content area, such as biology or chemistry, but they may not be designed in a manner that can provide teachers with the grain size of data that can inform instruction. Such tests may provide total test scores or subscores but may not allow teachers to drill down to specific content or even items to enable diagnoses of learning deficits. Thus, these tests may be valid as summative measures, but less valid for instructional purposes.

A trend that has gained traction centers around formative assessment. Whereas summative assessments are seen as measuring the culmination of learning on a specific unit, topic, or course, formative assessments are seen as more closely tied to instruction, helping teachers to understand students' learning strengths and weaknesses so that further instructional steps can be identified (see Black and Wiliam 1998; Bennett 2011). Stiggins (2005) differentiates between assessments *for* learning and assessments *of* learning. Assessments *of* learning are seen as summative indicators of what students have learned and are typically used for accountability purposes, whereas assessments *for* learning provide indications of what students have learned or not learned so that the information can help to drive instruction. These assessments have different purposes, and therefore different kinds of interpretations can be made from them. The most instructionally valid measures are assessments *for* learning. Formative assessment is a process, not just a measure (Bennett 2011). They are designed to be used by teachers to directly inform their instructional practice. The feedback loop between instruction and assessment is tight. Assessment is conducted in real time. Erickson (2005) refers to this as "proximal" formative assessment.

A major threat to the use of formative assessments, as Erickson (2005) notes, is whether teachers know how to interpret the results and link them to "pedagogical moves." This is what Mandinach (2012) refers to as pedagogical data literacy and what Means et al. (2011) call instructional decision making. A key skill for teachers is their ability to take data from an assessment, classroom activity, or project, understand what the students know and don't know, and then transform those data into actionable instructional steps. This skill is one that is not well addressed in typical professional development around data-driven decision making (Mandinach and Gummer 2012). It may, however, be a component of training around formative assessments. Thus, for science and other disciplines, assessments to inform instruction rely not only on test design, but also on the duration of the instructional/assessment feedback loop and teachers' ability to interpret the data in ways that allow them to transform the results into actionable instructional knowledge.

Assessment: An Overview

Audrey B. Champagne
University at Albany, State University of
New York, Albany, NY, USA

Assessment involves the collection of information to be used in making decisions. Some assessment information is used to describe the status quo, some to measure change, and some to make comparisons. Ultimately, however, the information is applied to making decisions. The decisions range from those having immediate effects on individual students to those having long-term effects on all of a nation’s students or on large populations of students within a nation. Few if any of the decisions are made on the basis of information alone. Philosophical, political, economic, and theoretical factors influence decisions and may override the information relevant to making the decision.

The importance of data in making educational decisions has global dimensions and is characterized by ever-increasing expenditures by nations on the design and implementation of **assessment systems**. At the classroom level there has been an increase in professional development for teachers to develop their abilities to design classroom measures that yield information, enabling them to make good instructional decisions and to use data from external assessment to facilitate their educational decision making.

Information/data is collected by individuals (students, teachers, principals, and administrators), by agencies with jurisdiction over a country, by agencies with jurisdictions over segments of a country, and by independent organizations formed by cooperative agreements among nations. Examples of independent organizations responsible for cross-national assessment are the International Association for the Evaluation of Educational Achievement (**IEA**) which oversees the design and implementation of **TIMSS** (Trends in International Mathematics and Science Study) and the Organization for Economic Co-operation and Development (**OECD**) which oversees the design and implementation of **PISA** (**Programme for International Student Assessment**).

The information/data from assessments is used to make many different kinds of decisions. The information that may have the most profound impact on student learning is that gathered by students as they either consciously or intuitively become aware of their own knowledge and abilities and how these match with the expectations of their science teachers and parents. Helping students systematize their **self-assessment** abilities is a goal of science education. Information/data collected by teachers is used to make instructional, grading, and promotion decisions. **Formative assessment** is used to describe information collection and analysis resulting in information used by teachers to make decisions regarding instructional practices related to materials and pedagogical strategies for their classes and for meeting the particular instructional needs of individual students. **Summative assessment** is used to describe the collection of information to be used to grade students and to make decisions regarding promotion.

Instructional, grading, and promotion decisions are based not only on information collected by teachers. Data from external assessments administered by countries and regions within countries are sometimes used to evaluate the effectiveness of educational materials and strategies, to determine grades, promotion, and future educational opportunities for students. (Insert examples here for several counties.)

Data/information about student performance from regional or country-wide assessments is sometimes used to make decisions regarding teacher compensation and placement in schools.

Data from assessments tracking performance over time or comparing the performance of students in different countries or regions often stimulate and inform policy development at the country or regional level. The United States' National Assessment of Educational Progress (**NAEP**) is an example of a nationally mandated assessment that influences educational policy at the national level. Examples of country wide science assessments include the German Abitur, the Israeli Bagrut, and New Zealand's National Education Monitoring Project (NEMP).

The posited relationship between the strength of a country's education system and that country's economic strength is the origin of interest in cross-national assessment activity and educational policy development aimed at preparation for the workplace and higher education. Comparisons of student performance on national assessments with performance on TIMSS and PISA are highly influential in national policy discussion. Consequently student performance on these assessments is **high stakes**.

Typically, the information collected by teachers describes that which students know about science and those science-related abilities that students are able to perform. This knowledge and these abilities are closely aligned with the objectives of the science curriculum students are experiencing. **Larger-scale** assessments collect more extensive information including information about students' science knowledge, abilities, and **attitudes** toward science, as well as background information about students (gender, socioeconomic status), science teachers (years of experience, academic preparation, favored instructional strategies), and opportunity to learn science (per-pupil expenditures, science instructional materials, science laboratory facilities, and Internet and computer access).

Science knowledge and abilities have many components. Among the topics students are expected to know about or to understand are scientific theories, principles, and concepts; cross-disciplinary principles and concepts; the nature of science; the history of science; the interrelationships of science, technology, and engineering; and the interactions of science and society. Among the abilities students are expected to develop are **inquiry** (**enquiry**), **communicating science ideas** (**explanation**, **argumentation**), and **self-evaluation**. Not all components of science knowledge or all abilities (skills) are assessed on all large-scale assessments. Some components, attitude toward science, for instance, are included in the main assessment of some assessments (PISA, for instance) and in the background information of others (NAEP, for instance).

Large-scale assessments are challenging to design. Typically a consensus process is engaged to determine the science content that will be assessed and background information that will be collected. The results of the consensus process are presented in a document, often referred to as the **assessment framework**. Either in the framework or in a separate **specifications document**, details of the assessment are described. The specifications include the relative emphasis the different components of science knowledge and understanding will receive, the kinds of items (selected and constructed response items, hands-on) that will be used, and the content of the background material that will be surveyed.

Time is a major constraint on the translation of the framework and specifications into the operational assessment. The student time available for responding to assessment tasks and teacher/administrator time available to respond to background questions is limited, constraining the breadth of content and background information that can be measured.

Including students with special needs and language learners is a challenge to ensuring that an assessment adequately samples the population of interest. Extensive testing in **cognitive laboratories** of assessment tasks to determine the **cognitive demands** of the tasks and language characteristics that make items difficult to understand is an essential part of the development of assessment instruments. Providing **testing accommodations** and **adaptive testing strategies** are approaches to implementation of the assessment to ensure that special needs and language are not preventing students from demonstrating their science knowledge and abilities.

Reporting the results of large-scale assessments is challenging involving the definition of various levels of student performance (**achievement levels**) and showing the relationship of the achievement levels to the tasks which students performing at each level successfully perform. Task performance is typically translated statistically to **scale scores** and achievement levels defined by locations on the scale (**cut scores**).

The quality and relevance of assessment information to possible decisions is a central issue in the decision-making process. In large-scale assessments statistical considerations influence the quality of the data. The characteristics of the population sampled, sample size, constructs measured, the way in which constructs are measured, instrument administration, methods of data reduction, and analysis ultimately determine the statistical quality (**validity and reliability**) of data collected no matter the decision under consideration.

In addition to statistical quality, the match of the constructs measured to the decisions under consideration determines the relevance of the information (data). If, for instance, the decision is to choose which of two science curricula to implement, data comparing differences in students' scores on a standardized mathematics assessment is poorly matched to the decision under consideration. Ultimately, evaluation of the quality of assessment information/data and its use in decision making requires consideration of the question: does the quality of the information warrant the decision made?

Measures

The assessment of the science component of the OECD's PISA project introduced a radically new intention for the assessment of science learning and operationalized this with a novel instrument that included item types that had not previously been used in such large-scale testing, either nationally or internationally.

The OECD's commission for the PISA project in 1998 was to provide information to participating countries about how well prepared their 15-year-old students were for twenty-first-century life in the domains of reading, mathematics, and science – an unusually prospective brief for the assessment of learning. Fifteen-year-old students were chosen because in a number of countries, it is the age when compulsory study of science and mathematics can cease.

This commission required PISA Science to be not another retrospective assessment of students' science learning, as is customary at the levels of classroom, school, regional, national, and international assessments (like those used by the IEA in its ongoing TIMSS project). Such testing is closely tied to the intended curriculum for science and can be used to indicate a student's readiness to progress to the next level of schooling or to further study of the sciences beyond schooling in universities or other tertiary institutions.

Future preparedness for life in society as an assessment intention was quite unknown in 1998 among the OECD countries. There were, thus, no existing models for such testing, and the one had to be developed that would lead to measures of the students' capability to apply their science knowledge to twenty-first-century contexts involving science and technology (S&T).

This innovative intention to measure preparedness was applauded and endorsed by the member countries of the OECD, but there was widespread skepticism about what would be found by such a study, since the application of science knowledge in unfamiliar contexts was not something that existing science education in schools was emphasizing. It was encouraging that the students in many countries performed well on the tests although there was clear scope for improvement in all cases.

Future Preparedness as a Goal for Science Learning

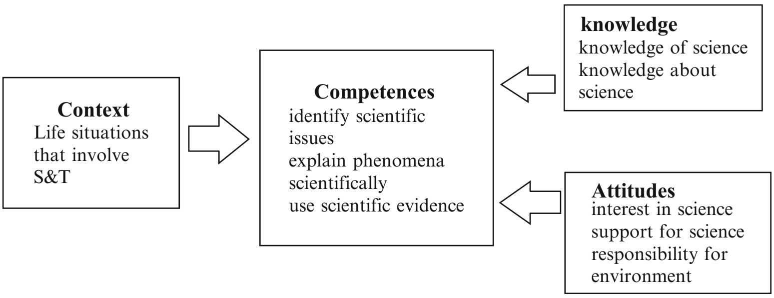
It is quite common to find the science content knowledge for teaching and learning listed in a curriculum's statement under a dual heading of knowledge and understanding. It is as if these two words are synonymous, since there is usually no explanation that they may be intended to refer to different learning of the same content from shallow recall to deeper application.

When this difference was made explicit, the countries interested in PISA Science suggested that it would primarily measure how well their students can apply the science knowledge they have learned to novel S&T contexts and hence go beyond the simple recall and application of the science as it is taught or presented in textbooks.

The organization of PISA meant that science was a minor domain in PISA 2000 and 2003, so that the Science Expert Group had the opportunity to explore several approaches to its task before settling on a framework that would deliver a defined goal for student achievement in 2006 when science was the major domain. The framework is presented in Fig. 1.

The goal was a measure of students' scientific literacy defined as an individual's:

- Scientific knowledge and use of that knowledge to identify questions, to acquire new knowledge, to explain scientific phenomena, and to draw evidence-based conclusions about science-related issues



Assessment: PISA Science, Fig. 1 Framework for PISA Science 2006 (from OECD 2007)

- Understanding of the characteristic features of science as a form of human knowledge and inquiry
- Awareness of how technology shapes our material, intellectual, and cultural environments
- Willingness to engage in science-related issues with science as a reflective citizen (OECD 2000)

With this definition, PISA Science was firmly committed to what Roberts (2007) was to describe as a Vision II approach to science knowledge, that is, one that looks outward to science and technology (S&T) in the everyday real world rather than inward to the sciences as specialized disciplines (Vision I).

The scientific literacy definition was differentiated as three cognitive and three affective scientific competences – identifying scientific issues, explaining phenomena scientifically, and using scientific evidence and interest in science, support for science, and responsibility toward resources and environments. The more specifically described competences were then the guides for the design of test units consisting of an S&T context about which several items could be asked relating to these competences. A fuller description of this use of science contexts in assessment and some of its shortcomings are discussed in Bybee et al. (2009).

The Mode of Assessment

The use by PISA Science of a paper and pencil mode of assessment has both positive and negative outcomes for science education. This mode made the testings, in general, a familiar activity to many (but not all) of the countries' students. Since PISA Science was not bound by a curriculum sense of science, PISA could use fewer simple multiple-choice items and hence more of more valid types of item, complex multiple choice, and free response. The inclusion of the range of item types in the projects should encourage countries and their schools to also use a wider range of assessment items since the more precise and open ones can then offer diagnostic as well as formative indications of student learning.

The development of the achievement tests for PISA Science (and for TIMSS) has involved procedures to ensure validity and reliability that go beyond those used in most countries. They include extensive face validity of the items among panels of experts, linguistic and cultural analyses for bias, and statistical analysis of extensive trials with student samples in several countries to establish each item's discriminating power (for PISA see McCrae 2009). These thorough approaches to test development now stand as exemplary models for the development of similarly intended assessment instruments at a national, regional, or local level of education, where extra-school tests and even fewer of the intraschool tests set by science teachers have such good item design.

Difficulty Level of Items

Retrospectively, the very large number of responses to its items enabled six levels of difficulty to be identified. The cognitive demand in the items of any of these levels was then described leading to quite new understanding of this feature of science learning that provides an indication of these depth dimensions for science learning that can have diagnostic usefulness for teachers when teaching an associated topic (OECD 2007).

Assessment of Affect About Science

In the years since PISA began, there has been an accelerating stream of reports from international and national studies that indicate a decline in student interest in science and in science careers, particularly across the more developed countries. As in its approach to cognitive science learning, PISA Science broke new ground in associating interest in, support for science, and responsibility for the environment to the specifics of the science content and context as well as with a more generic measure of the first two. Thus, affective items were embedded in the contextual units as well as being asked in the student questionnaire.

The embedding of affective along with cognitive items in the main assessment test was a major innovation and contribution to science education in two ways. Firstly, it signaled very clearly that both types of learning were natural expectations from compulsory school science. Secondly, the embedding meant that students could respond positively to the specific science in one contextual unit and negatively to what underlay another contextual unit. A much richer portrayal of their affect resulted. This approach to affective responses to science is discussed in detail (see Olsen et al. 2011).

A negative aspect of PISA Science lay in its use of the paper and pencil mode, since there are now a number of commonly agreed curriculum goals for school science education that are not amenable to this mode of testing. The classic and abiding example of these is the assessment of practical performance in science, but now decision making about socio-scientific issues, context-based science, and science project work in and outside school can be added as not amenable to this mode of testing (see Fensham and Rennie 2013). The OECD's and PISA's silence on this point can be interpreted as suggesting they are not of worth.

Another unfortunate practice in these large-scale projects is that they release only a small fraction of the items from any one testing so that their elegance as scales is never publicly evident. By now however, enough items have been released for them to be used as reliable "item banks" for the types of science learning that PISA Science intends.

Attitude Differences and Gender in Science Education

In US secondary and postsecondary schools, it is common to hear talented female students telling their peers that they are “not a [math/science] person,” even if their grades in these subjects suggest otherwise. Girls seem to develop this idea at a young age. Analyses of national data on US youth indicate that there are no notable gender differences in whether students “like science” in fourth grade, but differences emerge in eighth grade and grow stronger by 12th grade: 56 % of boys like science as compared with only 48 % of girls. This data shows that girls also have a greater tendency to report that they are not “good” at science (Bae et al. 2000, pp. 52–54). Fourth grade girls report being more likely to persist in science even if given a choice and less likely to consider science a “hard” subject, but this pattern is flipped by 12th grade, when 36 % of girls say they would not take more science (as compared to 30 % of boys) and 56 % say science is hard (as compared to 44 % of boys).

Studies suggest that gendered differences in attitudes toward science develop early, shaping female and male students’ pathways from early exposure to science through their choice of career. Parents and teachers play a role in shaping children’s gendered attitudes about science. When gender is salient in the classroom, preschool children appear to display preference for same-sex peers and exhibit behavior more closely in line with gender stereotypes (Hilliard and Liben 2010). When young people internalize the gendered messages they receive about certain career fields (e.g., science careers), they may steer away from areas in which they perceive that they are not expected to do well. Studies suggest that this pattern is heightened among the most mathematically and scientifically talented girls, representing a critical pool of potential “lost” scientific talent. These girls may consider their female identity to be mutually exclusive with a scientific identity. They may also be less likely to believe that they are indeed scientifically talented. Evidence suggests that girls develop lower assessments of their mathematical and scientific ability – irrespective of their observed ability – as compared to otherwise similar boys. These culturally influenced attitudes help to explain females’ higher rate of selection out of the pipeline to scientific careers. Biased attitudes about gender and science tend to be implicit, but nevertheless can shape behavior – including engagement and achievement (Nosek and Smyth 2011).

These biased attitudes have important effects on the available labor pool of scientists. Even though girls and boys who choose postsecondary specializations in the physical sciences, engineering, mathematics, and computer science have similar profiles, overall girls seem more likely to choose postsecondary majors in male-dominated fields like biology, clinical and health sciences, and the social and behavioral sciences, even when controlling for ability (Perez-Felkner et al. 2012). Males remain more likely to complete doctoral degrees in these scientific fields than females, across all racial-ethnic groups. The persistence of this trend is perhaps even more puzzling considering recent and mounting evidence that women are outpacing men in educational attainment, an emerging global phenomenon. Importantly, promising research shows that enrolling introductory physics undergraduates in short values-affirming writing assignments narrows the gender gap in course performance (Miyake et al. 2010). In conjunction with related research on the negative effects of salient gender stereotypes on female students’ performance on scientific tasks, these findings suggest that policy interventions aimed at affirming young women’s place in the sciences might mitigate the negative effects of persistent culturally influenced attitudes to the contrary.

Attitudes to Science and to Learning Science

Shirley Simon
Institute of Education, University of London,
London, UK

Introduction

The study of school students' attitudes towards science and learning science has been a prominent feature of science education for 40–50 years. Concerns about declining attitudes have led to many studies of the possible influences on students' attitudes and of strategies that can be undertaken to improve attitudes.

The entry draws on five selected major review articles to demonstrate key findings from a range of studies and to explore the field for future reference. The first of these, by Osborne et al. (2003), sets out the main issues arising from an extensive review of the literature up to 2003. The authors explore what is meant by attitudes towards science, provide an overview of how attitudes have been measured, and discuss findings about the influences of gender and environment (including teaching) on attitudes and what is known about the relationship between attitudes and achievement. The second article by Barmby et al. (2008) provides additional analysis of and references to attitude studies, with specific commentary on a range of similar issues arising from their own research.

More recently, with reference to the Programme for International Student Assessment (PISA), where students' interest was a component of scientific literacy, the focus in reviews by Christidou (2011) and Krapp and Prenzel (2011) has shifted towards studies of students' interest in science. The relationship between attitudes and interest is explored from analyses presented in these two articles, together with further insights into the measurement of students' interest. Additional to this focus on interest, the work of Swarat et al. (2012) presents a more detailed investigation into students' interest in school science that could enhance our understanding of how school science can serve to influence students' attitudes.

Attitudes Towards Science: What Do We Mean?

Osborne et al. point out that there has been a lack of clarity of meaning with respect to attitudes. These authors draw on earlier work to make a distinction between attitudes towards science and scientific attitudes; the latter being "a complex mixture of the longing to know and understand, a questioning approach to all statements, a search for data and their meaning, a demand for verification, a respect for logic, a consideration of premises and a consideration of consequences. . .these are the features that might be said to characterize scientific thinking" (p. 1053). Attitudes towards science on the other hand are the "feelings, beliefs and values held about an object that might be the enterprise of science, school science, the impact of science on society or scientists themselves" (p. 1053).

Osborne et al. draw attention to the complexity of attitudes and the many constructs that can comprise attitudes. They also focus on the relationship between attitude, intention, and behavior, with reference to the theory of reasoned action developed by Ajzen and Fishbein in the 1970s, which is concerned with predicting behavior. As Osborne et al. report, this theory has been applied to a range of attitude and behavior studies in science education, some of which demonstrate how attitudes towards school science (as distinct from science in society) influence choice to study science. A further, more precise, definition of attitudes is used by Barmby et al. who recognize three components of attitudes as cognition, affect, and behavior – "a person has knowledge and beliefs about objects that give rise to feelings about them, and these two components together may lead a person to take certain actions" (p. 1078). This definition of attitude is similar to that of student engagement as used in many other studies of student affect in science.

The more recent focus on interest raises the question of what "interest" means in relation to "attitude." Whereas Osborne et al. refer to interest as a form of attitude, Krapp and Prenzel draw attention to a distinction between attitude and interest, suggesting that a difference arises with respect to the evaluation criteria that are the focus: "general, nonpersonal evaluation viewpoints are decisive for an attitude to a particular object, whereas the subjective value attached to the knowledge about this object is important for interest" (p. 31). Thus, one can have a negative attitude towards something yet be interested to know more about it. The focus on interest in science and school science has contributed to our understanding of how attitudes may be shaped by both personal and environmental characteristics. Krapp and Prenzel draw on previous work in making a distinction between individual interest and situational interest, the overall notion of "being interested" coming from both personal motivation and also the conditions of a learning situation (interestingness).

Measurement of Attitudes and Interest

Many instruments have been devised to measure attitudes towards school science, and both quantitative and qualitative methods have been used in attitude studies. Osborne et al. review subject preference studies that include the use of surveys that require students to rank subjects and also focus group studies that explore views in more depth. Most common, however, is the use of questionnaires that consist of Likert scale items where students are asked to agree/disagree with various statements such as "science is fun"; "I would enjoy being a scientist" (p. 1057). Most scales use a five-point range – strongly agree/agree/not sure/disagree/strongly disagree – and include a set of items designed to cover a range of constructs and which have been piloted to test for reliability. A number of examples are included in Osborne et al.'s review. These authors caution that scales that include items covering a range of different attitude constructs cannot lead to a single attitude score, as this would be meaningless. Examples of qualitative studies in Osborne et al.'s review point to their value in providing insights into the origins of attitudes to school science.

Barmby et al. measure clearly defined attitude constructs in their study using a questionnaire, and these include "learning science in school; practical work in science; science outside of school; importance of science; self-concept in science; future participation in science" (p. 1077). The reliability values and factor analyses confirmed that the three factors of learning science in school, science outside of school, and future participation in science could be brought together to provide a combined "interest in science" measure.

In their review, Krapp and Prenzel point out that more domain-specific interest measures are less frequently used. They discuss at length the issues pertaining to domain-specific interest measures and describe an example of a differentiated instrument used for a study in physics, which included three dimensions: topics, contexts, and activities – within which were eight topic categories, seven context areas, and four kinds of activity, in all, 88 items. Factor analysis could then determine the construct of “interest in physics.” This kind of breakdown of what the interest is about can enrich studies that look at specific subjects/domains of science and environmental factors. Krapp and Prenzel review other research approaches for studying interest, including observations, interviews, and databanks available on the Internet.

Attitudes in Relation to Various Factors

This section provides an overview of the findings reported in the five articles that focus on key issues relating to students’ attitudes towards and interest in science and school science. Where it exists, a distinction is made between findings that relate to science, as opposed to school science or learning science.

Age

Osborne et al. report on a range of studies that show a decline in attitudes towards science in early adolescence, in some cases even earlier. A more detailed analysis of studies does highlight a distinction between attitudes towards science and attitudes towards school science, as many 15-year-olds have positive attitudes towards science, finding it interesting, useful, and relevant, particularly in relation to technological advances, whereas school science is seen as rooted in past discoveries. Barmby et al. found a steep decline in attitudes towards learning science between students aged 11 and 13. Qualitative evidence showed that reasons for this decline in attitudes included lack of practical or lab work, weak explanations, and the perception that school science is not relevant. Krapp and Prenzel question the theoretical and practical relevance of how these trends are measured and judged, as they do not provide an insight into interest development in specific subgroups or subjects. These authors call for a more exact analysis of data from longitudinal studies. They report on one such study in physics that demonstrated that when physics is taught so that students can recognize a direct connection to practical life situations, then interest remains stable or increases.

Science Subject/Domain

Students’ attitudes to school science can vary according to subject (Osborne et al.); some findings indicate that biology is perceived as more relevant as it addresses students’ interests in their own bodies and health and disease, whereas the physical sciences are seen as less relevant, particularly chemistry, with topics such as the Periodic Table, the Haber process, and the Blast furnace being seen as least relevant. Osborne et al. also report on subject preference studies that show chemistry to be less appealing than physics. Many studies show gender differences in attitude towards different subjects and topics; Christidou reports that physics is the least attractive discipline for girls, who tend to be more attracted to studying animals and health or aesthetic topics. Swarat et al. report on research that shows the interest of younger students to focus on biology, technology, and astrophysics. Their research with students in the sixth and seventh grades shows that activities or topics based on technology or the human body are significant predictors of overall interest in science.

Gender

Research undertaken between 1970 and 1990 demonstrated that boys had more positive attitudes to school science than girls (Osborne et al.). Analysis of reasons indicated a range of possibilities from the early childhood experiences of boys playing with more scientific toys to perceptions of difficulty of the subject – girls believing themselves to be better at other subjects. Studies undertaken after 1990 provide evidence that girls believe themselves able to follow careers in science, even though they are less likely than boys to do so. However, gender influences are complex, as personal attributes such as self-concept and self-efficacy are operating with environmental effects such as single-sex schools or style of teaching. Krapp and Prenzel highlight the importance that such attributes play in explaining gender-specific differences in interest in science.

As Barmby et al. report, more recent studies have shown that the factor “who students want to be” has more prominence than previously and they conclude that attitudes are influenced by the current social contexts in which they are conducted. They also report that differences between boys’ and girls’ attitudes towards science outside school increase markedly with age, the difference being quite small at age 11 and more marked at age 13–14 years. Decline in attitudes to learning science in school occurs with both boys and girls but is still more pronounced with girls. With reference to international studies, Krapp and Prenzel report that differences between boys’ and girls’ interest in future careers in science are now only small. Moreover overall interest is more markedly different between less industrialized countries (where interest is higher for both males and females) and countries with advanced technological development.

Christidou focuses more specifically on students’ images of science and scientists that reveal gender stereotypes regarding professions perceived as scientific. Girls more than boys see science as “competitive, impersonal, abstract, rule-founded, certainty-bounded, deprived of imagination and as a product of individual effort made exclusively by male scientists” (p. 144). Though her review of studies also suggests that boys are more interested in science than girls, particularly in relation to some subjects (see above), she has found convergence in male and female interest in topics related to human biology, plants and animals, light and sound, and astronomy. Moreover, girls are more influenced by the interpersonal dimension – the presence of other people who they admire.

Environmental Factors

Though background factors such as parental influence and socioeconomic status can play a part in contributing to students’ attitudes towards science and school science, the most significant determinant of attitude is classroom environment (Osborne et al.) and in particular quality of science teaching: “Good teaching was characterized by teachers being enthusiastic about their subject, setting it in everyday contexts, and running well-ordered and stimulating science lesson. . .. talking with the students about science, careers and individual problems” (p. 1068). One important aspect of good teaching that these authors report is specialist knowledge, for example, low attitudes to science subjects could be attributed to teachers teaching outside their specialist subject with less enthusiasm.

Christidou also reports on the relationship between negative attitudes and the way science is taught. Teachers themselves need to have a positive stance towards science and scientists in order to inspire their students. The situation is not helped when school science is fragmented into isolated disciplines, and is limited in how it addresses values and social issues. Christidou’s review also looks at the popular images of science in relation to students’ interest and attitudes towards science. In focusing on the implications of how science is perceived by students, she reviews studies that have aimed to enhance students’ involvement in science through providing different learning environments. For example, she points out that involvement in a variety of informal out-of-school science activities may be associated with a firmer commitment to science and science learning. Swarat et al. focus on “activity type” in their study of students’ interest and show that inquiry-based teaching practices impact positively on motivation, interest, curiosity and enthusiasm. Their study on instructional episodes shows how different types of activity account for most variation in students’ interest, as opposed to content topic or learning goal.

Achievement

The nature of any relationship between attitude and achievement has been a key concern of many studies, but the evidence is inconclusive regarding this relationship (Osborne et al.). While some studies show a positive correlation, others show that students can achieve highly in a subject without having a positive attitude towards it.

Implications for Future Research

The authors of these selected articles call for an agenda for future research to establish a greater understanding of how pedagogic practice can enhance students' attitudes. In spite of the wealth of studies reported in these articles, research is still needed that looks at the way science is presented to students, including the values connected to science (Christidou). Developments in science pedagogy could be the focus of attitude research; studies that build on Swarat et al.'s work on activity could determine the kinds of classroom interventions that are appealing to students and influence students' interest in and attitudes towards science and learning science. Related to this issue is the education of future science teachers and research on the impact of such preservice education; teacher educators and school mentors could focus on raising the awareness of new teachers of what students find interesting, relevant, and inspiring to engage with science. Changes in the curriculum could also form part of an agenda for future research, including how the content of the curriculum (including its omissions) is relevant to students' developing values, interests, and attitudes.

Attitudes, once formed, may be relatively stable for individuals, but the shaping of attitudes is complex and also context dependent, which makes the task of determining attitudes in a changing world dynamic and never-ending. As Osborne et al. point out "attitude cannot be separated from its context and the underlying body of influences that determine its real significance" (p. 1055). Findings of studies conducted over different time periods relating to age, gender, and cultural background do vary as different contexts and influences operate. Ongoing research is needed to capture changing trends in the relationship of age, gender, and culture to attitudes towards science.

Attitude studies that have included mixed methods have provided quantifiable data that is supported by more in-depth analyses that deepen our understanding of how attitudes towards science are influenced. The development and use of inventories that measure motivation and personal attributes of students can be coupled with studies of pedagogy and learning environments to determine relationships between variables. Longitudinal studies that take into account a host of such variables can be used to inform policy and pedagogy – how to resource and support science and communication about science and to fund the pre- and in-service education of science teaching.

Though we already have a rich resource of research in this field, these five articles provide some ideas for possible future research on attitudes towards science that would have considerable benefit for science education.

Students' Attitudes and their Measurement

Most children come to school ready and willing to learn. International surveys of primary age children generally reveal high levels of interest and positive attitudes of children to subjects such as science. Unfortunately, as children move through the education systems, their positive attitudes toward science typically decline, and increasingly fewer students are interested in studying science and to work in science-related careers.

Science and technology have enabled remarkable achievements, and their role in society continues to grow as the world faces the new challenge brought about by globalization and the serious test of how to protect the environment while promoting economic growth and sustaining an increasing world population. In order to successfully address these challenges, countries will have to make major investments in scientific infrastructure and the ability to attract, retain, and reward qualified individuals into science-related professions. Countries will also have to secure broad public support for scientific endeavor and ensure that all citizens are able to make use and benefit from science in their lives.

People's attitudes toward science are an integral part of whether they can be considered scientifically literate or not, as they determine whether individuals are willing to engage with science: attitudes and motivation in fact play a significant role in how interested people are in science and technology, how much attention they devote to scientific issues and technological progress, and how they respond to scientific challenges. The Programme for International Student Assessment (PISA) has examined how well 15-year-olds worldwide perform in science since 2000 and in 2006 closely examined what attitudes students have toward science and how motivated they are to study science and to work in science-related careers. In 2015 PISA will monitor closely student attitudes toward science for a second time and by so doing will be able to illustrate trends in what students think about science and their views on why studying science matters for them and society more widely.

Students participating in the PISA 2006 study sat for a 2-h test aimed at assessing their level of proficiency in science, mathematics, and reading. After completing some specific test questions related to science, students were asked to report their support for a number of statements directly linked to the science topics they had just encountered. After the test, students also completed a questionnaire where they were asked questions about themselves, their household situation and also whether they agreed or not to a series of statements developed to assess their attitudes toward science. Students' responses to the assessment-embedded questions and to the background questionnaire were used to develop measures identifying several aspects of student attitudes toward science: what motivates students to learn science and how motivated they are, to what extent students value and enjoy science, whether students believe in their own science abilities, whether they believe they can perform specific scientific tasks, and whether students expect to work in science-related occupations. The sections below describe how PISA measured attitudes toward science in 2006 and illustrate gender and socioeconomic disparities in students' attitudes toward science.

Motivation to learn science. PISA distinguishes two forms of motivation to learn science: students may want to learn science because they enjoy it and find it interesting, intrinsic motivation to learn science, but they may also wish to learn science and excel in science because they perceive learning science as useful, extrinsic motivation.

Intrinsic motivation refers to performing an activity purely for the joy gained from the activity itself: students are intrinsically motivated to learn science when they want to learn science because they find science interesting and enjoyable and when they want to study science for the pleasure it gives them, not because of what they will be able to achieve upon mastering science subjects. Intrinsic motivation affects how engaged students are, the learning activities students enroll in, student performance in science, and the types of careers students aspire to have and choose to follow. Generally, intrinsic motivation declines from elementary school to higher education, but can be importantly shaped by what teachers do, by students' peers, by classroom instruction and dynamics, as well as by parental motivational practices, attitudes, and behaviors. PISA indicates that, within countries, students who have high levels of intrinsic motivation to learn science are highly proficient in science, although countries where students have, on average, comparatively high levels of intrinsic motivation to learn science are not necessarily the countries with the strongest science performance in the PISA assessment.

PISA 2006 provides three measures of students' intrinsic motivation to learn science: general interest in science, enjoyment of science, and interest in learning science topics. The first two measures were computed using students' answers to the student questionnaire. Students were asked how interested they were in learning about the following science topics: physics, chemistry, biology of plants, human biology, astronomy, geology, the ways scientists design experiments, and what is required for scientific explanations. The *index of general interest in science* combines students' answers on whether they have "high," "medium," "low," and "no" interest to learn these topics. *Enjoyment of science* was assessed asking students to answer whether they "strongly agreed," "agreed," "disagreed," and "strongly disagreed" that they enjoyed five different aspects related to science and learning science. The *index of interest in learning science topics* on the other hand was assessed using embedded questions in the assessment of students' performance after students had worked on cognitive items so that object-specific interest could be evaluated. The students were asked to indicate their interest in the topics, objects, and activities that they had just encountered.

Extrinsic motivation to learn science refers to the motivation that drives students to learn science because they perceive it as useful to them and to their future studies and careers. Extrinsic motivation was measured in PISA 2006 by assessing students' instrumental motivation to learn science and by assessing students' future-oriented motivation to learn science. *Instrumental motivation* to learn science was measured asking students to report whether they "strongly agreed," "agreed," "disagreed," or "strongly disagreed" to five statements aimed at capturing the importance students attach to learning science because it is useful, because it will help students succeed in their future jobs, or because it will help improve career prospects. Instrumental motivation to learn science is an important predictor of course selection and career choices, and results from PISA 2006 indicate that students perceive science to be useful and that they believe science can help them in their search for jobs and can help them pursue better career prospects (OECD 2007). Although instrumental motivation to learn science was highly correlated with science performance in some countries, in others the relationship was weaker or negative, with few differences between boys and girls. *Future-oriented motivation to learn science* was assessed by asking students to report whether they "strongly agreed," "agreed," "disagreed," or "strongly disagreed" that they would like to have a science-related career, to continue studying science after completing secondary school, and to continue to use science in their future lives. Future-oriented motivation to learn science was positively associated with science performance in 42 PISA participating countries and economies, including all OECD countries except Mexico, and the strength of the association is quantitatively important in as many as 20 PISA 2006 countries and economies.

Support for science. In 2006 PISA explored the extent to which students appreciate science and scientific inquiry and whether they believe science plays an important role in their own lives by asking students questions about how much they support and value science. Responses provided in the context of the student background questionnaire were used to develop a measure of students' general value of science and a measure of students' personal value of science. Responses that the students provided to questions that were embedded in the science assessment, after students had encountered specific test questions, were used to capture how students value science in relation to specific topics. Personal values of science are fundamental antecedents of emotional feelings about science such as enjoyment, motivation for learning science, and motivation for a long-term engagement in science. When students value science in their own lives, they are more likely to enjoy science and to be interested in scientific topics. Both general and personal values of science are related to students support for scientific inquiry.

A general value of science indicates to what extent students value the contribution of science and technology. The majority of students participating in PISA 2006 reported that they value science, and while almost all students participating in PISA reported that they believe science is important to understand the natural world and that scientific and technological advances usually improve people's conditions, significant proportions of students did not agree that advances in science and technology usually bring about social or economic benefits. While the overwhelming majority of students reported valuing science in general, far fewer students feel that science directly related to their own lives and behavior: students across all participating countries and economies had lower levels of *personal value of science* than general value of science. Scientific inquiry refers to valuing scientific ways of gathering evidence, the importance of considering alternative ideas, the use of facts and rational explanations, and communicating with others. On average, only 59 % of students reported that they would use science when they left school, 64 % of students reported that they would use science as adults, and only 57 % of students agreed that science was very relevant to them. When participating students were asked about their support for scientific inquiry immediately after they had solved specific science tasks in the PISA science assessment, students reported strong levels of *support for scientific inquiry*, for example, students supported research to develop vaccines for new strains of influenza and they valued the systematic study of fossils and that scientific research should be at the basis of statements about the causes of acid rain.

Personal beliefs. In 2006 PISA also assessed students' self-beliefs as science learners. Students with positive self-beliefs believe in their own ability to handle scientific tasks effectively and to overcome difficulties and in their own academic ability. Autonomous learning requires both a critical and a realistic judgment of the difficulty of a task as well as the ability to invest enough energy to accomplish it. Students' views about their own competences have been shown to have considerable impact on the way they set goals, the learning strategies they use, and their performance.

Self-efficacy goes beyond how good students think they are in subjects such as science. It is more concerned with the kind of confidence that is needed for them to successfully master specific learning tasks and therefore not simply a reflection of a student's abilities and performance. The relationship between students' self-efficacy and student performance may well be reciprocal, with students with higher academic ability being more confident and higher levels of confidence, in turn, improving students' academic ability. A strong sense of self-efficacy can affect students' willingness to take on challenging tasks and to make an effort and persist in tackling them: it can thus have a key impact on motivation. To assess self-efficacy in PISA 2006, students were asked to rate the ease with which they believe they could perform eight listed scientific tasks. For each of the eight scientific tasks, the average percentages of students reporting that they could do it either easily or with a bit of effort vary considerably. Seventy-six percent of students on average reported that they felt confident explaining why earthquakes occur more frequently in some areas than in others. Similarly, 73 % of students reported that they could recognize an underlying science question in a newspaper report on a health issue. Around 60 % of students on average reported that they could interpret the scientific information provided on the labeling of food items, predict how changes to an environment will affect the survival of certain species, and identify the science question associated with the disposal of garbage. Less than 60 % of students reported that they could describe the role of antibiotics in the treatment of disease or identify the better of two explanations for the formation of acid rain. Students were least confident with discussing how new evidence could lead to a change of understanding about the possibility of life on Mars, with only around half of 15-year-olds in OECD countries reporting that they could do so easily or with a bit of effort.

Students' *academic self-concept* is both an important outcome of education and a trait that correlates strongly with student success. Belief in one's own abilities is highly relevant to successful learning. It can also affect other factors such as well-being and personality development, factors that are especially important for students from less advantaged backgrounds. In contrast to self-efficacy in science, which asks students about their level of confidence in tackling specific scientific tasks, self-concept measures the general level of belief that students have in their academic abilities. To what extent do the 15-year-old students assessed by PISA believe in their own science competencies? On average, 65 % of students reported that they could usually give good answers in science tests. Overall, however, a large proportion of students (between 41 % and 45 % on average) said they were not confident in learning science, reporting that they did not agree that they learned school science topics quickly or understood concepts or new ideas very well. Furthermore, 47 % agreed that school science topics were easy and that learning advanced science would be easy.

Within countries, student attitudes toward science are associated with higher performance in the PISA science assessment in virtually all OECD countries; however, countries that have, on average, positive attitudes toward science are not necessarily countries with high mean science performance. For example, PISA, as well as other international studies such as TIMMS and ROSE, suggests that students in low-performing countries have relatively high levels of interest in science, while students in high-performing countries show relatively low levels of interest in science. Within countries internal motivation to learn science and instrumental motivation to learn science, participation in science-related activities, self-efficacy, and science self-concept are all strongly associated with science performance, with self-efficacy having the strongest association. Results from PISA 2006 suggest that, across OECD countries, students who have values on the index of student self-efficacy that are one standard deviation above the OECD mean score 28 points higher on average than students with average levels of self-efficacy. The score point differences associated with one standard deviation rises in the index of general interest in science and in the index of student self-concept in science are also close to 20 points. The differences are lower in relation to both the index of student participation in science-related activities and the index of instrumental motivation to learn science (16 and 14 points, respectively).

Gender differences. PISA indicates that 15-year-old boys and girls generally perform at similar levels in science, but boys and girls do not hold similar attitudes. For example, boys tend to have greater self-concept and greater self-efficacy in science than girls, as well as higher levels of enjoyment of science and instrumental motivation to learn science, but boys and girls have similar levels of intrinsic motivation to learn science. Recent meta-analyses show that boys have consistently more positive attitudes toward science than girls, especially toward physical science and engineering. Girls, on the other hand, tend to be more interested in health and life sciences. In 2006, PISA asked 15-year-old students what they expect to be doing in early adulthood, around the age of 30. In general boys and girls reported expecting to pursue careers in very different fields. In recent years, girls in many countries have caught up with or even surpassed boys in science proficiency. Better performance in science or mathematics among girls, however, does not mean that girls want to pursue all types of science-related careers. In fact, careers in "engineering and computing" still attract relatively few girls. Results from PISA 2006 suggest that among OECD countries, on average, fewer than 5 % of girls, but 18 % of boys, expected to be working in engineering and computing as young adults. In no OECD country did the number of girls who expected a career in computing and engineering exceed the number of boys contemplating such a career. Moreover, the ratio of boys to girls who wanted to pursue a career in engineering or computing is large in most OECD countries: on average, there were almost four times as many boys as girls who expected to be employed in these fields.

Even among the highest-achieving students, career expectations differed between boys and girls; in fact, their expectations mirrored those of their lower-achieving peers. For example, few top-performing girls expected to enter engineering and computing. Although few girls expected to enter some science careers, such as engineering and computing, in every OECD country more girls than boys reported that they wanted to pursue a career in health services, a science profession with a caring component. This pattern holds even after nurses and midwives are excluded from the list of health-related careers. On average across OECD countries, 16 % of girls expected a career in health services, excluding nursing and midwifery, compared to only 7 % of boys. This suggests that although girls who are high achievers in science may not expect to become engineers or computer scientists, they direct their higher ambitions toward achieving the top places in other science-related professions, such as those in the health field.

Differences by socioeconomic background. PISA reveals that socioeconomically advantaged students tend to have more positive attitudes toward science, as well as higher science performance, than their less advantaged peers. Given the strong association that exists between science performance and attitudes toward science, could the socioeconomic gap in science performance be closed if socioeconomically disadvantaged students had more positive attitudes toward science? What role do attitudes toward science play in helping disadvantaged students overcome the adverse circumstances determined by their socioeconomic background?

Results from PISA 2006 (OECD 2011) indicate that socioeconomically disadvantaged students tend to have less positive attitudes toward science than socioeconomically advantaged students. They also tend to engage less in science activities, feel less prepared for science careers, attend fewer science courses, and spend less time in science lessons at school. For example, disadvantaged students report being less interested in science and having lower levels of self-efficacy than their more advantaged peers in every OECD country and in most partner countries and economies. The differences in the extent to which disadvantaged students and their more advantaged peers report having low levels of instrumental motivation to learn science, participation in science-related activities, self-concept, and information on science-related careers are also significant in most OECD and partner countries and economies.

PISA 2006 further reveals that both disadvantaged students and their more advantaged peers benefit from having positive attitudes toward science. With a few exceptions, disadvantaged students benefit, on average, as much as their more advantaged peers from having positive motivation, participation in science-related activities, confidence, and perspectives future careers in science. There are, however, some important differences across areas. For example, in several countries, the association between attendance at compulsory science courses and performance is stronger for disadvantaged students than for their more advantaged peers. In addition, in a number of countries disadvantaged students appear to benefit less than their more advantaged peers.

These results suggest that positive attitudes toward science are associated with increases in the PISA score across all socioeconomic groups but crucially that the increases are smaller for disadvantaged students in some countries. Policies aimed at promoting greater motivation to learn science and positive attitudes and approaches to science learning may therefore result in absolute improvements in science achievement but may also run the risk of contributing to wider performance gaps across social groups unless they are targeted at specific populations.

Attitudes, Gender-Related

Jane Butler Kahle
Teacher Education, School of Education, Health and Society, Miami University, Oxford, OH, USA

Keywords

Gender; Science education

Gender is defined in various ways, but for the purposes of the encyclopedia entry on gender-related attitudes, gender is considered a social construct, not a biological one; that is, gender is not determined by one’s DNA and hormones, but rather by the accumulation of one’s sociocultural experiences.

Gender-related attitudes are initially developed and formed in a child’s home, affected by the actions and attitudes of teachers and friends, and reinforced by experiences in the workplace – or in society in general. Self-confidence in studying science, attribution of success in science, fear of failure in science, participation rates in science, perceptions of the usefulness of science, and performances in science all contribute to one’s gender-related attitudes about science. Further, gender-related attitudes contribute to a student’s aspirations and interest in science and are heavily influenced by teacher beliefs, expectations, and classroom behaviors.

Gender-related attitudes in science education have been studied extensively since the early 1980s. During that time, girls, compared with boys, have consistently reported more negative attitudes towards science in local, regional, national, and international studies. Although gender-related differences decline as students proceed through school and the decline is greater for girls than for boys, girls’ interest in science does not increase over time (Scantlebury 2012).

Ausubelian Theory of Learning

Joseph D. Novak
Cornell University and Florida Institute for Human and Machine Cognition, Ithaca, NY, USA

David Ausubel: An Introduction

David Ausubel was born in 1918 and graduated from the University of Pennsylvania with honors in psychology in 1939. In spite of his outstanding undergraduate record, Ausubel suffered from the prevailing medical school prejudice against Jewish students and could not get admitted to any of the best medical schools. Instead, he studied Experimental Psychology at Columbia

University and earned an MA degree in 1940. He completed the MD degree at Middlesex University in 1943 and then did three psychiatric residences with the US Public Health Service in Kentucky, the Buffalo Psychiatric Center, and Bronx Psychiatric Center. After military service in Germany, where he worked in the United Nations Relief and Rehabilitation Administration, Ausubel earned a PhD degree in Experimental Psychology at Columbia University in 1950. It was at Columbia that he first began to formulate his ideas that evolved into his *assimilation theory* of learning first published as a paper in 1962 and then as his 1963 book, *The Psychology of Meaningful Verbal Learning*. In 1968 he published a more comprehensive book, *Educational Psychology: A Cognitive View*. This book extended his theoretical ideas and applied them to other areas of educational psychology. In this work Ausubel offered educators an alternative theory of learning to the behavioral psychology that was almost universally embraced by psychologists in the 1960s. It was his theory of learning I adopted and adapted to my research and instructional design programs from 1963, first at Purdue University and then at Cornell University.

When I was a graduate student in Education at University of Minnesota, I took a graduate course in Theories of Learning. The text was Hilgard's 1948 book, *Theories of Learning*, and it presented only behaviorists' theories of learning. I recall complaining to the professor teaching the class that there was nothing in these theories that was useful to classroom teaching. While he did not deny my claim, he argued that Hilgard's book was the only one of its kind and was almost universally used in universities. I recall that my colleague at Cornell, Bob Gowin, had a similar reaction to a similar course at Stanford University where he did his graduate studies at about the same time. After the information processing/cognitive psychology revolution of the 1980s, it is hard for present-day scholars to appreciate what a profound departure from the prevailing educational psychology Ausubel was promoting with his new theory.

In 1965, I attended a conference on Concept Learning at the University of Wisconsin, and here I had a chance to have extended conversations with Ausubel about his theory.

These conversations helped me gain insights into his theory and its application to education. These conversations began a continuing dialogue with Ausubel, and in 1977, he invited me to assist in the revision of his 1968 *Educational Psychology: A Cognitive View*. During the course of these revisions, where I revised the key chapters dealing with his assimilation theory, I got deeper insights into his thinking. I was also amazed at his prodigious knowledge of the literature. On several occasions I recall calling Ausubel to discuss his interpretation of some research studies that did not seem evident to me. On all of these occasions, he would describe his thinking in reaching the conclusions he did from these studies. Considering there are over 1,400 research references in his 1968 book, I marveled at his ability to discuss specific studies over the phone. Ausubel had a remarkable intellect, a genius in his own way! I marveled at how he could sift through the dustbins of behavioral psychology and tease out research findings that could be used to contribute to his assimilation theory.

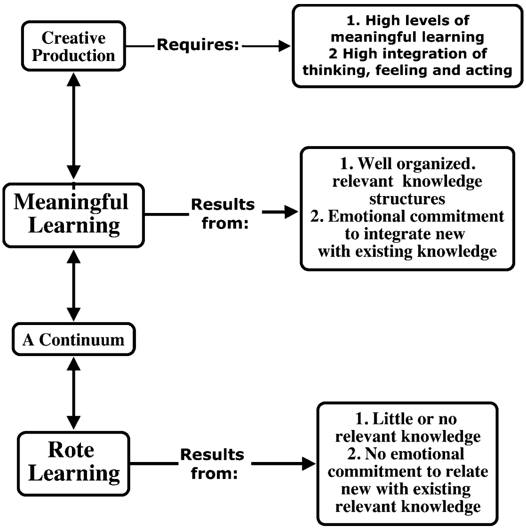
The Core of Ausubel's Theory

In the epigraph in his 1968 book, Ausubel wrote:

> If I had to reduce all of educational psychology to just one principle, I would say this: The most important single factor influencing learning is what the learner already knows. Ascertain this and teach him accordingly.

Now this may appear to be simple enough, or even to some simplistic. However, it is not easy to ascertain carefully what the learner already knows on a given topic, and it is even more difficult to determine how best to teach him/her effectively. Indeed many of the major research programs focused on the learning and teaching of science that have been conducted over the last 30–40 years, including mine, have at their core been concerned in some form with one or both of understanding ways to determine "what the learner already knows" and then what it would mean to teach the leaner "accordingly."

When Ausubel speaks about what a learner already knows, he is speaking about the concepts and propositions that have meaning for this learner. In our work we have slightly modified Ausubel's definition of these terms to better fit current epistemological thinking. We define a *concept* as a perceived pattern or regularity in events or objects, or records of events or objects, designated by a label, such as a word or symbol. *Propositions* are two or more concepts linked to make a meaningful statement about events or objects. Propositions can also be thought of as the fundamental units of meaning, for concepts standing alone convey little meaning. Getting smart about a domain of knowledge requires building a powerful cognitive framework of concept and propositions for that domain, together with supportive feelings and skills necessary to achieve this organized body of knowledge.



Ausubelian Theory of Learning, Fig. 1 The rote-meaningful learning continuum (Novak 2010)

The Essential Principles of Ausubel's Theory

Ausubel's theory has six basic principles: *The first two principles* are ***rote learning***, which occurs when the learner makes little or no effort to relate new knowledge to relevant elements of knowledge the learner already knows, whereas ***meaningful leaning*** occurs when the learner makes a deliberate, conscious effort to relate new concepts and propositions to existing, relevant concepts and propositions. Only the learner can choose to learn *meaningfully*, although there are strategies that can encourage this kind of learning. In the 1970s Ausubel argued that rote learning and meaningful learning are two different, distinct ways of learning. I argued that it was my experience at that time indicated that the quality and extent of meaningful learning depended both on how much effort and commitment the learner makes to relate new learning to her/his existing knowledge and also on the quality and degree of organization of that existing relevant knowledge. Therefore, cognitive learning should be viewed as a continuum, varying from very rote, arbitrary acquisition in information to very high levels of meaningful learning. More recently I have argued that creativity could be viewed as essentially very high levels of meaningful learning. This view is expressed in Fig. 1.

While Ausubel accepted the idea that rote and meaningful learning can be viewed as a continuum, he always held that creativity was a special capacity possessed by relatively few very gifted people. To be sure, only a very small fraction of the population have the capacity to organize their thinking, feeling, and acting in ways that lead to the extraordinary creativity of an Einstein or a Mozart. However, most normal individuals can on occasion gain novel insights in a limited sphere knowledge creation. This view is discussed later in this entry.

The third key principle of Ausubel's theory is ***subsumption***. When new concepts and propositions are incorporated into relevant, more general concepts and propositions, ***subsumption*** occurs and both the existing superordinate knowledge and the newly incorporated idea are modified. Ausubel maintained that subsumption is the most common form of meaningful learning. This view has been supported by our research and the research of others. In extreme rote learning, the process of subsumption does not occur where one can think of the new bits of knowledge as just kind of floating around in cognitive space, each in isolation of all other elements. There are two negative results from this kind of rote learning. First, there is no enhancement and refining of meanings for existing concepts and propositions. Consequently these existing ideas do not (and cannot) become more powerful subsuming concepts nor more differentiated ideas that can serve better for problem solving or creative work. Second, faulty ideas or ***misconceptions*** held by the learner do not get "corrected" or altered into more accurate forms. Research has shown that students who learn primarily by rote are poor at solving novel problems and they do not modify and correct their faulty conceptions; nor do they consider in any way relevant alterative conceptions they use to interpret their world.

The fourth principle in Ausubel's theory is ***obliterative subsumption***. This occurs when over a span of time, discrete ideas are subsumed into more general concepts and later can no longer be recalled as discrete ideas (hence "obliterative"). These concepts and propositions have contributed to elaborating the more general idea into which they were subsumed, but we can no longer recall them independently. All of us have experienced occasions when we knew that object or event belongs to a certain category of things or events, but we cannot recall the details of that object or event. Obliterative subsumption that occurs after some meaningful learning event is not the same as forgetting that occurs after rote learning. There remain some enriched concepts and propositions in your cognitive structure and these will *facilitate* new, relevant learning. When forgetting occurs after rote learning, there is usually *interference* or retarded learning of related material. No doubt the reader can recall being confused in trying to recall something recently learned because of the new ideas are still jumbled up with similar things in our minds and we cannot sort out the details. For many of us, including me, a good example of this is trying to recall names. Unless I have made some kind of meaningful connection to a person's name and something related to that name, I might forget the name in a minute or two!

The fifth principle in Ausubel's theory is ***superordinate learning***. This kind of learning occurs when several concepts or propositions are recognized as really subordinate units of some larger, more inclusive idea. For example, children learn that there are pigs, cows, dogs, and similar animals. When they acquire the superordinate concept of mammal, i.e., something with hair or fur and females with mammaries to nurse their young, superordinate learning has occurred. Similarly, one may learn about many events that occurred in France and Europe in the fourteenth to seventeenth centuries. This lays the foundation for coming to understand the period as the ***renaissance*** and this adds a superordinate concept to enrich the meanings of the individual events you have studied.

Finally (the sixth principle), there is Ausubel's principle of ***integrative reconciliation***. An example of this principle at work is when a child realizes that multiplication is really just a form of repeated addition. The child now sees that $2 \times 3 = 6$ is the same as $2 + 2 + 2 = 6$. So much of mathematics would be more easily learned and remembered if teaching was designed for encouraging repeated integrative reconciliation of component ideas. Of course, this is also true in every other discipline.

A general comment about these six principles: Many people have found it difficult to grasp Ausubel's assimilation theory of learning. In part, and in common with the totality of any complex theory in any discipline, this is because each of the principles in this theory is related to all the other principles. One cannot really understand integrative reconciliation until one understands meaningful learning and superordinate learning. One cannot grasp the meaning of all six principles in a single sitting or session. One must get a beginning understanding of each and gradually refine and build those meaning over time with numerous examples and experiences. Profoundly important ideas are profoundly difficult to master. My counsel is to just begin to work with these ideas and they will become more clear and powerful over days, weeks, and months.

Advance Organizers

Ausubel also advanced the idea of advance organizers, and at times in the past, it seemed he was better known for this than for his theory of learning. His, and others', research shows that if one precedes a segment of instruction with a more general, more abstract segment of instruction on a topic to be studied (an "advance organizer"), this can help the learner integrate the new details to be learned with existing relevant subsumers, thus facilitating meaningful learning. The advance organizer serves as a kind of "cognitive bridge" helping the learner to recognize existing relevant concepts and propositions she/he possesses and facilitating subsumption of the new information.

The idea of advance organizers is not part of his theory of learning but rather an instructional strategy. Other psychologists have advanced similar ideas usually termed ***scaffolding*** (Hogan et al. 1997) learning. In either case, the goal is to help the learner assimilate new more explicit material to be learned into her/his cognitive structure. When an advance organizer is well planned, it should help the learner see relationships between some more general, relevant idea they already know and the more specific, more detailed concepts and propositions to be learned. In other words, a good advance organizer facilitates the subsumption of new relevant concepts and propositions.

Many studies have shown that the use of advance organizers significantly enhances meaningful learning of more detailed, relevant information, including two studies done by one of my graduate students. Kuhn found that biology laboratory students who were given an advance organizer to study prior to instruction on homeostasis and levels of biological organization did significantly better when tested on these ideas at the end of the laboratory and 3 weeks later, when compared with students not given these advance organizers. Some research studies have failed to show a positive effect for "advance organizers," but in most of these cases, either there were inappropriate advance organizers or the achievement tests used did not require significant meaningful learning. Testing only for recall of specific details is not likely to show the advantage of using an advance organizer, because there is no logical reason to suggest that an advance organizer could do anything to assist rote learning.

Primary and Secondary Concepts

Ausubel distinguishes between primary concepts and secondary concepts. *Primary concepts* are those acquired from direct experience with objects or events, and these can be acquired readily by the young child. *Secondary concepts* are derived from perceived regularities in relationships between primary concepts, and these are more difficult to acquire. Energy is an example of a secondary concept, and acquisition of this concept requires direct experiences with objects or events that manifest the concept and guidance in observing the manifestations of the regularity that defines the concept. A young child can learn about atoms and molecules and energy and energy transformations providing they are given experiences where these concepts are manifest and they are given guidance to observe the patterns or regularities that manifest the concept. Thus, children can be provided with experiences and guidance to understand the particulate nature of matter and the effect of adding heat to a sample of matter, such as heating a balloon. In a 12-year longitudinal study, we showed that 6–8-year-old children when provided with appropriate experiences and audio guidance in their observations can begin to acquire functional concepts of matter and energy and energy transformations (Novak and Musonda 1991). Moreover, as these children progressed through the grades, those who had this early instruction demonstrated twice as many valid concepts about the nature of matter and energy and less than half as many misconceptions, compared with similar students who did not have this early instruction.

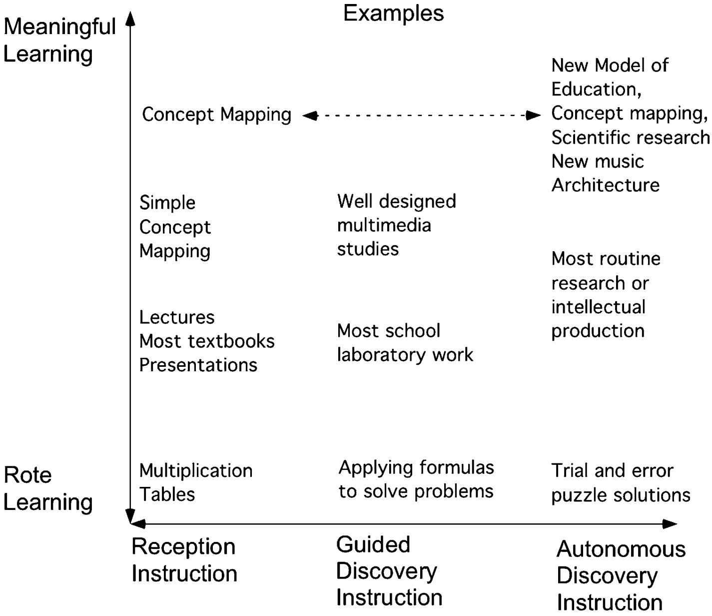
Reflections on Ausubel's Theory of Learning

Ausubel held a more conservative view about the learning capabilities of young children than many of the researchers who subsequently worked with his theory. I think this is due to the fact that he did very little research with young children, whereas the work of others (including my research programs) has involved this age group. In the last 20 years, there have been numerous studies by a range of researchers (from cognitive scientists to early childhood educators with expertise in science) that show we have consistently and grossly underestimated the learning capabilities of young children.

Many researchers, including many graduate students, embraced Ausubel's theory as a powerful and useful theory to guide their research on learning science. However, most of my colleagues in Science Education in the USA rejected his ideas or simply ignored them. The work of Piaget, interpreted as if he was a developmental psychologist, began in the mid-1960s to dominate thinking in Science Education in the USA and to a lesser extent in the UK and some other countries. The ways in which researchers interpreted Piaget held that children's intellectual development progressed in stages that were highly age determined and could not be accelerated. The unfortunate result of this doctrinaire interpretation of Piaget's writing in the USA, and in particular the less complex parts that related to views about stages of intellectual development, was that the teaching in the country of basic concepts of science such as the nature of matter and energy was delayed until around Grade 8 at the earliest. The consequence was that powerful superordinate concepts dealing with the nature of matter and energy were not introduced in elementary school and much learning facilitation that could have resulted from such teaching was lost.

It might be argued that no harm is done by delaying instruction in basic science concepts if it were not for the highly documented fact that children build their own *alternative* science concepts based on everyday experiences. While consistent with the child's interpretations of their experiences, the majority of these alternative concepts are completely inconsistent with science, and so are faulty concepts or misconceptions. For example, children think that one must keep applying a force to an object to keep it moving at a steady speed, whereas the much more powerful science explanation of this phenomenon is that for this motion the resultant force on the object is zero (and so no continuing force is needed if we remove the friction of air and the surface traveled). Children believe that plants get their food from the ground, since they observe people applying "plant food" to lawns and gardens. Without a basic understanding of atoms and molecules and energy and energy transformations, they cannot understand how plants synthesize their own food from carbon dioxide in the air and nutrients absorbed by the roots and transported to the leaves. Once these faulty alternative conceptions are acquired, thousands of studies have shown it is notoriously difficult to help students learn valid science concepts. Perhaps the central reason for this is that the faulty concepts seen by the child as relevant still function as Ausubelian subsumers to anchor learning of new relevant concepts and propositions, often further elaborating and distorting the alternative conception. Even conscientious efforts on the part of the teacher and the students to learn new material meaningfully can fail due to the student's faulty alternative conceptions (see Proceedings of International Conferences on Science and Mathematics Misconceptions held at Cornell University at: www.mlrg.org).

An early exploration of the value of Ausubel's theory for guiding and interpreting research and instruction in science was undertaken in 1971, when two of my graduate students and I reviewed over 100 published research studies in science education with the view of looking at these studies through the lens of Ausubel's theory of learning (Novak et al. 1971). We found most of the studies sorely lacking in theoretical foundations, many using inappropriate data analysis, or lacking adequate control of variables and



Ausubelian Theory of Learning, Fig. 2 High levels of meaningful learning can be achieved by both reception learning approaches and discovery approaches, and both approaches can result in little meaningful learning when poorly done (Novak 2010)

frequent use of inadequate assessment tools. More relevant here is that we found that Ausubel's theory would better explain the data obtained and could have guided better instructional and research design. One of the most powerful tools invented to establish what a learner knows, to represent expert knowledge, and to facilitate learning of new knowledge is the *concept map*. This tool was developed in Novak's research program at Cornell University in the early 1970s and is now used in all disciplines for all ages all over the world. Further discussion of this tool can be found in in the entries ▶ Concept Mapping and ▶ Concept Maps: An Ausubelian Perspective. Ausubel's learning theory was the primary theoretical foundation for the development of this tool.

For many years the science education literature, both research and professional, and wider public debate about science teaching and learning have been replete with recommendations for greater emphasis on *inquiry* approaches to teaching and learning. Sometimes, indeed too often, these recommendations derive from simplistic views of "discovery," "child centered," and other slogans. More substantively, many of these recommendations derive from the mistaken view that *reception learning*, where the learner is guided to acquire new knowledge primarily through didactic teaching, is basically inferior to "discovery" or "inquiry" approaches to learning. Ausubel points out that while poor reception teaching leads primarily to rote learning, with all the inherent shortcomings, when well done, reception learning can not only be highly efficient but also provide many of the benefits and future utility of knowledge acquired when reception instruction is well done. This is not to say that discovery or inquiry learning should have no role in school learning, as there are ancillary benefits that are valuable, such as learning to design experiments and gaining skills in using scientific equipment. As shown in Fig. 2, well-designed reception instruction can lead to highly meaningful learning, and poorly designed inquiry instruction can result in little or poor learning for understanding.

Today almost all educational psychologists subscribe to some form of cognitive or socio-cognitive learning theory. The pioneering work of Ausubel is of central relevance to cognitive considerations. It still merits careful study and remains a viable and powerful theory of human learning.

Definition

Many definitions of *authentic assessment* have been proposed in order to distinguish it from other kinds of assessment (e.g., Darling-Hammond et al. 1995; Wiggins 1998). Darling-Hammond et al. (1995) posited that authentic assessment is designed to provide students with opportunities to demonstrate what they can do in a situation that requires the application and production of knowledge, rather than mere recognition or reproduction of correct answers. According to Darling-Hammond et al., authentic assessments are contextualized in students' lives and learning experiences and so well-integrated into the teaching and learning process that they are indistinguishable from instruction.

Despite subtle differences among the proposed definitions of authentic assessment, it is a well-accepted notion that assessment becomes *authentic* when it exemplifies the real-life behaviors and challenges experienced by actual practitioners in the field, rather than merely eliciting easy-to-score responses to simple questions (Darling-Hammond et al. 1995; Wiggins 1998). A widely accepted framework for determining the authenticity of an assessment design was proposed by Wiggins (1998). According to Wiggins, an assessment task is authentic if it (1) is realistic, (2) requires judgment and innovation, (3) asks students to carry out work in the subject, (4) replicates the context in which adults are evaluated in the workplace or personal life, (5) assesses the students' capability to use a repertoire of knowledge and skill to perform a complex task, and (6) allows opportunities to rehearse, practice, consult resources, get feedback on, and refine performances and products. Table 1 contains Wiggins's summary of the key differences between authentic and typical tests.

Evolution of the Term

Early scholarship on authentic assessment was driven by an interest in assessment methods that

Authentic Assessment, Table 1 Key differences between traditional tests and authentic tasks (Adapted from Wiggins 1998)

Indicators	Tests	Authentic tasks
Output requirement	Require correct responses	Require quality product and/or performance along with justification
Pretest/ assessment exposure by students	Must be kept from students to ensure validity	Tasks, criteria, and standards are communicated to students in advance
Connection to real-world	Are disconnected from a realistic context and constraints	Require application of knowledge and skills related to realistic problems likely to be encountered outside of school
Type of knowledge and skill required	Contain items requiring use or recognition of known knowledge or skills	Are challenges in which knowledge and judgment must be innovatively used to produce a quality product or performance
Evaluation	Simplified to be easily and reliably scored	Involve complex and nonarbitrary tasks, criteria, and standards that can yield valid inferences about student learning
Frequency	Usually taken only once	Are iterative, typically including recurring essential tasks and standards
Validation	Depend on highly technical correlations	Provide direct evidence prompted by tasks that have been validated against key discipline-based challenges in adult practices
Result	Generate a score	Provide diagnostic feedback to improve performance and learning

were closer to classroom practice and more naturalistic than traditional testing, which was criticized for failing to measure many of the important aspects of meaningful learning (Chittenden 1991). Proponents argued that authentic assessment could evoke student interest and persistence through the employment of apt, challenging, realistic tasks and produce gains on conventional tests and in student learning (Wiggins 1998).

Archbald and Newmann's (1988) book on authentic academic achievement is often referred to as the earliest work that sought to promote assessment that centers on a variety of meaningful, real-world tasks. Wiggins (1998) brought the idea of authentic assessment to a broader audience through a series of publications advocating the concept and the use of authentic tests or assessments with real-world applications. By the 1990s, the topic had generated substantial interest. Persuaded by Wiggins's claim that understanding is developed and revealed through authentic work, feedback, and the use of knowledge in diverse contexts, educational researchers and practitioners experimented with alternatives to traditional testing (Darling-Hammond et al. 1995).

Initial efforts were stymied by difficulties with creating an operational definition that distinguished between *authentic*, *alternative*, and *performance* assessment. For example, there was some debate about whether *performance assessment* is synonymous with or a component of *authentic assessment*. There is now general agreement that assessment can be performance-based without being truly authentic: A performance assessment is not considered authentic if it does not involve tasks with realistic value (Wiggins 1998).

Another issue in the literature involved the distinction between authentic and alternative assessment. Since the term *alternative assessment* typically connotes any assessment other than traditional paper-and-pencil tests (Fischer and King 1995), authentic assessment usually can be a treated as a concept subsumed by alternative assessment.

Chittenden (1991) argued that terms such as *authentic*, *alternative*, and *performance* assessment are essentially nontechnical placeholders which should be replaced by more functional terms such as *portfolios* and *exhibitions*. This practical suggestion is reflected in the research literature: Since authentic assessment takes a variety of forms, empirical studies focus on a particular type of authentic task such as a *portfolio*, *hands-on laboratory*, *field experience*, *open-ended problem*, *computer simulation*, or *group discussion*. Therefore, although the term *authentic assessment* is still used to indicate a general category of assessment that involves tasks that model and demand important real-world work and elicit performances that allow direct examination of student learning and understanding (Wiggins 1998), more recent literatures tend to use activity descriptions that depict particular tasks and procedures associated with authentic assessment.

Authentic Science

Barbara Crawford
Faculty of Mathematics and Science Education,
The University of Georgia, College of Education,
Athens, GA, USA

Science is a way of thinking used to develop explanations of natural phenomena using evidence and logic. Authentic science is essentially the same thing, the term only having been coined to distinguish and separate the scientific ways of thinking from classroom science activities that do not, in fact, reflect the spirit and behavior of science. It is argued that traditional experiences in many classrooms charged with teaching about the science disciplines are outdated, in that they do not facilitate the learner in learning to think and behave in the manner of actual scientists. Authentic science is a variation of inquiry teaching that aligns closely with how scientists do their work and differs from traditional school science laboratory exercises (commonly called "laboratories" in the USA). Many traditional laboratory experiences are static and contrived, leading the student to a predetermined "correct" result, often known to the student. This is not to say such educational activities are totally without merit; but this change, from engaging students in experiences in which they already know the answer to engaging students in investigations similar to those conducted by scientists, is overdue.

The term "authentic science" refers to a science experience that embodies more of the qualities of actual or real science. Authentic refers to using data and logic to create an explanation for something not known or understood and using skepticism about the best explanations or applications to society. Authentic science involves engaging students in answering scientific questions currently being investigated by scientists in today's world. Traditional school "science" sometimes does not meet these criteria, and so the term authentic science was created to describe those science activities and experiences that come closer to meeting those standards. The importance of doing authentic science in classrooms is in the outcome for students, that of critical thinking. For example, Bybee (2006) described the way scientists work and think, “How scientists know and explain the natural world and what they mean by explanation and knowledge are both directly related to the processes, methods and strategies by which they develop and propose explanations” (p. 2). Many educators acknowledge that the nature of inquiry that takes place in a scientist’s laboratory differs to a certain degree from school science inquiry. Yet, school children can learn how to construct models and develop scientific arguments much like a scientist does, in developing explanations (Bybee 2006; NRC 2012). Authentic science differs from the view of science many children acquire through their experiences in traditional science classrooms. Making science learning in classrooms more aligned with authentic science practice has been a common goal of educators for over a hundred years. For example, as early as 1910 Dewey advocated that children should engage in authentic inquiry. By engaging students in authentic science, it is assumed that students will learn more about the practices of science (NRC 2012). Many science educators anticipate that if students can experience authentic science, they will become active learners, they will have the opportunity to understand the nature of science, and further, they will become lifelong learners. Yet there has been little progress made in changing classrooms to embrace more authentic science practices. Traditional school labs often give step-by-step directions that prevent the learner from experiencing what it means to think like a scientist. Teachers often disconnect the practices of authentic science from “school science.” Studies show that it is rare for teachers to shape their teaching practice by their declared epistemological beliefs; one reason may be the perceived barriers posed by their school administration and state national policies.

To give students more authentic experience of science, some educators advocate increased use of out of classroom experiences, including visiting scientists’ laboratories. Other experiences include spending extended time in scientific research laboratories. Some educators have suggested that apprenticeships in real scientific laboratories will translate directly into greater understandings of the nature of science. Interestingly, this apparently reasonable assumption is not fully supported by empirical studies.

In revising very structured classroom exercises to be more open-ended thus resembling authentic science, it is hoped that students will come to understand the nature of scientific inquiry and appreciate aspects of the nature of science. One method of integrating authentic science in the classroom involves the use of technology or as termed by cognitive scientists, learning technologies. One example of a learning technology that aligns with authentic science is probeware, equipment that is connected to a computer. Using probeware, children can collect real-time data and make interpretations, much like a scientist, if the lesson involves ill-structured problems and questions with no answer already known to the student.

Authentic science in the science classroom tries to replicate the kind of thinking done by scientists but, to be engaging, is also relevant to students. Authentic science forms a basis for developing effective ways of teaching children science. There have been and remain some critics of this way of teaching. However, its supporters claim that some critics indiscriminately lump many pedagogical approaches – constructivist, discovery, problem based, experiential, and inquiry based – under the category of “minimally guided instruction” (Hmelo-Silver et al. 2007, p. 99). Just moving authentic scientists’ science into the classroom is not automatically effective for students, without some modification of the curriculum and support from teachers. There are various forms of authentic science teaching in the science education literature. For example, some researchers describe their particular authentic approach to science learning as inquiry-based, project-based, or problem-based learning. In each case there is a real-world question or problem that sets up the learning experience.

Recent reforms in science education advocate that teachers engage children in posing and using authentic scientific questions, giving priority to data, using data as evidence in developing explanations and examining alternative explanations, using mathematics, building and using models, developing and using arguments, and communicating and defending explanations (NRC 2012). A fairly recent emphasis in the classroom is a focus on model-based instruction and use of argumentation. Regarding modeling, teachers guide students in building and using models and in learning about the nature of models and how scientists use models. Children engaged in model-based instruction learn how to reason about data and phenomena by using models. In developing students' use of argumentation as used by scientists, teachers support children in interacting with their peers, in discussing and debating their ideas. Children learn how to construct an evidence-based argument and defend it. This kind of teaching demands that a teacher has in-depth understanding of science concepts and principles, in addition to competency in supporting children in discussions of data interpretation, model building, and argumentation.

Authentic science in the classroom enables students to engage in investigations that are meaningful to them and are similar to tasks carried out by scientists (Chinn and Malhotra 2002). There is some empirical evidence that when students engage in authentic science in classrooms, they value the authenticity of the investigation. One example of an authentic science experience is an environmental study of a pond, stream, or river near a school. In this case, students use equipment to collect temperature, dissolved oxygen, turbidity, depth, and other physical parameters. In addition students can learn how to sample and identify the living organisms, such as macro-invertebrates, which serve as water quality indicators. When students analyze these data, they can, with support of the teacher, develop a model of the pond, stream, or river and make predictions. These data can be collected over several years to track changes in water quality over time. Although students realize that they themselves are not trained scientists, when carrying out similar kinds of authentic activities, they believe they can contribute meaningful data for others.

Authenticity can also provide a meaningful context within which children can actively reflect on aspects of nature of science (Schwartz and Crawford 2005). When students engage in authentic science in a classroom community, they can participate in social practices similar to those of a scientific community. Participation in a modeled authentic scientific community can help make science accessible to students of diverse cultures and students from populations not usually represented in the scientific community. There is an expectation that authentic science in classrooms can and will motivate students. However, more research is needed to determine the extent to which authentic science may increase an interest in learning science, in students of underserved populations.

Beliefs

William W. Cobern
The Mallinson Institute for Science Education,
Western Michigan University, Kalamazoo,
MI, USA

The concept of “belief” is frequently contrasted with the concept of “knowledge,” where in everyday language “knowledge” is thought of as “reasoned belief” that a proposition is true. One can understand a concept, for example, evolution, while believing the concept either to be true or false. Belief is a personal, subjective affirmation or rejection of the truthfulness of the proposition. Hence, belief and knowledge do not stand in opposition but work in conjunction (Cobern 2000; Quinton 1967). Because these concepts work in conjunction, it is also inaccurate to refer to things that are believed as opposed to things that are known. When belief and knowledge are contrasted in this way, it is typical for belief to be thought of as “blind” belief, in other words believing something to be true without any evidence or reason. However, no one holds a belief for no reason; it is just that there are many varieties of reason. For example, one may believe a proposition of science to be true because of the experimental data provided by a scientist in support of that proposition. That being said, a person may not be informed well enough to understand the evidentiary base for the proposition, but the person trusts in the authority of science. In this case, what is believed to be true is not blind belief but belief based on authority. Controversy arises however because not all authorities are equally trusted by all persons. Therefore in any discussion of belief, it is always important to understand the reasoning that is used in support of the belief (Stenmark 1995). Similarly, it should not be assumed that knowledge of something is the same as believing something to be true.

Bildung

Helmut Fischler
Freie Universität Berlin, Berlin, Germany

Introduction

The concept of *Bildung* is a major influence on discussions about, and reflections on, educational goals in the German-speaking countries and other Northern European countries with a similar cultural and linguistic background. *Bildung* in this regional and linguistic context is the central notion describing the process of personal development and the outcome of this development process. *Bildung* is more than education, and there is no English term that denotes the concept of *Bildung* accurately. Nonetheless, it may serve as a bridge between two educational traditions when an American educational researcher proposes the following explanation of the meaning of *Bildung*:

> *Bildung* is a noun meaning something like 'being educated, educatedness.' It also carries the connotations of the word *bilden*, 'to form, to shape'. *Bildung* is thus best translated as 'formation', implying both the forming of the personality into a unity as well as the product of this formation and the particular 'formedness' that is represented *by* the person. (Westbury 2000, p. 24)

This might function as a first orientation but it will be clear from the following text that the term "formation" runs the risk of being misinterpreted as a one-sided process.

Historical Roots

In 1784, the philosopher Immanuel Kant began an essay on the question "What is Enlightenment?" with the much-cited sentence: "Enlightenment is man's emergence from his self-imposed immaturity." Scholars of different disciplines adopted this idea and adapted it to their specific area of expertise. It became closely interwoven into the idea of Bildung.

Among these scholars the philosopher of language, anthropologist, neo-humanist, and Prussian politician Wilhelm von Humboldt reflected on consequences for the phase of human beings' growing up. According to von Humboldt's ideas, neither adolescents' alignment to the demands of society, where criteria like usefulness and efficacy play a dominant role, nor their growing up free from cultural influences in the sense of Rousseau should be the guideline for the process and the state of *Bildung*. Von Humboldt combined both aspects and advocated a balance between them, stating that "the true purpose of humans is their highest and most proportional cultivation of their strengths as a whole." An indispensable condition for this development is civil liberty and, connected with liberty, diversity of situations. These situations are defined by cultural and societal characteristics. In von Humboldt's world there is no individuation without cultivation. In his idea of *Bildung*, the individual and humanity are two facets that are strongly interrelated to each other.

In the 1790s, von Humboldt argued that the ultimate task of life is to endow the concept "humanity" with as rich a content as possible. He believed that this could only be done by associating with the world in the most comprehensive, lively and freest interplay possible. This statement is an early formulation of a characteristic feature of our modern time, i.e., the necessary and paradoxical concurrence of the processes of cultivation and individuation. Or as Immanuel Kant, the great apologist of the idea of liberty, put it shortly after von Humboldt:

> One of the most serious problems of education is how to combine the individual's subjection to the legal constraints with the ability to use his/her freedom ... How can I cultivate liberty with this restraint? (Kant 1803, p. 711)

According to Nordenbo (2002), "*Bildung* seeks to bring the unique individuality into a harmonious relationship with general objectivity" (p. 350). For von Humboldt, the people of ancient Greece were classic examples of humans struggling for a harmonious relationship between the individual self and the world; therefore, he preferred the ancient languages Greek and

Roman as paradigmatic media offering appropriate access to *Bildung*. This preference was one of the reasons for the restriction of von Humboldt's ideas to the Prussian High School (Gymnasium) and for a lengthy debate about the suitability of different school subjects like mathematics or arts for achieving the goals of *Bildung*. Natural sciences were not regarded as a domain contributing to *Bildung* because of their usefulness in the century of industrialization. Members of society who were interested in the integration of the natural sciences into the school curriculum – pedagogues and politicians with a scientific background, representatives of industry and economy – emphasized the potential influences of these subjects on students' *Bildung* in the sense of Humboldt. In Germany, it took about a hundred years until the natural sciences were integrated into the school curriculum of the higher educational institutions (e.g., the Gymnasium), on an equal footing with the subjects already established. In the end, two kinds of pedagogical justification have been responsible for this integration: the traditional idea of *Bildung* (natural sciences are part of the efforts of humans to understand themselves in relation to the world around them) and the demands set by the society which expects the school to lay the foundation of expertise among as many members of society as possible, in order to meet the requirements of a technically oriented world. This twofold rationale nowadays constitutes the framework for all discussions and decisions concerning the structure of the curriculum in all school types.

A Modern Approach to *Bildung*

The different educational contexts within the historical development of the societies in which the concept of Bildung played a significant role led to various shifts in the meaning of *Bildung*. Wolfgang Klafki, the most prominent educational scientist seeking to develop for a modern understanding of *Bildung*, draws on ideas and descriptions presented in the decades around 1800 and points to their most significant features. For him, one of the most fundamental ideas that emerged at this time was the idea of the self-responsible, cosmopolitan person, contributing to his own destiny and capable of knowing, feeling, and acting. For Klafki (2000), the terms "self-determination, freedom, emancipation, autonomy, responsibility, reason, and independence" (p. 87) are crucial notions in relation to Bildung. But this is only one side of the overall meaning of *Bildung*. Klafki also stresses that this list of concepts could be misinterpreted as a description of *Bildung* as an individualistic conception; so he adds: "…the basic concept of subject- or self-determination is anything but subjective!" (p. 88). *Bildung* is also characterized by a second group of factors: humanity, humankind and humaneness, world, objectivity, and the general. *Bildung*, therefore, develops in the interplay between individual attributes, achievements, and expectations on the one hand and the conditions a person has to cope with on the other. These conditions are results of societal processes and comprise different kinds of social life as well as systems of norms and beliefs that pertain to the fields of politics, arts, science, and other domains. The interplay described mirrors a more differentiated process than Westbury's notion of "formation" can reflect.

In Klafki's view, the societal part of this interplay described has been not sufficiently analyzed by those who strive for a widely accepted conception of *Bildung*. He writes that "… the economic, social, and political conditions needed for the realization of this general demand for Bildung" (p. 89) were not examined consistently. In order to adjust the traditional conception of *Bildung* to the characteristics of individuals' contemporary environments, Klafki (1998) points to the direction in which the development of a modern version should be heading. At the core of these processes should be elaborated "a more differentiated and critical determination of the relationship between Bildung and society" (p. 313). Three abilities were, in this way, to be promoted by *Bildung*:

- Self-determination
- Codetermination (all people are invited to take part in the development of the society)
- Solidarity (with those whose opportunities for self-determination and codetermination are limited)

Bildung, as a process and its result, has to be permanently balanced between an adolescent's self-determination and his/her conformation to the demands of society. The German word "Erziehung" and the English word "education" are often used with the connotation "preparation for the demands of society." Therefore, "education" (like "Erziehung") covers only a part of the considerably broader spectrum of features that are characteristic for *Bildung*.

Variety

Because of the lack of a generally held understanding, there is a vast variety of contexts in which the notion of *Bildung* is part of the pedagogical and political discourse and of meanings that are linked to the term. Especially in public discussions, *Bildung* is reduced to become almost synonymous with "education." On the level of politics, the notion of *Bildung* has got such a general connotation that an interpretation is almost impossible. The German ministries that are responsible for the organization and structure of the educational systems (schools, kindergartens, vocational schools), and for the content-related issues within these systems, are ministries of *Bildung* although their political decisions mainly refer to the functioning of the state-run institutions. Because of this indistinct use of the term, the leading German theorist of *Bildung*, Tenorth, commented that *Bildung* can be regarded as a German myth, a pedagogical program, a political slogan, and an ideology of bourgeoisie. Often the term is used in connection with criticism of current society. In the light of this variety of meanings, does it make sense to use the term *Bildung* when any speaker or writer is likely to have a different conception in mind from that of the listener or reader? In Tenorth's view, *Bildung* still has great potential for describing the goals and processes of human growing up, especially if empirical aspects are integrated into the reflections on *Bildung* that have been shaped by mainly philosophical arguments.

Bildung and Scientific Literacy

In spite of the lack of a generally accepted understanding of *Bildung*, at least the core of the concept becomes clearer when it is compared or contrasted with the way the term "scientific literacy" has often been used in the last two decades. On the international level, in the OECD PISA project, scientific literacy focuses on the application of knowledge in science and so has a more functional connotation than *Bildung*. This interpretation of scientific literacy becomes visible in the statement of the OECD that the cognitive aspects of students' scientific literacy include students' knowledge and their capacity to use this knowledge effectively. The idea behind this statement is that education should prepare students for the demands imposed on them during their whole life. This idea becomes clearer in the OECD's more precise affirmation that the PISA tests cover scientific literacy, not so much in terms of mastery of the school curriculum, but in terms of important knowledge and skills needed in adult life. The conception of *Bildung* does not ignore the task of helping adolescents deal with the challenges of their future life. However, this educational aspect is embedded into a more holistic view, where universal principles like rationality, humanity, and morality are interwoven with an individual's growing up.

The dominant position of the term "scientific competency" in the description of the PISA program signals additional differences between *Bildung* and scientific literacy. As discussed above, the functional aspects of students' knowledge (competencies and skills) contrast with the concept and process of *Bildung*. So, for example, a phrase like "We teach children to be competent in a special domain," due to its one-sidedness, is not in line with the concept of *Bildung*. *Bildung* cannot be interpreted as the European version of scientific literacy, and in the process of selecting topics for the school curriculum, the question "Is it useful knowledge?" could be a guideline at best of secondary importance. An individual's knowledge and competencies represent only one facet of *Bildung*; another points to the individual's efforts to find his/her place in the rational, humane, scientific, and esthetic world. One of the most distinguished contemporary German pedagogues Hartmut von Hentig, well known as an author of fundamental reflections on *Bildung* and as a school and university teacher, has condensed these two facets into a depiction widely accepted: *Bildung* describes the tension or the bridge between ideals passed on and current needs of competence, between philosophical self-assurance and the practice-oriented self-preservation of society. In Plato's allegory of the cave, *Bildung* is both the rise towards sunlight and the descent towards the cave. The one without the other makes no sense.

Bildung Within Natural Sciences

Martin Wagenschein (2000) and other scholars have discussed how students' *Bildung* in natural sciences can be achieved. For Wagenschein, the main goal of science education is to help students understand phenomena of the natural world. To "understand" means to have gained insight into the essence of scientific relationships; it does not mean just to know the formula or to be able to apply it to a concrete problem. According to Wagenschein, there are three characteristic teaching-learning situations in which *Bildung* in this sense can develop:

- *Exemplary teaching*: In order to gain a deep understanding of a piece of content, it is necessary to invest a sufficient amount of time. Therefore, "we need the courage to leave gaps, in other words to be thorough and to deal intensively with selected examples" (Wagenschein 2000, p. 116). These examples have to be representative of the domain (its topics or methods) and at the same time exemplary as regards their contribution to students' *Bildung*.
- *Genetic teaching*: If the knowledge is to become an integral part of a student's Bildung, it is important that he/she has the opportunity to search productively for the solution of a problem, to find it, and to check it critically. From this perspective, Wagenschein, in the early 1950s, introduced elements of an idea that later, in its cognitive dimension, became known as the constructivist view of learning. Wagenschein emphasized the development of knowledge as much more than the result of the process of acquiring knowledge.
- *Socratic teaching*: A teaching-learning process which focuses on the development of knowledge is best arranged in a Socratic conversation. The teacher has to talk with his/her students not in a lecturing and dogmatic way but, like Socrates in his dialogues, focusing on their ideas and moderating their learning processes.

According to Wagenschein, teaching environments with this triad of principles are particularly suitable (and often necessary) for learning episodes in which a basic understanding of central notions and processes in natural sciences is to be acquired. This is the case especially in upper grades of elementary school and in lower grades of secondary school. However, Wagenschein's triad is meant to be effective at all levels, since the process of *Bildung* does not come to an end. Examples from physics and chemistry education (and a fuller discussion of several of the ideas discussed above) can be found in Fischler (2011).

Critics of Wagenschein's view of teaching and learning complain that it is too time-consuming and, because of its exemplary character, about students lacking knowledge, that they need to systematically build up concepts of natural sciences. But there is no strict alternative, no either/or. Students have to get to know the basics of natural sciences as a cultural domain of mankind and to have the chance to achieve this goal on the way of exemplary, genetic, and Socratic teaching and learning.

What Is Unique to Teaching of Biology? What Are the Problems and Challenges?

The education of biology teachers, like those for their counterparts in other science disciplines, typically pays attention to common and key issues such as teaching of scientific inquiry, nature of science, and dealing with students' alternative ideas, etc. – the ultimate goal being to develop in teachers the pedagogical content knowledge necessary for effective teaching of science in general and biology in particular.

First, biology is the study of life and its evolution. Indeed, evolution is increasingly used as one of the unifying concepts in developing school science education standards around the world. However, for different reasons, not all biology teachers embrace the notion of teaching evolution in schools (Bybee 2004).

Second, many advances in biology are based upon experimental results and accurate observations in the field. In other words, fieldwork is a key component in understanding biology. However, there has been a decline in fieldwork in schools. One major reason is the insufficient preparation of biology teachers for teaching in the outdoors, teaching in nature (Barker et al. 2002).

Third, biology teachers need to be able to help their students discuss bioethics and the societal implications of biology. They are also expected to help students undertake a range of activities which can help them to develop criticality and to enhance their potential for action. This new vision of biology education for action as well as for knowledge and understanding presents additional challenges for biology teacher education (Zeidler 2003).

How Can Teachers Be Prepared for the Challenges?

Addressing issues of teacher preparation to teach evolution should begin with an assessment of their attitudes, perceptions, and confidence for teaching evolution. Results from surveys suggest that the importance and relevance of evolution to the school science curriculum may need to be explicitly addressed in the education of biology teachers. However, given the politics of teaching evolution in schools (in some countries) and the complexity of the issues involved, a quick solution to this problem is rather unlikely.

To develop critical thinking about societal issues and to enhance the potential for action, students need to be able to analyze scientific information critically as well as to apply it to real world issues. To prepare teachers who can guide instruction of this type, reform of preservice teacher education has been a constant over the past two decades. Promising results were reported by some programs. In these programs, preservice teachers were engaged in identifying research questions where their knowledge of biology could be applied to solving real-life problems. Besides learning how to make informed decisions about science and technology issues in real-life contexts, the preservice teachers were also asked to look into their pedagogical practices to determine the techniques that could be employed to help learners (students) appropriately apply biological knowledge. Hence, through the experience of their own science investigations based on real-life issues, the preservice teachers are given opportunities to learn the various ideas about the pedagogy of science teaching and learning.

Preservice teachers rarely get to prepare and practice teaching in the outdoors in their methods courses or during their practicum. To address this problem, examples of engaging student teachers to actively conduct field trips and having part of their teaching practicum attached to outdoor environments (such as an aquarium or eco-garden) are beginning to emerge. Results show that actual teaching in an outdoor environment empowers teachers and provides them with positive experiences that impact implementation of future outdoor teaching. Results also indicate that teachers should play different roles, rather than traditional ones, in order to function effectively in out-of-school settings. Furthermore, these studies illustrate the potential of reimagining and re-/forming preservice programs to incorporate practicum experiences that go beyond classroom settings. This helps preservice teachers expand their views of biology teaching and learning beyond the boundaries of the classroom-based environment and provides firsthand experience to equip them to move beyond textbook-based biology teaching.

To conclude, while there are commonalities between education for biology teachers and their counterparts in other science disciplines, there are also unique features (as outlined above); some of which require ongoing attention in order to lead to the improvement sought by biology teacher educators more generally.

Biology

William James distinguishes between tender-minded philosophers and tough-minded philosophers. No one would use tender-minded as a term referring to Aristotle, the first and the best of philosophers to look at biology, but it does seem true that in the millennia succeeding (especially since the scientific revolution) biology has attracted thinkers who do want to find meaning and comfort in the material world and its explanations. Vitalism, holism, and emergentism were the terms commonly favored.

Things started to change significantly about 50 years ago, when a small group of analytically trained philosophers, including David Hull and Michael Ruse, turned their attentions to the biological sciences, determined to bring understanding and rigor to meta-analyses of the life sciences (Ruse 1988). Today, philosophy of biology is one of the strongest and most popular areas of Anglophone philosophy, with related interest in other academic cultures.

For fairly obvious reasons, evolutionary theory has attracted most attention. It is a topic that raises many issues, for instance, theory structure, the nature of laws, the problems of causation, making claims about past events, many of which were unique, and much more. However, in recent years more and more attention has been paid to related and other areas of the life sciences, including molecular biology, ecology, systematics, and human biology, with special reference to culture and the ways it changes and its interactions with the underlying biological base (Ruse 2008).

Almost all philosophers who have looked at the evolutionary theory have been deeply committed evolutionists. However, in recent years a small group of vocal Christian philosophers, notably Calvinist Alvin Plantinga (2011), have been arguing that so-called intelligent design theory – supposing occasional, nonnatural, important changes – has much to commend it. There is also in such circles considerable doubt about the major claims of paleoanthropology, namely, that humans evolved from apelike creatures, in Africa, breaking free about five or six million years ago, and never were a population less than at least 10,000 members. The critics worry that this kind of thinking is incompatible with the creation story of Adam and Eve in the book of Genesis, and with the subsequent Fall, something thought undeniable for the Christian faith.

Philosophers accepting evolutionary theory have their own controversies, generally focusing on the adequacy or otherwise of the Darwinian account of change, an account that privileges natural selection (the survival of the fittest) as the major cause of change. No one denies that natural selection – the differential reproduction of organism, with consequent success for some with useful variations and failure for others without such variations – has a role to play in the evolutionary process. Intended to speak directly not just to change but to change of a particular kind, namely, adaptive or design-like change, the existence of organic features that used to be known as “final-cause” features, because they serve organisms’ needs or ends – features like hands and eyes, bark and leaves, and hunting ability and defense mechanisms – cries out for a selection-fueled origin.

But how universal is adaptation? Are all or virtually all features of animals and plants adaptive, or is adaptation the exception rather than the rule? Take, for instance, something like the facial hair of human males. Does this have an adaptive role to play, for instance, in keeping men warm (in which case, why do women not have beards) or in sexual attractiveness (in which case why are some human races relatively facially hairless), or is the case rather that facial hair is a by-product of other things, namely, hormones required for the production of male genitalia and so forth, and so in itself has no adaptive function at all.

The philosophically inclined biologists Richard Lewontin (a geneticist) and Stephen Jay Gould (a paleontologist) made much of the supposed nonadaptive nature of many organic features, referring to them as “spandrels,” meaning that they are simply part of the architecture of organisms and selection played no role in their production (Gould and Lewontin 1979). Gould particularly was prepared to state that the Darwinian obsession with what he called “pan-adaptationism” was a relic of earlier natural theological beliefs about God’s omnipotence in designing the universe and its contents and as such should have no place in modern secular science.

A related debate has revived the relevance of James's tender-minded/tough-minded dichotomy, for there is much concern about the way in which natural selection operates when it is clearly active. Obviously much that selection does is directed to the benefit of the individual. My eyes are for me to see, not for you to see. But not everything works quite this way. The mammary glands of mammals – breasts, teats, and so forth – are for the benefit of the offspring, not the mother (ignoring possible dual roles like sexual attraction). In a case like this however, since selection operates to promote reproduction, inasmuch as the offspring thrive, the mother's ends are met. But what about nonrelatives? Can selection in one organism promote features that will be of benefit to other organisms? There has been much heated philosophical debate on this subject, with some claiming that selection always acts primarily for the individual and others that it can frequently promote the good of the group, even at cost to the individual. It is clear that much that motivates supporters of "group selection" is a strong dislike of the selfishness of "individual selection," where organisms are seen in a constant struggle of one against all. Nature, such tender-minded thinkers claim, has a gentler, softer side to it. Nature, as the tough-minded thinkers respond, cares nothing for niceness. Thomas Hobbes was right – life is "solitary, poor, nasty, brutish, and short."

Is the philosophy of biology relevant to – or particularly relevant to – science education? Many think that it is and few would want to deny this entirely. On the one hand, a strong case can be made for saying that as soon as the science teacher goes beyond the collecting or observing of particular objects and facts and starts to move towards understanding, philosophy necessarily enters in. One is going to start talking in terms of generalities, laws, and means of explanation, models and hypotheses and theories, and all of this is by its very nature philosophical. In teaching biology, the philosophy of biology has an obvious and essential role.

The following are three examples. First, the student having taken a course in physics where final-cause language is barred – no one asks the function of a volcano or of the moon – wonders why such language is not just allowed but happily and positively permitted in biology, you talk about the function (or nonfunction) of the leaves on a tree or of the appendix in humans. At once one is plunged into metaphors about design and whether a mechanism like natural selection can speak to them. Second, the student having taken a course in chemistry, where substances tend to be substances and no argument, comes to biology and finds that species have all sorts of boundary problems and higher orders like genera are very subjective and fluid. Are modern humans and Neanderthals one species or two, and why? At once one is plunged into all kinds of debates about classification and natural and artificial systems. Third, the student having taken a course in genetics where DNA rules now looks at ecology and wonders what on earth the molecules have to do with the nature of things. What do molecules have to do with the fish in a lake? At once one is plunged into discussions about the relationships between different levels of understanding and whether claims at one level can be explained by, "reduced to," claims at other levels and whether this should always be the aim of science.

On the other hand, in America particularly, but increasingly in other countries, there are those who would constrain or oppose biological understanding for religious reasons. Increasingly this is happening across the board, from evolutionary theory to biomedical technology. Focusing just on evolution, philosophy can and has played a major role in defending the integrity of science. In the past few decades, there have been a number of court cases in America where religiously minded politicians and others have tried to introduce biblically inspired accounts of organic history into state-supported science classes – in Arkansas in 1981, in Louisiana later in that decade, and in Pennsylvania in 2005. In all of these cases, philosophers played an important role in articulating the nature of good science and then showing that modern evolutionary biology, for all its controversies, qualifies as good science, whereas biblically inspired accounts – be they so-called creation science or intelligent design theory – not only are not good science but fail to qualify as science at all. At best they are religious wolves in scientific sheep's clothing, trying to get around the First Amendment separation of the church and the state (Pennock and Ruse 2008).

Philosophy of science is in major respects molded and shaped by the science itself, and as the science changes and develops, so the philosophy likewise changes and develops. The past 50 years have been exciting times for biology, molecular and organismic. The same has been true of philosophy of biology. One expects biology to keep up the same exciting pace of change and development. The same will no doubt be true of the philosophy of biology, and, if anything, its relevance to science education can only grow and deepen.

Black or African Ancestry

Mary M. Atwater[1] and Melody L. Russell[2]
[1]College of Education, Department of Mathematics and Science Education, University of Georgia, Athens, GA, USA
[2]College of Education, Department of Curriculum and Teaching, Auburn University, Auburn, AL, USA

An examination of Black ancestry provides insight into both US history and world history. From a historical perspective, Black Americans are the only racial/ethnic group that came to the United States of America initially as involuntary immigrants. Much of their African ancestral language and cultural traditions were destroyed after two centuries of enslavement and bondage. Africans represent a myriad of ethnic groups with over 800 languages. From a more modern perspective, primarily the miscegenation between Africans and Europeans and Africans and Native Americans resulted in the ethnic group more currently identified in the United States of America as "Black Americans" or "American Americans." Furthermore, Black Americans in the United States of America, though descendants of Africa, do not identify with the culture, language, and traditions of their African ancestry since much of their history has been defined on US soil through a lens of westernized culture.

Black ancestry can be characterized through a plethora of historical turning points in US history (i.e., slavery, Civil War, Emancipation Proclamation, Jim Crow, etc.) as the United States of America transitioned from slavery states to free states. It is well known that the largest number of slaves in the Western Hemisphere was in the United States of America, and the gradual transformation from the African identity to the African American identity society that is most familiar with today reveals juxtaposition that has been the source of much internal struggle or conflict.

African Ancestry

The African Diaspora characterizes African ancestry that emerged out of both the voluntary and involuntary migration of Africans throughout the world. The slave trade made the African presence global starting with their capture and enslavement that existed among ethnic groups in Africa, ancient Greeks, and Romans. At least 1,500 years before the Europeans participated in the trade of African slaves, the Arabs (the first mass enslavers of Africans) conducted slave trades of Africans throughout the Sahara Desert, Mediterranean Sea, Indian Ocean, and Red Sea transporting Africans to India, Arabia, and the Far East (Harris 1996). Even with the cruel and inhumane treatment of Africans, many arrived abroad and preserved their languages and traditions calling themselves Africans and Ethiopians. Hence, the African Diaspora refers to what is considered a triadic relationship between Africans as a dispersed group of people back to their homeland and their adopted or host countries (Harris 1996). Even though Africans were enslaved in many places around the world, many valued family and community, preserved cultural traditions, and learned European languages and advanced technology.

Race

Race is socially constructed and has no biological basis as a racial identification and classification. Simply put, there is no Black, White, or Asian gene; technically, there are more genetic differences within a supposedly racial group than across or between groups in order to protect genetic diversity within a group of people. The term “Black” or the notion of “Blackness” emerged as a racial category in Europe and was embraced in the United States of America after the forced relocation of West Africans to the Western Hemisphere. Consequently, the history of Blacks in the United States of America has been largely defined through the lens of Western racism and oppression and has caused a legacy of social, psychological, and economical damage. Specifically, Black Americans in the United States of America have been marginalized and considered a largely “homogenous” group of people, although there is a tremendous amount of diversity within the ethnic group. Even though US history identifies Blackness with a mark of inferiority, the most recent evidence on the origin of *Homo sapiens* points to a single genetic lineage that can be traced back to Africa within the past 200,000 years.

Science

The word “science” in this entry refers to the natural sciences, i.e., biology, chemistry, physics, and geology. The term “science education” refers to the discipline that deals with issues of learning, teaching, curricula, and assessment/evaluation of science in K-14 settings. Due to sociocultural-historical events, people of African ancestry either have not been allowed or few now pursue postsecondary degrees in the natural sciences or science education.

Even though enrollment of international students continues to be critical to the success and diversity of US graduate programs, the relative dearth of students of color in graduate programs is particularly troubling in light of the changing US demographics. Demographers predict that the largest increases in growth among US citizens will continue to be Latinos, African Americans, and Asian Americans. People of African ancestry are 12 % of the US population and 11 % of all students beyond high school; the following percentage of Black high school graduates completed the following science courses: 93.6 % biology, 63.6 % chemistry, 25.8 % physics, 62 % biology and chemistry, and 21 % biology, chemistry, and physics (Aud et al. 2010). Yet in 2009, they received only 7 % of all STEM bachelor’s degrees, 4 % of master’s degrees, and 2 % of Ph.Ds. (National Science Board 2012). In 2008, 824 Blacks out of 48,802 received doctorates in science and engineering (National Science Foundation 2009), while in 2009, only 88 Black males (1.3 %) out of 6,957 received Ph.Ds. in the biological and biomedical sciences.

Historical and Social Factors

These low numbers are the result of complex historical-sociocultural factors from self-doubts, stereotypes, discrimination, oppression, and economics. Arliner Roger Young, a zoologist, was the first African American woman to receive a Ph.D. from the University of Pennsylvania in 1935 professionally published in the field. She had to deal with gender, race, and educational barriers of her time which were no small matters. Unfortunately, she died on November 9, 1964 in New Orleans, poor and alone (Hodges n.d.). In 1943, Lloyd Noel Ferguson was the first African American male to receive a Ph.D. from the University of California, Berkeley, in chemistry and authored more than 50 journal articles and seven textbooks on cancer chemotherapy, the relationship between structure and biological activity, and the chemistry of organic compounds and properties such as odor and taste (Morris 1992).

With segregation legal in the United States of America for many years, it was difficult for Blacks to pursue degrees in the sciences and even more difficult for them to gain employment. Those who obtained science Ph.D. in the early years usually gained positions at Howard University. When segregation was no longer legal in the United States of America, many traditionally White institutions (TWIs) fought against desegregating its student body. Even today, many Blacks cannot pursue science degrees because they do not meet the entry requirements of TWIs. However, progress is being made by those Black students who receive quality precollege education that allows them to meet entry requirements to pursue science degrees even though the cost of postsecondary science education remains to be prohibitive for many.

Present Major Challenges at the Precollege Level

Based on international, national, and state science achievement scores, the quality of K-12 science student learning varies. In the United States of America, suburban, middle class K-12 Asian and European American students perform better on standardized test than other student groups. These test scores usually are used as indicators of the quality of student science learning. Even though differentiated teaching is encouraged, the practices of “grouping by ability” and tracking continue to occur in US schools. These practices give students different access to school resources such as certified teachers with advanced science degrees, updated science textbooks and other curricular materials, and modern science laboratory equipment and materials and opportunities to participate in other science enrichment programs such as summer science programs, after-school science programs, and field trips to museums and zoos.

Science is a way of knowing; the key to understanding science is to grasp the language of science and education The native language of students influences their opportunities for quality science learning because it (a) structures both students’ and teachers’ science learning and (b) determines how they use the language to understand and communicate their understanding of natural phenomena. If the language of science is truly understood, it helps the learner to engage in deductive and inductive reasoning, make hypotheses, generalize research findings, connect evidence to theses, and persuade others. Home language, instructional language, and science language problematize science learning because students must move across communities of family, school, and science. This is especially true when students’ home language is not the same as their instructional and science languages. Since language is a part of students’ culture, it has been suggested that students’ limited adeptness in English restricts their science learning and performance when instruction, assessment, and evaluation are done exclusively or predominantly in “standard English.” Hence, students who are Black English language learners (ELLs) such as Haitians do not perform as well as students whose first language is English. However, when the Black language dialect of African-Americans is used by physics teachers, these students build new physics understanding (Elmesky 2001).

To encourage learning in some groups, adaptations are made for different groups of students. Unfortunately, large numbers of Black students are found in “special education classes” in which few adaptations such as (a) altering the directions, assignments, and testing procedures and (b) including more activity-oriented lessons occur. According to Moje et al. (2001), compatibility among literacy, science learning, and language in diverse classrooms requires four interrelated classroom interactions. Science teachers need to (a) draw from students’ everyday languages and understandings, (b) develop students’ awareness of those various languages and knowledge bases, (c) connect student everyday understandings and languages with the science language of science classrooms and of the science community, and (d) help students to negotiate understanding of both languages and understandings so that these understandings not only inform each other but also merge to construct a new kind of language and understandings.

The science teaching force in the United States of America does not reflect the K-12 student population. In 2007, 45 % of the US K-12 students were Blacks, Latinos, Asian/Pacific Islanders, native Americans, and Alaskan natives (Hussar and Bailey 2011), while in 2008, 21 % of students aged 5–17 spoke a language other than English or spoke English with difficulty (Aud et al. 2010). However, only 7.8 % of the elementary and secondary teachers in 2008 were Blacks, native Americans, Alaskan natives, and Asian and Pacific Islanders (School and Staffing Survey 2008). Haberman (1996) maintains that urban teachers are successful if they have experiences similar to their students such as tragedy in the form of the death of a loved one; critical, life threatening injuries to family members; violence at home; serious unforeseen injuries; poor nutrition and sleep habits; or mental and emotional problems.

Present Major Challenges at the College Level

Blacks are about as likely as White freshmen students to declare science and engineering fields as majors, and Blacks who enroll in or graduate from college are about as likely as Whites to choose science and engineering fields (National Science Board 2012). However, Black females are more likely to complete undergraduate degrees than males (Harper 2012) and more likely to obtain bachelor degrees in biology. Once Black students enter a college or university to major in the sciences, they have additional challenges such as high school preparation, financial support, and the lack of mentoring. If they enter a traditionally White university, additional coping skills are needed to deal with the university’s culture. Even if these Black students graduate with a science degree and pursue doctorates, they continue to have challenges such as having the lowest rates of research assistantships and research publications (Council of Graduate Schools 2012).

People of African ancestry will continue to be challenged to experience equitable science learning and teaching and to contribute to scientific fields. But as in the past, Blacks in the future will continue to enhance the world’s understanding of natural phenomena and to utilize those understandings to better the lives of all human beings in novel ways. Blacks have made tremendous contributions to science, and though presently there are more of them in the biological and physical sciences, their representation in degree programs and careers is still sparse compared to other US groups. In order to increase their numbers, more must be done to overcome the legacy of racial and social inequities that still persist today in the United States of America and the world.

Blogs for Learning

A blog is an online space where individuals can publish any form of written work, such as reflections, as a sequence of entries that are often presented in reverse chronological order. In most cases, anyone with Internet access and access permissions can read blog entries and leave comments, which allows interactive communication between writers and readers. Blogs are used widely across the Internet as a means of informal publication and commentary and have also been applied within education communities as a teaching and learning tool to help students develop a range of skills. For instance, blogs can provide rich opportunities to improve students' writing skills. Blogs can create collaborative learning environments that enable students to share various ideas and perspectives, not only with their classmates, but also with a broader audience. Blogs also allow teachers or peers to assess student progress at various stages of instruction and provide timely feedback. Recently, researchers have begun to explore the benefits of such ongoing and iterative written reflections for students' learning. For example, Alexander Renkle and his colleagues (Glogger et al. 2012) have developed a program of research to study the effects of journal writing as a follow-up activity of classroom instruction in helping students reflect on what they have learned in the classroom and identify areas for improvement.

Blogs have the potential to create unique learning opportunities that encourage students to write longer accounts of scientific phenomena than typical short response items and facilitate iterative refinement — important yet often ignored elements of science instruction. For instance, blogs can be implemented in science instruction as a journal that allows students to continuously add their own ideas or other evidence they have discovered about scientific phenomena across topics and grade levels. As students progress through instruction, they can generate, reflect on, and organize their growing repertoire of ideas. Students can also monitor their own progress by reviewing the history of their writing entries and iteratively refine their ideas. Such opportunities could help students develop a more sophisticated understanding of complex science concepts and make connections among various science topics.

To take advantage of blogs for science learning, teachers need to carefully create activities and prompts that engage students and facilitate reflective, iterative writing processes. One instructional strategy is to embed blogs within inquiry activities. Inquiry-based instruction challenges students to develop a deep understanding of scientific concepts through scientific practices, such as making predictions, designing experiments, collecting evidence, analyzing data, and articulating their ideas. This approach requires students to constantly reflect on their learning progress and integrate multiple ideas and perspectives to develop a coherent understanding. Blogs could be used to support students through this process by keeping track of their evolving understanding in the form of written artifacts.

One example of reflective writing in a technology-enhanced inquiry approach is found in the student-generated explanatory narratives, called Energy Stories, employed by the Web-based Inquiry Science Environment (WISE – see Slotta and Linn 2009). Energy Stories prompt students to write a coherent story about energy concepts within a system by making connections among various energy ideas, such as energy sources, energy transformation, and energy transfer. For instance, seventh-grade students wrote Energy Stories about how a rabbit gets and uses energy from the sun across two WISE units in life science (Ryoo and Linn 2012). Students were asked to incorporate all the information from instruction, as well as evidence collected from visualizations, to write coherent narrative accounts of where energy comes from, how energy is transformed, and where energy goes. Students wrote three Energy Stories as they progressed through the units and revised their stories based on feedback from teachers. Energy Stories captured the details of students' understanding about the role of energy in the ecosystem and revealed how they built on their prior knowledge. Many students started with non-normative ideas about energy but became able to synthesize normative energy ideas, such as how light energy is transformed and how chemical energy is transferred, and use those ideas to restructure their initial understanding of energy flow in life science (see Table 1 for one example of a progression of student Energy Stories).

Energy Stories provided students with opportunities to reflect on the ideas they had investigated in two WISE units and to articulate them in their own words, which increased the coherence of their scientific explanations and deepened their understanding of how energy flows in life science. Energy Stories also helped teachers better understand how students were developing an integrated understanding of complex scientific concepts and linking energy ideas across the two units. One of the seventh-grade science teachers was amazed by the value of Energy Stories as both a learning activity and an assessment tool, saying, "It's a summary of what has happened, and they're writing it in their own words. . . it just encapsulates everything that had happened."

These findings underscore the value of blogs in providing recurring opportunities for students to iteratively integrate, reconsider, and refine their ideas about complex scientific phenomena. For teachers, this type of reflective writing provides opportunities to assess students' progress and provide timely feedback, which can strengthen instruction. Blogs can thus be an effective means of enacting such practices in the classroom.

Blogs for Learning, Table 1 Sample Energy Stories from a seventh-grade student across two WISE units

Initial Energy Story	The energy comes from the sun which goes into the chloroplast of the plant cells. There the energy gets transformed into plant food
Revised Energy Story	Once upon a time there was a plant. The plant had a job of making food for his rabbit. To make energy-rich food for the rabbit, the plant's chloroplasts collected water, light energy and CO2 for the food which is called glucose. Glucose is a type of sugar used to help plants stay alive and grow. In the plant's chloroplast, the light energy breaks apart the little water and CO2 atoms. When the light energy broke apart the atoms, it turned into chemical energy which decided to go inside the glucose and help give nutrients to the rabbit and the plant. The glucose traveled around the body and the extra ones were stored in the roots and leaves. When the rabbit ate the plant, the plant gave away some of the glucose. Even though it was very complicated to make glucose, the plant was happy to be generous
Final Energy Story	Once upon a time, there was a plant. The plant fed a rabbit named bobby. Bobby ate the plant's nutritious leaves full of glucose. The plant woke up every morning just before dawn. To make glucose, the plant needs sunlight, water, and CO2. The plant collected sunlight and CO2 with his leaves. His roots soaked up the water. All the CO2, water, and sunlight gathered up at the chloroplast where the water and CO2 atoms were broken apart and the sunlight was changed into chemical energy. The atoms were assembled into glucose molecules and the chemical energy was stored in the glucose. The left over atoms were made into oxygen. The glucose was stored in the leaves and roots for later use. Then Bobby came along and ate a leaf from the plant. The leaf went into Bobby's stomach and his stomach cells extracted the glucose from the leaf. The glucose went into the mitochondria with oxygen and the glucose and oxygen were broken apart into smaller pieces (atoms). The chemical energy was taken away from the glucose and the atoms of the glucose and oxygen molecules assemble themselves into CO2 and water molecules

Borders/Border Crossing

Maria Andrée
Department of Mathematics and Science Education, Stockholm University, Stockholm, Sweden

Border crossing provides a lens for analyzing science learning as cultural acquisition and science teaching as cultural transmission. Thus, science is deemed as culture rather than absolute truth. The generic construction of border crossing assumes the existence of borders between two (or more) distinguishable cultures/subcultures that, to a varying degree, represent obstacles for individuals to cross. The notion of border crossing has been used widely in science education research to conceptualize difficulties that students encounter in science education. In research, science classroom experiences of students and teachers have been theorized in terms of the ease with which students and teachers cross cultural borders of the science classroom. Border crossings have been categorized as *smooth*, *manageable*, *hazardous*, or *virtually impossible* (Cobern & Aikenhead, 1998). The concept of border crossing was borrowed from cultural anthropology and first applied to Western students studying science by Aikenhead (1996) with an expressed aim to encourage science educators to acknowledge inherent border crossings between students' lifeworld subcultures and the subculture of science. The theoretical framework of cultural borders and border crossing have later been challenged for assuming subcultures as given entities and not fully taking hybridity, heterogeneity, and the situatedness of cultural practices into account (Carter, 2008).

Botanic Gardens

Ellen McCallie
National Science Foundation, Arlington,
VA, USA

Botanical gardens are collections of well-documented and maintained living plants. While best known for aesthetic displays and tranquil settings, botanical gardens are key scientific research and conservation institutions as well as rich environments for learning.

The Purposes and Value of Botanical Gardens

The International Association of Botanic Gardens estimates that there are just under 1,800 botanical gardens in approximately 150 countries worldwide. Collectively, they serve approximately 150 million visitors a year. Botanical gardens generally aim to promote (1) scientific research, (2) conservation, (3) education, and (4) leisure experiences.

Learning in Botanical Gardens

Learning is a diverse endeavor. It encompasses a wide range of experiences, such as content acquisition, excitement and motivation, skill development, reflecting on the process of science, contributing to the generation of scientific knowledge, and identifying oneself as a scientist or science learner.

As places for learning, botanical gardens are designed to evoke emotion and reflection, prompt questions and exploration, and provide guidance and information. They actively seek to repair people's relationship with nature (sometimes referred to as "nature deficit disorder" (Louv (2005)), as well as people's lack of recognition that plants form part of the foundation of human culture and society by providing food, medicine, fiber, and building materials (referred to as "plant blindness" (Wandersee and Schussler 1999)). Learning experiences across botanical gardens vary, because they leverage the specific mission and resources of each botanical garden in order to meet the needs of their communities.

Botanical gardens' most prominent educational (and leisure) resources are their outdoor gardens and greenhouses (glasshouses) that focus on plant and garden displays. Common plant and garden displays include native plants; specialty plant groups like cacti; cultural gardens;

home gardens with flowers, edible plants, and sustainable living components; immersive environments that seek to replicate specific ecosystems like cloud forests; children's gardens; and scientific gardens that highlight biodiversity and evolutionary relationships among plants. In addition, botanical gardens often incorporate art and historic buildings as part of their displays.

Most botanical gardens offer educational programming. Four examples illustrate the range and diversity of learning opportunities offered. First, some botanical gardens train volunteer master gardeners and "plant doctors," who provide identification services and advice to visitors, in-person, online, or on the phone.

Other institutions have community gardens tended by local residents. In some programs, recent immigrants or rural transplants grow plants that represent their culture or life experiences. Using their harvests, participants share culinary and cultural practices. This facilitates community understanding as well as intergenerational dialogue within families. Such programs may also be combined with literacy opportunities for participants.

Common across botanical gardens are professional development offerings for K-12 teachers. Since the early 1990s, these classes have focused on teaching inquiry-based pedagogy and lending hands-on kits for classroom and community use. The classes and kits align closely with local, state, and national curricula in science, technology, engineering, and mathematics (STEM), as well as art and literacy standards.

Finally, many botanical gardens host festivals. Whether focused on green living and energy conservation, the sculpture of a country or an artist, seasonal changes, or religious observances, these festivals bring communities together and enrich the lives of visitors and increase their understandings of the natural world and human cultures.

Scientific Research, Conservation, and Learning at Botanical Gardens

Though few outside the botanical community get "behind the scenes," many botanical gardens are major research institutions, focusing on plant biodiversity, evolution, conservation, and sustainability. Documenting, studying, and preserving plant life and ecosystems are consistent with the history and commitment of botanical gardens. Some of the major botanical gardens in the world were founded in order to grow the strange, beautiful, medicinal, or economically important plants collected during times of exploration. Today, scientists at gardens are in a race against time to collect and study plants before they disappear due to urbanization, suburbanization, and agriculture. Approximately 80,000 of the 270,000 known species of plants are in cultivation in botanical gardens, including those that are threatened or endangered.

Scientific research, conservation, and learning at botanical gardens are often integrally connected. Programs at botanical gardens may include lectures or workshops on current scientific research and conservation efforts, tours of research labs or herbaria (collections of dried plant specimens; herbarium, singular) and conservation areas, or volunteer opportunities to work with research and conservation staff. In addition, some botanical gardens offer classes and degree programs at the university level. In addition, learning research also occurs at botanical gardens (see, e.g., Eberbach and Crowley 2009).

Challenges for Learning in Botanical Gardens

There are at least three major challenges for botanical gardens in achieving their educational aims. First, as enthusiasts and professionals alike report, becoming a gardener, a scientist, or someone knowledgeable about plants and the environment entails getting directly involved with one's subject matter. Whether crushing leaves to identify a plant by smell, collecting seeds for spring planting or conservation efforts, or using blossoms to create art, hands-on experiences are critical for learning. These authentic experiences are a resource challenge for botanical gardens. For example, for a garden to provide digging, planting, and harvesting opportunities for visitors, it must make a significant commitment in terms of staff, greenhouse space, and other resources to maintain a continuous supply of plant materials and supervised experiences.

Second, by striving to reach multiple and varied audiences, botanical gardens experience ongoing tensions between achieving a well-tended garden with a tranquil, idyllic atmosphere and creating a garden that is welcoming to people of all ages and interests. This tension plays out in terms of what learning experiences are offered, when, and to whom (Sanders 2007).

Third, time is needed for learning in botanical gardens. It is needed in two ways: time for nature and time for people. For example, time is necessary for plants to grow, for experiments to take place, and for seasons to change. In addition, time is needed for people to experience and enjoy the breadth and intricacies of botanical gardens and their offerings. In order to address both these issues, botanical gardens often promote memberships and events, provide classes in extended series, and encourage repeat visitation throughout the year and over years to foster greater understanding of the natural world and human cultures.

Summary

Botanical gardens are institutions that are deeply committed to and actively engaged in providing visitors with meaningful learning experiences, focused on the themes of biodiversity, evolution, conservation, and sustainability. The displays and programs botanical gardens offer are designed to appeal across age and interest groups and to address the full spectrum of what it means to learn.

Broadcast Media

David Robinson
Faculty of Science, The Open University, Milton Keynes, UK

Broadcasting is primarily about dissemination. One source distributes to many potential recipients, who, if they are aware of the broadcast at all, can choose to engage or ignore. It is essentially a one-way communication process although technological advances are increasingly adding forms of interactivity and audience involvement. The principal broadcasting media are sound and vision, initially distributed in real time using signals transmitted through the air, but now accessible through a wide range of other distribution channels. The advent of recording media, and later on download on demand via the Internet, removed the need to make "an appointment to view," but listening and viewing scheduled transmissions is still the main way in which people access broadcast media.

Broadcast media contribute to science education in a variety of different ways. The BBC in the UK was founded with a commitment to public service broadcasting that aimed to contribute to cultural life. The first director general, John (later Lord) Reith, formulated the purpose of the BBC as to "educate, inform and entertain." The annual broadcast lectures that now bear his name have, since 1948, allowed some of the leading scientists who are also great science communicators to bring science to a wide, and international, radio audience. Although the lectures provide an immediate experience for the listener at the time of transmission, the archived lectures provide a continuing resource for education, both formal and self. These lectures can prove powerful calls to action. For example, the 1969 lectures by the ecologist Frank Fraser Darling are a major milestone, because from a position of great authority, he articulated an early warning of global warming.

Science broadcasting in Germany started in 1923, and by 1925 one regional radio station broadcast a science lecture every Monday at 7:30 p.m. Across the radio stations the quantity of science programming was high, and science was generally broadcast during prime time, not so much because it was popular then among the listeners, but more because it matched the educational and cultural philosophy of the state. Deutsche Welle (1926–1932) was a national educational radio station with science programs that were aimed at a general audience. There were also programs aimed at a learning audience and those wishing vocational training. The regional stations did not reduce their science contact, so science enthusiasts had choice. Additional supporting material was provided for some programs through a magazine, so the idea of the use of multiple media in educational broadcasting is quite an old one (Schirrmacher 2012). The present Deutsche Welle is a German international broadcaster and is unrelated to the earlier radio station.

The lecture is a traditional form of communication that transfers well to radio, but developments in television have produced two strong new strands of science education and involvement. Firstly, there is the involvement of viewers in scientific events, in the past the moon landings and in more recent times the search for the Higgs boson. Here, broadcast media clearly have a role in communicating science by explanation, but there is also the immersion of the audience in the atmosphere and excitement of the event itself. For almost 50 years postwar, this strand of science education represented a unique selling point for terrestrial and satellite broadcasters. Now, the Internet has provided new channels which can provide the experience and often enhance it. CERN, the European Organization for Nuclear Research, has a channel CERN News that provides regular programs about the physics experiments conducted at the laboratories. NASA TV has live coverage of its space research, viewable on computers and mobile devices.

The second strong strand that developed in television, particularly in the UK, was direct broadcasting to specific groups. School radio was established early on, and by 1930 there were already science broadcasts for schools, with programs designed to be included within the planned lessons during the day. Schools broadcasts on science on television followed in the 1950s, again being used within the school timetable. In 1971, the Open University started to broadcast programs directly related to individual undergraduate degree courses. Television and radio became the medium for the distribution of learning to students, and the programs were much more than lectures, encompassing in due course some very innovative science programming. The Open University of Japan broadcasts lectures in a traditional format to its students nationwide. The key point about all these developments is that while they are targeted at particular audiences, the "drop-in" audience can be highly significant. An Open University program between 1971 and 2000 might well have been aimed at a course of 400 students, but the drop-in audience would have been many times that figure, and, on at least one occasion, it reached one million for a single program. It is difficult to measure the educational effectiveness for the drop-in audiences, although there are a number of students who give broadcasting as their reason for applying for courses.

As technology has developed, so has the broadcast model. A science broadcast now may be part of a complete package focused around a "call to action." The call might be for audience participation in a specific activity or a more general call to do something positive, for example, volunteering for conservation projects. The package, supported by web pages, might also include a free print item that can be requested by telephone or online and road shows that provide the opportunity for some hands-on science. A recent innovation has been to associate a Twitter feed with a program and build the audience into a community who take the subject beyond what was actually broadcast. The ready availability of podcasts for download enables people to choose when to listen to a program and effectively increases the size of the audience. There have also been courses for credit linked to TV programs. The BBC's Natural History Unit (Gouyon 2011) produced a blue chip documentary series in 2011 called "Frozen Planet." It was presented by Sir David Attenborough, and the series had a free poster and a short, 10-week course of the same title, dealing with polar science. The packaging of many components around a broadcast, sometimes called 360° programming, has considerable potential for science educators to harness the power and reach of the broadcast media to bring science activities to a wide audience.

BBC Lab UK is a website where the public can take part in scientific experiments linked to broadcast programs. Scientists are invited to submit experiments that could benefit from mass participation. One of the most successful was the 2006 Sex ID experiment that formed part of the TV series "Secrets of the Sexes." Scientific papers based on the data collected were published in a complete edition of the journal *Archives of Sexual Behaviour*. There were 250,000 participants, a figure that demonstrates the power of the broadcast media to promote engagement with science.

There is plenty of potential for the broadcasting media to grow their role in science education, but analysis of factual science output suggests that the overall penetration of science into broadcast media is poor (Table 1). A study of the share of science programs on the Flemish Radio and TV network VRT showed that between 1997 and 2002 it varied between 2.97 % and 5.23 % (Maeseele and Desmet, 2009).

Broadcast Media, Table 1 Science broadcasting on terrestrial free-to-view channels in the UK for 1 week (October 2005)

Available broadcast hours on channels with a minimum of 1 program on science in the week (10 in all)	1,022 h
Broadcast hours devoted to science	29 h including repeats
Percentage of available time	2.9 %
Categories included	Science, earth science, nature, forensics, health, scientific archaeology, science history, and science medicine

The image of scientists as projected by radio, and more particularly television and film, is often negative and in drama sometimes far removed from reality. Male scientists tend to be represented as the norm and female scientists as exceptional. *MythBusters* from the Discovery Channel is a program that explicitly sets out to depict the culture of science and engineering in as accurate a way as possible, with the aim of remedying the lack of understanding of the subject areas among high school students and encouraging more to take them on. The series also tries to show people in the fields of science and engineering as realistically as possible (Zarvel 2011). The representation of science and scientists by the broadcasting media is an area of continuing debate, with the impression among scientists that they and their subject are underrepresented in broadcasting. Such figures as there are seem to bear this out. In 2012 the BBC appointed its first science editor, a welcome move, but editors for other subject areas have existed for many years.

There are tensions between, on the one hand, engaging the attention of the audience and retaining it through a program and, on the other, showing authentic and accurate scientific knowledge. This can be a very fine line, as the *MythBusters* series in the US and the *Bang Goes the Theory* series in the UK demonstrate. In each, audience excitement and scientific accuracy go hand in hand, but it is a difficult relationship to maintain. There are also tensions visible in programs about extinct animals where CGI (computer-generated imagery) techniques bring extinct animals alive on the screen. *Walking with Dinosaurs* was produced as if it was a natural history series, and although it had input from many scientists, particularly concerning biomechanics, it was criticized for including behavior, such as "bonding for life" for which there is no scientific basis (Campbell 2009). When fact and guesswork are mixed, without signposting, the science educator becomes uneasy.

The power of broadcast TV to disseminate science has been covered by a number of authors (e.g., the book by Willems and Göpfert 2006). However, there is an element of broadcast TV that is less well studied, and that is the commercial breaks between programs, which also contain science content. A study carried out in 1999 found that 65 % of all advertisements over a 2-week period marketed science-based products. It has been suggested that advertisements could be used to learn about science and, by examining them in detail, demonstrate the need for objectivity.

So for the future, science educators increasingly will be using the broadcast media as a source of material for learning, as a way of educating the general audience about science and its place in society, and for demolishing the negative stereotypes of scientists.

Café Scientifique

Ann Grand
Science Communication Unit, Faculty of Health and Applied Sciences, University of the West of England, Bristol, UK

Cafés scientifiques (also known as science cafés, particularly in the USA) are informal, accessible, gatherings in which members of the public and scientists meet to talk about issues in science and technology that affect people's everyday lives.

Café scientifique has its roots in the *Café Philosophique* movement, begun in France by the philosopher Marc Sautet. Café scientifique began almost simultaneously in France (1997) and the UK (1998); the network has gradually spread until now 2012, there are cafés on every continent, although the distributed nature of the café network makes it difficult to be precise about exactly how many there are at any time.

Café scientifique is a philosophy, rather than an organization. The café scientifique website and other country-based sites offer support, guidance, and mentoring to café organizers, but all cafés are organized locally and autonomously, with no one person or group in overall control of the network. This means that the format of cafés varies from town to town and country to country; this entry focuses on the "classic," British café scientifique model.

The defining feature of a café scientifique is the venue. Cafés take place in bars, cafés, pubs, art galleries, village halls, bookshops, restaurants, and similar generic venues, not in universities or lecture theaters. This removal of the location from the academic milieu to the community context is important on two counts. First, the nature of the venue shapes the nature of the discourse. The atmosphere of cafés is relaxed, informal, and egalitarian; in a café, we expect to have a conversation. In a lecture hall, we expect to be lectured at. Therefore, in a café scientifique, the emphasis is on dialogue among equals, not on the one-way transmission and reception of information. Second, the seating of participants around tables ensures that they engage as much with each other as with the speaker, tipping the balance of power toward the audience, rather than the speaker.

Cafés are cheap, simple, and people-focused. Most operate without any kind of formal funding. This is made possible by the peer-to-peer, informal nature of the movement. Café organizers are normally volunteers; the venues are often free or very low cost, as cafés fill the venue on otherwise quiet nights. Entrance is likewise free, although many cafés ask participants to make a donation toward the speaker's expenses. Speakers are often drawn from local industry or universities, so expenses are kept fairly low. Most cafés eschew the use of technology such as presentation software or microphones, in line with the philosophy of keeping the interaction between audience and speaker as egalitarian and balanced as possible.

The classic format for a café scientifique is that the speaker gives a short introduction to

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

the topic, usually about 15–20 minutes. This is followed by a break, of around 20 minutes, to allow glasses to be refilled and conversations to start. Then there is an open discussion in which comments, questions, thoughts, and opinions are exchanged, as often among the audience themselves as between the audience and the speaker. Cafés usually have a “host,” or facilitator, whose role is to keep the discussion moving. The length of the discussion time varies from café to café but is typically around 45 minutes to an hour. Most commonly, cafés meet once a month, sometimes with a break in the summer.

This simple model is highly adaptable to different cultures. For example in continental Europe, cafés often have two to four speakers; this is seen as a way to maintain a balanced argument. In Japan, discussion points are sometimes submitted by SMS, to avoid the disrespect of directly questioning an elder or superior. The model has, with varying success, also been used in schools in the UK, the USA, France, and Uganda (see www.juniorcafesci.org.uk).

The beginnings of café scientifique coincided with the cultural change from the promotion of “public understanding of science” to “public engagement with science.” Cafés scientifiques perfectly caught the mood for direct and open public dialogue, in which scientists recognized the importance not only of talking to people about their work but also of listening to people’s views. This change also found favor with governments, as they sought innovative ways to sustain public discussion about issues in current science and technology. This cultural acceptance has meant that what started out as an avant-garde, independent, and bottom-up movement has become a widely accepted model for public engagement with science, embraced by the science communication establishment: research funders, governments, researchers, policy-makers, learned societies, and more. While many of these groups operate very effective cafés, there is a danger that their needs and agendas may override the basic principles of conversation, democracy, equality, and accessibility espoused by café scientifique.

Careers and Gender

Megan Grunert
The Mallinson Institute for Science Education,
Department of Chemistry, Western Michigan
University, Kalamazoo, MI, USA

Across science fields, women have been and continue to be underrepresented. Some disciplines are approaching parity, such as biology, while others, such as chemistry and physics, still lag behind. The issue of representation is a complex and multifaceted one and, even with years of research, is not something that can be easily fixed. Many issues are culturally embedded and very difficult to address, including implicit bias and gender roles. Other issues are a result of the historical progression of women into the sciences. For hundreds of years, women weren’t allowed to be scientists. By the early twentieth century, several exceptional female scientists were making contributions to various fields, but the norm was for women to stay out of science. In the United States, the passage of Title IX ushered in a new era for women’s educational attainment. These early generations of women scientists fought for opportunities and to be treated equally. The current generation of women entering science has more options available to them and as a result makes active and complex decisions, which often lead them out of academic scientific research.

At a national level in the United States, there has been a recognized need to promote gender equality in science careers. Starting in the 1980s, the National Science Foundation developed programs to help female faculty become more successful researchers. The current incarnation of these is the ADVANCE program, which funds research on female faculty, research on gender issues within institutions, and transformative programs to support female faculty at individual institutions.

The University of Wisconsin and the University of Michigan were in the first cohort of institutions to receive ADVANCE funding. Both institutions implemented workshops to train faculty and search committees on subconscious or implicit bias. Using empirical data, these workshops were effective in increasing the number of women interviewed and hired for STEM faculty positions. This highlighted one of the challenges facing women's progress in science – the bias they faced anytime they were evaluated on their work or qualifications.

The culture of scientific research was founded on the male scientist working long hours and being devoted to research, while his wife supported him and was a homemaker. Indeed, American pop culture has supported the male "breadwinner" and the female "homemaker" as the ideal family for quite some time. These images strongly conflict with a female scientist pursuing a career and cause considerable gender role tension for many women and dual-career couples. Females still feel pressure to be the primary caretaker for children and elderly parents, regardless of their employment status outside the home. There is a prevailing perception that scientists should be devoted to their research, putting in long hours and working constantly, in order to be successful. Managing these two roles, as female and as scientist, causes struggles for many women in science.

One solution to this conflict is to pursue a scientific career at the expense of family. While this was often the case for early generations of women scientists, current generations are not willing to make that sacrifice. Associated with lifestyle issues is the cost or stress that can be associated with pursuing a career in scientific research. Women perceive that there is a lot to give up when pursuing a scientific career, including family and personal time. Additionally, there is often a lot of pressure to publish and secure grant funding, leading to a competitive and high-stakes environment. These factors often mean choosing careers outside of academic research, which they believe will allow them to balance their personal lives and careers.

Another challenge is the perceived lack of value in certain disciplines of scientific research. Many women report wanting to make a difference in the world through their careers, also known as career altruism. For some research, particularly in the physical sciences, the outcomes of research are very far removed from daily life. It can be challenging for women to feel they are spending their time on something worthwhile if they cannot see the value of research. For this reason, teaching and industrial careers often seem more appealing because they are perceived to have more tangible and immediate impacts.

Women tend to have a lower expectation of success in science than men, which may be partly due to bias or socialization. Most people do not choose to pursue careers they expect to fail at, so expectation of success is a necessary component in someone's decision to pursue a scientific career. Having multiple successful experiences, a supportive network, and an enjoyment of the work lead to a greater expectation of success.

With few women in scientific careers, a lack of role models can be a problem for women and girls looking to enter science. Additionally, students report that women faculty often are negative role models, embodying examples of women they do not want to be. Challenging these negative role models requires women to enter scientific careers despite the lack of positive role models, which can seem risky.

When making career decisions, it is common to construct multiple possible selves that are associated with different career options. These possible selves are then compared to a person's ideal self or the life envisioned in a perfect world. The career chosen typically is the possible self that is most like the ideal self.

One challenge for students making career decisions is a lack of knowledge about available careers. There is often partial knowledge or misinformation that is used to make career decisions. With the information available, though, women go through a complex decision-making process when choosing a career. Often, this process leads them away from scientific research for any number of reasons discussed previously, which further serves to reproduce the culture of scientific research that they are resisting and trying to avoid.

Causal Reasoning

Tina Grotzer
Harvard Graduate School of Education,
Cambridge, MA, USA

Keywords

Causal induction; Understanding causality

Causal reasoning is a broad term used to refer to thinking that depends upon or aims to uncover a causal relationship between entities, events, or processes. It moves beyond the process of discerning patterns or covariation by looking for mechanisms that explain why two or more entities are related. Science often describes patterns – that something is connected, relates, or covaries with something else. It also seeks to define the reasons why particular patterns exist and this invites reasoning about mechanism – a key aspect of causal explanation. Human beings are sense-makers from an early age. Understanding the regularities in our world and knowing what accounts for them enable prediction and afford a sense of psychological control. An understanding of causality and its differences from correlation is therefore a central matter for science education.

When reference is made to causal reasoning, people often think about the ability to reason in particular ways. However, engaging in causal reasoning also involves perceiving or being sensitive to the occasion to engage in causal reasoning as well as being inclined to do so. This conception draws upon the triadic notion of thinking dispositions put forth by Perkins, Tishman, and colleagues. The research on what people do when cued to the existence of a causal pattern and asked to reason about it in contrast to how people engage in causal reasoning in everyday contexts is a key tension in research on causal reasoning as the paragraphs that follow elaborate.

Causal Mechanisms

Causal mechanisms refer to what makes the causal relationship happen. Mechanisms come in many forms. They may be physical as in mechanical devices, social as in intentions and goals, and biological as in germs and bacteria. Mechanisms can be described at different levels. For instance, one might explain why something happens by reference to a mechanical device or, at a finer level of grain, by reference to the forces involved. Consider causal explanations for what makes current in a simple circuit flow. One could respond at a number of levels, including flipping the light switch; opening a circuit and allowing current to flow; voltage that creates a push from the battery that moves electrons along a circuit; or a differential between electrons and protons at the poles of the battery that repels and attracts electrons so they move. Science often allows for more than one scientifically accepted mechanism. For instance, sinking and floating may be alternatively described with buoyancy or density explanations.

Causal Patterns

Causal patterns describe the covariation relationships and direction(s) of impact. When people think of cause and effect, they often think of a simple linear relationship involving a cause directly and immediately followed by an effect. However, causal relationships can be defined by a variety of patterns. For instance, there may be a bidirectional relationship between causes and effects as in mutual causality exemplified by symbiosis, commensalism, gravitational attraction, and so on. There may be a reentrant or cyclic causality involved as in relationships with inherent feedback loops, for instance, convection currents. Visualize the process involved in a home thermostat where convection currents trigger the thermostat to go on and off as the room cools and heats. When cyclic causal patterns have an amplifying feature, they can take on an escalating or spiraling pattern. Relational causal patterns involve a relationship between two variables, of equilibrium or of differential, that are responsible for an outcome. For instance, pressure differentials are responsible for air currents. Differentials in density account for the layers of our atmosphere – whether one layer sinks or floats on another.

Definitions of “pattern” and “mechanism” interact. For instance, if one believes that only the weight of an object is responsible for whether an object sinks or floats, they are likely to attribute a simple linear pattern. If one believes that a differential in density is responsible, then they are more likely to attribute a relational pattern.

Causal Features

Causal relationships are also characterized by features that can complexify the inherent causality. There can be time delays between causes and effects; causal action can be at a distance such that causes and effects are spatially separated. Causes can be obvious or nonobvious; for instance, carbon in the environment cannot be directly observed but its impact can, through adoption of specific causal reasoning based on extensive data. Other complicating features include tipping points or triggering features. These features result in departures from steady accumulation models and make it harder to detect when effects might occur. They tend to “hide” early accumulation because there is a certain amount of insurance in the causal system that accommodates early impacts. Therefore effects seem sudden and dramatic. Predicted climate change impacts are characterized in this way. Once a certain threshold is reached, a cascade of effects can dramatically occur. Reasoning about causality is impacted by these complexifying features because they affect the salience of the components in the causal equation and thus our ability to attend to them.

A significant body of research reveals that people operate via various default assumptions concerning the patterns, mechanisms, and features of causal interactions. A well-substantiated set includes a tendency toward assuming:

1. linear rather than nonlinear patterns
2. direct as compared to indirect impacts
3. unidirectional instead of bidirectional causal forces and impacts
4. sequentiality as opposed to simultaneity between causes and effects
5. that causes and effects will be obvious (until those possibilities have been exhausted) before considering nonobvious ones
6. that causes involve an actor and are intentional and active rather than non-intentional and passive
7. that causal investigation is warranted when a specific event occurs as opposed to recognizing that while events draw attention, they can be part of processes and steady states playing out over time that are inherent to a broader causal system
8. explicit notions of causality that are deterministic with one-to-one correspondences between causes and effects even if in our everyday reasoning (as discussed below) we

allow for causality based upon statistical regularities

9. that local causes and effects are local before considering distal ones
10. that the causal components are immediate to the outcome rather than time delayed or part of change over time
11. that causes are centralized with effects unfolding from that centralized cause in contrast to distributed or decentralized with emergent effects arising out of the many micro-interactions involved

These assumptions have a significant impact upon how we engage in causal reasoning. While these assumptions are driven largely from the modes of induction that we engage in (as discussed immediately below), attempts to make students aware of these patterns through higher-order reasoning and metacognition suggest some ability to moderate these expectations in situations that warrant it.

(Note: These default assumptions are elaborated and exemplified in Grotzer (2012).)

The cognitive science of how humans discern causal relationships

Three prevailing bodies of literature have made strong contributions to our understanding of how everyday causal reasoning works: Causal Bayes Nets (CBN) theories and the research on covariation that preceded it, specific generative transmission notions of mechanism, and the role of testimony from others (See Harris 2012).

CBN (Causal Bayes Nets) Approaches

CBN (Causal Bayes Nets) approaches are one of the prevailing model of how humans connect across statistical profitabilities to realize that a cause and effect are linked. Preceded by as rich research literature investigating how people attend to covariation between cause and effect, CBN theories argue that people sum across instances to discern causal patterns by association and that they also intervene upon and partition off certain variables to assess their impact. This, it is argued, allows people to detect causal structure by disambiguating causes. Intervention can refer to one's own actions, those of others, or those changes wrought by nature. A focus on covariation without attention to intervention or mechanism can lead to confusing correlative patterns for causal ones. Research by Alison Gopnik and her colleagues suggests that even young children follow Bayesian rules in summing across their experiences and that they are comfortable overriding imperfect correlation and using patterns of probability in contiguity to make causal inferences. Preschoolers were able to intervene to figure out the causal structure of problems with limited numbers of variables in deterministic and probabilistic contexts.

The existing studies on CBN reasoning were conducted in lab contexts without the attentional challenges and cognitive load of features that make "real-world" causality complex. Causal Bayes Net theories are effective in explaining how people meet with success in simple causal induction, but when causality becomes complex, issues arise. The CBN theory assumes acyclic patterns and the independence of the variables except for their direct and indirect effects (known as the Causal Markov Assumption). The real world is far more complex. One of the essential puzzles for CBN theories is to explain the ontological problem – how people get from a messy, complex world to a set of meaningful variables to reason about. Research on how initial, unconscious perception leads to attentional capture and then to focused perception shows that we miss a lot of information – especially when it does not fit with one's current expectations. So the question of how people know what to attend to from the wealth of stimulation coming their way poses challenges for applying a CBN model to a complex world.

For research purposes, CBN researchers often give the variables to the subjects. Further, intervening effectively in a complex world is a nearly impossible thing to do without sophisticated analysis. The unaided human mind in everyday contexts is unlikely to be able to effectively intervene and build effective causal models of such complexity. CBN accounts cannot fully enable complex causal reasoning. While much of the research on CBN reasoning is carried out in a lab in one attentional context, complex causal reasoning involves reasoning across spatial scales, extended time frames, instances where nonobvious variables compete for salience with more obvious ones, and complex patterns where effects may not become noticeable until substantive accumulation has occurred. If CBN reasoning is a predominant part of our causal repertoire, its shortfall may help to explain why people struggle so with causal complexity.

Reasoning About Mechanism

Reasoning about mechanism constitutes a second prevalent view in the cognitive science literature, represented by researchers such as Keil, Atran, and Leslie. It argues that people use their knowledge of mechanisms to reason about causality and that they amass considerable knowledge about types of causes, the causal force of particular mechanisms, and situation-specific details about where this information applies. For instance, consider how children learn about mechanisms such as remote controls, webcams, telephones, and so on, and then use this knowledge to reason about causality in particular instances. One strand of this research argues that what develops is a general notion of mechanism that children apply, but the other strand argues for domain-specific forces. Research supports the notion that children expect causal mechanisms and do not allow for causeless effects. Lacking knowledge of a causal mechanism, they may substitute magic as a mechanism – but they understand that explanation requires a mechanism. Further, even preschoolers reveal an understanding that mechanisms may not be obvious – as is the case with germs and contamination. Development appears to be in the direction of increasing knowledge of mechanisms and toward the realization that nonobvious mechanisms exist.

Testimony from Others

Testimony from others, a third body of research, focuses on how people learn from trusted others. Harris has argued that there are many concepts that children would never learn from firsthand experience alone and that the testimony of trusted others is an important source of learning about causal relationships. Complex causality offers many examples. For instance, the connection between automobile usage and changes to the polar bear habitats is unlikely to be discerned through covariation relationships and/or without deep and extensive knowledge of mechanisms that people would be unlikely to figure out on their own. Even the concept of sunburn – that a distant object in the sky can result in a painful burning sensation on one’s skin but over time and not necessarily when one is still in the sun but hours later – is most likely to be learned from others. Harris argues that testimony is an important avenue to learning about mechanisms that cannot be seen – germs, oxygen, and so forth. Testimony also comes in the form of powerful narratives. A well-known body of research by Daniel Kahneman and colleagues demonstrates that people have a tendency to override statistical data, such as that discussed above under the CBN approach.

Instead, in a tendency referred to as the availability heuristic, people use narratives in the form of powerful available cases to reason from. For instance, consider reasoning about food safety. A certain food may have been safe 100 % of the times a person has eaten it and may be deemed safe to eat by the scientific community. However, one highly visible or emotionally laden case where a trusted food turned out to be dangerous can change people’s consumption behaviors, at least for a period of time. This has happened in recent years with spinach, tomatoes, and cantaloupe, for instance. The cognitive load of summing across many cases may explain why we override this information with narratives motivated by affect; it may be adaptive to do so.

The research of Harris and colleagues demonstrates that even young children can be discerning about their informants and use subtle cues as to the reliability of the testimony that they hear. They attend to information about the informant: how much the informant is like them; how much consensus exists in the opinions of different informants; how familiar the informant is; and the perceived accuracy of the informant.

This suggests that variables in how causal information is communicated impacts how we incorporate and reason about that information.

In Conclusion

While these three modes of causal induction are often found in contrast to one another in the cognitive science literature, effective complex causal reasoning draws upon these forms of knowledge in ways that support and interact with one another. When cast in real-world contexts with messy, ill-structured problems, where sensitivity to causal instances, ability to reason in complex ways, and the inclination to do so are all in play, it makes sense that humans will bring their entire reasoning repertoire to bear on complex problems.

What Is Required of Chemistry Teacher Education

Certain key ideas appear to be necessary in any chemistry teacher education program. Gess-Newsome (1999), for example, highlights the need for integration of knowledge bases with informed decision making, exposure to examples of teaching excellence, and multiple supported experiences. These ideas are often in contradiction to preservice teachers' expectations as they expect to learn a "script" for chemistry teaching in line with their own successful learning experiences of chemistry in school. These ideas can also be in contradiction to chemistry teachers (and possibly the general public) who often believe that there is a received wisdom about learning to teach that can only be received by being in the classroom (an apprenticeship model).

How Is Chemistry Teacher Education Different from Studying Chemistry?

Studying chemistry is different from studying chemistry teacher education. Both chemistry and chemistry education are dependent on developing chemistry knowledge and their personal experiences, particularly in terms of how they know their chemistry knowledge. Chemistry teacher education also requires the development of knowledge in other domains such as pedagogical knowledge; subject-specific pedagogical knowledge (or pedagogical content knowledge (PCK) as defined by Shulman 1986); knowledge of educational contexts, purposes, and values (inclusive of curriculum, assessment, and evaluation); and knowledge of learners. It takes not only experience of teaching chemistry in schools if all of these knowledge bases are to be integrated, but also experience of other possibilities, feedback on different experiences, and time to make links between all of these factors.

Learning Progression: Big Ideas in Chemistry and How to Teach Them

One of the most cognitively demanding aspects of learning to teach chemistry is to identify the "big ideas" of chemistry which is followed by questions such as: what are age-appropriate views on these big ideas and if students do not hold the view, how does the teacher shift students' thinking in appropriate ways? For example, the idea of structure is one big idea, another would be chemical reactions. In looking at the idea of structure, the notion of particles is an early important idea, followed by progressively sophisticated ideas about what such particles might look like: a model for the particles (atoms). Understanding of the appropriateness of such a model rests in its ability to explain and predict most situations/phenomena, something that needs to be reached by the final years of secondary schooling. Understanding the progression of learning these ideas and that which is important and less important to learn also distinguishes chemistry education from chemistry and incorporates a small portion of the decision making that needs to occur when teaching chemistry.

Different Approaches

There are two dominant ways of viewing chemistry teacher education, with variations of each of these also apparent. These are chemistry teacher as learner and chemistry teacher as apprentice.

Chemistry Teacher as Learner

This approach concentrates on the development of pedagogical knowledge generally by paying attention to the learning experience (and its consequence then for teaching), with a clear focus on such understanding within a specific content area such as chemistry. Such an approach often requires the chemistry teacher educator and the preservice teachers to be co-learner and cocreators of knowledge (Corrigan 2009). Assessment tools need to focus on making judgments about the growth of the learners and identify what knowledge has been created in this approach. Reflection can often play an important role in assessment of this type with its ability to focus on a "problem" (a perplexing or curious situation) that can be framed and possibly reframed. In chemistry teacher as learner approaches, preservice teachers need to focus on their own "problems" rather than the problems of others.

Chemistry Teacher as Apprentice

This approach focuses on the development of pedagogical knowledge within the classroom, where continued experience promotes mastery of particular situations. However, if the apprenticeship occurs in a narrow range of situations, the ability to transfer what has been learnt to other settings is often hampered (Kennedy 1999). The integration of knowledge bases is often far less explicit, particularly if the range of experiences are limited. The focus remains on teaching rather than personal learning experiences, and so challenges to teaching styles can also be limited.

Chemistry Teacher as Clinical Expert

A variation on these models could be represented as *chemistry teacher as clinical expert* where there is a focus in the school component on developing particular expertise and competence in specified targeted areas. While this is more focused than the apprenticeship model, it is less reliant on reflection than the *teacher as learner* approach and therefore has differing consequences for understandings of being a teacher and doing teaching.

Philosophy of chemistry aims to provide robust analyses of the concepts, theories, and methods characteristic of chemistry and of the interrelations between them, including reflection on the ways in which they are related to, and potentially distinct from, the concepts, theories, and methods of other sciences. The following entry provides a brief survey of the main lines of investigation in contemporary philosophy of chemistry. More detailed treatments of these topics are found in Hendry et al. (2011), Van Brakel (2000), and Weisberg et al. (2011).

Core Concepts in Chemistry

Philosophy of chemistry, like the philosophical study of other particular sciences, devotes attention to the analysis of core concepts, including the concepts of chemical substance, chemical element, chemical bond, and reaction mechanism.

Chemical substances are the fundamental kinds of chemistry and are as important to understanding chemistry as the species concept is to understanding the biological sciences. There are three long-standing questions about substances: (i) What makes something a sample of the chemical substance that it is? (ii) What kinds of change can an exemplification of that substance survive? (iii) What is the difference between pure compound substances and mixtures? There are two general strategies for tackling these issues. One appeals to the molecular constituents of a substance and the other appeals to macroscopic criteria.

In either case, the theoretical building block for making sense of substances is the concept of the *chemical element*. Because it underwrites all chemical classification (discussed more below), an adequate analysis of the concept of element is necessary for an adequate account of substance. For individuating substances composed of a single element, the molecular strategy seems sufficient because the chemical properties of these substances are largely determined by the nuclear charge on the constituent atoms (i.e., the "atomic number" of the element). But compound substances are less amenable to a parallel treatment. Different substances may share the same elemental composition (in the case of isomers), elemental composition alone cannot distinguish between compounds and mixtures (e.g., hydrogen chloride gas and a mixture of hydrogen and chlorine gases in the corresponding proportions), and many compounds are simply not homogeneous at the molecular level. The most famous example is water: Pure liquid water consists of complex congeries of different species like H_3O^+, OH^-, and hydrogen-bonded oligomolecular structures, rather than collections of H_2O molecules, and this molecular heterogeneity is responsible for water's characteristic properties. If the relationship between molecules and substances is this complex, some have argued, the notion of "substance" may need to be understood independently of molecular constitution.

In fact, simple macroscopic criteria can clarify some of these cases. For example, a compound and a mixture of the same elements in the same molar proportions will exhibit radically different behavior under equivalent conditions of temperature and pressure. At room temperature and pressure, water is liquid but the mixture of hydrogen and oxygen is gas, and under conditions in which both are gaseous, the compound occupies two-thirds the volume of the same mass of the mixture. But the same thermodynamic grounding that captures our intuitions well in such cases would seem to view different isotopes of oxygen (^{16}O, ^{17}O, and ^{18}O) as different substances, because mixing samples of the different isotopes gives rise to measurable entropy changes. Yet chemical properties (i.e., dispositions to undergo chemical change), as mentioned earlier, are determined overwhelmingly by nuclear charge, which the different isotopes share, rather than atomic mass, with respect to which they differ.

Mixed substances pose a related set of problems concerning the persistence conditions of substance identity. When common salt (NaCl) dissolves in water, the ionic lattice breaks down, and the sodium and chloride ions form complexes with H_2O molecules. Is salt still present in brine? If not, what essential property of salt has been lost? On the other hand, if salt is said to be present, what should we say about a solution containing sodium hydroxide and potassium chloride? Is there salt here too? And how should we characterize the difference between pure and mixed substances in the first place? Potential answers drawing on either molecular or macroscopic criteria remain contentious, and the distinction between compounds and solutions itself comes under pressure with the recognition of nonstoichiometric compounds in the twentieth century.

After substance, perhaps the most central concept in modern chemistry is that of a *chemical bond*. The chemical bond serves to explain an extensive array of phenomena ranging from basic properties of bulk substances to whether particular reactions will occur under given circumstances, and what reaction pathways will be followed. In turn, the chemical bond is itself an object of explanation within the discipline. In contemporary practice the bond concept is a conceptual amalgam generated by the creative melding of classical and quantum notions following the incorporation of quantum mechanics into chemistry in the early twentieth century. At least two distinct conceptions of the chemical bond, the structural and the energetic, have been distinguished by philosophical analysis (Hendry et al. 2011). Each conception faces challenges with respect to internal consistency, coherence with physical theory, or explanatory completeness, and either would require significant development to provide an analysis both satisfying and sufficient. But can the chemical bond concept serve its explanatory role if it cannot be given a fully coherent interpretation within chemistry or if it is not fully consistent with more fundamental physical theory?

Another concept worthy of sustained attention is that of a *reaction mechanism*. To the extent that chemistry is the science of the transformation of substances, reaction mechanisms become a primary tool for explaining and predicting key facts about complex reactions: the nature of the various products, the quantities in which they are produced, and how these vary as the physical conditions change. William Goodwin has argued that organic chemistry actually employs two related mechanism concepts, the "thick" and the "thin" (Hendry et al. 2011). The thin conception is entrenched in practice, littering laboratory blackboards with diagrams and supporting the common reasoning patterns required to meet organic chemistry's particular predictive and explanatory aims. The thick conception, on the other hand, most readily connects mathematical models of chemical transformation to the experimental data measured in the laboratory. Further analysis of reaction mechanisms, especially as they relate to mechanism concepts in other sciences, remains a fruitful topic for future research.

Chemical Methods

In addition to conceptual analysis, many of the issues that demand philosophical attention concern the methods of chemistry, broadly construed.

Chemistry has an enduring concern with *classification* because of the multiplicity of distinct substances within its domain. Since the introduction of a compositional nomenclature in the 1780s, chemical classification has been erected principally upon a theory of constituents. The *periodic table* of elements is the most visible, and most fundamental, classificatory structure in chemistry. In its contemporary incarnation, the table serves to connect the realm of substances with the realm of atoms and molecules through the concept of *chemical element* (mentioned earlier). By highlighting the role of periodicity in chemical inference (roughly, analogical reasoning based on chemical similarity), the periodic table is a prime example of a representational tool that provides a framework for robust reasoning.

Indeed, the pragmatic significance of *representation* emerges as a general theme in recent philosophical work. The periodic table's two-dimensional matrix explicitly organizes elements in terms of horizontal and vertical relationships that facilitate identification of chemical similarity groups and trends. Similarly, because physical models effectively support reasoning involving spatial relations, such models flourished during the development of both nineteenth-century stereochemistry and twentieth-century macromolecular biology. Graphical formats support identification of potential energy surface maxima and minima that are crucial for determining reaction pathways. And the shift from largely intractable mathematical representations to diagrams was instrumental in allowing quantum-mechanical models of molecules to guide chemical reasoning regarding chemical bonding and reactivity. Perhaps most centrally, *chemical equations* function as an explicit bookkeeping device that relies on an inherent ambiguity regarding whether the equations represent facts at the level of substances or molecules. In each of these examples, the specific representational format is crucial for the efficacy of the inferential scaffolding.

More generally, investigations concerning the role, function, and significance of chemical *models* mirror those prominent throughout contemporary philosophy of science. As seen across the sciences, models in chemistry rely frequently on idealization and approximation for their power. We see this vividly in models ranging from the ideal gas law to mathematical models in quantum chemistry to ball and stick physical models in the classroom. Some models aim to provide explanation, others generate predictions, and still others facilitate and entrench common patterns of reasoning. Philosophical discussion of models as "mediators" between theory and phenomena is especially relevant to understanding this range of functionality.

Chemistry's laboratory practices are also distinctive, guided as they are by focus on the reliable manipulation and manufacture of substances. Control of this sort has been realized through the conjoined methods of *analysis*, by which chemists determine the constituents of a given substance, and *synthesis*, by which predetermined substances, or more minimally substances with desired properties, are produced. The basic questions are clear: How are synthesis projects conceptualized and organized? How are laboratory practices coordinated with theoretical representations? What are the characteristics of rational search for synthetic pathways? Innovations such as the development of automated search techniques raise interesting methodological questions, as does the heavy reliance on technological *instrumentation*, especially various forms of spectroscopy, for identification of chemical kinds. The epistemic challenges, as well as advantages, that accompany reliance on such instrumentation require systematic analysis.

At a more basic level, we might consider whether, and how, synthetic goals shape the very nature of chemistry as a science and ask how greater understanding of chemistry's orientation toward the controlled production of designed novelty clarifies or challenges traditional assumptions involving the relative disciplinary homogeneity of the physical sciences, the distinction between science and engineering or pure and applied science, and the role of values in science generally.

Relations Between Chemistry and Other Sciences

Intuitively, chemistry seems individuated by its characteristic concepts (substance, element, bond, etc.), but can these concepts be fully understood in terms of the concepts of physics? If not, can the chemical explanations that employ them be replaced by explanations that appeal only to physical concepts? Critically examining the assumption of reducibility is a theme that runs throughout contemporary philosophy of chemistry.

Any general framework should distinguish between *inter-theoretic* and *ontological reductions*. Traditionally, inter-theoretic reduction has been the central topic of debate. But even if chemical theories are irreducible to physical theories (inter-theoretic), the question remains whether the subject matter of chemistry is, in some sense, just that of physics (ontological). Recent arguments demonstrate that a robust conception of molecular structure cannot be recovered in a fully principled manner from the equations of nonrelativistic quantum mechanics (i.e., without making what is normally called the Born-Oppenheimer approximation). Molecular structure is effectively introduced ad hoc rather than explained. More generally, quantum chemistry appeals to concepts and traditions of representation from both physics and chemistry. This suggests a synthesis of chemistry and physics, rather than a reduction of one to the other. In a similar vein, the laws of thermodynamics provide constraints on chemical explanations without providing such explanations in full, again suggesting a non-reductionist model for the explanatory role of physical theories in chemistry.

Alongside these long-standing issues, *disciplinary differences* have emerged as a distinct philosophical concern and one that does not reduce to relations between theories. The historical development of molecular biology in relation to biochemistry reveals clear differences in the explanations offered within each subdiscipline, suggesting the disciplines may be meaningfully differentiated by their respective explanatory strategies. Meanwhile, consideration of prominent techniques for rational drug design, a landscape that places chemistry in close contact with pharmacy, suggests that we would do well to attend to the materiality and explicitly productive (medical, industrial, technological, and otherwise commercial) orientation of much chemical research. A broader issue concerns whether chemistry is currently fracturing from a unified discipline into a wide range of importantly distinct interdisciplinary enterprises such as molecular genetics, environmental science, and nanoscience. Examining interdisciplinary relations provides a different perspective on issues of reduction and autonomy, although they do not, by themselves, settle any traditional philosophical issues. More modestly, they highlight the social nature of theoretical, experimental, and technological achievements within chemistry.

Citizen Science

Rick Bonney, Jennifer Shirk and Tina B. Phillips
Cornell Lab of Ornithology, Cornell University,
Ithaca, NY, USA

Citizen science is a term most often employed to describe projects for which volunteers collect data for use in organized scientific research. This usage of the term emerged from the Cornell Lab of Ornithology in 1994 when the lab desired a new name for its rapidly growing assemblage of data collection projects focused on birds. At that time, volunteer data collection efforts were relatively few in number, and most of the ones that did exist focused on monitoring the quality of lakes, streams, and rivers. Twenty years later, data-driven citizen science projects number in the thousands, and their participants number in the many hundreds of thousands. Projects cover a breadth of topics ranging from native bees to invasive species, from urban birds to arctic glaciers, and from pollen to stardust. Some projects engage a handful of participants in one small watershed, while others enroll many thousands of observers dispersed across several continents. Although projects vary in the degree of collaboration between volunteer participants and science researchers, in most projects volunteers receive some degree of guidance in project procedures to ensure consistency in data collection and accuracy in data analysis. The scientific impact of these projects, which yield knowledge by collecting and analyzing vast quantities of data at unprecedented scales, is easily measured by the rapidly growing number of publications based on volunteer-collected data (listings of projects and published papers are available at www.citizenscience.org).

While citizen science is sometimes considered a recent phenomenon, amateur scientists have been studying the world for much of recorded history, usually by noting observations of the environment around them. Also known as "volunteer monitoring" and "community science," citizen science efforts have yielded important datasets, specimen collections, and scientific insights since the seventeenth century and probably before. Much of our current information about the distributions of plants and animals, the timing of events in nature such as plant budding and bird nesting, the quality of water in streams and rivers, and the impacts of climate change on organisms around the world is derived from data collected by members of the public.

Although citizen science as a concept has a long history, the strategy of involving the public in scientific research as a method for increasing public science literacy is relatively recent. In the late 1980s, a group of educators pondering innovations in science education realized that by providing participants in volunteer monitoring projects with materials to support learning – for example, information about why a project was started, what scientific questions it was investigating, how a participant's data would be combined with data from others to answer those questions, and details about the organisms or phenomena being studied – the participants might learn scientific facts and concepts and also begin to understand how scientists conduct investigations that yield evidence-based results. For example, for The Birdhouse Network – which began in 1995 and is now part of Project

NestWatch (www.nestwatch.org) – participants kept track of the birds nesting in birdhouses in their yards and communities. They noted the species, number of eggs laid, timing of hatching and fledging, and overall nesting success and then submitted their data to a centralized project database. The data were then analyzed by scientists to determine information such as the influence of latitude on nesting success. At the same time, through the process of learning about cavity-nesting birds and studying their breeding behavior – which was supported by instructional booklets, posters, and simple data forms – project participants increased their knowledge of a number of aspects of bird biology.

As the twentieth century got under way, the idea that public participation in organized research could yield "hands-on" science learning took hold rapidly, and the number of projects intended to achieve goals for increasing both science knowledge and public science literacy began to multiply. The expansion of complex citizen science projects was further fueled by the development of the Internet, which allowed project participants to submit data to online databases and, in some cases, to be able to access project data for their own interpretation. Also, some citizen science projects, such as the University of Minnesota's Monarch Larva Monitoring Project, began to develop science curricula specifically designed for K-12 teachers who wished to incorporate citizen science into their classroom activities. Such curricula have been shown to help students learn many different aspects of science such as content knowledge and understanding of key features of scientific investigations and the nature of scientific research.

In response to the burgeoning field, the US National Science Foundation funded a workshop in 2007 that assembled 50 citizen science project leaders to discuss "best practices" for citizen science project design. The workshop yielded the "Citizen Science Toolkit," which provided guidelines for developing, implementing, sustaining, and evaluating projects designed to achieve outcomes for both science and education. The NSF funded a second citizen science conference in 2011; this one focused on how citizen science projects could advance the field of biological conservation. The proceedings of these two conferences, both available at www.citizenscience.org, are a rich introduction into the field of citizen science and its outcomes for a wide range of project types. And in 2012, an open conference on citizen science held in Portland, Oregon, attracted nearly 300 professional scientists and educators who discussed a wide range of project models and who launched an International Association for Citizen Science (reports from this conference also are available at www.citizenscience.org).

In the early 2000s, a new form of data-driven citizen science began to emerge, born of developing technology and the concept of crowdsourcing. At the vanguard was a project called Galaxy Zoo, which employed the power of the Internet to enable members of the public to classify images of space captured by the Hubble Space Telescope. This form of citizen science became very popular as new projects were developed to explore the surface of the moon, model Earth's climate using historic ship logs, and explore the ocean floor (www.zooniverse.org). Like the earlier monitoring projects, many of these data classification projects were intended not only to achieve scientific goals but also to help participants learn scientific information and develop positive attitudes toward science while participating in the scientific process. For example, participants in a project called "Citizen Sky" have demonstrated a positive change in scientific attitudes, apparently related to their engagement in the project's social activities.

In 2009, a group of researchers working under the auspices of CAISE (Center for Advancement of Informal Science Education) produced a document that described different models of citizen science for which participants collect or classify data. These authors introduced the term "Public Participation in Scientific Research" (PPSR) as an umbrella concept to refer to a range of project types that engage participants in the scientific process to varying degrees. The authors found that different PPSR models yielded different types of learning outcomes and suggested that project developers be deliberate in their project designs, carefully matching design to desired outcomes.

An additional form of citizen science also exists as described by Alan Irwin in his 1995 book *Citizen Science: A Study of People, Expertise, and Sustainable Development*. In contrast to the definition of citizen science as the engagement of volunteers and professionals in collaborative research to generate new science-based knowledge, the concept of citizen science that Irwin champions aims to bring the public and science closer together, to consider possibilities for a more active "scientific citizenship," and to involve the public more deeply in issues related to risk and environmental threat. Some data-driven citizen science projects do have objectives for achieving better linkages between science and society and even "democratizing" science, such as work currently being conducted in Europe by the Extreme Citizen Science group (ExCiteS: http://www.ucl.ac.uk/silva/excites).

With its goal of transforming the world through the bottom-up creation of knowledge, the future of the citizen science field seems nearly boundless. The ultimate success of the field will be measured by the ability of citizen science to empower members of the public to invoke transformative change for themselves, society, and the environment, blending concepts and ideas from all forms of public participation into powerful societal change.

Classroom Learning Environments

Barry Fraser
Science & Mathematics Education Centre, Curtin University, Perth, WA, Australia

Keywords

Assessment; Environments; Learning

Students spend a huge amount of time at school – approximately 7,000 h by the end of elementary school, around 15,000 h by the completion of secondary school, and nearly 20,000 h by the completion of university. However, despite the obvious importance of what goes on in classrooms, most teachers and researchers rely heavily and sometimes exclusively on the assessment of academic achievement and other learning outcomes.

This entry is devoted to conceptualizing, assessing, and investigating what happens to students during their education by drawing on the field of classroom learning environments. Clearly, having positive classroom environments is a valuable goal of education. But, it should not be assumed that the equally important issue of student outcomes is ignored in this entry. Extensive past research provides consistent evidence that the classroom environment is so consistently associated with student outcomes that it should not be ignored by those wishing to improve the effectiveness of classrooms.

A milestone in the historical development of the field of learning environments occurred approximately 40 years ago when Herbert Walberg and Rudolf Moos began seminal independent programs of research that formed starting points of the work encompassed by this entry. Walberg developed the Learning Environment Inventory as part of the research and evaluation activities of Harvard Project Physics, whereas Moos developed social climate scales for various human environments, including the Classroom Environment Scale. Although learning environments research originated in the United States, it soon spread to other countries, especially Australia and the Netherlands. Furthermore, particularly in the last decade or so, Asian researchers have made comprehensive and distinctive contributions (Fraser 2012).

Assessing Learning Environments

Although classroom environment is a subtle concept, remarkable progress has been made in conceptualizing, assessing, and researching it. A considerable amount of work has been undertaken in many countries on developing methods for investigating how students and teachers perceive the environments in which they work. In particular, over the years, researchers have developed numerous questionnaires to assess students' perceptions of their classroom learning environments. For example, these questionnaires provide information about whether a class is dominated by the teacher or is student centered; whether students actively participate in class or sit and listen to the teacher; whether students cooperate and discuss with each other when they are learning, or whether they work alone; whether the teacher is supportive and approachable; whether the students have a say in the choice of teaching and assessment methods; and whether differences in students' interests and speeds of working are allowed for by the teacher. Some examples of popular classroom learning environment questionnaires, together with the dimensions that they assess, are given below:

- What Is Happening In this Class? (WIHIC) – student cohesiveness, teacher support, involvement, investigation, task orientation, cooperation, and equity
- Constructivist Learning Environment Survey (CLES) – personal relevance, uncertainty, critical voice, shared control, and student negotiation
- Science Laboratory Environment Inventory (SLEI) – student cohesiveness, open-endedness, integration, rule clarity, and material environment

These questionnaires have been used in different countries and at different grade levels. They have been translated into various languages, including Spanish, Arabic, Chinese, Korean, Indonesian, Thai, and the South African language of North Soto. They have been used by hundreds of researchers, thousands of teachers, and millions of students around the world. Most teachers and researchers find that it is easy and convenient to use these instruments to obtain information about learning environments from students.

Over the past four decades, learning environment researchers have attempted to answer many interesting questions. Does a classroom's environment affect student learning and attitudes? Can teachers conveniently assess the climates of their own classroom, and can they change these environments? Is there a difference between actual and preferred classroom environment, as perceived by students, and does this matter in terms of student outcomes? Do teachers and their students perceive the same classroom environments similarly? How does the classroom environment change when a new curriculum or teaching method is introduced? Do students of different abilities, sexes, or ethnic backgrounds perceive the same classroom differently? These questions represent the thrust of the work on classroom environment over the past 40 years (Fraser 2012).

Researchers have carried out many dozens of studies into the relationship between student outcomes and the quality of the classroom learning environment. These studies have been carried out in numerous countries and at various grade levels with tens of thousands of students. The consistent evidence from these studies is that the nature of the classroom environment is related to student outcomes (both cognitive and affective). Therefore, teachers should not feel that it is a waste of time for them to devote time and energy to improving their classroom environments because research shows that attention to the classroom environment is likely to pay off in terms of improving student outcomes.

Classroom environment instruments have been used as a valuable source of process criteria in the evaluation of educational innovations. For example, Martin-Dunlop and Fraser (2008) evaluated an innovative science course for prospective elementary teachers in a large urban university in California. When learning environment scales selected from the WIHIC and SLEI were administered to 525 females in 27 classes, very large differences were found on all scales (of over 1.5 standard deviations) between students' perceptions of the innovative course and their previous course.

Feedback information based on student perceptions has been employed in a five-step procedure as a basis for reflection upon, discussion of, and systematic attempts to improve classroom environments at various levels of education (Aldridge et al. 2012). First, students respond to the preferred form of a classroom environment instrument, with the actual form being administered in the same time slot about a week later (assessment). Second, the teacher is provided with feedback information derived from student responses in the form of profiles representing the class means of students' actual and preferred environment scores (feedback). These profiles permit identification of the changes in classroom environment needed to reduce major differences between the nature of the actual environment and that preferred by students. Third, the teacher engages in private reflection and informal discussion about the profiles in order to provide a basis for a decision about whether an attempt would be made to change the environment in terms of some of the dimensions (reflection and discussion). Fourth, the teacher introduces an intervention of approximately 2 months' duration in an attempt to change the classroom environment (intervention). Fifth, the students' actual form of the scales (i.e., the environment that the students perceive that they actually are experiencing) is readministered at the end of the intervention to see whether students are perceiving their classroom environments differently from before (reassessment). These studies usually reveal that there has been an improvement in classroom environment and that teachers value their involvement in this action research aimed at improving classroom environments (Fraser 2012).

Although this entry gives emphasis to assessing classroom environment questionnaires that tap students' perceptions, which has been the predominant method in past research, it is important to note that significant progress has been made in using quantitative and qualitative methods within the same study of classroom environments (Tobin and Fraser 1998). For example, in a multilevel study of the learning environment, qualitative methods involved visiting classes, using student diaries, and interviewing a teacher-researcher, students, school administrators, and parents. A video camera recorded activities, field notes were written during and soon after observation, and team meetings took place regularly. Based on this study, Tobin and Fraser (1998, p. 639) concluded: "We cannot envision why learning environment researchers would opt for either qualitative or quantitative data, and we advocate the use of both in an effort to obtain credible and authentic outcomes."

Conclusion

Several implications emerge from this entry for improving science education. First, because measures of learning outcomes alone cannot provide a complete picture of the educational process, assessments of learning environment should also be used to provide information about subtle but important aspects of classroom life. Second, the evaluation of innovations and new curricula should include classroom environment instruments to provide economical, valid, and reliable process measures of effectiveness. Third, teachers should use assessments of their students' perceptions of actual and preferred classroom environment to monitor and guide attempts to improve classrooms. Fourth, when assessing and investigating classroom environment, a combination of qualitative and quantitative methods should be used instead of either method alone.

Classroom management; Discipline; Effective teaching; Instructional repertoire; Learning environment; School culture

Since 1970, the journal Phi Delta Kappan has reported Gallup Poll results on US public perceptions of schools. Amongst other things, the poll identifies the biggest problems facing public schools; in 2010 and 2011, lack of funding for schools was number one with discipline and classroom control being second. Discipline and control has been number one or two for the last 42 years. Why is the issue of "discipline" so persistent? My guess is that we fail (collectively) to grasp the complexity of the teaching and learning process and the ways that more effective teachers encourage appropriate behavior and how they respond to students who behave inappropriately. The conundrum with effective teachers (science teachers included) is that they are often so smooth and seamless that we don't notice what they do unless we are actually looking for it.

Teaching is one of the most complex, demanding, and important of all occupations. Teachers (on average) interact with 20–30 students for 180–200 days a year, for 6–8 hours a day, encouraging students to focus on approximately 400 learning outcomes per year; during that time, very little is predictable. Each day students of different cultures, races, and genders enter science classrooms. Those students bring by-default factors over which the teacher has little control (e.g., fetal alcohol syndrome, dyslexia, autism, deafness, blindness, parents divorcing, living in poverty, being gifted, witnessing violence, being abused at home either physically, emotionally, mentally, etc.). To increase the complexity still further, those factors get nested into the literature on multiple intelligence and learning styles.

Striving to balance students working alone, competitively, and cooperatively in a laboratory-oriented science educational setting creates an intense context that can often result in conflict. Conflict (like change, stress, and competition) is not inherently good or bad. What makes conflict "good" or "bad" is the stance we take towards conflict combined with the skill sets we invoke to restore social order so that learning can continue.

So, for example, a student may say, "This is boring!" The less effective science teacher is more likely to take this personally and respond in a way that "pushes back" with the consequence of bonding the student against the teacher. The "expanded problem" is that if that student has friends, those friends also bond against the teacher. The effective teacher is unlikely to get "caught" and might say, "Boring for you? Listen, I had to plan it last night PLUS I have to teach it today. You should be feeling sorry for me right now," or "You're right, this is boring; tomorrow I'll do a better job" (the Tai Chi response), or "Thanks for being brave enough to let me know," or "Boring today? Well, enjoy today because it is downhill the rest of the year." They use humor, wit, truth, and humility – the Tai Chi's of classroom management: they merge the heart and mind.

The key idea here is that if the rest of the class has bonded with the teacher, the teacher's response works; if not, the response is less likely to work. Over the years, I have found that the issue is not the specific response, but rather the respect the students have for the teacher. No matter how well prepared teachers are, all students, at some time, are going to behave inappropriately and teachers have to deal with it.

In this brief entry, I explore the complexity of designing and enacting a science learning environment as it relates to how teachers encourage appropriate behavior and how they respond to students who choose to behave in a way that makes it difficult for teachers to teach and students to learn. The ideas being shared are the result of having worked with teachers for almost 40 years: having worked with teachers who ranged from those at risk of losing their teaching credentials to teachers identified as the most effective. I start with a few "prevention" ideas to consider before I develop an introduction to a repertoire of ways to interact with student off-task behavior.

The prevention side involves the intersection of numerous factors. I briefly discuss five factors. Whenever one of these five areas is not enacted effectively, the teacher increases the chances students will behave inappropriately and decreases the chances of resolving the issue: (1) teacher personality, (2) teacher's knowledge of curriculum, (3) teacher's ability to assess student learning, (4) teacher's instructional repertoire, and (5) the school culture.

Teacher Personality

When we ask science teachers to reflect on their great teachers, what comes up is sense of humor, enthusiasm, caring, challenge, and politeness. When we ask the same teachers to think of teachers they did not respect, the answers are the opposite, boring, didn't want to be there, embarrassed you publically, etc. You can see that teacher personality is a key piece. Interestingly, teachers can easily remember how the less effective teachers responded to students who were off task; however, they struggle to remember the specific responses of effective teachers. Why? Because they were smooth, seamless, kind, and kept it low-key emotionally.

Curriculum

Students also talk about being challenged, being involved in engaging, meaningful science lessons. They enjoy teachers "who really know their stuff," who make connections between science and other aspects of life, help students make a quilt of ideas. Students are less likely to be off task in those classrooms; and when they are off task, the teacher simply reminds them to focus by enacting a glance, a name, a pause, a gesture, a cough, a please, a "shift" of proximity, or some combination, but done respectfully so as not to provoke an escalation. These skills augment, rather than override careful planning, particularly where practical science activities are concerned; teachers need to plan and sequence physical enactment and intellectual engagement of students with each learning activity.

Assessment

Feedback has one of the highest effects on student learning; how we choose to assess student learning, how we encourage them to give us feedback, and how we give them feedback are critical. Hattie's (2012) research identifies feedback as one of the most powerful ways to impact student learning. Successful science students are less likely to be off task. Of course, when it comes to assessing student learning, if we as teachers fail to first assess our instructional repertoire and its effectiveness, then any decisions we make about student learning are going to be suspect.

Instructional Repertoire

Current research (Leithwood et al. 2009; Hattie 2012; Fullan 2011) reports that the teacher's instructional repertoire and their ability to differentiate their instruction are key predictors of student success. That said, teachers will struggle with 'differentiating instruction' in the absence of an extensive instructional repertoire. Instruction is one part of how teachers respond to the different intelligences, learning preferences/roadblocks, etc. Although most science teachers reserve the revered lab experiment as the means by which instructional practice is intentionally altered. However, teachers who structure groups effectively, frame questions effectively, listen and respond to student interest, etc., in varied and interesting ways are going to have less classroom conflict.

School Culture

If the school culture is balkanized, with no norms of collegiality or collaboration, then the school is unlikely to have a clearly articulated (enacted) school-wide set of procedures for effectively encouraging appropriate behavior. The reverse would be the case for a more collaborative school culture. The front "office" is of little value if school administrators have no idea why the student ended up in the office and what the teacher did to prevent the student ending up in the office in the first place. And just as problematic, the science teacher who sent the student has no idea what will happen at the office once the student ends up in the office.

When considering those five factors, one senses that prevention is more complex than it looks. In terms of school culture, all staff members must work together to create and enact a system that responds to student unacceptable behavior and to make sure they are not the reason the student(s) behaved inappropriately.

In the next section I situate how teachers respond to students once students get "off task." (See *Power Plays*, Bennett and Smilanich 2012). As science teachers, we must consider that students may be off task because the lesson is boring, meaningless, or of no interest or the classroom is not a safe place to learn. If that is the case, the teacher is part of the problem. Metaphorically speaking, if a restaurant gave us poor service, unpalatable food, and an ambience not conducive to eating, we would not return, and we would inform our friends so that they could avoid it too. We all assess before, during, and after eating. Students do the same thing: they assess before, during, and after learning, and they inform their friends of their conclusions. The "teaching" problem is that the science classroom is the only "restaurant" in town. How would you behave if the restaurant you had to eat in 200 days a year had poor food, poor service, and a poor eating environment?

Our students, albeit tacitly, have "scored" us. If our customer service rating averages out at 75 % or higher, things will go relatively smoothly; we can rely on a smaller set of skills to respond to the students because the students have bonded with us instead of against us. If our service rating is less than 50 %, we are going to struggle in the science classroom. Science teachers with higher ratings tend to believe that no matter how well planned, prepared, kind, and thoughtful they are, all students, at some time are going to misbehave and that they have to deal with it. They are less likely to be disappointed and are less likely to take it (show it) personally. As a result, the more effective science teachers have a more extensive enacted repertoire – they show greater flexibility (are more artful) in how, where, and when they respond to students: they are much less likely to judge. They are also more likely to spend more time working to understand how to work with students rather than how to control them.

When we ask grade two or grade 12 students to tell us what their teacher uses to get them to refocus, the students will say things like "they look at us,” or “they say our name,” or “they come over and sort of take it away,” or “they just come close to us so we stop.” Those are not secret skills, parents use them as well. We call these “invisible discipline skills.” The problem is that having the skills is the science, enacting them is the art. I explain the “art” piece in the next paragraph.

When I work with at-risk science teachers to identify the skills, they employ to respond to students, and we compare their responses to highly effective teachers; we get no difference in that list. They identify the same “skills.” The difference is that the effective teachers know when, how, where, etc., to employ those skills. They understand how to use the look inside of a “gradient of intensity” (i.e., the glance, the look, the stare, and the glare). They get the idea of a “light pink” look, a “medium pink” look, a “dark pink, look, a “light red look,” etc. They don’t use a “dark red” when the situation requires a “light pink” (and vice versa). Effective science teachers get the “art of enactment.” That same idea of the “gradient of intensity” plays out with how they apply proximity, use a student’s name, etc. That gradient of intensity plays out as the student or students’ behavior escalates and the skills the teachers enact also become more sophisticated. That escalation is seen as “bumping it up”; as the student bumps up the situation, the teacher has to have a corresponding set of skills.

I don’t have the space in this entry to describe the following nine “bumps,” but they are simply logical responses to classroom situations. For example, Bump Three relates to effective choices with the follow through on the choice being Bump Four. Bump Five refers to power struggles. Bump Ten is when the student has made the decision to be expelled; the key with Bump Ten is that the student understands that he or she made that decision to be expelled, not the school staff. Classroom management is delightfully complex, our challenge is to make sure we become consciously competent (collectively), and not simply accidentally adequate (individually) in our thoughts and actions, to prevent and to respond to that complexity.

Code-Switching in the Teaching and Learning of Science

Audrey Msimanga
Audrey Msimanga, Science Education,
University of the Witwatersrand, Johannesburg,
South Africa

Code-switching has been defined variously over time and in different contexts, since Haugen’s (1956) definition of code-switching as the ability of a bilingual to introduce unassimilated words from another language into his or her speech. It has since been defined as the alternation between two (or more) languages; the ability to segregate competing languages and switch between them when contextually appropriate; the movement by a speaker from one language to another; the use of more than one language in order to contextualize communication; and the habit of switching from one language to another. According to Setati (1996), code-switching involves a word, a phrase, a sentence, or sentences and cannot happen between monolinguals, only bilinguals. It is a skill that requires competence in more than one language.

For a long time, code-switching was regarded as an inferior form of engagement. However, research findings in both language teaching and cognition continue to show that code-switching can serve important functions to facilitate and contextualize communication. Its importance in education has been investigated. For example, a few decades ago, some argued that code-switching might be linked to lower intelligence levels. However, subsequent research showed that there was no significant relationship between code-switching and intelligence. It is now believed that the ability to switch between codes may help with conceptual organization or thinking about things in a new way. In other research, code-switching has been identified as one of the strategies used in coping with the challenges of teaching and learning in a language that learners (and sometimes teachers too) are not competent in. However, in spite of these merits, code-switching has its constraints. If not mediated appropriately, it may interfere with meaning-making and may have a negative impact on the learning process. Also, learners may find it difficult to navigate the two languages, especially if they are not sufficiently competent in the second language as is usually the case where the language of instruction is not the learners' first language. Since the ability to switch between codes is indicated in conceptual organization, it could be inferred that failure to navigate between the codes may interfere with conceptual understanding. Code-switching in science teaching and learning is under-researched (e.g. Probyn 2004; Rollnick 2000; Setati et al. 2002).

Introduction to Cognitive Acceleration

Cognitive acceleration is a term used to describe an approach to pedagogy and a research tradition in science education that is based on two broad principles: (1) that there is a general intellectual function in children which develops with age and (2) that the development of this general intellectual function is influenced both by the environment and by maturation (Shayer and Adey 2002). Cognitive acceleration pedagogy sought to stimulate and advance students' general intellectual functioning beyond what would happen as a result of maturation through the use of specially designed thinking lessons. The intention of these lessons is to improve students' intellectual capacity, thus leading to an improvement in their ability to participate in the school curriculum and an improvement in their school achievement.

This entry has five sections. The first very briefly outlines the Piagetian theory underpinning cognitive acceleration, the second describes the development of the cognitive acceleration interventions, the third outlines the findings from evaluations of cognitive acceleration interventions, the fourth describes the structure of the intervention, and the final section raises relevant issues of professional development.

Piagetian Theory and Cognitive Acceleration

The pedagogy of cognitive acceleration is largely based on Jean Piaget's theory of cognition and his constructivist theory of epistemology. This is the subject of an extended entry in this encyclopedia (Piagetian theory). Piaget regarded the development of cognition as an active process in which the brain constructs a reality based on the stimuli received through the senses, rather than as a passive process in which the brain assimilates representations of phenomena in the environment. He viewed this active process as a structural adaptation that enables the human organism to interact with and assimilate stimuli to construct an understanding of the environment.

Piaget and his associates concluded that as cognition or thinking develops, it changes in qualitatively different ways. Concrete operations consist of schema of student behavior such as the ability to order and classify in simple ways and to conserve number and volume. The more advanced schema of formal operations includes the ability to control variables and understand equilibrium, probability, and formal modeling.

An extensive study in the 1970s of Piaget's levels of cognition within a student population of 12,000 from a wide range of urban, rural, and high and low socioeconomically ranked schools in England and Wales indicated that, by the age of 16, only 10 % of these students had attained the level of late formal operational thinking and a further 20 % a level of early formal operational thinking. The remainder of the sample remained at or below concrete operational thinking. This level of cognition is well below that predicted by Piaget's estimates (Adey and Shayer 1994).

Development of the Cognitive Acceleration Intervention

In order to understand scientific concepts and methodology at any depth, students need to have reached the level of formal operational thinking. For example, the use of the particle model of matter as an explanatory model requires early formal operational thinking. Students who have not reached this level may be able to memorize information about the behavior of particles and recall it when tested, but they will be unable to use the model to explain observed phenomena or write scientific explanations that demonstrate an understanding of the implications of the model. The development of formal operational schema enables students to systematically use forms of higher-order thinking which include multivariate, abstract thinking, compound variables, ratios and proportions, probability and its implications, formal scientific models, equilibrium, and correlation.

Adey and Shayer were concerned that, as above, 30 % of 16-year-old students were able to think at the level of formal operations. These researchers believed that the stages of thinking exhibited by a class of students are not fixed and that it is possible to teach students how to think in new ways. In response to these concerns, Adey, Shayer, and colleague Carolyn Yates developed the Cognitive Acceleration through Science Education intervention (commonly referred to by the acronym CASE and commercially known and referred to by many teachers as Thinking Science) (Adey et al. 2001). CASE is a program of 30 lessons designed to demonstrate to teachers how to stimulate student cognitive development and improve students' ability to understand science. The lessons are part of a professional development program that supports teachers over a 2-year period as they learn the pedagogical skills required to fulfill the purpose of the lessons.

Evaluations of the Cognitive Acceleration Intervention

CASE developed into one of the most widely employed and highly lauded programs for developing high school students' thinking ability in the United Kingdom (UK) and internationally. Considerable evidence has been published on the effects of the CASE strategies on children's cognitive development and school achievement (Shayer and Adey 2002). Research with over 2,000 high school students in 11 UK schools showed that after 2 years of participation, the proportion of students using high-order thinking was significantly higher than the national average. The statistically significant gains made by the CASE students over the national average were large, 0.67–1.26 standard deviations. There also is evidence of long-term transfer effects of CASE on scholastic achievement, even beyond the area of science. Improved student achievement in subjects other than science has been attributed to CASE having an effect on general intellectual growth, as well as on science-related thinking skills. The achievement gains were found for the full ability range of pre-intervention students. Independent reviews have supported these findings. Some researchers have noted the lack of attention to the students' attitudes and motivations in the CASE research (e.g., Leo and Galloway 1996).

The general approach to cognitive acceleration has since been applied to other disciplines, including mathematics and technology, and programs have been developed for younger children in the early childhood and middle primary years (Shayer and Adey 2002). Cognitive acceleration programs also have been successfully adapted and trialed in many countries.

Structure of the Cognitive Acceleration Intervention

Thinking Science lessons are structured around six pillars:

1. Concrete preparation: The teacher spends a short time explaining the purpose of the lesson to students and advising them of necessary procedures such as matters of safety.
2. Data collection: Students participate in a scientific activity. The data collected forms the basis of the challenge they will discuss.
3. Cognitive conflict: Cognitive conflict is one aspect of a Thinking Science lesson that drives cognitive development. It involves a challenging or difficult situation; for example, when the data students collect are different to what they expected, they are stimulated to think in new and different ways to comprehend the data.
4. Social construction: The challenging problem is discussed by students in a group of three or four. It is important that students are explicitly taught how to discuss, listen actively, and work constructively in a group. Social construction, which is a challenging discussion, is the second pillar that stimulates cognitive development.
5. Metacognitive questioning: Metacognition involves students reflecting on their own thinking and articulating the approaches they took to problem solving. This gives other students insight into different ways of thinking and evaluating. During the lesson, the teacher and students use metacognitive questions to probe thinking during discussion, for example, "Why do you think that? How did you work that out? What made you feel confused?" Metacognition is the third pillar that stimulates cognitive development.
6. Bridging is the process of contextualizing the problem discussed in a particular lesson. It enables students to relate what they have discussed to their everyday life or to other experiences they have been exposed to in science classes.

The teaching of higher-order thinking, and/or critical and creative thinking, is an underlying assumption of almost all current secondary science curricula across the globe. Examples of such thinking include critically analyze, deduce, evaluate, explain, justify, and synthesize. However, rarely is a definition of these terms provided, and teachers often are unaware of how to teach in ways to ensure their students are able to develop these higher-order thinking skills. Thinking Science pedagogy leads to this development that is also the basis of critical and creative thinking.

Professional Development of Teachers

As with all new pedagogical approaches, effective professional development is an essential pathway to the high-quality pedagogy required for cognitive acceleration. Professional development is defined as effective when it changes teachers' pedagogical practice and improves student outcomes (Adey 2004). Widely recognized problems in the provision of effective professional development include a lack of executive support, history of innovations with little or no theoretical basis, lack of ownership of teacher learning, scant acknowledgement of teachers' current contributions in the classroom, failure to consider the whole school context and the teachers' work within that context, no direction about how to recognize and build effective collegiality, and lack of long-term support while new pedagogical approaches are explored and adopted.

Thinking Science professional development has followed well-documented principles for effective professional development and attempted to resolve these problems in the following ways. School administrative support is gained before the implementation of the program; teacher ownership of the program is developed by providing an understanding of its theoretical basis and involvement in the analysis of its effectiveness. Professional development is long term including central in-service days and an emphasis on in-class coaching to support teachers as they practice and acquire new approaches to pedagogy over the 2 years of the program. Furthermore, the development of collegiality is encouraged for mutual support and sustainability of the program. Thinking Science professional development focuses on the development of effective student-centered pedagogy and on the relationship between this and improved student outcomes.

Cognitive Demand

Georgios Tsaparlis
Department of Chemistry, University of
Ioannina, Ioannina, Greece

Keywords

Cognition; Information processing; Mental capacity; Mental demand (*M*-demand); Problem solving; Working memory; Working-memory capacity; Working-memory overload model

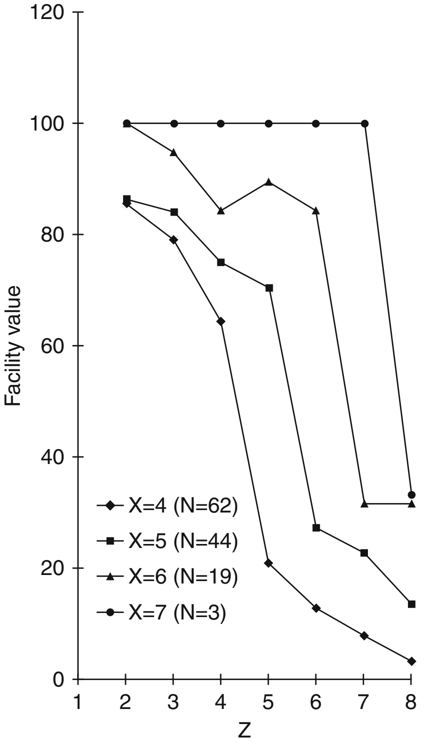
Cognitive demand or **mental demand** (*M*-demand) is a construct that is applied to the study of cognition and especially of problem solving. As such, it relates to science teaching, learning, and assessment of teaching and learning. In psychology and cognitive science, *cognition* relates to information processing, which in turn relates to a number of psychological or ► cognitive abilities or functions or variables (also called *psychometric variables*). Essentially, the cognitive demand of a mental task, such as a problem, is related to the complexity of the task/problem. In general, as a problem increases in complexity (in terms of what information has to be held and what process has to be performed), performance decreases. The complexity of a problem in science education is described by (a) the "*M*-demand" and (b) the "logical structure" of the problem. In this article, *M*-demand will be treated first.

The assignment of *M*-demand to a problem follows from the optional or minimum number of component steps required to accomplish the solution to the problem. This can be judged by comparison of the allocated *M*-demand by independent expert solvers of the problem. Another extended definition of *M*-demand is "the maximum number of thought steps and processes which have to be activated by the least able, but ultimately successful candidate in the light of what had been taught" (Johnstone and El-Banna 1986). The assigned *M*-demand of a problem can further be verified by a posteriori analysis of the students' solutions. This method is consistent with the four-step procedure for the evaluation of the *M*-demand known as *dimensional analysis* (Niaz and Logie 1993). In addition, the confirmation of the validity of the *working-memory overload model* can provide further support to the estimation of the *M*-demand of a problem (see below).

A central construct in information processing is that of *working memory*, of which a measure is provided by the *working-memory capacity* (Baddeley 1986). Alternatively, the construct of *mental space* is used, which is measured with the *mental capacity* (*M*-capacity) (Pascual-Leone 1970). Both the working-memory capacity and *M*-capacity variables are operationalized and measured by means of corresponding psychometric tests. Specifically, one way of assessing working-memory capacity is by means of the *Digit Backward Span Test*, which is part of the Wechsler Adult Intelligence Scale, while *M*-capacity is assessed by means of the Pascual-Leone's *Figural Intersection Test*.

A characteristic model involving working memory is the *working-memory overload model* (or hypothesis), which states that a subject is likely to be successful in solving a problem if the problem has an *M*-demand, which is less than or equal to the subject's working-memory capacity (W) ($M \leq W$), but fail for lack of information or recall, and unsuccessful if $M > W$, unless the student has strategies that enable him/her to reduce the value of M to become less than W (Johnstone and El-Banna 1986). Information processing relates then to a "holding/thinking space" (i.e., working memory), which has a finite limit, after which the decrease of achievement may be rapid. The rapid decrease in students' achievement has been connected to *working-memory overload* and has been usually demonstrated by an inverse *S*-shaped curve, which is the graph of the percentage of successful subjects as a function of the *M*-demand of a problem (see Fig. 1). For instance, from the graph for the working-memory capacity of 6, it follows that students with this capacity are, as a rule, successful in problems with *M*-demands of 2 up to 6, but fail when the *M*-demand assumes values of 7 and 8. The part of the curve with the largest slope is thought to correspond to the subjects' working-memory capacity overload.

Research has shown that the model was found not to apply to all kinds of empirical data, except for some specific cases. The following have been found to operate as limitations and necessary conditions for the model to be valid (Tsaparlis 1998): (a) the logical structure of the problem must be simple; (b) the problem has to be non-algorithmic; (c) the partial/component steps must be available in the long-term memory and accessible from it; (d) the students do not employ "chunking" devices (by means of which they



Cognitive Demand, Fig. 1 Facility value (%) in organic-synthesis problem solving versus *M*-demand (*Z*) versus various levels of working-memory capacity (*X*) for a sample of students ($N = 128$) without previous training in these problems (From Tsaparlis and Angelopoulos (2000), Reprinted with permission from Wiley)

chunk the problem into familiar chunks and thus are reducing the *M*-demand); and (e) no "noise" should be present in the problem statement; as "noise" is assumed the irrelevant and potentially misleading information that might be included in a problem.

In general, a sudden decrease in students' performance might occur not only because of the limitation of their working-memory capacity but also because of the interference of other variables; thus, it has been shown that psychometric variables, such as *disembedding ability* (degree of "field dependence/independence") and/or *logical thinking* (previously referred to as "developmental level" in the Piagetian sense), play an essential role in science problem solving. It is worth noting that in the working-memory model, field dependence is seen as a moderator variable: field-dependent subjects appear to possess lower working-memory capacity because they use part of their capacity to process irrelevant information. "Spatial ability," involving also disembedding of information, has also been found to affect student achievement in problem solving.

It was stated above that the complexity of a problem in science education is described by (a) the *M*-demand and (b) the logical structure of the problem. The *logical structure* is associated with the number of different *logical schemata*, which the solver has to retrieve from his long-term memory in order to solve the problem (Niaz and Logie 1993). According to Jean Piaget, a *schema* is an internal structure or representation (apparently in long-term memory), while the ways we manipulate schemata are called "operations." In ▶ Piagetian theory, schemata are continually growing and developing rather than remaining fixed. Describing thinking at various stages becomes thus an issue of trying to define the schema (or mental structure) and the operations (or internal actions) that a problem solver is using. In the case of chemistry, examples of logical schemata are chemical stoichiometry, gas laws, and the state of chemical equilibrium.

In a study about the validity of the overload hypothesis, organic chemical-synthesis problems were used, with a simple logical structure and varying *M*-demand from $M = 2$ to $M = 8$ (Tsaparlis and Angelopoulos 2000). In general, organic-synthesis problems are very difficult for the students, being very demanding in terms of information processing, because the number of pathways by which students could synthesize target substance "X" from starting substance "A" may be numerous. These problems are unique in that they can satisfy the necessary conditions that must be fulfilled for the validity of the tested problem-solving model (see above): they (i) exclude numerical or algebraic calculations, (ii) have a simple (one-schema) chemical logical structure, and (iii) cannot be answered by the application of an algorithmic procedure. The latter requirement is equivalent to them being real *problems* and not routine *exercises*. Two samples of students (ages 17–18) participated in the study: one sample had received some previous training in these problems, while the other sample had not. Although the predicted pattern was observed in both samples, it was found that the model was more useful in the case of the students without previous training (see Fig. 1). Finally, as expected, the model predicted better with the field-independent and the field-intermediate students than with the field-dependent ones.

The construct of *cognitive demand* or *mental demand* (*M*-demand) and its connection with *information processing* and other psychological functions have important implications for science teaching, learning, and assessment of teaching and learning. The findings of research can guide the construction of a series of problems in a science topic with the same reasoning pattern (the same logical structure) and varying *M*-demand. Student success, especially for novice learners, can be facilitated by the careful control of the *M*-demand, that is, by first introducing problems of low *M*-demand and by leaving problems of high *M*-demand for later use, when students have acquired experience and motivation. Teachers must feel their responsibility for this student transition: they must emphasize and consciously employ the relevant strategies throughout their teaching. Only when strategies have been learned should complexity be allowed to increase, so that students can learn to keep the value of *M*-demand (not the actual but their own modified by "chunking" *M*-demand) well within their working-memory capacity. In this way confidence, and hence motivation, can be maintained while complexity increases, leading novices toward the expert state.

Cognitive Labs

Maria Araceli Ruiz-Primo
University of Colorado, Denver, CO, USA

Keywords

Cognitive interviews; Protocol analysis; Talk-aloud protocols; Think-aloud interviews; Think-aloud protocols; Verbal analysis; Verbal protocol analysis; Verbal reports

Cognitive lab is a term frequently used to refer to a set of procedures and conditions (experimental situations) in which verbal reports are elicited and collected to study cognitive processes. Such verbal reports serve as a major source of data on the cognitive processes that subjects engage in when completing diverse tasks such as solving a problem, responding to a survey question, answering a test item, or reading different types of texts. Cognitive labs are used in diverse fields, but one in which it is frequently used is in the development and evaluation of assessments and questionnaires (or surveys).

Two issues are important to consider when discussing cognitive labs: (1) the necessity to focus on the actions intended to elicit and collect verbal reports and the information they provide about the inferred cognitive processes, rather than on the conditions in which they take place and (2) the liberal way in which certain words are used to refer to the methods to gather the verbal reports (e.g., think-aloud protocols, think-aloud interviews, talk-aloud protocols, verbal protocols, or cognitive interviews). Not all terms can be treated as equivalent and they impose their own characteristics to the experimental situation. The discussion of cognitive labs here is then centered on the issues related to verbal reports rather than the cognitive labs as a physical space or experimental situation.

Verbal reports have been considered by cognitive psychologists to be the available method that most closely "identifies the content of a person's mind..." (Leighton 2009, p. 2). A common feature to all the procedures used to obtain verbal reports is that subjects respond orally to an instruction or probe (Ericsson and Simon 1980, 1993). Two general procedures can be indentified for gathering verbal reports: protocol analysis and verbal analysis. *Protocol analysis* is often used to tap cognitive processes underlying the completion of a task; it helps to confirm cognitive models of task performance. *Verbal analysis* is used to tap knowledge structures; it helps to explore and generate cognitive models of task performance as well as beliefs and attitudes about the task at hand. Due to the space constraints, this entry focuses only on protocol analysis given the wide use of this procedure. For information about verbal analysis, see Chi (1997).

Protocol Analysis

Protocol analysis is guided by human information-processing models. It is used mainly for identifying, through verbalizations, cognitive processes involved in problem solving. These verbalizations constitute the verbal reports. Once they are transcribed, the verbal reports are referred to as the *protocols* (Ericsson and Simon 1993) that will be the subject of the *analysis*. Verbal protocols provide a source of evidence for tracing and documenting the representations and processes used by subjects to approach a task (e.g., generate a solution). These processes are compared to a hypothesized cognitive model of solution – a model of the possible logical sequences of cognitive steps needed to produce a correct response. In other words, protocol analysis helps to *confirm cognitive models* of task performance (Leighton 2009).

There are two types of verbal reports:

1. *Concurrent verbal reports*, in which subjects are instructed to verbalize their cognitive processes as they work through (or perform) a task. Talk aloud and think aloud are different forms of verbal reports that can be produced in concurrent verbalizations. Each represents different levels of information processing. In the talk aloud, the verbalization is direct; the subject verbalizes or reproduces the information as she or he is attending to the information. In the think aloud, the verbalization is mediated by another type of processing. The instructions to the subjects are also different: "Talk aloud as you multiply 24 times 36!" versus "What is the result of multiplying 24 times 36?"
2. *Retrospective verbal reports*, in which subjects are instructed to verbalize, retrospectively, the sequence of thoughts that occurred during the performance of a task. Ideally, retrospective reports should be done by the subject immediately after the task is completed since most of the information will still be stored in the short-term memory.

Conditions for Protocol Analysis

Experimental situation. Minimizing social interaction is critical to collecting verbal reports through protocol analysis. For example, the researcher or data collector should be seated behind and not visible to the participant. The rationale for this arrangement is that socially motivated verbalizations require additional cognitive processing to present the verbalizations in a coherent and understandable manner, which might affect the sequence and depth of thoughts (Ericsson and Simon 1993). Hence, when subjects are reminded to talk or think aloud, the preference is to instruct them to "keep talking" rather than saying, "please tell me what you are thinking" or "what are you thinking?"

Selection of tasks. Tasks used in protocol analysis should have a clear focus and avoid vagueness. This helps to ensure not only that subjects will be fully engaged while completing the tasks but also that the cognitive model of the task can be more easily developed. When subjects are fully engaged in the task, it is more likely that their verbalizations follow the same sequence of thoughts as occurring in a silent condition (Ericsson and Simon 1993).

Critical to protocol analysis is the identification of the cognitive model that is expected that subjects will use to approach the task at hand (the knowledge of the cognitive demands imposed by the task assigned to the subjects). This knowledge can be obtained through *task analysis* – the specification of the logically possible sequences of cognitive steps to produce a correct response (i.e., the solution path or the cognitive model of the task). Task analysis is usually conducted by experts.

When verbal reports are used in the context of assessment (mostly for validation purposes), another condition is required: tasks selected for verbal reports should be of *moderate difficulty* relative to the population of interest (Taylor and Dionne 2000). This moderate level of difficulty allows for more *controlled cognitive processing* – awareness of how the task is being approached. Easy tasks elicit rapid recall (automatic cognitive processing), leaving the subject unaware of how he or she approaches the task. On the other hand, difficult tasks may overload the working memory by exhausting all the mental resources in responding to the task, such as understanding the task, retrieving information from long-term memory, and selecting appropriate strategies to approach the task. With all the working memory occupied by these activities, few if any mental resources will be available for concurrently articulating verbally the cognitive processes involved in approaching the task.

Instructions. Critical to the generation of valid verbal reports is the nature of the instructions provided. Instructions need to be carefully worded because they can influence the nature of the verbal reports (Ericsson and Simon 1993; Tyler and Dionne 2000; see examples of instructions for talk aloud and think aloud in the concurrent verbalization section). The instructions for protocol analysis should emphasize general reporting of the participants' thoughts, and they should not include requests to report specific aspects related to the explanation or justification of responses (see conditions below). It is important to remember to use "keep talking" to remind the subject to talk rather than any other form that invites for social interaction.

Ericsson and Simon (1993) suggest the use of a couple of easy warm-up tasks which cognitive processes are well known but are not associated with the task at hand (e.g., "Talk aloud as you tie your shoelaces."). Warm-up tasks are intended to ensure that the instructions for generating appropriate verbal reports are understood. They are also intended to reduce anxiety and make subjects more comfortable in the experimental situation.

Analysis of Verbal Protocols

Steps for analyzing verbal protocols can be summarized as follows (Ericsson and Simon 1993; Taylor and Dionne 2000): (1) Transcribe the verbal report verbatim; transcriptions should capture as much detail as possible (e.g., pauses, emphases, tone). (2) Develop a valid coding system, based on the cognitive model of the task, to identify the processes and patterns of knowledge in the verbal data collected. The level of detail of the coding system will vary accordingly. It is important to remember that task analysis plays a critical role in the development of coding systems. This analysis along with the generation of the cognitive model of task performance constitutes a significant portion of the work required to segment and code the verbal protocols. (3) Segment the verbal protocols in units that will be the focus of the analysis, what will be coded. Ericsson and Simon (1993) suggest segmenting the protocol by statement. However, the segments can be aggregated to conduct other types of analysis (e.g., by episode or major process or steps in solving the problem). (4) Code each segment at the level suggested by the coding system. The complexity of the coding system will determine the number of codes applied to each segment. (5) Evaluate the reliability of the coding system. Clearly defined codes illustrated with prototype examples help to increase the consistency across coders. (6) Develop a complete model of the subject's cognitive procedures reported in the verbal reports that reflect the problem-solving process. Such models can be a description of the interconnection of the problem-solving stages or a pictorial model such as a decision tree graph (Ericsson and Simon 1993) or flowchart (Gierl et al. 2009). Graphical representations of the verbal protocols are used to match the path the subject took with the sequence of steps specified in task analysis and reflected in the cognitive model.

Limitations of Verbal Reports

The use of verbal reports raises three critical areas of concern (Wilson 1994): (1) *Completeness* refers to the difficulty of determining with certainty the completeness of a verbal report. Even in concurrent verbalizations, verbal reports can become incomplete if the cognitive processes cannot be easily verbalized, for example, when certain cognitive processes have become automatic. (2) *Reactivity* refers to the potential interference in the cognitive process when participants are asked to verbalize their thoughts – reactivity may change the cognition of interest, leading to a misinterpretation of the subject's cognitive processes. (3) *Non-veridicality* focuses on the issue that simply asking someone to verbalize their thoughts does not guarantee access to the cognition of interest, which may lead to misunderstanding their cognitive process. Still, a fourth concern can be mentioned inherent to protocol analysis; it is *costly* and *time consuming*.

To minimize the concerns raised above, three actions are recommended (Ericsson and Simon 1993; Taylor and Dionne 2000): (1) Use the two forms of verbal reports, concurrent and retrospective, as complementary methods to obtain a more complete picture of cognitive processes. The former helps to identify the knowledge and skills being used to approach the task; the latter helps to elaborate or clarify what was found in the concurrent reports. Retrospective reports also can be used to gather information about participants' metacognitive knowledge (Taylor and Dionne 2000). (2) Once the participants finished the task, do not wait too long to obtain retrospective verbal reports. What subjects remember, and how well, will generally depend critically on the interval between the moment the information is being processed and the moment of recall (Ericsson and Simon 1980). (3) For think-aloud verbal reports, do not allow subjects to rationalize or conjecture as they are engaged in the task.

A Final Note

It is important to acknowledge that cognitive labs are implemented in many different ways. The procedures used have become a big array of practices, and the names used to refer to these practices are now a complex combination of terms previously used for other purposes. This state of affairs is also due to the lack of effort from the research community to incorporate and clarify the use of terms in a more accurate way. An effort toward this end is needed not only to avoid confusion in the procedures used but also to have clarity about the inferences made based on the verbal reports. Inferences made about subjects' cognition depend on the type of procedures conducted and the type of verbal report collected.

Cognitive Preferences

Richard Gunstone
Faculty of Education, Monash University,
Clayton, VIC, Australia

Keywords

Cognitive style; Conceptual understanding; Learning style

Cognitive Preference is a particular form of cognitive style that has at times in the last 50 years been a significant component of aspects of research on science learning. It was particularly prominent in research in the 1960s and 1970s because of strong logical links between the construct and the changes in emphasis to conceptual learning that characterized the dramatic developments of science curriculum and curriculum projects in the late 1950s and 1960s in the Anglophone world.

"Cognitive Style" (or, sometimes, "learning style") describes the notion that individuals have consistent patterns in the forms of information they seek and the ways they then gather and process this information. While there is continued debate about the extent to which any individual consistently behaves in this regard and as to the extent to which such consistency is a singular or multiple dimension of the individual's characteristics, cognitive style in a range of forms is a concept of significance in scholarship relating to human learning and behaviors (particularly in studies in the fields of education and management).

The curriculum projects of great influence in the late 1950s and 1960s began with PSSC Physics, closely followed by CHEM Study and BSCS Biology. These are often referred to as the First Generation projects or the "alphabet phase" of large-scale science curriculum development. These projects were all strongly characterized by a focus on conceptual content and developing student understanding of these concepts and a clear move away from descriptive, applied, and historical aspects of science. This focus on conceptual understanding as the most significant learning outcome to be sought went as far as attempting (sometimes implied, occasionally explicit) to more generally change the intellectual approaches of students towards a seeking of understanding in all contexts. This led quickly to Heath, a psychologist specializing in educational measurement, constructing in 1964 the notion of Cognitive Preference.

Cognitive Preferences were seen by Heath to be particular modes used by students in learning science (dealing with scientific information). He identified four of these modes:

1. Recall (R): Acceptance of information without consideration of implications, applications, or limitations.
2. Principles (P): Acceptance of information because it exemplifies or illuminates a fundamental scientific principle, concept, or relationship.
3. Questioning (Q): Critical questioning of information regarding its completeness, generalizability, or limitations.
4. Application (A): Emphasis on the usefulness and applicability of information in a general, social, or scientific context. Any student was seen to be consistently more inclined to use one of these modes above the other three.

Explorations of Cognitive Preference then quickly became very common in a range of approaches to researching the First Generation curriculum projects, from large-scale curriculum evaluation studies to studies of individual science learning that resulted from the use of the curricula. Assessment of an individual's cognitive preference has, I believe, always been done via pencil-and-paper testing. Questions on these tests always follow the same format:

– An introductory statement that relates to some aspect of the curriculum content that is the focus of the study is followed by four statements that extend or elaborate the introductory statement, with each of these four corresponding closely to one of the four modes of cognitive preference described by Heath.
– It is noted that all the four extension/elaboration alternatives are correct statements and the respondent is asked to either (i) select the statement they find most appealing or they would most like to learn more about, or (ii) rank all four statements (in terms of appeal or most like to learn more about), or (iii) choose both the most and the least appealing statements (or more/least like to learn more about).

The following is a typical Cognitive Preference test item:

> The pressure of a gas is directly proportional to its absolute temperature.
> (a) The statement as given above fails to consider effects of volume changes and changes of state.
> (b) Charles' or Gay Lussac's Law.
> (c) The statement implies a lower limit to temperature.
> (d) This principle is related to the fact that overheated automobile tyres may 'blow out' (Tamir 1985, p.2).

In this item option A corresponds to the mode Questioning (Q), option B to Recall (R), option C to Principles (P), and option D to Application (A).

Individual research studies using Cognitive Preference tests have consistently reported high reliabilities for these instruments. In his 1985 review and meta-analysis of then approximately 100 extant science education studies involving cognitive preferences, Tamir concluded "…the results reported here indicate that the cognitive preference construct demonstrates a reasonable level of validity, that Cognitive Preferences make significant contribution to learning, and that their inclusion in further educational research as well as their consideration in educational practice is to be encouraged" (p. 13). Despite this exhortation studies that include the construct, Cognitive Preference has been extremely rare since this time. It is almost certain that this is due to the moves that began in the early 1970s to expand the intentions of the science curriculum beyond the essentially singular focus on conceptual understanding that characterized the First Generation projects.

Keywords

Assessment; Formative assessment; Learning progressions; Summative assessment

Assessment may serve different purposes in different contexts. In the context of classroom learning, teachers use assessment to collect information about students' competence in a particular domain (e.g., science) at the beginning of and throughout an instructional unit for planning and monitoring student learning. At the end of the unit, the school year or even a particular stage of education, teachers use assessment to collect information about student competence to evaluate the outcomes of student learning in scope of the unit or school year. In the school, district, state, or national level context, assessment is used for monitoring student learning across multiple school years. All these assessments may be considered to serve the eventual aim to improve student learning. However, only assessments that have an immediate effect on the assessed students' learning are considered formative assessment. Assessments used for certification purposes (e.g., grading) and monitoring purposes (e.g., comparing different curricula) are considered summative, as these assessments typically aim to comprehensively assess student competence in a domain without an immediate impact on student learning. Still, such assessments – better: the information obtained through these assessments – are utilized to send students to a school track that suits their level of competence the best. Or these assessments may be used to increase funding for those school districts whose students have been found to fall behind in mastering the required level of competence at a particular stage of their educational career. Sometimes the same assessment is used for different purposes. Teachers, for example, may use assessments carried out for certification purposes (e.g., an end-of-year test) and also for formative purposes (e.g., to plan student learning in the following school year).

However, while a single assessment can be meaningfully used for more than one purpose, that does not mean that one assessment can serve all purposes (National Research Council [NRC] 2001). Assessments need to be designed to first and foremost serve the purpose they are intended for. Formative assessment in the context of the classroom is typically designed around rich tasks that require the application of a combination of in-depth knowledge (e.g., an understanding of the core ideas of science) and complex skills (e.g., scientific practices). Summative assessments in large-scale contexts on the other hand typically build on multiple-choice items for more efficient scoring. And whereas information obtained through multiple-choice large-scale summative assessments can be used for formative purposes, for example, at the beginning of a unit, the information will not provide in-depth information of student thinking and as such is not suitable for monitoring student learning throughout a unit. In order to ensure that – despite their design to fit different purposes – the various assessments used within an education system all serve the eventual purpose of improving student learning, coherence needs to be established across the different assessments (NRC 2014).

Assessment should build on three foundational elements: a model of student competence development, a set of beliefs about typical tasks or situations students at each level of competence development can solve, and a set of (statistical) procedures to aggregate the information aimed for from the raw data. As the latter two elements are specific to the purpose the respective assessment serves, the first foundational element is the one by which to establish coherence. A comprehensive model of student learning about a domain (e.g., science) is needed that describes student learning at different grain sizes, across multiple-grade bands, within one grade band, from lesson to lesson, and even within one lesson. That is, multiple models of student learning about different aspects of the domain are required describing learning at the smallest meaningful grain size. These models then need to be integrated into a system which allows to describe student learning across time as a function of the content taught. So far, science education research has provided many assessments that can describe student learning on smaller timescales. What is missing is an empirical foundation for larger models of student learning that can align the structuring of content (i.e., curriculum) across several grade bands and serve as a framework for aligning assessments both horizontally and vertically (NRC 2006). This function is to be fulfilled by learning progressions (e.g., Wilson 2009, p. 727).

Communicating Science, Classroom Assessment of the Ability to

Alandeon W. Oliveira
University at Albany, State University of New York, Albany, NY, USA

Introduction

Scholars of science education have become increasingly interested in the classroom assessment of science communication ability. This interest is partially due to a growing realization that effective science instruction leads to improved communicative ability. In addition to mastering important science concepts, learners also develop a variety of communicative skills such as an improved ability to talk, write, argue, and reason scientifically. The following text introduces readers to scholarly work in which such communicative outcomes have become the object of classroom assessment efforts. Attention is given specifically to the different ways that classroom science communication is conceptualized and methodologically approached as part of science classroom assessment efforts. In some studies, science learners are viewed as developing the ability to express their thoughts in the language of science, and what is assessed is their ability to "talk science." In others, science classroom communication is viewed rhetorically, and what is assessed is students' competence in oral argumentation.

Talking Science

Classroom assessment of students' ability to talk science has been largely informal and formative, typically being conducted in the context of whole-class discussions at elementary grade levels. These oral assessment efforts are strongly influenced by the book *Talking Science* where Lemke (1990) identifies the stylistic norms to which speakers must abide in order to talk "proper science" in classroom settings: 1. Be as explicit and universal as possible. . . 2. Avoid colloquial forms of language. . . 3. Use technical terms. . . 4. Avoid personifications and. . . human attributes or qualities. . . 5. Avoid metaphoric and figurative language. . .6. Be serious. . .7. Avoid personalities and reference to individual human beings and their actions. . .8. Avoid reference to fiction or fantasy. . .9. Use causal forms of explanation and avoid narrative and dramatic accounts. (p. 133)

Lemke conceives of science as a school subject whose communication requires mastery over a specific register, that is, a specialized and context-specific variety of the English language. This characterization of "the language of science" has been used in recent studies as a basis to assess the effectiveness of elementary teachers' oral strategies in encouraging students to talk scientifically (i.e., make use of the scientific register). Pappas et al. (2003) describe how primary students tend to recount previous events and experiences in a generalized and impersonal manner when allowed to make spontaneous and unprompted contributions to the discussion during a loud reading of science trade books. Oliveira (2010) reports that referential questions (i.e., student-centered oral queries that require pupils to express their own conceptual understandings) prompt long, explicit, and precisely articulated student responses. Oliveira (2011) identifies provision of participant examples (oral descriptions of actual or hypothetical situations wherein the teacher presents himself/herself and/or students as characters to illustrate topics under discussion) with the generalized "you" as a strategy effective in encouraging students engaged in oral discussions to speak in a generalized manner consistent with the scientific register.

As a dynamic, continuous, qualitative, and formative endeavor, classroom assessment of students' ability to talk science informs subsequent teacher moves (reactive comments, follow-up question, and feedback provision). However, the feedback given to students is often too implicit and hence of limited informational value to pupils. Rather than explicitly commenting upon students' emergent ability to talk science, teachers tend to simply communicate their positive evaluation by indirect means such as pleased face expressions, affirmation (selective endorsement of student ideas), and topic uptake (selective follow-up on student ideas).

Arguing Scientifically

The literature on classroom assessment of students' ability to argue scientifically is considerably larger and more diverse. Focused on the rhetorical dimension of classroom science communication, a large number of studies have been conducted aimed specifically at assessing the quality (i.e., soundness and logical coherence) of students' science arguments by examining the extent to which they align with generic models such as Toulmin's Argument Pattern or TAP. This rhetorical type of assessment usually entails identification of argument components such as data, claim, warrant, backing, qualifier, and rebuttal.

Some studies focused specifically on the structure, justification, and content of arguments or student-generated products. Sampson and Clark (2008) used a variety of criteria (soundness, acceptability, coherence, correctness, and epistemic status) to assess an artifact written by a middle-school student to explain the thermal sensation of different objects (wooden, metallic, etc.). This study highlights how the same argument can be assessed as strong or weak and of high or low quality depending on whether the assessment is conducted from a perspective that is domain general, domain specific, content focused, or structure focused.

Others examined the process of argumentation or argumentation discourse, that is, the dialogic or interactional processes utilized by students to orally propose and justify arguments through whole-class or small-group discussions. In many of these studies, assessment was aimed at determining the quantity of scientific argumentation in science discourse. Erduran et al. (2004) quantitatively assessed small-group argumentation by determining the relative frequencies of five different levels of argument. High-quality arguments were operationalized as being extended and composed of multiple rebuttals, whereas low-quality arguments were limited to claims and counterclaims.

In many studies, quantitative assessment was combined with the construction of visual representations of classroom oral argumentation designed to visually assess the soundness and rhetorical quality of student arguments. Maloney and Simon (2006) used "discussion maps" to assess the relative levels of rhetorical sophistication of small-group discussions among 10- and 11-year-old students in the UK. This visual assessment method led to the identification of different levels of argumentation, including sustained evidence-based argumentation (highest rhetorical quality), series of arguments, repetitive and dispersed argumentation, and discussions without arguments.

Conclusion

In sum, classroom assessment of science communication can take varied formats (qualitative, quantitative, verbal, visual, etc.) depending on whether emphasis is placed on communicative style (manner of talk) or interpersonal persuasion. This trend suggests that science classroom communication serves two distinct and often competing communicative goals: expressive and rhetorical. Therefore, care must be taken to ensure alignment between the particular communicative goal being pursued and the assessment strategies adopted to determine its achievement as a result of science instruction and learning.

Communicating Science, Large-Scale Assessment of the Ability to

Alandeon W. Oliveira
University at Albany, State University of New York, Albany, NY, USA

Introduction

At the international level, research on large-scale assessments of science education has focused on two distinct aspects of science communication. The first body of work is concerned with how science is communicated to test takers and the potentially adverse impacts that particular communicative patterns can have on international comparisons of student performance in science. The second area of research deals specifically with students' ability to communicate science content to assessors when writing in response to short open-ended test items.

Communicating Science to Test Takers

Research in this area has examined both verbal and visual aspects of science communication in international assessments. Ercikan (1998) examined the IES science test, a large-scale examination given by the International Association for the Evaluation of Educational Achievement to Canadian students. The IES test was developed in English and then translated into French. Differential Item Functioning (DIF), a statistical analysis that controlled for differences in student ability, indicated that 26 % of the 70 test items were linguistically biased, that is, favored speakers of a particular language due to poor translation (e.g., replacement of unfamiliar science terms with everyday expressions, word choices that hinted at the answer, varied degrees of sentence complexity, etc.). The specific ways that each language was used to communicate science to test takers differentially affected their performance, thus undermining the equivalence and comparability of test items across languages. Hatzinikita et al. (2008) reported that the way that scientific knowledge was communicated in PISA science test items and Greek school textbooks differed both verbally and visually. PISA science materials combined nonspecialized, everyday language with highly specialized forms of visual representation (abstract images designed according to scientific visual conventions, symbolism, and notation), whereas the exact opposite combination (specialized language and everyday/realistic imagery) was predominant in school science textbooks.

Writing Answers Scientifically

This body of work has given attention specifically to students' ability to provide scientific explanations in international assessments. Combining both structural and conceptual assessment criteria, Zuzovsky and Tamir (1999) examined written explanations provided by Israeli students (fourth and eighth grade) in response to short-answer science questions on the TIMSS examination. Their findings reveal that student communication of scientific explanations usually takes the form of poorly articulated verbal accounts that are often incomplete, highly fragmented, simplistic, and devoid of specialized scientific terminology. The authors emphasize that many students have difficulty in producing scientific explanations for the purpose of exhibiting and demonstrating their conceptual understanding in large-scale assessments. However, it remains somewhat unclear whether the issue is one of conceptualization (student inability to conceptualize according to scientific principles) or communication (student inability to communicate their ideas scientifically). In a more recent study, Frändberg et al. (in press) examine students' written responses to two constructed response items from the Swedish part of TIMSS 2007 and report that only 10 % (86 out of 954) of the answers explain physical and chemical changes in matter at the submicro level (contained explicit references to atoms, molecules, or particles). Evidence is provided that, without careful and explicit prompts from assessors, student written communication of scientific knowledge and ideas in large-scale assessment is predominantly limited to the macro level (i.e., focus exclusively on perceptible and tangible properties and aspects of natural phenomena rather than microscopic entities).

Conclusion

In sum, the above studies problematize the relationship between content and form (communicative format) in large-scale science assessments. The reported findings challenge the general assumption that what is being assessed and compared in international testing is scientific content knowledge and not science communication ability (students' ability to interpret and produce scientific texts). Student performance across languages and countries may reflect student (in)ability to engage with certain forms of science communication rather than mastery of science concepts, thus deserving more careful consideration and critical analysis on the part of international test developers.

Communities of Practice

Troy D. Sadler
University of Missouri, Columbia, MO, USA

The idea of communities of practice (COP) emerged from sociocultural traditions of research in education, anthropology, and sociology and is a fundamental element of situated learning theory. Situated learning offers a perspective on learning that prioritizes the contexts in which thinking, doing, participating, and learning take place. This focus on context should not be simply construed as environments having superficial influence on activities, but rather that learning is fundamentally associated with engagement in social practice. Here, the idea of social practice denotes more than interactions among multiple individuals; it is a characterization of human activity such that practices are embedded within systems of social expectations, norms, and negotiated meanings. In other words, social systems give rise to and afford meanings to practice and learning. The social systems that emerge relative to particular tasks, problems, or activities are communities of practice. Therefore, all knowing and learning are situated, and communities of practice define, in large part, the situational realities that shape the knowing, learning, and activities that can transpire.

It is important to note that communities of practice do not just provide a referent to opportunities for group learning. COP offer a theoretical orientation to the basic nature of knowledge and learning. Jean Lave and Etienne Wenger first introduced the notion of situated learning and COP in an attempt to formulate a new theory of knowing, doing, and learning that accounted for their anthropological observations of communities and how individuals developed expertise in these communities. In their seminal work on the topic, they define a community of practice as

> A set of relations among persons, activity and the world, over time and in relation with other tangential and overlapping communities of practice. A community of practice is an intrinsic condition for the existence of knowledge, not least because it provides the interpretive support necessary for making sense of its heritage. Thus, participation in the cultural practice in which any knowledge exists is an epistemological principle of learning. (Lave and Wenger 1991, p. 98)

Defining Elements of Communities of Practice

Three basic elements comprise communities of practice: (1) a community, (2) a domain, and (3) practice. The community references a group of practitioners who come together through interactions. Such a community may interact physically, but interactions can also be facilitated through virtual tools. So, communities do not necessarily need to share physical proximity, but they do need to facilitate actual interactions among the practitioners. A single teacher accessing a static lesson plan through a website is not participating in a community with the author of that lesson plan if there are no ways for these teachers to share ideas, respond to one another, collaborate, etc. We could generate a near-infinite list of possible communities relative to the science education enterprise. To help illuminate some dimensions of communities of practice, I suggest three such hypothetical communities: a middle school science class, a group of science teachers working together within an online professional development program, and scientists conducting research in a particular subdiscipline of biology. In the case of the middle school science class, a group of students and their teacher are the primary members of the community, although there may be other community participants depending on the role school administrators and others such as teacher aides or class volunteers may play. This community likely comes together on a near-daily basis, and creation/dissolution of the group is mediated by the academic calendar. A community of science teachers participating in an online professional development program may never interact in a face-to-face format, but they have opportunities to interact dynamically through Web-based tools.

A community of scientists contributing to the same research subdiscipline likely come together periodically through venues such as annual conferences, but they also interact through peer review processes, Web-based networking, and personal communications. Whereas the other examples of communities may have a naturally defined period of existence, the community of scientists may persist indefinitely or at least as long as the subdiscipline has interesting questions to pursue. The mechanisms for communication, size of the groups, and temporal dynamics of these communities may vary, but they share commonalities in terms of bringing people together with shared interests.

Communities of practice are more than just a group of individuals; a COP develops with respect a particular domain. The domain references the area of interest around which individuals come together. The idea is that COP do not emerge from random groupings, but rather are built by a network of people with shared interests and who are pursuing related goals. Each of the hypothetical community examples presented above is organized around particular domains. The middle school class comes together around the goal of learning science. This may be an idealistic representation of a middle school science class; critics may argue that this community is more interested in navigating the disciplinary and social expectations of the school and this may very well be the case for most middle school classes. In either case (and for other interpretations including those in which members of the community may have a combination of these and other intents), the community is organized around a domain. For the online teacher community, the domain relates to improving teaching practices, and the domain for the scientist community is defined by the focus and research questions driving their subdiscipline.

The third element is practice. Here, the focus is on the idea that individuals, who organize around a domain, engage in particular activities, access particular resources, use similar tools, etc. Communities of practice are not static assemblages of individuals who just happen to share a common interest, but rather are dynamic and necessarily involve participation. Referring back to the science education examples, the middle school class engages in shared practices such as routines related to things like taking notes and completing laboratory reports. Most classes have particular repertoires of acceptable (and unacceptable) activities that may involve use of classroom equipment, access to technology, and classroom discourse. Similarly, the teachers participating in online professional development will likely engage in community-specific practices such as the sharing of lesson plans and activities, sharing feedback with one another, interacting with new materials, etc. The scientific researchers employ various methods that have been negotiated through the community such that shared perspectives on standards for and the validity of evidence are evident (at least internally) and shared (although these shared perspectives may also be challenged).

Wenger, highlighted above as one of the scholars who introduced situated learning, continued to theorize about the conceptualization of communities of practice. He defines the COP construct in terms of three constitutive ideas that map to the three elements just presented: mutual engagement, joint enterprise, and shared repertoire (Wenger 1998). Mutual engagement highlights the social norms and expectations that define community structure. Joint enterprise represents the shared focus of group participation, that is, the domain of the community. Importantly, this joint enterprise is defined and continually refined by the community. The shared repertoire of a community consists of the resources, tools, protocols, and negotiated standards for practice. Here again, this repertoire is dynamic and can be continually renegotiated.

Communities of Practice and Learning

A community of practice perspective defines learning in terms of community-specific activity. A community member learns as she participates in the culturally mediated activities of the community. Lave and Wenger (1991) offered legitimate peripheral participation as a construct to account for social practice, which necessarily includes learning, within communities of practice. Legitimate peripheral participation provides a way to think about how community members with varying levels of experience (e.g., newcomers to the community versus more established old-timers) participate in the community. As newcomers develop understanding of community norms and expectations for participation as well as appropriate tools and processes for participation, they move toward "full participation" (Lave and Wenger 1991, p. 37). This trajectory of participation constitutes learning.

Whereas engagement in community-defined practices represents a fundamental aspect of learning, the identities that members create/assume within the context of their community determine the kinds of practices in which they can engage. There is a co-constitutive relationship between practice and identity, but importantly, practice and identity interact in dynamic ways such that an individuals' repertoire of practice and identity shift over time. A note on the use of identity is warranted: identity is a widely used construct across the social sciences and takes on various meanings depending on the framework used to define it. Sociocultural perspectives suggest that identity represents processes of positioning within a particular COP and this positioning is shaped by history and norms of the group. Therefore, this process and ultimately the identities that individuals assume (or create) are constructed together by the individuals and influential others within the community. As newcomers and their communities construct identities, the newcomers develop evolving views about competencies and potential relative to the community's domain making it possible for them to understand, use, and engage with disciplinary ideas and tools in new ways. From this perspective, identity construction is central to appropriating community practices and therefore is a fundamental aspect of learning.

COP as a Research Framework

Communities of practice offer a way of thinking about what it means to know, engage in activity, and learn, and this perspective has been used to frame science education research. In the final section of this entry, I introduce five recent studies, from major research journals in the field of science education. All five studies utilize COP as a construct to define and/or analyze problems related to the teaching and learning of science. This is not a comprehensive or even representative sampling of research framed in terms of COP. The presentation offers some examples of the diverse ways in which researchers have conceptualized and used COP. Table 1 presents citations for the five studies and abbreviated descriptions of each study's focus and main findings. In the table, I also describe the COP studied in terms of the three basic constitutive elements introduced above: community, domain, and practice.

The five articles showcase different kinds of communities of practice relevant to science teaching and learning. Feldman and colleagues (2013) study science research groups and explore how undergraduate and graduate students learn through apprenticeship in these groups. This research, which explores how newcomers to an established community appropriate community norms and practices, is highly consistent with Lave and Wenger's studies of apprenticeship that served as the basis for conceptualizing situated learning and communities of practice. Olitsky (2007) explores how a class of middle school students and their teacher shape interaction rituals within their classroom-based COP. Saka and colleagues (2013) study the phenomenon of new teacher induction by conceptualizing a first year teacher's experiences in terms of his enculturation in the school's community. This article provides an interesting case in which the community newcomer has expectations and anticipated practices that contradict community norms. These tensions have important implications for the identity the new teacher constructs. Kisiel (2009) presents a study of interacting communities of practice. Potential connections between an elementary school and an informal science institution are easy to draw in theory, but Kisiel's

Communities of Practice, Table 1 Examples of science education studies that have utilized communities of practice to frame the research

Citation	Focus	Community	Domain	Practice	Key findings
Akerson et al. (2009)	Development of a COP for elementary teachers learning about nature of science (NOS) and how to teach NOS	17 elementary (K-6) teachers, a science education faculty member, and three graduate students	Teaching NOS ideas to elementary students	Engagement in a summer institute, monthly workshops, use of explicit NOS activities, formal reflection on classroom practices	Participation in the COP supported development of NOS ideas and improved NOS teaching. NOS modeling and explicit reflection were needed to achieve these gains
Feldman et al. (2013)	Build understanding of how graduate and undergraduate students learn to do scientific research while participating in science research groups	Graduate students, undergraduates, postdocs, and faculty members working on a particular scientific problem	The study documented three COP with unique domains: microbiology, geology, and hydrology	Weekly group meetings, journal club, various scientific procedures, field work	Advanced students provided much of the mentoring for newer students and hypothesized a progression of positions within a research COP: novice researchers, proficient technicians, and knowledge producers
Kisiel (2009)	Explore a partnership between a school and an informal science institution and how implementation of the collaboration impacts stakeholders and students	Two COP are investigated: (1) a new elementary school and (2) an aquarium education department	(1) Establishing a new school and supporting student learning	(1) Teach science 1 day per week (lessons are typically repeated in successive years)	Boundary objects (artifacts shared across the COP) and brokers (key individuals who mediated connections) facilitated the creation of an overlap between the two COP
			(2) Outreach and education programs for school groups and the public	(2) Teach the same lesson to many school groups	
Olitsky (2006)	Ethnographic exploration of teaching practices and classroom environmental factors that support positive "interaction rituals" such that solidarity, feelings of group membership, and interest in learning were achieved	33 grade eight students and their science teacher. The students were racially diverse and came together in an urban magnet school	Learning physical science concepts and developing interest in science	Engagement in class discussions, hands-on laboratory activities, group problem-solving, linking science ideas to areas of student interest (like sports)	Classroom conditions that supported positive interaction rituals: low-risk participation opportunities, activities with sufficient time and challenge, and positioning of students as knowledgeable and capable
Saka et al. (2013)	Exploration of a new science teachers' participation in a school's community and how this influences his induction into the profession	The teachers of a midsized, public high school with a racially and ethnically diverse student population	Supporting development and learning of the school's students	A wide range of classroom- and school-oriented activities including faculty meetings, mandatory math "warm ups" in class, and informal conversations among teachers	Inconsistencies in individual teacher aspirations and school expectations shape the induction of a new teacher and lead to the teacher leaving the school

study highlights ways in which the two communities, which share some of the same goals, maintain unique repertoires of practice that can present constraints to collaboration. The article also addresses ways in which these community boundaries were traversed. Finally, Akerson and colleagues (2009) explore professional development to improve elementary teachers' understandings of and abilities to teach nature of science. Whereas the other articles cited here study existing COP, Akerson and colleagues create a COP to support their professional development goals.

Summary

Communities of practice offer a theoretical orientation for what it means to know and learn. The construct emerged through studies of learning communities not associated with schools and classrooms, but the idea offers important implications for how learning is situated within community contexts relevant for efforts to support teaching and learning in any context. In science education, there are numerous communities of practice, many of which are overlapping and mutually influential. Science education researchers apply the idea of communities of practice in varied contexts to illuminate how people know, do, and learn science.

Companion Meanings

Leif Östman
Department of Education, Uppsala Universitet,
Uppsala, Sweden

In science education, a central aim is that students learn scientific facts, models, and theories. In many countries they are also expected to learn the skills associated with the work of scientists and about science as a practice and a field of knowledge. So, in general, we can say that in science education students are supposed to acquire scientific knowledge, scientific skills, and knowledge about science.

Even when knowledge about science is not one of the objectives of a specific teaching activity, it could be argued that we cannot teach scientific knowledge without at the same time teaching about science, i.e., about the kind of knowledge and the kind of activities that are regarded as valid. In the same vein, we could say that it is not possible to teach students scientific concepts without communicating something about nature, e.g., what nature is, how it works, and so on. It is also obvious that when learning science, students also learn about themselves in relation to school science activities and perhaps also to science. All these extras in teaching and learning are known as "companion meanings."

The term "hidden curriculum" has sometimes been used to capture these extras. However, it is important to note that companion meanings are communicated and learned while learning science, i.e., companion meanings accompany scientific meanings. As such, companion meanings have a pivotal role in the learning of a worldview in science education and are a crucial component in the socialization content of science education.

The idea of companion meaning is based on the reminders of pragmatic philosophers that it is not possible to act in the world without involving choices and values. These values are sometimes visible in our actions, while at other times we follow norms without reflecting on them. In the latter case, we are not mindful of the values that guide our choices; we just do what we usually do.

As teachers we develop certain teaching habits, and in executing these habits, the values by which we choose the teaching content may be invisible to us. But it becomes obvious that we need to make value judgments when we realize that we cannot teach all the facts of science within, for example, the framework of compulsory education. Our values come into play every time we plan a lesson since we must include certain facts and exclude others for the simple reason that it is not possible to accommodate all the scientific claims about, say, energy in a single lesson. Thus, we have to grapple with the question of which fact or facts about energy are more worthy than others. Here it is important to recognize that this is not necessarily a relativist standpoint, but simply a plain recognition that actions inevitably involve some kind of value judgment.

When Wertsch introduced the term "privileging," we could say that he brought this insight into the heart of learning. Learning is not a mystery; it happens all the time. What is puzzling, though, is how or why learning takes one direction rather than another. Privileging facilitates one of a number of possible directions of learning and results in a specific learning outcome. In certain practices, specific privileging processes prevail, and in order to become part of a scientific practice, we have to learn specific habits of privileging. Since the privileging process is about choice, values are naturally involved.

We can make a crude distinction between ethical and epistemic values, where the former are often described as dealing with what is a good and correct way of, for example, treating human beings and nature. Epistemic values concern the practical values that are crucial for a specific activity, and it is those we are concerned with here because they build up companion meanings.

One of the major systematic changes that occurred during the scientific revolution that began in the seventeenth century was the separation of humans from nature to the extent that scientists became the observers and manipulators of the object "nature." Science required that nature be approached as an object, or thing, leading Thoreau and many others to criticize science for stripping nature of all its qualities. Regardless of whether or not we agree with that criticism, we have to learn to approach and talk about nature as a thing in order to learn and communicate science. For example, if we want to give the word "heat" scientific meaning, we cannot associate it with qualities that are connected to our bodily experience of feeling hot. Instead, we have to understand and use it in the context of a language game, where, for example, the word is given a meaning that is connected with the movement of things, i.e., atoms. The separation of nature from humans is one example of an intelligibility demand that we learn to practice as we learn science. Such demands are examples of companion meanings that we learn in the same time as we learn scientific concepts, models, theories, etc.

When we learn science, we also learn a new way of perceiving the world. Companion meanings play a crucial role in this learning because they help us to discern the things that really matter. When a biology teacher takes students to a forest, most of the students will see trees, while the teacher will also see connectedness. In order to perceive the forest in such a way, we need to master the practice of an intelligibility demand that is common in ecology, namely, that phenomena and events in nature are explained in relation to other phenomena and events.

Aesthetic expressions of likes and dislikes can also function as epistemic values and be crucial for the privileging process. Aesthetic values such as elegance are sometimes used in the privileging process in a laboratory: the fewer tests we use in order to reach the right results, the more elegant the experiment becomes. In this sense, learning science is akin to learning specific aesthetics. This becomes obvious if we look at the history of science. For example, biologists have long been dependent on artists' representational aesthetics, i.e., making perfect representational drawings of animals and plants, for a valid science.

In science education, there is an almost constant production of companion meanings concerning what counts as valid or invalid knowledge and what counts as proper ways of proceeding in investigations in order to produce valid knowledge. These companion meanings concern what we sometimes call the view of science or the epistemological dimension of an activity. It is important to note that these companion meanings are learned, as the intelligibility demands, at the same time as we learn science. Companion meanings are sometimes reflected on by students, although more often than not students just learn to practice them. It is also important to note that the practice is learned in the context of school science and not in the context of science. Thus, the epistemology students learn is situated in the school science activities. Much of the learning revolves around learning how to discern between valid or invalid knowledge and ways of producing knowledge in school science. Many of the questions that students ask teachers, and a lot of teachers' communications, relate to this discernment. For example, nodding or other encouraging actions often confirm that the activity that a student has staged is valid in order to, for example, generate a correct answer to a question (Lidar et al. 2006). This learning of a practical and situated epistemology can be an important part of the learning of a view of school science and of science.

The learning of companion meanings and the learning of a specific way of privileging in the meaning-making process occur in the same time. Thus, when we have learned a practical and situated epistemology, i.e., a practical epistemology (Wickman and Östman 2002), we have acquired a specific perception and a specific manner of producing meaning and knowledge.

When creating meaning and when learning, we cannot avoid creating a relation to the practice we are experiencing. Thus, the learning of science often involves an identification process. For example, we might learn that we are very successful or unsuccessful in relation to the ongoing learning process or that for one reason or another we are not cut out to be scientists. The identification process is often connected to the companion meanings that are communicated in science education, for example, the gender bias that accompanies a dominance of pictures of males in text books.

As companion meanings have a crucial role to play in the privileging process, paying attention to companion meanings can enhance educators' control of the learning process and thereby make the transition from everyday discourse to a scientific discourse as smooth as possible for the students.

Another benefit of paying attention to companion meanings is that it makes us better equipped to deal with crucial questions about worldviews, citizenship, identity, and scientific literacy in science education (Östman and Almqvist 2011). Worldviews do not only consist of things like conscious values and commitment, but also our way of practically perceiving and approaching nature, our fellow beings, truth, arguments, etc. Companion meanings are epistemic values that concern the latter. Moreover, there is plenty of historical evidence to show that epistemic values can be questioned and criticized from an ethical perspective. The criticism of Thoreau and others during the Romantic period is one example of this. Many biology teachers have also experienced that the practice of dissecting can no longer only be judged from an epistemic point of view, but must also include ethical values.

One way of furthering the benefits of companion meanings is to create typologies of the different types of content that make up science education. For example, the Curriculum emphases typology (Roberts 1998) highlights companion meanings about science, the Nature languages typology highlights the intelligibility demands regarding nature, and the Subject focus typology concerns companion meanings about the relationship between human beings and nature that is learned in conjunction with science (Östman 1998).

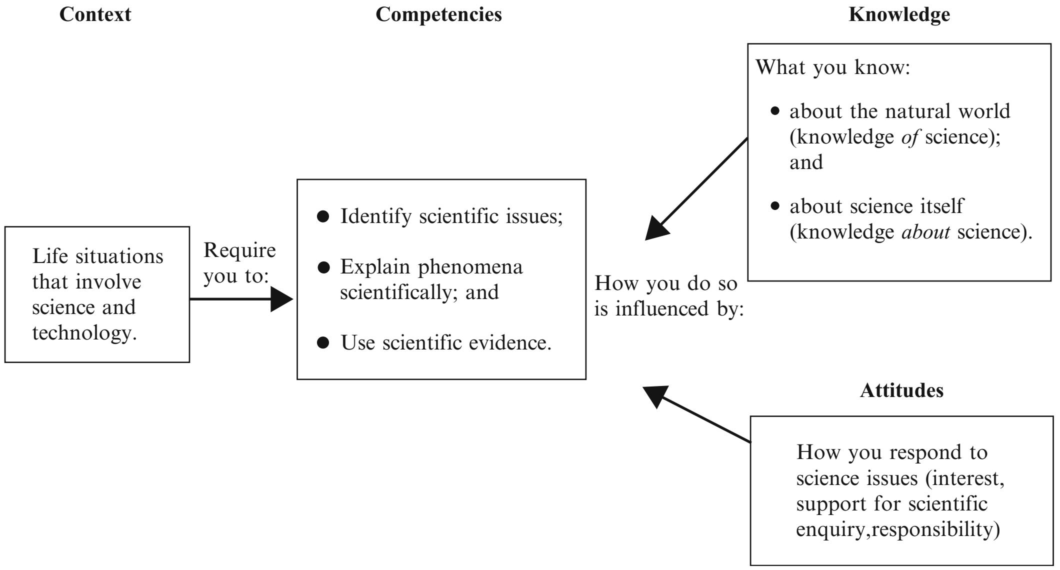
Competence in Science

Jens Dolin
University of Copenhagen, Copenhagen,
Denmark

It is an international trend that national curricula and descriptions of expected learning outcomes from schooling are increasingly framed in competence terms, rather than in knowledge and skills to be learned. Competence in this usage refers to a certain "capacity" or "potential" for acting efficiently in a given context. The idea of competence has come into the educational sphere from the business community and society in general. Both business life and vocational training have for many years operated with job competence as something that reflects the expectations of workplace performance, the ability to accomplish a particular task. Also, in a globalized world, educational goals are increasingly being formulated across nations via global institutions such as the United Nations/UNESCO (e.g., "Education for all"), the OECD, and the European Union (e.g., "Lifelong learning") in order to capture some overall strategic aims. In this respect the introduction of competence into the educational world reflects the role of schools as providing a general socialization and preparation for life, rather than only specific knowledge.

The reasons for the concept of competence having such a huge impact on education, despite its origins in the economic sphere, are manifold. Generally speaking, the impact of competence reflects the need for a concept to capture the complexity of demands placed on the individual person by modernity and post modernity in a time of diminishing social and cultural cohesion. This goes together with changing views on learning and teaching, from behavioristic approaches based on the transfer of canonical knowledge to constructivist ways of creating meaningful understanding through acting in authentic situations. This, in turn, is consistent with other factors influencing education such as the amount of factual knowledge growing in



such an uncontrollably rapid fashion that education must shift focus to methods of knowledge acquisition and general practice within a subject, instead of selecting and transferring often quite randomized knowledge.

Due to its widespread and varying usage, competence is not an easy concept to capture. As Weinert (2001) expresses it: *There is no basis for a theoretically grounded definition or classification from the seemingly endless inventory of the ways the term competence is used. . . . There (is) . . . no single common conceptual framework.* Competence can be seen as an extension of the former goal category "qualification," based on knowledge and skills, by adding to this the ability and willingness to use the knowledge and skills in complex situations. Fulfilling complex demands and tasks requires not only knowledge and skills but also involves strategies and routines needed to apply the knowledge and skills, as well as appropriate emotions and attitudes, and effective management of these components. Thus, the notion of competence encompasses cognitive but also motivational, ethical, social, and behavioral components. It combines proficiency and intentionality into a capability to solve tasks and problems of some complexity.

The most authoritative, international definition is probably from OECD's DeSeCo project:

> A competence is defined as the ability to successfully meet complex demands in a particular context through the mobilization of psychosocial prerequisites (including both cognitive and non-cognitive aspects). This represents a demand-oriented or functional approach to defining competencies. The primary focus is on the results the individual achieves through an action, choice, or way of behaving, with respect to the demands, for instance, related to a particular professional position, social role, or personal project. (Rychen and Salganik 2003, p. 43)

The term competence is very often seen as interchangeable with competency, without any consistency in this interchangeability. Some will argue that "competence" is mainly referring to the concept as such (e.g., competence assessment problems), while "competency" is used referring to a specific ability (e.g., the competency to model in physics) but usage is inconsistent. The use of the plural "competencies" seems more widespread.

Competencies can be defined within the area of personal development (e.g., creative or innovative competence) and social behavior (e.g., teamwork competence) as well as within academic, subject-specific areas, like science. To become effective, science competencies require integration with personal and social competencies. For example, to design or to use models in science requires creativity and a certain level of affective involvement to enable one to overcome disappointments and criticism; further, working in groups and communicating the results requires social competencies.

Science competence can be attributed to a narrow part of science such as a part of a discipline or to a wider aspect of science performance, such as the ability to model. Used in the wider sense, science competence is closely linked to the concept of science literacy, where the construct of scientific literacy can be defined in terms of a set of competencies that a scientifically literate individual would be expected to display. This is for instance seen in the PISA 2006 Science Framework (OECD 2006), shown in the figure immediately below. In this framework scientific literacy is defined as the ability to use scientific knowledge and processes not only to understand the natural world but also to participate in decisions that affect the natural world; here the competencies are the specific processes that are seen as characteristic of science.

In other competence formulations of science, competence is seen as an integration of the processes and the knowledge and the attitudes in a practice – performed within relevant contexts. Many European countries have implemented competence models in science. For example, the Danish science competencies, used across all educational levels, are an attempt to capture what it is to do science, independent of the specific discipline or content. The Danish educational system operates with four core science competencies:

- An empirical, experimental competence (i.e., the ability to measure and to perform experiments and do fieldwork, to go into clinch with reality)
- A modeling competence (i.e., the ability to develop, use, and analyze models)
- A representational competence (i.e., the ability to describe and present knowledge using different modalities and formats and to transform between different representations of the same phenomenon)
- A putting-into-perspective competence (the ability to put science into cross-curricular, historical, philosophical, and personal perspectives, a “bildung” dimension).

These science competencies are described specifically in the different science domains/subjects together with general competencies like communication, argumentation, asking questions, etc. which are common for all subjects.

Teaching for competence is different to other science teaching. Conventionally a teacher will ask: “What must the pupils know?” – and will then plan what the students need to do in order to achieve this. In competence-directed teaching, the teacher will ask: “What must the students be able to do?” – and will then consider what they must know to be able to do this. The knowledge is subordinate to the actions and the situations the students are expected to control. The different elements necessary for performing the task are learned in coherence in a whole task approach in a realistic situation. It could typically be in a project-oriented sequence where the students learn actively and organize the learning processes themselves, with the support of the teacher.

Correspondingly, assessing science competence is different from assessing knowledge and skills. The more complex the learning goals, the more difficult they are to measure. The understanding of competences as the ability to cope with relatively complex challenges in an adequate way means that assessment methods necessarily have to be relatively advanced, flexible, and process oriented. And, at the very least, they have to be valid. Thus, artificial tasks such as multiple-choice test items that might test simple skills or knowledge recall can hardly measure competencies. For validity reasons competence assessment should be able to examine how students perform while going through the processes that constitute the competence to be assessed. Coincident with this, the assessment of a multifaceted concept like competence should be based on a competence model with multiple dimensions, and some clear criteria and some levels of performance should be described to establish a progression for scoring and for formative feedback reasons. The assessment also has to take place in real world or authentic situations to which the competence can be ascribed. For reliability reasons some kind of standardization should be applied to the expected activities. All these conditions are not easy to fulfill. At the one extreme students are observed in their everyday setting solving problems and tasks during a considerable time span, and the overall impression is judged. This is a costly method with high validity but often to the disregard of reliability and generalizability. At the other extreme students are placed in a room with paper and pencil to tick boxes and write short answers within a short time limit. With this relatively cheap method you can achieve high reliability, but this is clearly at the expense of validity. Irrespective of approach it is the nature of the test assignment (or the items) and the test situation that determines whether it is reasonable to consider the test a competence test. Especially for large-scale competence assessment, there is a risk that what is assessed is more isolated skills and detached knowledge than competence in the proper sense.

WestEd, Redwood City, CA, USA

Keywords

Computer based; Digital; Innovative; Next generation; Technology based; Testing

The next generation of assessments in science and other domains is taking advantage of technologies to transform what, how, when, where, and why testing occurs (Quellmalz and Pellegrino 2009). The capabilities of technologies are being harnessed to support assessment of the kinds of complex science understandings and practices advocated in the *Framework for K-12 Science Education* and the *Next Generation Science Standards*. These documents, along with other national and international science frameworks and standards, advocate teaching and testing of deeper learning about systems in natural and designed worlds integrated with application of the practices used by scientists and engineers to study and design these systems. Assessments of the *Next Generation Science Standards* will require dynamic, richer, and more extended and complex representations of science phenomena along with ways for students to actively investigate and modify the interactions among system components and emergent system behaviors. Forms of computer-based assessment are migrating from delivery on computers to other devices such as tablets, handheld devices, and tools not yet imagined. The increased mobility of assessment instruments permits greater flexibility for where and when evidence of learning can be gathered. Significantly, technology-enhanced assessments can blur the distinctions between assessments *of* and *for* learning.

Computer-Based Testing in Large-Scale Assessments

Initial forays into computer-based testing came from large-scale assessment programs administered by states, nations, and major testing companies. Economics and logistics were the primary factors that drove the search for efficiencies of assessment functions such as test development, delivery, adaptation, scoring, and reporting. Authoring shells and item banks aligned to content standards enable efficient development and assembly of items into comparable test forms. Online administration eliminates costs for shipping, tracking, and collecting print booklets yet simultaneously introduces other challenges related to computer access, server limitations, and security. Computer scoring provides rapid return of results and generation of reports tailored to multiple audiences. Flexible administration times and locales can shift annual, on-demand testing to interim, curriculum-embedded, and just-in-time challenges.

Large-scale computer-based testing now occurs in numerous international, national, and state assessment programs. In many of these programs, technologies are used not just to support testing logistics, but to also design innovative tasks and items that aim to measure understanding of dynamic science system interactions and the kinds of science inquiry practices not well measured by the traditional multiple-choice item format. In 2006, the Programme for International Student Assessment (PISA) began piloting computer-based science assessments and in 2015 will administer simulation-based science tasks. Similarly, the 2009 National Assessment of Educational Progress (NAEP) of science fielded interactive computer tasks to better assess science inquiry and will continue to administer these interactive investigations. The 2014 NAEP for Technology and Engineering Literacy will be delivered entirely online and include long and short scenario-based tasks to assess crosscutting practices for understanding technological principles, for developing solutions and achieving goals, and for communicating and collaborating. The state assessment consortia developing tests for common core math and literacy standards will be computer delivered and scored. One of the consortia will employ computer-based adaptive testing. It is likely that similar state consortia will be formed to develop new assessments for the *Next Generation Science Standards*. The next-generation assessments for science will be able to take advantage of advances in the use of simulations and games for promoting science learning to design innovative, interactive technology-enhanced science assessments (NRC 2011).

Technology Supports for Science Assessment

The rapidly advancing capabilities of digital and networking technologies are changing the ways that science assessments are developed, administered, and scored. These expanded logistical functions, in turn, will permit the design of richer, deeper, more interactive, and extended assessments that can measure coherent science knowledge and practices.

Technology-Based Assessment Infrastructures. Technologies support assessment functions related to authoring, delivering, collecting, and reporting measures of learning so that they are more efficient and economical. Technology can also assist the development and recording of alignments of the learning and assessment targets in state, district, and classroom science programs with the broader *Next Generation Science Standards*. Item banks and digital, multimedia collections of performance assessment tasks and products can be created and searched by the standards they test.

Technologies can expand the range of science and engineering design knowledge and strategies that can be tested. Not only can the core disciplinary ideas, crosscutting concepts, and science and engineering practices in the *Next Generation Science Standards* be assessed in real-world contexts and problems, but evidence of hard-to-test crosscutting practices such as scientific literacy, use of the “tools of the trade,” collaboration, and communication can be collected. For example, Twenty-first-century skills for finding and using resources and for collaborative problem-solving can be more easily observed and recorded when the information searches, collaboration, and communications occur online. By permitting access to online resources and expertise, technologies can at the same time record those searches and assess them. Digital records of collaborations with virtual and real peers and experts can be tracked and evaluated. Summative tasks can be designed to provide specified science resources and virtual peers and experts. For performance assessments, planned assessment probes and tasks can be unobtrusively inserted by technology into activities and automatically scored or stored for rubric-based evaluations by teachers and students. Online training for reliable use of the rubrics by students and teachers can establish and document rater reliability. Electronic notebooks and portfolios can collect student work in multiple static and dynamic modalities, including samples of designs and work in progress as well as scans and video of final artifacts and performances. Customized reports of assessments and evaluations of interim work and artifacts and performances by individuals and teams can be analyzed, summarized, and reported to multiple audiences. For example, collections of engineered solutions and the records of their designs and iterative tryouts can support assessments of effective engineering design practices.

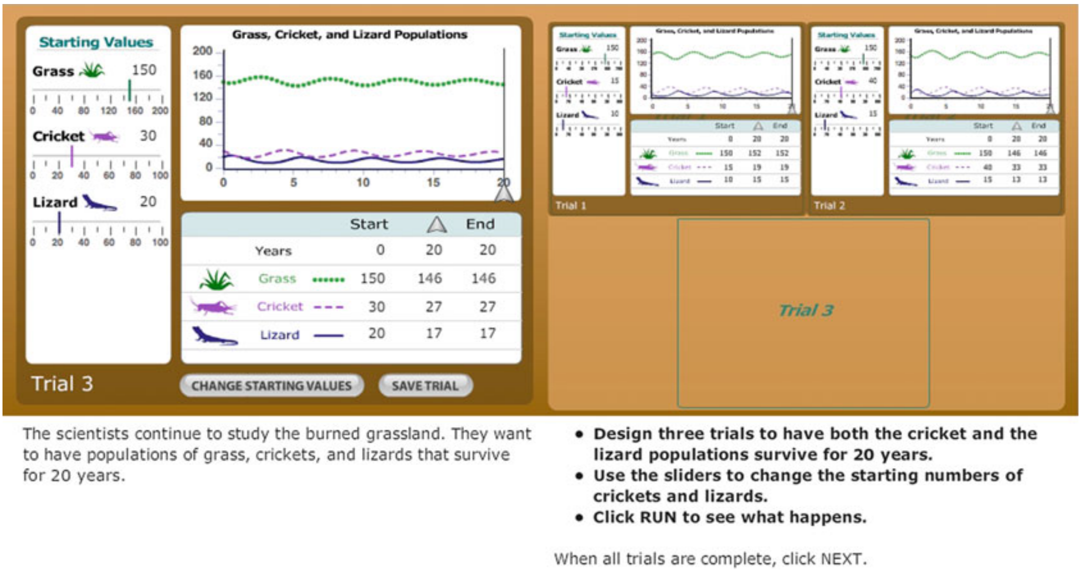
Innovative Technology-Enhanced Assessment Task Designs. Once the disciplinary core ideas, crosscutting concepts, and science and engineering practices to be tested have been specified, plans can be laid for collecting observations of learning to serve formative purposes during instruction and to serve summative interpretations of achievement. Technology-based formative assessments could be blended into hands-on and digital tasks during classroom-based science and engineering projects. Designs of assessments for summative judgments of learning would involve gathering evidence from final solutions and performances. Some of the component knowledge and practices involved in final performances or solutions could be responses to explicit tasks and questions that could be scored by the system automatically. Rubrics could guide evaluations of the complex performances.

A major technological advance is the capacity for representing dynamic natural and man-made systems "in action" and for making visible the invisible system interactions that are otherwise too fast, slow, big, small, or dangerous. Simulations can support student interactions with these dynamic displays to scaffold understanding and active investigations of how components interact to produce emergent system properties. Engineering projects can prepare alternative designs, tryout digital mockups and prototypes, run simulations to predict outcomes, and iteratively troubleshoot.

Technologies can support designs of innovative assessment tasks that will elicit observations of progressions of science learning (Quellmalz et al. 2012a). Technology-based interactive tasks can not only monitor learning, but also respond to student input with just-in-time feedback and coaching. These interactive, technology-based tasks can be designed using simulations, virtual immersive environments, and games.

Research on the benefits of system models and simulations for science teaching and assessment can offer guidelines for development of interactive science and engineering assessments (NRC 2011). Simulations can present models of natural and designed systems and their key components, interactions, and resulting system behavior. Simulation-based assessment tasks can be embedded within authentic, significant, recurring problems in the science and engineering domains. Computer-based modeling tools can allow students to see and iteratively test interactions among structural components of a system across time, scale, and levels. Student problem-solving and inquiry processes can be logged and assessed.

For example, the SimScientists Assessment System is developing suites of simulation-based formative and summative assessments for middle school science units (Quellmalz et al. 2012a; http://simscientists.org). Figure 1 shows a screenshot of an excerpt from an end-of-unit benchmark assessment that tests students' inquiry skills. The screenshot is from an assessment scenario set in an Australian grassland. The overarching problem is that the ecosystem needs to be restored after a wild fire. In the first part of the scenario-based assessment,



Trial 3

	Start	△	End
Years	0	20	20
Grass ••••••	150	146	146
Cricket - - -	30	27	27
Lizard ——	20	17	17

Trial 1 (Starting Values: Grass 150, Cricket 15, Lizard 10)

	Start	△	End
Years	0	20	20
Grass	150	152	152
Cricket	15	19	19
Lizard	10	15	15

Trial 2 (Starting Values: Grass 150, Cricket 40, Lizard 15)

	Start	△	End
Years	0	20	20
Grass	150	146	146
Cricket	40	33	33
Lizard	15	13	13

The scientists continue to study the burned grassland. They want to have populations of grass, crickets, and lizards that survive for 20 years.

- **Design three trials to have both the cricket and the lizard populations survive for 20 years.**
- **Use the sliders to change the starting numbers of crickets and lizards.**
- **Click RUN to see what happens.**

When all trials are complete, click NEXT.

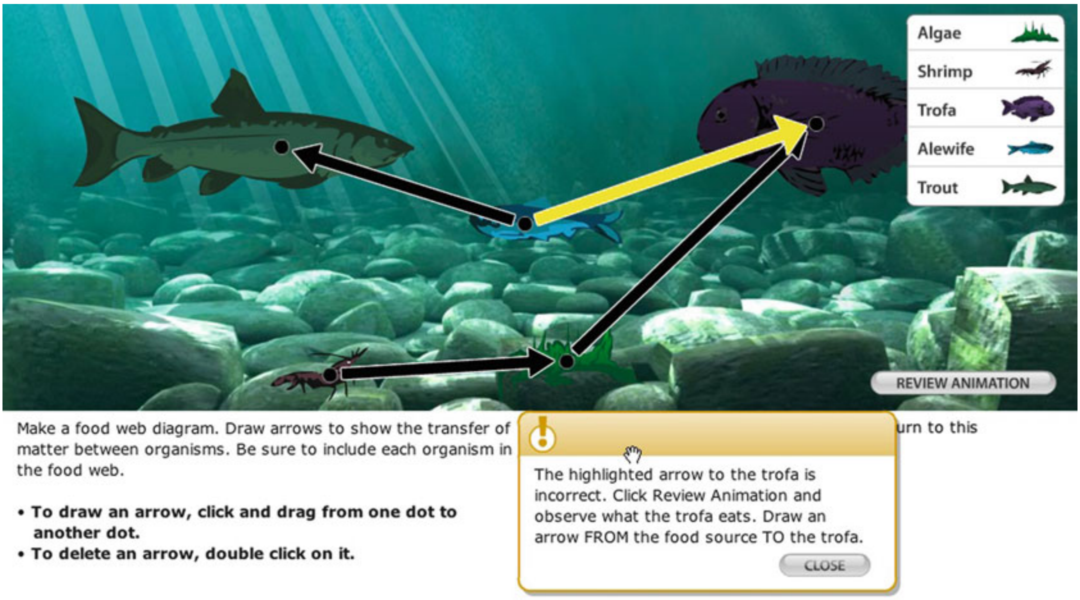
Computer-Based Assessment, Fig. 1 Screenshot of SimScientists Ecosystem benchmark assessment to test use of simulations to investigate effects of changing population sizes

students observe the interactions of the organisms to create a food web representing the flow of energy and matter through the system. In the Fig. 1 screenshot, students' inquiry skills are assessed for using a simulation to conduct three investigations of what different numbers of organism populations would survive in a balanced ecosystem.

An important benefit of such technology-based interactive assessment tasks is that they can provide students with opportunities to use some scientific "tools of the trade." These might include manipulations of models and simulations for science and engineering tasks or use of computer design systems for an engineering task. Digital tools can allow students to find, organize, and analyze data and represent findings in multiple formats such as visualizations, graphs, tables, and models. Mobile devices can allow students to collect, store, and retrieve a range of observations and data in settings beyond the classroom. Presentation software can allow students to share designs, models of work in progress, and findings and solutions. Each of these tools of the trade can provide evidence of learning as they are being used.

Technology Supports for Classroom Science Assessment

Classroom-based science assessments can also take advantage of a range of technology affordances. One genre of computer-based classroom products mimics the item formats in state tests, thereby limiting the types of science knowledge and inquiry strategies that are and can be tested. Simulations, virtual immersive environments, and games are being developed to present dynamic, interactive representations of science systems and to integrate feedback and hints that can serve as formative assessments to benefit learning. For example, the SimScientists Assessment System is developing suites of simulation-based assessments to be embedded within middle school instructional units. The assessments are intended for formative purposes – to provide feedback and additional scaffolding to reinforce learning and to generate reports of learning progress. The simulation-based assessments are designed to measure assessment targets for understanding the components, interactions, and emergent behavior represented in models of science systems and also to assess inquiry practices



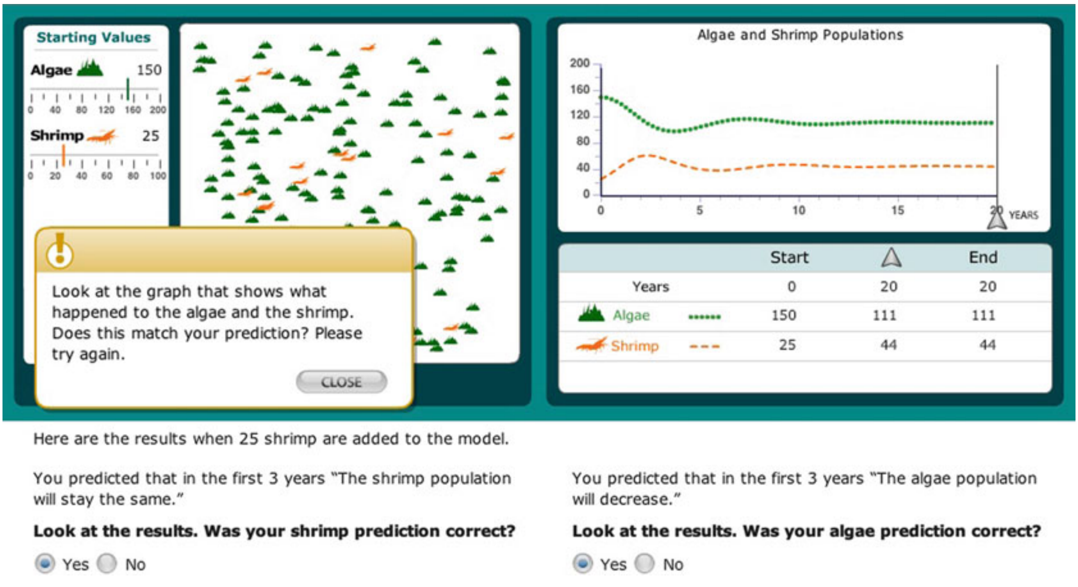
Make a food web diagram. Draw arrows to show the transfer of matter between organisms. Be sure to include each organism in the food web.

- **To draw an arrow, click and drag from one dot to another dot.**
- **To delete an arrow, double click on it.**

urn to this

The highlighted arrow to the trofa is incorrect. Click Review Animation and observe what the trofa eats. Draw an arrow FROM the food source TO the trofa.

Computer-Based Assessment, Fig. 2 SimScientists screenshot of ecosystems formative assessment with feedback and mid-level coaching for drawing a food web



Look at the graph that shows what happened to the algae and the shrimp. Does this match your prediction? Please try again.

		Start		End
Years		0	20	20
Algae	••••••	150	111	111
Shrimp	- - -	25	44	44

Here are the results when 25 shrimp are added to the model.

You predicted that in the first 3 years "The shrimp population will stay the same."

Look at the results. Was your shrimp prediction correct?

● Yes ○ No

You predicted that in the first 3 years "The algae population will decrease."

Look at the results. Was your algae prediction correct?

● Yes ○ No

Computer-Based Assessment, Fig. 3 Screenshot of population dynamics inquiry task with coaching

for investigating the science systems. Figures 3 show ecosystems embedded assessments within the context of a remote mountain lake. When students are asked to draw a food web diagram in the embedded assessments, they are provided with graduated feedback and coaching that helps them complete the task before they can continue. Figure 2 shows the mid-level coaching students receive if they have not completed the task successfully on the second try. Students are coached to review the animation to observe the interactions between the organisms in order to correctly draw the arrow to depict the flow of energy from the energy source to the consumer.

Figure 3 shows a screenshot of a SimScientists Ecosystem curriculum-embedded assessment task for the science inquiry practice of using a simulation to predict, observe, and explain changes in the ecosystem. The embedded assessment is designed as a formative assessment that provides individualized feedback, graduated coaching, and a report of progress on the assessment targets.

When aligned with interactive summative assessments, curriculum-embedded simulation-based science assessments can become powerful components of a balanced state science assessment system (Quellmalz, et al. 2012b). Computer-based testing is rapidly evolving to support assessments of richer, deeper, interactive collaborative science learning. The capabilities of technologies will enable next-generation assessments to represent next-generation science learning.

Argumentation; Assessment; Computers; Inquiry; Knowledge integration

Introduction

The Computer as Learning Partner (CLP) project, funded by the National Science Foundation, has leveraged new technologies to strengthen inquiry activities and improve science learning in a research program involving a partnership of learning scientists, classroom teachers, discipline experts, technologists, and designers. CLP started by researching how Apple II computers with temperature-sensitive probes that generate dynamic, real-time graphs could serve as classroom *laboratory partners*. Later, taking

Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author and do not necessarily reflect the views of the National Science Foundation or CASBS.

advantage of the Internet, the partners designed the Web-based Inquiry Science Environment (WISE) as a *learning partner* to guide students as well as tools for teachers to monitor student progress, flag student work for class discussion, and provide feedback, making WISE a *teaching partner*. Recently, the partners have developed ways to analyze student work and provide adaptive guidance as students grapple with complex scientific ideas that allow the computer (via the WISE environment) to serve as an *inquiry partner*.

CLP classroom research involves longitudinal, comparison, and case studies that have been synthesized in the *knowledge integration framework*. The framework takes advantage of the multiple ideas students encounter and develop about each science topic. For example, when asked to predict the temperature of objects in their room, students make a wide variety of comments, like (a) metal objects are colder than wooden objects based on how they feel; (b) each object has its own temperature, like rabbits and humans; (c) objects come to the same temperature; (d) objects never come to the same temperature; (e) metal objects contain cold that can be used to keep people cool; and (f) objects get their temperature from the sun. CLP research revealed that a lecture on thermal equilibrium, telling students that all the objects (except those with their own heat source) are the same temperature, had little impact. Some students added this idea to their repertoire, but did not use it exclusively. Even when students used the temperature-sensitive probes to measure the temperature of the objects in the room, some asserted that the probes were “broken” because they showed that metal and wood objects were the same temperature! The CLP partnership designed instruction to help students build on their prior reasoning (e.g., that metals impart cold) to help them consider new evidence, construct better arguments, and articulate a coherent account of thermal equilibrium (Linn and Hsi 2000).

CLP research has focused on two main questions about knowledge integration. First, how can science instruction take advantage of visualizations and virtual experiments to design representations for new ideas that, when added to the repertoire of ideas, promote coherent accounts of science? Second, what forms of computer and teacher guidance encourage students to refine their reasoning strategies so that they can distinguish among their repertoire of ideas, increase the coherence of their ideas, and develop lifelong learning capabilities? For two decades, CLP has addressed these questions by experimenting with new technologies, refining curriculum materials, and identifying instructional principles and patterns that promote knowledge integration (Linn and Eylon 2011; Slotta and Linn 2009).

The curricular units developed by the CLP research program promote knowledge integration by engaging students in actively making sense of the evidence they encounter and iteratively improving the coherence of their arguments. Often, science instruction tells students accurate information and expects them to recall it in the future. But when new ideas are not integrated, students either forget them or conclude that they are appropriate for classroom activities but not everyday life. For example, one student remarked that objects in motion remain in motion in the classroom, but they come to rest on the playground!

Computer as Laboratory Partner

As a laboratory partner, CLP took advantage of temperature-sensitive probes that generated graphs as liquids cooled or were heated. These graphs helped to make ideas about thermodynamics visible to students. An unanticipated consequence was that watching data collection in real time also helped students understand the nature of graphs. When students used probes rather than recording data manually, they were more likely to accurately interpret a graph of a bicyclist going down a hill [speeding up] and then going up another hill [slowing down] rather than seeing the graph as an actual picture of a hill.

CLP recognized the importance of helping students to integrate their ideas. For thermodynamics, studies showed that students integrated more of their ideas when instruction featured an accessible "heat flow" model rather than a model based on molecular kinetic theory. A simulation, where students could conduct virtual experiments to determine the rate of heat flow in varied materials surprised many students, who initially thought that heat flowed at the same rate in all materials. This visualization also helped students interpret their sensory experiences, when touching metal and wood objects in hot and cold environments. They could develop the notion that they were detecting the rate of heat flow between their hand and the object, realizing that metals were better conductors than wood, and comparing the temperature of their hand relative to that of the object. The teacher, in the CLP classroom, asked his students to compare how metal and wood objects feel on a hot day at the beach and on a cold day in the mountains. CLP labeled ideas that promoted integrated understanding pivotal cases. Pivotal cases feature controlled experiments (such as comparing materials in hot and cold contexts), illustrate situations that are likely to reoccur in the lives of students, stimulate discussion among students by supporting narrative accounts of experiences, and connect multiple scientific principles (such as connecting insulation and conduction to thermal equilibrium).

CLP conducted a longitudinal study that led to four principles that guide the design of new curricular activities and materials (Linn and Hsi 2000):

Make science accessible – calls for encouraging students to connect new knowledge to preexisting knowledge and appreciate the relevance of science to their lives. In CLP, students connected their investigations of thermodynamics to personal experiences, like packing lunches so that food stays hot or cold.

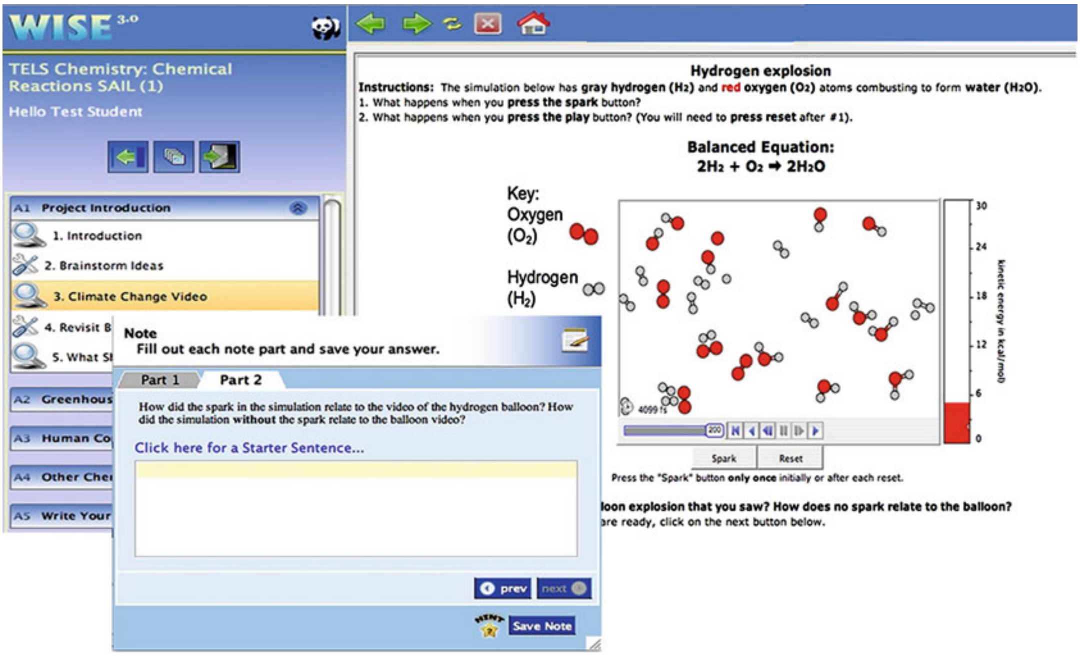
Make thinking visible – refers to both the process of modeling how ideas are connected and organized in normative understanding and the process of students articulating their own ideas to help teachers monitor progress. In CLP, our use of visualizations, pivotal cases, and real-time data collection with probes all served to make thinking visible.

Help students learn from others – calls for negotiating ideas with others, in order to jointly explain complex ideas. To achieve this in CLP, students worked in pairs to interpret their experiences. Often they appropriated ideas from their partner to advance their understanding.

Promote autonomy and lifelong learning – involves helping students monitor their progress and reflect on their ideas. To achieve this in CLP, students were guided by an inquiry cycle, reflected on their ideas in short essays, and explained their ideas to others in classroom debates. Thus, when students articulated their ideas, they benefitted in two ways. First, they reconsidered and often reorganized their ideas. Second, they made their ideas visible for others.

Computer as Learning Partner

Powerful classroom computers and Internet connectivity enabled the development of the Web-based Inquiry Science Environment (WISE) to further explore the computer as a learning partner. WISE logged in students and captured records of their inquiry activities, linking to embedded assessments and virtual experiments using an inquiry map (see Fig. 1). Using WISE, the research partnership could design comparison studies where students conducted different activities within the same classroom. Comparison studies revealed difficulties students had interpreting visualizations or conducting virtual experiments and supported our investigation of promising instructional sequences (Slotta and Linn 2009). A wide range of comparison studies included embedded and end-of-unit knowledge integration items that were scored using a rubric that emphasized the use of evidence to build an argument. Students generate short essays, concept maps, virtual experiments, and drawings, as well as annotations of scientific materials such as microscope slides to document their reasoning. These assessments



Hydrogen explosion

Instructions: The simulation below has **gray hydrogen (H_2)** and **red oxygen (O_2)** atoms combusting to form **water (H_2O)**.
1. What happens when you **press the spark** button?
2. What happens when you **press the play** button? (You will need to **press reset** after #1).

Balanced Equation:
$2H_2 + O_2 \rightarrow 2H_2O$

Press the "Spark" button **only once** initially or after each reset.

loon explosion that you saw? How does no spark relate to the balloon?
are ready, click on the next button below.

Note
Fill out each note part and save your answer.

How did the spark in the simulation relate to the video of the hydrogen balloon? How did the simulation **without** the spark relate to the balloon video?

Computers as Learning Partners: Knowledge Integration, Fig. 1 Screenshot of chemical reactions unit in WISE

contribute to learning by asking students to make sense of their ideas and explain them to others.

For example, in the *WISE Photosynthesis* unit, students explore how light energy is transformed into chemical energy and is stored as glucose, but have difficulty distinguishing among their views that energy from the sun is "used up," "disappears," and "gets stored in the chloroplast." Experiments comparing static and dynamic representations of photosynthesis and cellular respiration demonstrated that dynamic representations were better at promoting knowledge integration (Ryoo and Linn 2012).

In performing the *WISE Chemical Reactions* unit, students have multiple ideas about what happens between one side of the equation and the other. They often believe that "there are no intermediate states," that "all the molecules break into atoms and recombine," and that "extra atoms disappear." When students make drawings of the initial, final, and intermediate states of the reaction (i.e., to articulate their predictions) and interpret the visualization (Fig. 1), they gained a more integrated understanding than those who just conducted additional virtual experiments (Linn and Eylon 2011).

WISE researchers synthesized a knowledge integration instructional pattern, combining the comparisons studies and related research (Linn and Eylon 2011). The pattern has four processes:

Making predictions. When students make predictions before encountering new ideas, they articulate their repertoire of ideas. Asking for predictions acknowledges the individual backgrounds and experiences that students have and enables designers and teachers to appreciate the diverse ideas students bring to science class. By testing their predictions, students are guided to interpret the results of their investigations in light of their own ideas.

Adding ideas. The knowledge integration pattern calls for adding pivotal cases that students find accessible. It incorporates research showing that dynamic, interactive visualizations only succeed when combined with other knowledge integration processes including making predictions and distinguishing ideas.

Distinguishing ideas. WISE researchers found that students need to distinguish new ideas from existing ideas within their repertoire to fully integrate their understandings. For example, when students were asked to fill in four boxes to draw how a chemical reaction progresses, they tended to revisit the visualization to test their conjectures and add more normative ideas. Those who only conducted more experiments also watched the visualization additional times but did not pay attention to elements, such as lone atoms, that eventually were combined into molecules.

Reflecting. When prompted to reflect after encountering new ideas, students explain their reasoning and construct knowledge – both well-documented strategies for increasing learning outcomes. When combined with activities that support students' distinguishing among ideas, prompts for reflection and explanation ensure that students reconsider nonnormative ideas.

WISE investigations led to a set of design principles to help teachers and curriculum designers take advantage of the knowledge integration processes (Kali et al. 2008). For example, one principle calls for encouraging students to critique flawed experiments that require them to distinguish among ideas in their repertoire.

Computer as Teaching Partner

Embedded assessments can provide formative evaluation of student learning that also helps teachers refine their practice. In a busy classroom using computer-based materials, it is hard for a teacher to distinguish between a student who is learning intently by exploring a model or experiment and one who is just going through the motions or is confused. As materials become more sophisticated, it is increasingly difficult for teachers to play an active role in planning their delivery or enacting instruction within the classroom. WISE developed tools for teachers such as "flag student work" so they could monitor classroom activities and review student work to plan their next lesson.

The knowledge integration framework is also valuable for designing professional development programs to improve use of technology-enhanced materials. When teachers used the knowledge integration framework and evidence from student work to revise their instruction during a summer workshop, they were able to improve student outcomes the following year. A review revealed that, in general, when programs engaged teachers in the knowledge integration processes of making predictions about the effectiveness of instruction, introducing new ideas as pivotal cases, reviewing student work to distinguish among alternative teaching practices, and reflecting on their plans to implement the unit in the following year, they were more successful than programs lacking these elements (Gerard et al. 2011).

Computer as Inquiry Partner

WISE is taking advantage of new technologies such as natural language processing to explore how automated guidance, when added to proven online inquiry units, can augment teacher effectiveness and encourage students to integrate their ideas. By diagnosing the student's knowledge integration level within a reflection or other assessment, encouraging the student to revisit relevant visualizations or conduct a new activity, and asking the student to regenerate their argument, automated guidance can help students distinguish among their ideas. Comparison studies suggest that knowledge integration guidance is more effective than either specific guidance (identifying inaccurate ideas) or general encouragement (e.g., to add more evidence) for helping students build coherent understanding.

The CLP and WISE research programs have identified promising ways to ensure that all learners can succeed at science inquiry. Designing powerful pivotal cases that take advantage of visualizations and guiding students with the knowledge integration patterns have the potential to prepare scientifically literate citizens. The knowledge integration framework offers designers principles and patterns that can improve assessment, curriculum materials, instruction, and professional development.

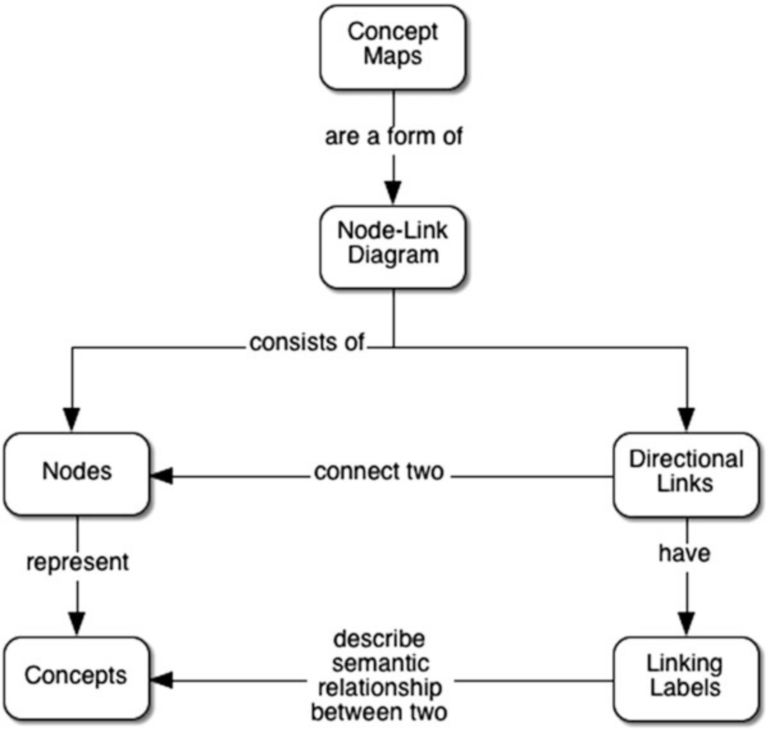
Definition

From the perspective adopted in this entry, a concept map is a node-link diagram showing the semantic relationships among concepts, where the process of constructing concept maps is known as "concept mapping." A concept map consists of nodes (concepts), arrows as directional links, and usually captions for each link that describe the relationship between nodes [see Fig. 1]. Concepts can be described as perceived regularities or patterns of events or objects, or records of events or objects. Two concepts connected with a labeled arrow can be described as a proposition. Concept maps are versatile graphic organizers that can represent many different forms of relationships between concepts. The relationship between concepts can be articulated in the link captions, for example "leads to" (causal), "consists of" (part-whole), "follows" (temporal), "is inside of" (spatial), "increases" (quantified), or "is different than" (comparison). Nodes (usually nouns) and linking phrases (usually verbs) can be interpreted as a semantic network of propositions.

Difference to Other Forms of Node-Link Diagrams

Various forms of node-link diagrams have been developed for educational purposes. Some of the earliest examples of node-link diagrams were developed by the Greek philosopher Porphyry of Tyros in the third century AD to graphically visualize the concept categories of Aristotle. Commonly used examples of node-link diagrams are mind maps, flowcharts, and concept maps. Mind maps, in which connections are unspecified associations represented by nondirectional lines without linking phrases, are often arranged in a radial hierarchy around a single central concept. Flow charts, first presented by engineer Frank Gilbreth in 1921, show the intermediate steps between input (e.g., problem) and output (e.g., solution) of a system. Flow chart connections are usually ontologically of the same kind, such as information, energy, time, or material. In contrast, linking phrases in concept maps can represent any form of relationship (e.g., temporal, procedural, functional, subset, superset, causal, etc.) and topological arrangement (e.g., hierarchical, hub, decentralized network, circular, etc.).



Concept Mapping, Fig. 1 Concept map about concepts maps (By Beat A. Schwendimann)

Background

One theoretical perspective that influenced concept mapping is that of David Ausubel's assimilation theory [see "► Ausubelian Theory of Learning," "► Meaningful Learning"], which stresses the importance of individuals' existing cognitive structures in being able to learn new concepts. Inspired by this perspective, Joseph D. Novak and his research team at Cornell University developed concept mapping as a means to graphically representing concepts, based on their research on understanding changes in children's science knowledge (1984). With its emphasis on actively engaging learners in eliciting and connecting existing and new concepts, concept mapping is considered as being consistent with a constructivist epistemology, as it aims to support the elicitation of existing and missing concepts and to promote the construction of connections.

Construction of Concept Maps

Concept map setups can vary from open-ended to very constrained forms. Concept mapping tasks with few constraints can provide learners with a focus question while giving them free choice to select their own concepts and links. A "focus question," such as a how or why question, can help students to understand the purpose of the concept map activity and guide their concept map generation. A somewhat more constrained form of activity would provide learners with premade lists of concepts or link captions but give free choice of which concepts to connect. Highly constrained applications of concept mapping would perhaps provide learners with a skeletal network structure and premade lists of concepts or link captions, with which the learner fills in blanks within the structure. Concept maps can be constructed by hand using paper and pencil, flash cards, and post-its or by using computer software, of which there are many educational offerings, including Inspiration and CMap. Research indicates that concept mapping can facilitate the development and revision of concepts with software supports for hyperlinks (e.g., to Web pages or other concepts) and multimedia (Canas 2003). Concept mapping requires initial training to familiarize learners with the concept mapping principles and criteria for concept map evaluation.

Concept Maps and Learning

Concept maps have been applied as learning tools in many science disciplines, including chemistry, biology, earth science, ecology, astronomy, and medicine. They have been used with all ages from children to adults, using individual or collaborative activities, in asynchronous or synchronous formats. Meta-analyses have shown that concept mapping produces generally positive effects on student achievement and large positive effects on student attitudes (Horton et al. 1993; Canas 2003; Nesbit and Adesope 2006).

Concept mapping, especially in its more constrained forms, has also been found to be a reliable and valid form of assessment for changes in students' understanding of science concepts. Research comparing concept maps to multiple-choice tests indicates that concept maps assess different forms of knowledge (e.g., propositional or hierarchical). Concept maps can reveal students' knowledge organization by showing connections, clusters of concepts, hierarchical levels, and cross-links between concepts from different levels. Cross-links are of special interest, as they can indicate creative leaps on the part of the learner (Novak and Gowin 1984).

Concept maps can be analyzed either qualitatively or quantitatively. Quantitative analysis can include concepts, hierarchy levels, cross-connections, propositions, or network structure. The number of links and concepts, while easily countable, provides limited insight into a student's understanding. Propositions are more informative elements of a concept map and can be used to track changes in students' understanding. Proposition analysis can include all links or only a selection and can value all propositions equally or attribute weights differently. Research suggests that scoring only selected propositions can be more sensitive to measuring conceptual change because it focuses only on key concepts of the concept map (Schwendimann 2014). Concept map analysis often compares student-generated maps to an expert-generated map. This approach can provide instant and authoritative feedback but has limits in terms of capturing the wide range of alternative expressions of student understanding. Network analysis methods often focus on elements like network density or the connectedness of selected concepts. Qualitative analysis of concept maps can include changes in types of link captions or topographical analysis methods to describe the overall geometric structure of the concept map.

Applications of Concept Maps

Concept maps can be used in many ways in science education, for example, as tools for lesson planning, as advanced organizers, as learning tools for students, as online navigation interfaces, as knowledge management interfaces, or as assessment tools. Different explanations have been proposed to explain the observed benefits of using concept maps. Concept mapping can support eliciting existing concepts and connections and serve as a memory aid by off-loading them as external node-link diagrams. Concept maps can support learning science by identifying central concepts from different contexts. The explicitness and compactness of concept maps can help learners to maintain a "big picture" view. The "gestalt effect" of concept maps allows for the viewing of many concepts at once, increasing the probability of identifying gaps and making new connections. In a concept map, each concept is represented by only one node, and all connections related to that concept are presented in one location. Concepts derive their meaning in part from their connections to surrounding concepts. Visual chunking of related concepts or the arrangement of concepts in hierarchies can reveal epistemological structures.

Compared to written linear summaries, clustering-related concepts into meaningful patterns can foster quick information retrieval, in part because concept maps use a simple syntax for propositions (node-link-node) and limited amounts of text to represent concepts. Concept mapping can be seen as a first step in ontology building and can also be used flexibly to represent formal arguments. Fast information retrieval from concept maps can be beneficial for collaborative activities. Viewing or generating concept maps may also promote the integration of concepts in both verbal and visuospatial memory. According to Paivio's dual coding theory, the verbal information and the visuospatial information of concepts reside in separate but potentially interlinked memories. Integrating verbal and visuospatial information of concepts can be simultaneously processed and provide alternative ways to retrieve concepts. Finally, the process of translating concepts from texts and images to a node-link format may foster deeper reflections about concepts and their connections and prevent rote memorization.

Limitations of Concept Maps

Similar to geographical maps, concept maps do not aim to include all possible concepts but rather only a selection of meaningful ones. Concept maps usually constrain connections between two concepts to a single relationship, which requires distinguishing and selecting between multiple possible relationships. Concept map construction requires an initial training phase to learn how to generate, interpret, and revise concept maps. Generating, revising, and evaluating concept maps can be time-consuming. More constrained forms of concept mapping can be faster and more reliably evaluated, but they offer limited freedom to express one's understanding. Also, the same concept or linking phrase could take on different meanings for different learners or contexts. Concept mapping activities can be beneficial to improve conceptual understanding but may have limited effects on basic recall.

Implications for Science Education

As a learning tool, concept maps can support eliciting scientific concepts and connections and can make students' organization of concepts visible to themselves and their peers and teachers. Graphic organizers, such as concept maps, can support the integration of students' isolated concepts toward a more organized, interconnected network of concepts. Research indicates that the implementation of concepts maps can shift the epistemological authority from the teacher to the student, reduce emphasis on right and wrong answers, and create visual entry points for learners of varying abilities. Findings suggest that concept mapping may be particularly beneficial for lower performing students by providing scaffolds (e.g., a selection of important concepts) and by modeling active inquiry. When introducing concept mapping, the teacher should make the possible benefits for the learner explicit: that they will help students to reflect, to communicate what would otherwise be incommunicable, and to retain a trace of what otherwise would disappear. Concept maps are cognitive artifacts that help elicit students' concepts and support self-explanations; but they can also be seen as social artifacts through which students communicate or make their ideas accessible to others. When concept maps are generated collaboratively, they become shared social artifacts that elicit existing and missing connections and spur discussion among students and teachers. The constraint to only one link between two concepts requires collaborators to negotiate, creating a genuine need to support arguments with scientific evidence.

Keywords

Knowledge Map; Knowledge Visualization

Origin

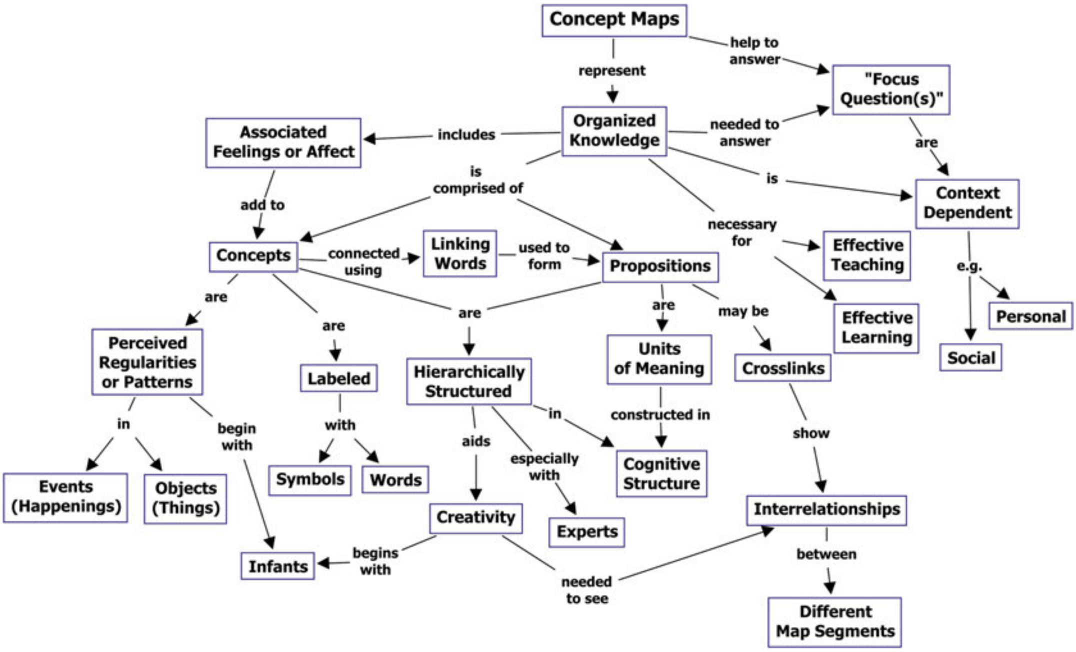
Concept maps were invented at Cornell University in the early 1970s in response to a need to explore growth in conceptual understanding of children in a 12-year longitudinal study of children's learning of science concepts (Novak and Musonda 1991). Audio-tutorial science lessons were provided to children in grades one and two (ages 6–8), and they were subsequently interviewed to assess their understanding of the concepts presented. Similar interviews were done with the same children as they progressed through school through grade 12. Building on Ausubel's assimilation theory of learning and constructivist epistemology, Novak's research group found they could summarize the interviews on a concept map and show specific changes in children's concept and propositional knowledge of basic science concepts over the 12-year span of the study. Figure 1 shows an example of a concept map and describes the nature of concept maps. Figure 2a, b show concept maps drawn from an interview with a child at the end of grade 2 (a) and for the same child at the end of grade 12 (b). The figures show clearly the child's growth in understanding of basic concepts dealing with the nature of matter and energy and also the good organization of this knowledge. These figures illustrate the Ausubelian principles of meaningful learning including subsumption of new concepts and propositions under more general concepts, acquisition of new superordinate concepts, and progressive differentiation of knowledge in this domain.

Application of Concept Maps to Learning How to Learn

Graduate students working on the 12-year study noted above found the use of concept maps helped them learn in the work they were doing. This led Novak to develop systematic approaches to learning how to learn and eventually to a book with this title (Novak and Gowin 1984). The book has subsequently been translated into Arabic, Chinese, Finnish, Italian, Japanese, Portuguese, Spanish, and Thai. Concept mapping and Ausubel's ideas about learning began to be used worldwide.

Development of CmapTools Software

In our early work at Cornell, we made concept maps mostly with pen and paper. While this

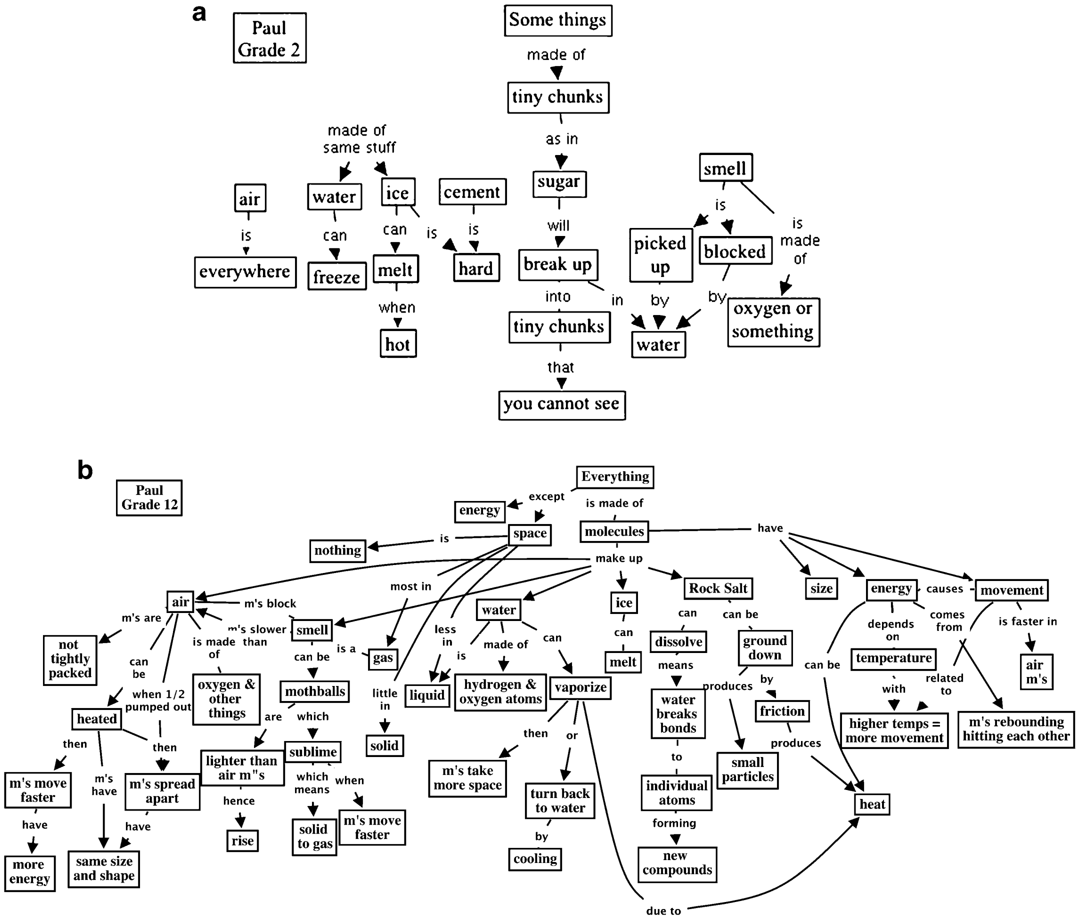


Concept Maps: An Ausubelian Perspective, Fig. 1 An example of a concept map

works well with small concept maps, it becomes very awkward with maps containing 50 or more concepts, especially as one chooses to make alterations to these maps. We used Post-itsTM notes in some of our work, and while these provide for easy team work and easy movement of concepts, changing linking lines and linking words often required completely redoing the whole concept map. As appropriate computer software became available in the early 1980s, we began to use this for preparing maps for publication, but at that time essentially all students lacked computers and/or the software to do concept maps.

In 1987, while on sabbatical leave at the University of West Florida, Novak began working with Kenneth Ford and Alberto Cañas, who later became Director and Associate Director, respectively, of the Florida Institute for Human and Machine Cognition (IHMC). Ford pointed out that the primary problem in the field of artificial intelligence, his specialty, was to find a way to represent knowledge and to extract knowledge from experts in a precise and reliable way. He saw concept maps as a solution to this problem and so began a collaboration that continues today. NASA, the Department of Navy, the National Security Agency, and other US federal and private organizations found the use of concept maps an excellent tool for capturing and archiving expert knowledge and for facilitation of team problem solving. With grants from these organizations, IHMC, under Cañas's leadership, developed excellent software for creating concept maps of the form shown above, CmapTools. This tool makes it easy to show individual concepts in nodes connected by linking lines with appropriate linking words attached and arranged hierarchically. Figures 1 and 2 were drawn using CmapTools, based on the original paper and pencil maps. The software is available at no cost at http://cmap.ihmc.us, a site that also provides access to numerous research studies and other documents that give additional information on concept mapping.

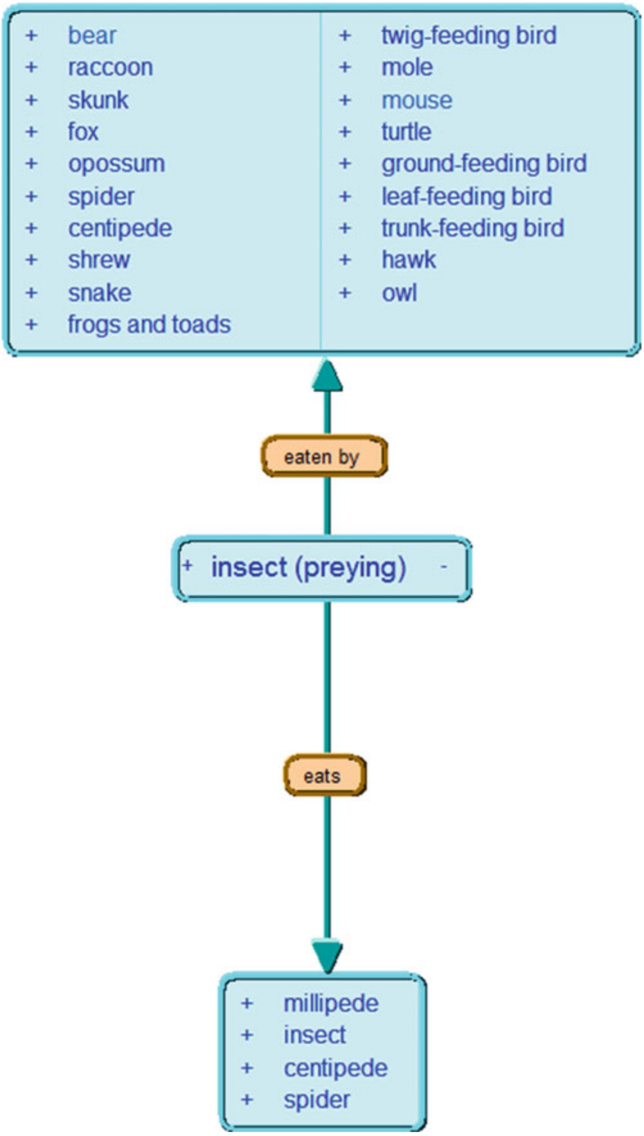
Fisher and her colleagues saw concept maps as a useful tool for identifying and changing student misconceptions/alternative conceptions (Fisher et al. 2000), and Fisher and Faletti created



Concept Maps: An Ausubelian Perspective, Fig. 2 (**a**) Concept map drawn from an interview transcript, grade 2 (age 7) student. (**b**) Concept map drawn from an interview transcript, same student as (**a**), now grade 12 (age 17) (Note how superordinate learning and extensive subsumption and integration of new concepts and propositions have occurred)

SemNetTM software in 1986 (also available at no cost at: http://www.biologylessons.sdsu.edu/license.html). Figure 3 illustrates some of the factual details identified by Fisher and her colleagues that need to be properly assimilated by biology students to overcome some misconceptions and build a valid knowledge structure.

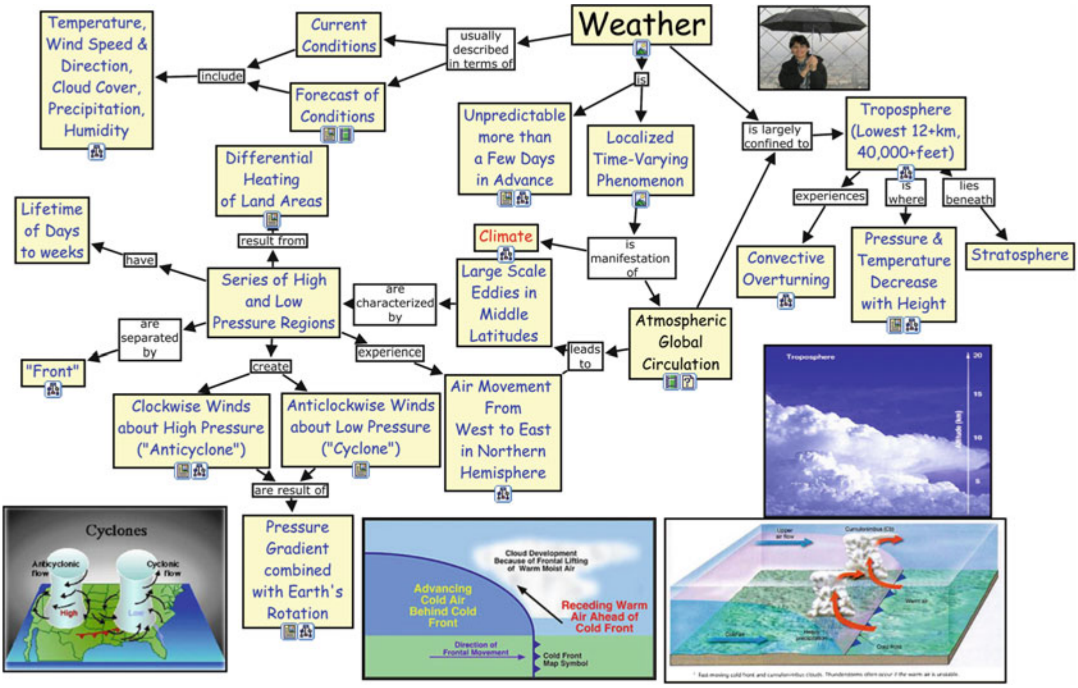
CmapTools has the unique, patented feature that allows a person to attach any digital resource to any concept on a map by simply dragging the icon for this resource to a target concept and dropping it on the concept. This resource becomes part of a "knowledge model" that is stored with the concept map. The resource can be opened by simply clicking on the icon for the resource type and selecting the desired resource. In this way, one can do more than just create a concept map; one can create essentially a digital knowledge portfolio with a broad range of digital resources linked into the map. Figure 4 shows an example of a concept map with resources attached, and inserts show some of the resources that can be accessed via icons at the bottom of concepts. The complete file of concept map and all resources is referred to as a "knowledge model." There are many such "knowledge models"; these can be accessed at http://cmex.ihmc.us.



Concept Maps: An Ausubelian Perspective, Fig. 3 A sample of concepts needed to assimilate properly to understand some biological relationships

Further Developments with Concept Maps: Focus Questions and Parking Lots

As our work with concept maps progressed, we found the clear identification of a focus question the concept map sought to answer was critically important, especially when working with individuals or groups that were seeking to solve some problem. A parking lot is a list of concepts suggested by an individual or group that they deem as important to answering the focus question. This step is usually relatively easy for individuals or groups and in some ways resembles what is done in mind mapping. After identifying pertinent concepts (say 15–20), these are ordered from the most inclusive, most general concept to the least inclusive, most specific concept. Then these concepts are used to begin building the concept map. If computer software is used, this is mechanically quite easy, since concepts from the list can be simply moved into the developing concept map, and then appropriate



Concept Maps: An Ausubelian Perspective, Fig. 4 A sample concept map on weather showing some of the resources that can be accessed via icons attached to concepts (From Briggs, with permission)

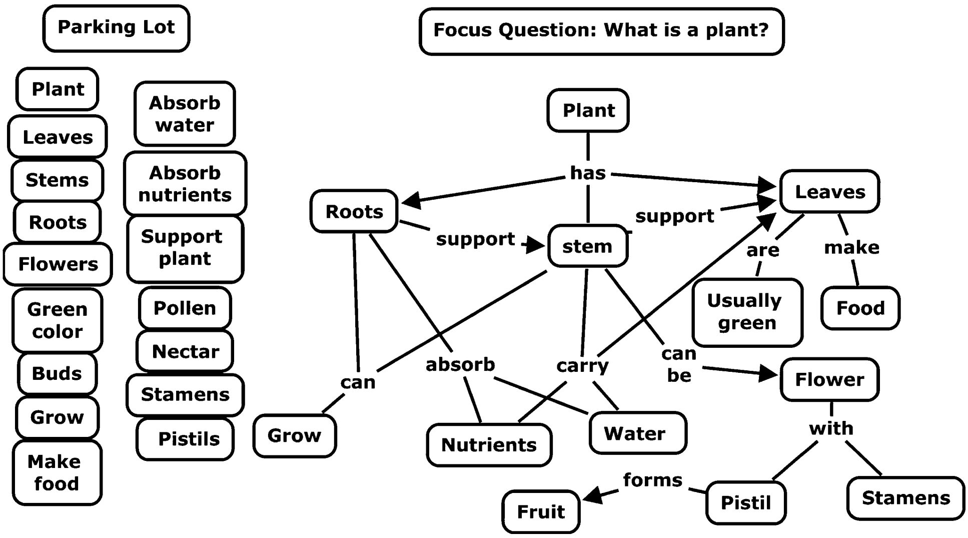
linking words can be added. Figure 5 shows an example of a concept map so created. This map can be elaborated by adding pictures, video clips, etc. Because of the importance seen in the development of a good focus question for good concept mapping, the CmapTools software has this built into its protocol.

Often, with older groups in particular, as they began to build a concept map, they see the original focus question is not actually the central question they are trying to answer. It is then common for a group to modify or even completely change their focus question as they began to map concepts and propositions pertinent to the question.

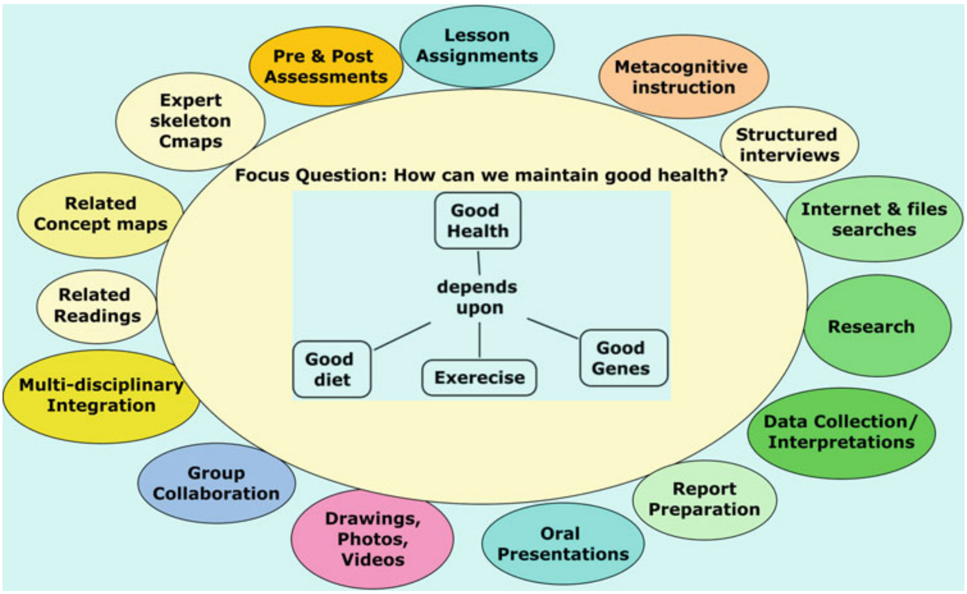
Focus questions may deal primarily with the structure of an object or an event of interest or they may deal with the process of creating an object or event. Sometimes when mapping a sequence of events dealing with some process, maps can be more cyclic or flow chart in form. Depending on the kind of question to be answered or the purpose of the concept map, the structure of a good concept map can vary (Derbentseva et al. 2006). However, we have found hierarchical structures to often be the most useful.

Concept Maps as Metacognitive and Metaknowledge Tools

Constructing a concept map requires a learner to identify key concepts in the material and to show meaningful relationships between concepts as explicit propositions. Moreover, to arrange these concepts into an appropriate structure takes further thought and action. To do this well, the learner must engage in relatively high levels of meaningful learning, and concept maps have been shown to be powerful aids for achieving high levels of meaningful learning in virtually every discipline and from preschool to adult research teams. The more learners engage in concept mapping, the more keenly they become aware of the central role that concepts play in meaningful learning and in understanding any



Concept Maps: An Ausubelian Perspective, Fig. 5 A concept map about plants, showing the focus question used to begin and a parking lot



Concept Maps: An Ausubelian Perspective, Fig. 6 Schematic showing how to employ a new model for education using CmapTools, via an expert skeleton concept map on health, WWW, and other resources (identified in smaller ovals) integrated together into one digital file

domain of knowledge. In short, they become better learners.

We often hear science defined as an organized body of knowledge, but seldom are we shown exactly what this means. As learners become skilled in concept mapping, they become acutely aware of the organized concept and propositional nature of science. If they also engage in science project work, they see sharply how concept and propositional knowledge guides the creation of new knowledge in any discipline. In short, they become aware of the nature of and construction of new knowledge. This consequence is part of the reason for concept maps being valuable as “metacognitive and metaknowledge tools.” More generally, since tools that facilitate learning can also be seen and used as metacognitive tools, concept maps are important tools for developing metacognition. This is demonstrated by both the *Learning How to Learn* book (Novak and Gowin 1984) and by the value of concept maps as one significant strategy in the classroom-based approaches to enhancing student metacognition in the Project for Enhancing Effective Learning.

CmapTools Make Possible a New Model for Learning

As noted above, from 1987 and continuing today, IHMC worked to refine and add functionality to what evolved into CmapTools. Also during this period, there were exponential increases in computer power in personal computers and materials available on the World Wide Web. Among the features developed in CmapTools were means for easy collaboration between learners and mapmakers permitting easy collaborative learning and virtually unlimited information on any topic. In 2004, Novak and Novak and Cañas proposed a new model for education that employs the power of collaborative learning utilizing CmapTools, a wide range of learning activities, the relatively unlimited WWW resources, and expert skeleton concept maps to scaffold early learning.

The idea behind expert skeleton concept maps is to provide some initial conceptual guidance to a team of 2–4 learners who subsequently engage in a variety of learning activities, as depicted in Fig. 6. Prepared by experts, the expert skeleton concept maps serve to define an important domain of knowledge to be studied and also provide cognitive scaffolding to make it easy for an accurate starting point for organizing knowledge in this domain. Learners who have used expert skeleton concept maps in this way have reported considerable merit in this use, particularly in impact on learning of concepts. They value expert skeleton concept maps; their value in reducing the problem of prior misconceptions still needs to be researched. The teacher’s role is primarily to serve as a guide and coach and also to model her/his own learning as the student’s progress on their projects. As students do WWW searches, their own interviewing of experts, experimentation, reading, etc., they record their progress using CmapTools to create a comprehensive knowledge model. Figure 6 illustrates how, using CmapTools and building on an expert skeleton concept map, materials from all other forms of learning can be combined into a digital knowledge portfolio. These can be stored for future reference or used to further elaborate understanding in this domain of knowledge. Such portfolios have powerful potential, including if used from an early age and then throughout schooling.

Conceptual Change in Learning

Claudia von Aufschnaiter and Christian Rogge
Institute of Physics Education, Justus Liebig University Giessen, Giessen, Germany

Keywords

Cognition; Conceptual Change; Conceptual Understanding

Introduction

With his idea that the most important factor influencing learning is what a learner already knows, Ausubel could in some ways be argued to have started a new and still ongoing research area at the end of the 1960s: conceptual change. Since then, a very large volume of research has addressed students' understanding of a given topic and how it changes with different ages or as a result of instruction. The notions of "concept" or "conception" are used to describe a certain piece of knowledge which has to be learned by a student (concept) or refer to the understanding a student holds at a particular point in time (conception, alternative conception, or misconception). "Conceptual change" describes and assesses how naïve, nonscientific, or "wrong" conceptions develop to become improved, scientific or "correct" concepts. Predominantly, research on conceptual change is based on a constructivist epistemology assuming that concepts are a result of personal or social constructions.

During the last 40 years, strong evidence has been gathered that students entering a science classroom typically hold conceptions which are very different to those of scientists. In order to adapt instruction to students' prior ideas, research has aimed to assess students' conceptions in various science topics. The body of literature describing content-specific conceptions involves studies that number, literally, in the thousands and is still noticeably increasing. Issues addressed are not only subject-matter concepts but also students' ideas about nature of science (NOS) or scientific inquiry (SI) and their concepts about learning.

Even though conceptual change has a relatively long research tradition and some basic assumptions are shared, there are also noticeably differences between frameworks used to describe conceptual change (e.g., Duit and Treagust 2003; Scott et al. 2007). Coming to terms with conceptual change research is not only difficult because theoretical frameworks differ, but also because the focus on concepts and conceptual change can be very different. Concepts and conceptual change can be addressed from a social or an individual perspective. Whereas the first perspective aims to describe how communities (e.g., scientists, engineers, or classmates) create, develop, and share concepts which are new for the community (Thagard, pp. 374–387 in Vosniadou 2008), the latter describes how concepts are developed by individuals (e.g., scientists or students). Furthermore, conceptual change research can address expert learning (scientists, engineers) or novice learning (students). In science education research, the vast majority of work in conceptual change aims to describe and explain students' difficulties in establishing fundamental scientific concepts by adapting an individual perspective. In addition, the transition from a naïve to a more scientific understanding is investigated, and how this process can be best promoted. In this line of research, it is stressed that conceptual change should not be confused with the notion of learning: Conceptual change is part of learning but not all learning is conceptual change (e.g., Vosniadou, p. 1 in Vosniadou 2013).

This entry is dedicated to Phil Scott.

Even though science education researchers can share the observation that students hold particular misconceptions in various topics, the assumed reasons why these misconceptions exist and why learners are resistant to change cannot be observed directly. As a consequence, theoretical frameworks have taken different routes depending on the assumptions as to what are the main barriers for conceptual change. Among the different approaches which can be identified, four frameworks are frequently mentioned: the "classical conceptual change approach" which was introduced during the 1980s and developed further by Strike and Posner (1992), Vosniadou's "framework theory approach" (Vosniadou et al., pp. 3–34 in Vosniadou 2008), Chi's "categorization approach" (Chi, pp. 61–82 in Vosniadou 2008), and diSessa's "knowledge in pieces approach" (diSessa, pp. 29–60 in Limón and Mason 2002). Even though these four frameworks frequently appear in association with conceptual change, other frameworks can be identified which also seem to describe issues of conceptual change, for instance, Marton's "phenomenographic approach" (Marton and Pang, pp. 533–559 in Vosniadou 2008), Stavy's "intuitive rules approach" (Stavy et al., pp. 217–231 in Limón and Mason 2002), or von Aufschnaiter's "level approach" (von Aufschnaiter and Rogge 2010). Even though the frameworks differ, they all have a primary focus on the same three broad questions:

- What are concepts? Is there any other knowledge or understanding which is "more" than a concept or "less"?
- What are the mechanisms by which conceptual change takes place? Why is particular conceptual understanding difficult for students to achieve?
- How can conceptual change be promoted?

Within the following sections, issues addressed with these three questions are discussed with reference to the frameworks offered by Chi, diSessa, Strike and Posner, and Vosniadou, as well as, where it applies, Marton, Stavy, and von Aufschnaiter.

Concepts

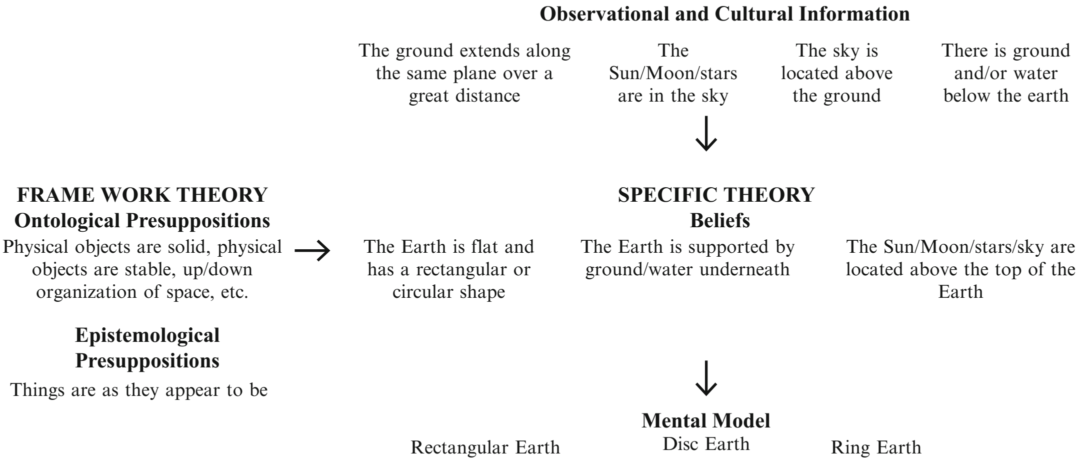
Within the different frameworks, different notions for concepts are used (for instance, belief or coordination class), and also understanding of the same terms (such as mental model) can vary. Thus, frameworks cannot be compared easily. However, common to most frameworks is the (usually implicit) idea that concepts are specific mental elements and refer to an understanding of certain principles (e.g., von Aufschnaiter and Rogge 2010). Moreover, most frameworks assume that human cognitive structure is composed of more than one type of mental element. The notion of grain size is often used to express that "smaller" and "larger" mental elements are considered (see Table 1). Grain size can differ in two ways: Typically, mental elements of smaller grain size form an interrelated set to establish mental elements at greater grain size which have the character of networks. Grain size can also refer to the context specificity of mental elements. Here, elements at smaller grain size refer to a particular context whereas mental elements at larger grain size are assumed to encompass varying contexts. Common to the majority of the frameworks is the idea that the cognitive structure described is central in organizing individual thought and learning (Strike and Posner 1992, p. 148).

In Strike and Posner's framework, the cognitive structure is composed by a conceptual ecology which comprises learners' knowledge and of which concepts are constituent parts. Different sorts of concepts are integrated into the conceptual ecology, such as organizing concepts, analogues concepts, metaphors, or epistemological beliefs. Vosniadou describes a more elaborated idea of the cognitive structure (Fig. 1) in which unspecific framework theories have an impact on specific theories in which beliefs have the status of concepts. From these theories, mental models are formed while individuals make sense of the current situation (such as a task, a problem, or a question).

In diSessa's approach, the cognitive structure is composed of coordination classes which have

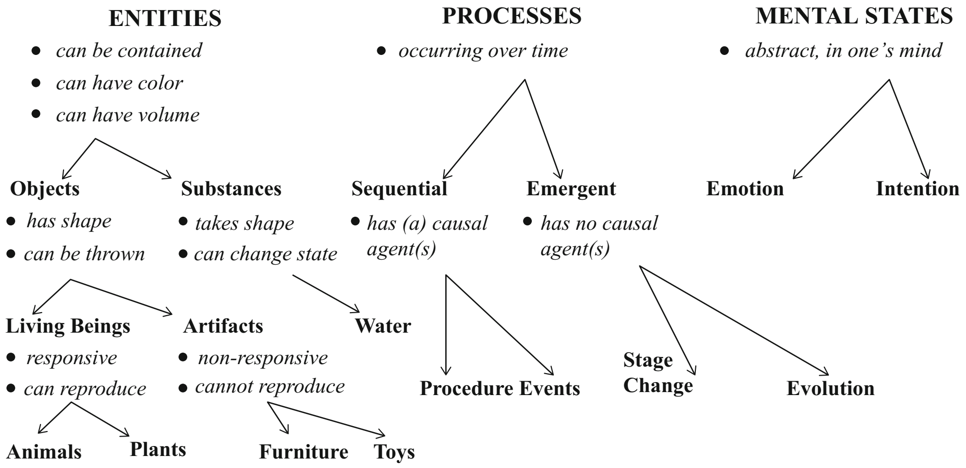
Conceptual Change in Learning, Table 1 Grain size of mental elements described in different frameworks

Approach	Grain Size Small	⟶	Grain Size Broad	Grain size increases with
Chi	belief	—	mental model	interrelationship between elements; classification can also differ (ontological categories or "lower" categories, see Figure 2)
diSessa	p-prim	— readout strategy, causal net —	coordination class	interrelationship between elements (only coordination classes have the status of concepts)
Strike & Posner	concept	—	conceptual ecology	interrelationship between elements
Vosniadou	mental model	— belief (part of specific theory) —	presupposition (part of framework theory)	reducing context specificity (only beliefs and presuppositions have the status of concepts)



Conceptual Change in Learning, Fig. 1 Conceptual structure described by Vosniadou (similar to Vosniadou et al., p. 8 in Vosniadou 2008)

the status of concepts. These coordination classes are an integration over causal nets as a knowledge base and readout strategies as ways in which current situations are observed. As very basic mental elements, unrelated phenomenological primitives (p-prims) are described which are applied to everyday situations. An example of a p-prim is "force as a mover." In similar ways, Stavy assumes that activities of learners are often established from underlying intuitive rules.



Conceptual Change in Learning, Fig. 2 Ontological trees with hierarchical and lateral categories described by Chi (similar to Chi, p. 58 in Vosniadou 2013; see also Chi, p. 64 in Vosniadou 2008)

In contrast to diSessa, Stavy argues that only a limited number of intuitive rules can be identified, whereas diSessa assumes that a very large number (several hundreds) of p-prims exist.

In Chi's framework, a mental model is an organized collection of beliefs and has either the status of a concept or a system of concepts. In addition to distinguishing between mental models and beliefs, Chi argues that mental elements refer to ontological categories which classify as to whether the mental model and its beliefs are about entities, processes, mental states, or another category not yet identified (Fig. 2). Different ontological categories do not belong to the same tree (capitalized terms in Fig. 2) whereas lateral properties do. Categories of different trees or different branches do not share properties, for instance, a tennis match can last 200 min (processes) but cannot be green (entities). Thus, the network character in Chi's approach has a more hierarchical layout than typically described in other frameworks. As a consequence, ascribing a grain size to ontological categories (see Table 1) does not make much sense as these are used to classify mental models and beliefs which themselves have different grain sizes.

Research Debates About These Frameworks

(a) *Coherency of cognitive structures*

Among different ideas as to what limits students' understanding of science concepts, two distinct reasons are frequently discussed. For many researchers, an individual cognitive structure is composed of a coherent set of mental elements which have been established via repeated everyday experiences and are therefore stable and resistant to change (e.g., Chi, Strike and Posner, Vosniadou). On the other hand, some researchers argue that students' conceptual understanding is limited because the underlying conceptual structure is not very coherent. Even though there is an ongoing debate about the issue of coherency (e.g., diSessa, pp. 31–48 in Vosniadou 2013), there is not as yet any resolution between these two clearly contrasting positions. It has to be stressed that empirical evidence aiming to clarify the issue as to whether a learner's knowledge base is coherent is difficult to gather as the underpinning assumptions about conceptual structures heavily influence how evidence is gathered and interpreted.

(b) *Mental elements versus situated constructions*

The large majority of conceptual change frameworks describe specific mental elements which are assumed to determine individual activity (e.g., Chi, diSessa, Posner and Strike, Vosniadou; see Table 1). In contrast, some researchers argue that concepts are constructed from moment to moment and refer to ways in which a particular situation is experienced (e.g., Marton, von Aufschnaiter). Thus, these latter researchers do not claim any specific layout of a cognitive structure; rather, they investigate variability and stability of a learner's ongoing activity. They also stress that research needs to take care that a learner's utterance is not interpreted from the researchers' point of view (first-order perspective) but needs to be investigated from the learner's point of view (second-order perspective).

(c) *Usefulness of prior conceptions*

Conceptual change research typically focuses on those conceptions which are "wrong" (misconceptions) and have to be developed to more scientific ("correct") concepts. Thus, research is oriented towards learners' mistakes rather than towards the potential of their initial ideas (Halldén et al., pp. 509–532 in Vosniadou 2008). With their focus on areas in which students typically hold misconceptions, the frameworks are also limited in their power to explain why sometimes correct conceptions are established and what exactly differentiates situations with successful concept formation from those in which misconceptions are established. In order to have a more productive approach towards students' conceptions, those aspects of existing conceptions which can be used successfully to develop a student's conception further should be understood and taken into account.

Conceptual Change

The notion of conceptual change covers the description and analysis of how a learner or a group of learners (including expert learners) progress from prior conceptions to disciplinary or new scientific knowledge. In science education research, typically students' conceptual change is investigated by interpreting their written answers or statements, utterances, and/or drawings. Overall, two fundamentally different approaches can be identified. Those researchers who model a cognitive structure infer specific mental elements from students' products. Afterwards, these elements are classified, partly by using content-specific categories (e.g., diSessa, Vosniadou; see Fig. 1) or by more general categories (e.g., Chi; see Fig. 2). Researchers, who do not aim to describe cognitive structures which determine individual activity, classify students' products and utterances directly. Again, classification can either be content specific (e.g., Marton) or using more general categories (e.g., von Aufschnaiter).

In order to distinguish conceptual change that is more likely to occur or is less demanding for a learner from change which requires larger revisions, some authors introduce the distinction between "weak" and "strong" restructuring. Similar to the idea of grain size, "weak" revisions (also labeled as "assimilation" or "conceptual capture") are considered to be smaller and/or less demanding, whereas "strong" revisions ("accommodation" or "conceptual exchange"; see Duit and Treagust 2003) are considered to heavily affect the knowledge base and should therefore be harder to achieve. The distinction between weak and strong can be used to provide an overview about conceptual change dynamics described in different frameworks (see Table 2). Table 2 also contains some information about the conditions seen to be needed for conceptual change which are described in the different frameworks. It should be stressed that the overview in Table 2 is meant to give a brief introduction and serve as an orientation. As such, it cannot communicate all details of the different frameworks.

Concepts and conceptual change are typically assessed by interviews or tests. A widely known example of the latter is the "Force Concept Inventory" which was initially developed by Hestenes, Wells, and Swackhamer; its revised version was developed by Halloun, Hake, Mosca, and Hestenes and is available online (http://modeling.asu.edu/R&E/Research.html [accessed

Conceptual Change in Learning, Table 2 Brief overview of conceptual change described in different frameworks

	Weak restructuring	Strong restructuring	Remarks
Chi	*Revision and transformation*: False beliefs and flawed mental models ("inaccurate misconceptions") are revised and transformed	*Schema creation and categorical shift*: Not yet established (ontological) categories are created and/or "incommensurate misconceptions" assigned to another category	If information is only added to belief/mental model, this is not considered as conceptual change Missing categories and tree swapping between ontological categories are demanding
	Conditions of conceptual change: Weak restructuring can be based on refutation; strong restructuring requires information on alternatively available categories and may require to build (a) new category/categories		
diSessa	*Development of a "sense of mechanism"*: Priority of p-prims being activated in specific situation changes (cuing priority), development of new p-prims, or established p-prims are expanded to more situations	*Development of coordination classes*: Causal nets or readout strategies are expanded, integration of causal net and readout strategy is improved, or coordination class can be aligned to a larger number of situations	Learning difficulties can be caused by single p-prims, not-well-established causal nets, or readout strategies Conditions for conceptual change not described in detail
	Conditions for development of coordination classes: Causal nets emerge when coherency across p-prims is established		
Marton	*Development from undifferentiated to differentiated way of experiencing*: More aspects of a phenomenon considered or more interrelation of aspects, reaching higher levels of ways of experiencing		Does not differentiate between weak and strong
	Conditions for development of ways of experiencing: Create focus on specific aspect of phenomenon (relevance structure) and vary aspect systematically		
Strike and Posner	*Assimilation*: Integration of a new concept into existing cognitive structure (alternatively: conceptual capture, Hewson 1981)	*Accommodation*: Major revision of existing cognitive structure in order to establish new conceptual understanding (alternatively conceptual exchange, Hewson 1981) *Conditions for accommodation*: Dissatisfaction with prior conception, new concept has to be intelligible, plausible, and fruitful	Description based on Piagetian theory and on philosophy of science Accommodation should not be confused with abrupt change, can be gradual and slow, but results in major revisions
von Aufschnaiter	*Development of concepts*: From exploration (level I) to formation of intuitive rules (level II) to the development of phenomenon-based concepts (level IIIa) which are established by generalizations over concrete experiences. Model-based concepts (level IIIb) are developed late in learning processes. Iteration in levels constitute learning dynamics		Does not differentiate between weak and strong Model-based concepts are considered being more difficult for learners Understanding can be "correct" or "incorrect" at all levels
	Conditions for conceptual development: Establish experiences that match the concept to be developed, create opportunities to rediscover already "established" concepts, do not introduce model-based concept at early stages of learning of particular content		
Vosniadou	*Enrichment*: New information is added to existing cognitive structure without alteration of structure	*Revision/replacement*: If new information is in conflict with existing conceptual structures, either elements or their interrelationship have to be revised/changed *Conditions for conceptual change*: Rather than a mental model itself, beliefs and presuppositions have to be changed; metacognitive reflections are important for this change	Revision of framework theory more demanding than revision of specific theory Revision slow and gradual because of stability of beliefs and presuppositions

October 7, 2013], background articles can also be downloaded from that website). A prominent example of conceptual change interviews is Vosniadou's work about children's mental models of the earth (e.g., Vosniadou et al., pp. 3–34 in Vosniadou 2008). Both approaches, tests and interviews, seek to identify individual conceptions and, often via a pretest-posttest design, how these change as a result of instruction. Furthermore, conceptions of individuals at different ages or grades are often compared. Whereas interviews are often chosen to explore details of students' conceptions with a limited number of participants, tests are widely used to investigate students' conceptions with a large number of participants. Here, multiple-choice formats which offer common student misconceptions along with scientific answers can be analyzed objectively and quickly.

Research Debates About Conceptual Change

(a) *Replacement versus revision*

Even though the notion of "conceptual change" implies that prior concepts are replaced by scientific conceptions, it is widely accepted that conceptual change needs to be regarded as a more gradual and slow process (see also last column in Table 2 and Duit and Treagust 2003). Further, even if a scientific concept is already established, learners (and experts) may very well still use a prior/alternative conception depending on the problem or the context with which they are dealing. It is assumed that during learning, the status a specific prior conception has for a learner decreases over time while the status of a more scientific concept increases (e.g., Hewson 1981; see also the idea of cuing priority of p-prims in diSessa's framework).

(b) *Lacking focus on processes of conceptual development*

As noted above, conceptual change is typically either assessed by comparing results of interviews or tests between individuals of different age/experience or assessed pre- and post-intervention. These procedures can detect change as a result of instruction, experience, or age but they cannot inform research and practice about either the processes by which change has taken place or how new concepts have evolved. So far, only a limited number of projects have paid attention to the development of concepts while students learn (diSessa, p. 58 in Vosniadou 2008; von Aufschnaiter and Rogge 2010). It is noticeable that ideas on how to promote conceptual change (see below) and interventions based on these ideas are only rarely assessed by addressing the processes by which conceptual change occurs. Thus, for effects detected it is not fully clear which specific component of the intervention will have caused the effect. Also, information about what exactly "gradual" and "slow" might empirically mean is still lacking.

(c) *"Cold" conceptual change*

Conceptual change has frequently been criticized for its dominant focus on cognition. Pintrich and others (1993) have argued that this kind of research is about "cold conceptual change," paying little attention to emotional and motivational factors or the social environment which can affect conceptual change (see also Strike and Posner 1992). These noncognitive factors will help to understand why learners who seem to have a very similar knowledge base progress differently in their conceptual understanding. Assessments for conceptual change have also been criticized because they do usually not include interaction with peers which can have an effect on which understanding is demonstrated by a learner. Furthermore, as to whether concepts identified within a specific context can be transferred to other contexts (within the same topic) or are activated under varying social conditions is rarely investigated (see also diSessa, pp. 43–51 in Limón and Mason 2002).

Promoting Conceptual Change

In order to develop approaches for promoting conceptual change, it is helpful to analyze first why some conceptual change seems to be more demanding or difficult for learners (see also Table 2, last column). Some researchers argue that the stability of conceptual structures which already have a high integration makes the development of different structures difficult (Strike and Posner, Vosniadou). However, these researchers might not be able to explain well why knowledge which is completely new to a learner and not in conflict with existing ideas (especially likely for younger children) can still be difficult to learn. Other researchers, in contrast, assume that learning is challenged by the integration of unrelated elements (e.g., diSessa). These researchers might struggle with explaining why contradictory knowledge (at the same grain size) can also be difficult. For Chi, categories of the different ontological trees (see Fig. 2) over which a learner does not have command or assignment of ideas to a wrong category are major learning obstacles.

Across the different frameworks, several researchers stress that misleading, missing, or incomplete everyday experiences can cause learning difficulties. These existing and missing prior experiences may, for instance, cause a learner to create synthetic models being a mix of correct and incorrect ideas or the learner might add information rather than revise ideas (Chi, Vosniadou). In addition, prior experiences are assumed to often hamper a learner in focusing on relevant aspects of a situation (diSessa, Marton, von Aufschnaiter). Von Aufschnaiter and Rogge (2010) also stress that the nature of specific scientific concepts makes them difficult per se: Concepts that cannot be extracted from observable features (e.g., the concept of energy) are called model-based concepts. It is argued that learners fairly often do either not grasp these scientific concepts or misunderstand them. Researchers who adopt a Piagetian theoretical position may argue that children cannot establish particular concepts because of lacking general cognitive abilities to reach a formal operational stage. However, empirical evidence indicates that conceptual understanding can be reached at fairly young ages.

Even though different ideas exist as to what makes conceptual change difficult for learners, it is widely assumed that in order to promote conceptual change, learners need to be exposed to cognitive conflict (see also Table. 2 “Conditions for. . .”). Based on prior work, Strike and Posner (1992; see also Duit and Treagust 2003; Hewson 1981) have introduced four conditions necessary for conceptual change: (1) First a learner needs to be dissatisfied with his/her existing conception. Dissatisfaction is likely to occur if conflicting information is offered or problems cannot be solved successfully with existing conceptions. (2) Then the new concept which is introduced must be intelligible to the learner, (3) the new concept must be plausible, and (4) the new concept needs to be fruitful in helping a learner to solve problems. The more these four criteria are fulfilled during learning, the more likely it is that conceptual change will occur and scientific concepts receive a higher status for a learner (Hewson 1981; see also Duit et al., pp. 631–632 in Vosniadou 2008). However, it should be noted that how to identify which information is likely to be intelligible or plausible at a specific stage in learning is not yet well described. In addition to establishing cognitive conflict, it is often stressed that metacognition is an important process for a learner to become aware of the conflict (Chi, Stavy, Strike and Posner, Vosniadou). During metacognition, the differences between individual and disciplinary concepts should be made explicit and reasons should be identified why a learner holds a particular conception. In some contrast to other approaches, both Marton’s and von Aufschnaiter’s frameworks do not have a primary focus on cognitive conflict but rather stress the importance of specific experiences. For conceptual change, they argue, specific variations in phenomena are considered to help a learner to discover or “discern” (Marton) underpinning patterns and rules.

It is obvious for the frameworks described that conceptual change is considered as an individual process. However, as already mentioned at the beginning of this entry, conceptual change can also be observed and assessed among a community of (expert) learners. An argument for the common individual focus on conceptual change is the reference to constructivism:

Individual meaning making can be shaped but not determined by any social situation or artifact. On the other hand, individual contributions to a social environment change the environment and the artifacts everyone can use for his/her own constructions. Therefore, conceptual change has always a social component (see debates about "cold conceptual change" above). This interplay between a social and an individual plane for conceptual change and the necessity to create an optimal difference between what an individual knows and the knowledge of a community to which the individual can adapt is sometimes described with Vygotsky's zone of proximal development.

Research Trends in Conceptual Change

Over the last 30–40 years, conceptual change research has covered several science topics in great detail. These include mechanics and electricity in physics, the particle model in chemistry, and students' understanding of evolution in biology. However, various topics are not yet fully examined which are currently explored, for instance, students' understanding of radioactivity. Identifying fundamental concepts and how these have been developed by scientists and students does not exclusively belong to science education. Thus, conceptual change research has been expanded to other areas such as mathematics or social sciences. By expanding conceptual change research to domains other than science, the validity of frameworks which use categories not bound to specific content (e.g., Chi's categorization approach or von Aufschnaiter's level approach) can be analyzed.

In addition to expanding conceptual change to other topics and subjects, the focus has become more developmental: Rather than just identifying incorrect conceptions and aiming to change them to correct conceptions, the necessary and important intermediate steps are considered. Research on learning progressions takes into account that conceptual development is more a gradual process than a sudden shift from naïve to scientific ideas. Approaches towards learning progressions cover both the analysis of fundamental concepts and how their progression should be organized in a curriculum as well as how students' progress in their understanding of fundamental science concepts (Alonzo and Gotwals 2012). The latter approach considers current debates on conceptual change and stresses the relevance and usefulness of prior conceptions.

In addition to cognitive aspects of conceptual change, research has been addressing the challenge of expanding frameworks and empirical approaches towards including motivational, emotional, and social aspects. Even though it is obvious that a more inclusive approach towards conceptual change is needed, it is also evident that both theoretical frameworks and empirical approaches become more complex. Designing investigations which control variables such as motivation, emotion, cognition, and social setting is very demanding.

Besides more content-related aspects of future development, technological and methodological advancements offer new opportunities for conceptual change research. Video recording in classroom and laboratory settings has become more prominent and helps to understand better how concepts are established, used, and changed while students are exposed to learning material over a longer period (von Aufschnaiter and Rogge 2010). Whereas video is an approach typical for smaller sample sizes, item response theory (such as Rasch analysis) which has been established in science education research during the last years can be used to gather information on students' knowledge with larger sample sizes. Here, ordered multiple-choice items are helpful in understanding better how learners progress to a scientific understanding. Taking recent developments into account, it can be expected that a revised and extended conceptual change research will remain a major research focus also during the twenty-first century.

Cognitive constructivism; Critical constructivism; Personal constructivism; Radical constructivism; Social constructivism

Introduction

For nearly 50 years, constructivist theory has been making a significant contribution to education, shaping the way we think about the active role of the mind of the learner, whether student, teacher, or researcher. But to answer the question “what is constructivism?” is not an easy task; it depends on which version of constructivist theory we are asking about. There are many versions of constructivism in the literature, with labels such as cognitive, personal, social, radical, cultural, trivial, pedagogical, academic, contextual, C1 and C2, and ecological. And there are also allied terms that have a strong family resemblance, including social constructionism, enactivism and pragmatism. For this entry, I consider four versions – personal constructivism, radical constructivism, social constructivism, and critical constructivism. These have had a major impact on science education and greater impacts than other forms/versions. I start with a brief consideration of Piaget's cognitive constructivism, which laid the foundations for the emergence of the "Big Four," and I conclude with an integral perspective on using different versions of constructivism to shape science teaching and learning.

Cognitive Constructivism

By the second half of the twentieth century, science educators had begun to move away from behaviorist theories of learning, especially classical stimulus–response conditioning which was criticized for shaping teaching approaches that privilege learning by memorization and rote recall. The successor to behaviorism was the cognitive constructivism of Jean Piaget, in particular his theory of mental operations and age-related developmental stages of reasoning (from the concrete operational reasoning of early childhood to formal reasoning of the mature adult mind). Piaget's ideas persuaded science educators to take account of the active "constructing" mind of the individual student which had been largely overlooked by the dominant teaching method of lecturing to silent classrooms. Teachers began to reevaluate their established practice of "transmitting" knowledge to the seemingly empty minds of students, realizing that students' failure to learn meaningfully could not necessarily be overcome simply by lecturing more slowly or more forcefully. A radical shift in pedagogical perspective from didactic teaching inputs to students' meaningful learning experiences formed the basis of the constructivist revolution in science education.

Personal Constructivism

Based on research in the 1970s/1980s on "children's ideas" by leading science educators such as Rosalind Driver, personal constructivism captured the imagination of science educators worldwide and led to an ongoing and fruitful program of research into students' conceptions of the physical world. Researchers discovered that students' intuitive understandings of their experiences are so strongly held that in many cases they block development of counterintuitive scientific concepts. For example, the child's experience of applying a constant force to the pedals of a bicycle to maintain constant speed is very often seen by the child as completely contrary to Newtonian dynamics which holds that constant force applied to a point mass on a frictionless surface yields accelerated motion. In the past 30 years, almost every topic in the science curriculum has been researched to identify sources of potential student misconceptions. As a remedy, researchers developed "conceptual change" teaching strategies that enable students to experience dissatisfaction with their naïve understandings and to experience the "intelligibility, plausibility, and fruitfulness" of scientific replacement concepts, aided by metacognitive strategies for reflecting on the meaningfulness of their new knowledge.

Personal constructivism drew on the personal construct theory of two cognitive psychologists. George Kelly's personal construct psychology emphasizes the role of "personal construction" in the development of both scientific community knowledge and children's attempts to make sense of their experiences of the world. David Ausubel's theory of cognitive learning argues that meaningful learning involves building on learners' prior knowledge or existing mental constructs. Both models of learning focus on concept development rather than on Piaget's generalized cognitive structures or "content-independent" forms of thought.

The popularity of personal constructivism owes much to its neat fit with the content of science curricula, providing prescriptive means for teaching more effectively the knowledge base of school science. In the hands of science educators, personal constructivism has inspired a range of research and teaching methods for monitoring students' conceptual profiles and facilitating the process of meaningful learning, especially by means of inducing cognitive conflict. Well-known methods include "concept mapping," "interview about instances and events," "predict-observe-explain," and "two-tier diagnostic tests."

However, controversy surrounds the term "misconceptions," with many arguing that it is not a good constructivist teaching practice to regard as misconceived (i.e., wrong) students' intuitive conceptions when they do not accord with canonical science. A deficit view of students' prior knowledge can lead to a didactic teaching approach in which the teacher's knowledge is imposed on the basis of his/her authority, eliciting little more than rote learning and social conformity among students. A preferred term is the more respectful "alternative frameworks." Controversy also surrounds the constructivist agenda of conceptual change when it is used as an "ideology replacement therapy" for students whose worldviews do not necessarily accord with the Western modern worldview, especially children of indigenous populations (see critical constructivism below for more on this issue).

Radical Constructivism

Ernst von Glasersfeld's radical constructivism was thrust into the limelight by science educators dissatisfied with the objectivism of personal constructivist pedagogy, where objectivism entails a naïve realist "correspondence theory" of truth, which regards scientific knowledge as an accurate depiction of physical reality. Radical constructivism draws on Piaget's lesser known background theory of "genetic epistemology" which emphasizes the inherent uncertainty of the constructed knowledge of the world by all cognizing beings, from children to scientists. According to the defining principle of radical constructivism, cognition serves an adaptive purpose inasmuch as it organizes our experience of the world, rather than enables us to "discover" an objective ontological reality. This is not to deny the existence of external reality, a world of physical things that we can sense, just that we cannot peer around our conceptual frameworks and see it directly in an unmediated or pure sense. Furthermore, from a proof-of-concept perspective, we do not have access to an objective "God's eye" standpoint from which to judge the match between the so-called essence of external reality and our cognitive constructions. We are, therefore, restricted to "dancing" with the shadows on the wall of Plato's cave, the shadows of our own taken-as-shared experiential realities. Thus, our knowledge can only be judged in terms of its "viability," or fitness, for representing or modeling the physical world. For radical constructivism, the cornerstone concept of "objectivity" is reconceptualized as consensual agreement by scientific communities of practice. This instrumentalist perspective on knowledge production and legitimation is in close accord with David Bloor's "strong program" of the sociology of science knowledge (SSK) and with the philosophy of science of Thomas Kuhn who argued persuasively that scientific knowledge is "paradigm bound."

Radical constructivism directs science educators to facilitate students' epistemological understanding of the nature of science, especially the inherent uncertainty and confidence limits of scientific knowledge. A legacy of earlier science education is the naïve view that science generates absolute truths about the workings of the physical universe. As a result, many "well-educated" people reject the Intergovernmental Panel on Climate Change report (IPCC 2013) that climate change is human induced. The skeptics are not happy with a finding (i.e., consensus by the scientific community) that is expressed "only" at the 95 % level of probability. This public controversy raises the question of how well science education enables students to understand the social and cognitive processes of scientific modeling. It also raises the question of how well science education enables students to understand the epistemological status of scientific concepts, theories, and laws (and to be able to differentiate between them). A naïve belief in the permanence and immutability of scientific knowledge can breed arrogance among "true believers" that debate with the skeptics is unnecessary; it is not uncommon to hear science educators claim, for example, that Darwin's theory of evolution is unassailably right and creation science is simply wrong, end of story! The tendency of science education to reproduce the ideology of "scientism" has been challenged by critical constructivism.

Within the science education constructivist movement, a "paradigm battle" between radical and personal constructivists broke out, with vociferous opposition evident in international conferences. Radical constructivists labeled (somewhat pejoratively) the objectivist standpoint of personal constructivists as "trivial constructivism," with the latter countering that the idealism of radical constructivism leads to rampant relativism. This battle was part of the larger war in educational research between the opposing epistemological armies of positivism, with its quantitative epistemology of objectivism, and interpretivism, with its qualitative epistemology of social constructivism. Another critical view of radical constructivism, articulated by social constructionism, is that it perpetuates the subject-object dualism of subjective idealism, rendering the individual mind as primary and failing to explain adequately the intersubjectivity of the social world.

Radical constructivism does not stand alone as a theory of learning; it works best in conjunction with social constructivism to support inquiry learning.

Social Constructivism

Social constructivism entered the pedagogical arena drawing on theories of social psychology such as the "socially situated cognition" of Jean Lave and Etienne Wenger, which recognizes that people co-construct meaningful knowledge in communities of practice, and the "social activity theory" of Lev Vygotsky, which identifies the essential co-development of language and thought. Social constructivism extends the "psychologistic" focus on the mind of the individual learner of both personal constructivism and radical constructivism, recognizing that learning is also a social process. A social constructivist perspective directs teachers to situate learning activities in the context of students' out-of-school lives, thereby enhancing the meaningfulness of learning science. Applying science to contexts that are familiar to students, such as testing water quality in a nearby river or monitoring energy use within the home, gives science a perceived relevance that is often missing when it is confined to the school laboratory or textbook.

In the 1990s, pioneering mathematics educators Grayson Wheatley and Paul Cobb developed pedagogies of problem-centered learning and inquiry mathematics, respectively, based on the principles of radical and social constructivism. What these approaches have in common is a perspective that students should be engaged in learning environments that allow rich inquiry-based dialogue within small groups and at the whole-class level, facilitated by the teacher. Students learn to construct explanations and justifications of their reasoning, share and negotiate with other students and the teacher, and develop the patterns of discourse of a community of mathematicians. For the teacher, eliciting students' multiple solution methods is more important than students obtaining "the correct answer" by following (robotically) a standard procedure. The teacher exercises his/her authority to legitimate students' solution strategies and does so indirectly by stimulating students to reflect critically on their assumptions and chains of reasoning.

For science education, social constructivism emphasizes the importance of engaging students in classroom discourse in order to develop the "social capital" of science (i.e., values, knowledge, skills, language), especially scientific ways of reasoning and negotiating to reach consensus in a community of practice. Engaging in discussion, whether it be teacher-directed whole-class question-and-answer or student-directed small-group work, gives students opportunities to put language to their ideas and test their viability against the ideas of other students. Peer learning is a powerful socializing process, involving a strong emotional relationship with significant others. Contributing actively to classroom discussion or listening actively to other students' questions and responses can help develop the metacognitive skill of reflective thinking (i.e., thinking about one's own thinking) which is an important step towards developing an ability to assess the viability of one's own prior knowledge and developing concepts. In collaborative learning, especially in small groups, students have opportunities to develop social inquiry skills, including active and empathic listening, learning to "take turns" in speaking, offering strategies for investigating a problem or issue, and negotiating a consensual solution or conclusion to their scientific inquiries.

The invisible frameworks that restrain teachers from creating vibrant social learning environments gave rise to critical constructivism.

Critical Constructivism

The next articulation of constructivist theory involved an extension into the cultural-political realm. Science educators sensitive to issues of social justice, such as Joe Kincheloe, were inspired by various social theories, including Peter Berger and Thomas Luckmann's theory of the "social construction of reality," Jurgen Habermas' critical social theory of "knowledge-constitutive interests," and Paulo Freire's "pedagogy of the oppressed." These social philosophers explained how the construction of socially sanctioned knowledge, such as science, is framed by powerfully invisible (i.e., hegemonic) value systems embedded in society's social structures that serve the interests of dominant sectors of society while disenfranchising others. From this perspective, science is a cultural activity, rather than being transcendental of culture, and thus, many sciences exist around the world, grounded in a variety of communities of practice (e.g., Masakata Ogawa's "multi-sciences perspective"). Critical constructivists argue that science educators, blind to this perspective, perpetuate oppressive ideologies lurking (like Trojan horses) in science curricula and assessment systems. By means of politically naive teaching methods, such as a narrowly conceived conceptual change approach, science teachers inject (unwittingly) into students' "cultural DNA" distorting ideologies such as scientism, masculinism, and Western imperialism. Cultural anthropologists describe this process of socialization as "enculturation" or "one-way cultural border crossing."

From a critical constructivist perspective, Western modern science is but one form of science, albeit the dominant form, that thrives in concert with modern technological developments and capitalist market economies to fuel twenty-first-century globalization. For postcolonial scholars, the culturally blind, one-size-fits-all Western modern science curriculum export industry is tantamount to neocolonialism. Although studies of the cultural history of science reveal that Western modern science owes much to earlier developments in Africa, China, Japan, India, Persia, and Arabia, little of this history is included in science curricula. Critical constructivism recognizes that science learning is situated in a cultural context of historical and political considerations. The science learner's construction of his/her social capital is recognized as a complex intercultural process involving the reconstruction of children's cultural identities. If science education is to become culturally inclusive, in a global sense, it cannot afford to ignore the potential "collisions" between the starkly contrasting worldviews of Western modern science and culturally different others. The mutually beneficial process of "acculturation," or intercultural borrowing, should not be left to chance.

Critical constructivism points out that science educators are deeply implicated in values education inasmuch as they are preparing future citizens to participate in their societies, not only as professional scientists, engineers, and mathematicians but also as community-minded citizens who have a stakeholding in the survival of the life-support system of the planet. It is essential, therefore, that we enable science students to develop higher-level abilities (e.g., Derek Hodson's "critical scientific literacy") such as critical reflective thinking, communicative competence, and a social conscience. These abilities and habits of mind are essential for participating in social decision-making about the ethical use of innovations in Western modern science and technology for resolving global crises such as climate change, pollution of the means of supporting life, loss of biocultural diversity, and so on, much of which has resulted from humanity's past misuse of science and its technological products. Critical constructivism calls for "socially responsible" science education.

An Integral Perspective

As science educators, how do we resolve these philosophically and politically contrasting views of constructivist theory? And how do we avoid turning constructivist theory into yet another privileged ideology that restricts science educators' evolving theories of teaching and learning? What is clear from this short history of constructivism in science education is its adaptability to a range of agendas driven by a variety of interdisciplinary interests. What emerges is an image not of a many-headed monster threatening the unwary (the Hydra of Greek mythology) but a multidimensional hologram that integrates a range of discrete images into a coherent and complex whole (for more on this, see Steffe and Gale 1995). To change metaphors, we can choose to be like the proverbial blind men and the elephant, each one identifying only one part of the whole, or we can choose to embrace the whole, making use of powerful synergies as we integrate the parts.

The power and adaptability of constructivist theory lies in its central metaphor – constructed knowing – which enables us to see ourselves as dynamic professionals undergoing constant reconstruction as we embrace and test the viability of diverse ideas. Dialectical reasoning is the catalyst that enables us to hold together in creative tension these competing and contradictory ideas, thereby immeasurably enriching our professional repertoires (e.g., Willison and Taylor 2006). But this is not to say that multidimensional, or integral, constructivism is the only game in town. Clearly there are a host of other theories about teaching and learning, including behaviorism, that are available to us now or that will emerge in the future. From a dialectical perspective, these too can be integrated into our ever-expanding repertoires.

As science teachers, at times it might make good sense to engage students in memorization and rote recall, and at other times, we might want to correct a common student misconception or enhance students' epistemological understanding of the nature of science or direct students to explore collaboratively indigenous knowledge systems or investigate the historical roots of contemporary scientific theories; and we might want to engage students in debate or role play or theater production or community projects and so on. All of this is possible; nothing is excluded by virtue of ideological conflict. The critical factor in choosing a teaching and learning strategy should be the professional judgment of the epistemologically astute science teacher as to which theory of knowing (or epistemology) is most appropriate for achieving a particular curriculum goal at a particular point in time.

As the past 50 years has shown, constructivist theory is adaptable to many science teaching and learning scenarios, not in a simplistic sense as a method of teaching and learning but, as explained by Tobin and Tippins (1993), as a powerful epistemological "referent" that enables teachers to think creatively about how to make learning science more motivating, memorable, and meaningful, no matter the number or mix of students or the quality of available resources or the constraints of the curriculum and examination system. If the challenge of engaging students in deeply meaningful learning seems too great for science education alone, then interdisciplinary collaboration offers an exciting pathway for school-based development and implementation of integrated curricula.

Constructivism: Critiques

Jonathan Osborne
Graduate School of Education, Standford
University, Standford, CA, USA

There are three essential lines of criticism of constructivism in the literature:

1. That the constructivist perspective is indistinguishable from “discovery learning”
2. That the constructivist theoretical perspective is essentially attempting to make something out of a triviality
3. That the constructivist perspective has little or nothing to say about the nature of an effective pedagogy

Each of these is now discussed in turn.

Criticism 1: The Constructivist Perspective Is Indistinguishable from “Discovery Learning”

Central to the basic critique of those who see constructivism as a form of discovery learning is a questioning of the constructivist belief that all knowledge has to be personally constructed. The inference made by these critics is that constructivists believe that knowledge constructed by the students themselves is more valuable than knowledge which is modeled, told, or explained to them; for instance, advocates of discovery learning very commonly concur with Piaget’s assertion that “each time one prematurely teaches a child something he could have discovered for himself, that child is kept from inventing it and consequently from understanding it completely.” These critics also argue that constructivists believe that students are more likely to apply and extend that knowledge than those who receive direct instruction. Furthermore, there are some notable studies that provide evidence that purport to show that learning by direct instruction is more efficient than discovery learning. Hence, the empirical evidence contradicts the premises of constructivism. However, the model of discovery learning consistently used within this research was one where the students were simply left to discover, in a totally unguided manner, the role of the control of variables strategy in scientific investigation. Leading constructivists, such as Rosalind Driver, have pointed explicitly to the need for an “input from the teacher” and see teaching as a process of negotiating meaning. Adopting a constructivist perspective on learning does not mean, or even imply, that the child is left to reinvent, in a very limited period of time, what has taken very bright people years to create. Thus, this critique is overly simplistic and has erected a straw man – in short a vision of constructivist pedagogy which very very few constructivists hold.

Matthews (1993) offers a somewhat related but more philosophical and more sophisticated critique of constructivism. He argues that constructivists subscribe to a view that sees all knowledge as grounded in sense impressions or experience. Drawing on Hanson’s notion that all observation is theory dependent – that is, what we perceive is determined by our prior conceptions – Matthews argues that scientific ideas are abstractions of reality where phenomena are idealized, e.g., frictionless planes, point masses, and the absence of air resistance. Such ideas are not born of sense impressions but by imagining the world not as *it is* – but as it *might be*. If anything observation is an obstacle to the development of the scientific idea. For instance, observation would lead to the construction of an explanation for day and night being caused by a moving Sun rather than a spinning Earth. Therefore, constructivism is correct in stressing the invention of the theoretical ideas of science but flawed if it thinks that these can be developed solely by empirical investigations of the material world. Statements that science should be an attempt to "make sense" of the living world are not helpful as scientific advances commonly involve a "commitment to propositions that literally defied sense." Matthews essential criticism then is that what constitutes science is a set of ideas or theoretical propositions. These are not lying around to be discovered but must be explicitly introduced to children, and this requires the teacher to be competent in the subject in which they teach and accountable for presenting the commonly accepted knowledge in that domain.

While most people would agree with the details of Matthews' argument, the problem with his case is that he has equated "constructivism" as having a commitment to the pedagogy of "discovery learning." This is not so and nowhere do constructivists make such a commitment. Rather, in science education most of constructivist pedagogy has been guided by Ausubel's seminal statement that if he had to reduce the whole of educational psychology to just one thing, it would be that "the most important single factor influencing learning is what the learner already knows. Ascertain this and teach him accordingly" (Ausubel 1968). So widely cited has this statement become that it has required the status of a mantra for constructivists. Notably though, it makes no statement about the nature of the teaching that would be appropriate.

Discovery learning, in contrast, is based on a set of pedagogic commitments about how students should learn and be taught. The term "discovery learning" has been used in a quite wide range of ways and contexts. At the heart of these multiple usages is reference to a curriculum where students are exposed to particular questions and experiences in such a way that the designers suggest that students "discover" for themselves the intended concepts. However, the experiences and activities are carefully selected by the teacher to help reveal the ideas that are considered important. In that sense, the "discovery" process is very guided. Those who hold a view that teaching is a process of discovery see teaching and learning as an uncertain and contingent process. Curriculum in that sense is largely determined "in the moment" and emergent through a process where the teacher guides students with activities that are largely responsive to their students' ideas and the classroom discussion. Thus, discovery learning is essentially a contingent experience and a set of pedagogic commitments about how students best learn. Constructivism, in contrast, is a set of epistemic beliefs about how individuals come to know and it is not legitimate to equate the two. Thus, while Matthews makes salient points, his and others' critiques based on comparisons of constructivism with discovery learning essentially founded on a misconstrual of the pedagogic beliefs of constructivists.

Criticism 2: Constructivism Attempts to Create Significance from a Triviality

The second critique mounted against constructivism is that the basic tenet, captured by the Ausubelian mantra, is little more than a truism. Most people would agree that humans are born with some innate capabilities for conceptual and linguistic processing and that these develop through acting on the world and through social interaction. However, by and large much of what we commonly term to be knowledge – whether it be public or personal knowledge – is *constructed.* It cannot be acquired by a process of simply telling. Rather we all have to construct an understanding of something we are told. For instance, if you ask somebody for directions to the nearest train station, as they explain the route, in your mind you run a mental picture of the route to be walked constructing a mental map to retrieve shortly. Failure to do this means that the information does literally go in one ear and out the other. Thus, the only reasonable inference that can be drawn from Ausubel's dictum is that the construction of knowledge must be an active process even if the learner is simply listening to a lecture. Nothing will be understood and no change will occur in the individual's conceptual structures unless the learner makes a cognitive effort to assimilate the information presented. What then is the insight provided by constructivism?

The Ausubelian mantra clearly has value in reminding the teacher that the lens through which all new ideas are filtered is the existing set of knowledge and concepts that the student holds. As such it is essentially nothing much more than a statement of common sense (Osborne 1996). Yes it has value as a theory for reminding teachers that students' existing ideas are the foundations on which new ideas must be laid – but it has no predictive validity. Another criticism of this tenet is that it fails to acknowledge the social nature of knowledge construction. All knowledge can be seen as a product of a dialectic between construction and critique. While it is possible for the individual to engage in this process, most knowledge is generated by engaging in dialogue within a community. All scientific knowledge, for instance, is the product of an ongoing social interaction between scientists. Within that community, hypotheses are proposed, experimental designs are developed, and data are collected. A disposition to circumspection within the community means that only those ideas found not to be wanting survive to a later day. Argument from evidence is, therefore, very much a core practice of science. Strangely, however, it is notable by its absence in the science classroom. The constructivist overemphasis on the need to engage in construction, be it personal or social, has neglected the role of critique in helping students to identify flaws in their own thinking and generate dissatisfaction with their existing mental schemas.

A considerably body of evidence has now accrued that the learning of new concepts is essentially best done through social interaction with others where ideas are tested and challenged. In a meta-analysis of a range of studies on learning, Chi (2009) categorized activities on a continuum from passive (listening only) to active (any activity requiring physical activity) to constructive (the production of a physical artifact that transcends what was given to the student) to interactive (where the learner engages in dialogue with a partner). Her analysis shows that this hierarchy is supported by the empirical findings of research, with interactive being the most effective. Interactive approaches to learning force students to justify their views by constructing explanatory justifications for their views. In one study, for instance, students were instructed to explain to a partner what a text really said. Their interaction generated a large number of critical questions, something which is a feature of generative dialogue helping students to identify why the wrong answer is wrong as much as understanding why the right answer is right.

Criticism 3: Constructivism Has Little or Nothing to Say About the Nature of an Effective Pedagogy

Issues such as those discussed immediately above raise the third criticism about constructivism, that "a weak or at least a controversial epistemology has become the basis for a strong pedagogic policy" (Phillips 1995, p. 11)). The primary influence underpinning much of the theoretical commitments of constructivist pedagogy was a highly influential paper written by Posner et al. (1982). This paper, which drew heavily on Thomas Kuhn's work on conceptual development in the sciences and the structure of scientific revolutions, argued that learning was a process of conceptual change where prior conceptions were replaced by new conceptions if there was first initial dissatisfaction with existing ideas, and then if the new idea was "plausible," "intelligible," and "fruitful." Posner et al.'s argument was that for learning to occur, there must be a change in the student's conception, albeit gradual and piecemeal, such that there is a substantial reorganization and change in the conceptions held by the student. The problem is that there is little empirical evidence to support this view. In one of the most systematic examinations of conceptual change within young students, other research suggests that most students undergo a process of "weak restructuring" of their knowledge or "belief revision." Hence, the idea that any form of pedagogy could overturn or displace an existing conceptual schema rapidly was flawed. Rather students undergo a process of assimilation or accretion in which ontological categories are increasingly differentiated or in some cases coalesce.

Another view, developed by the psychologist Guy Claxton, goes further and argues for a triadic view of the nature of the conceptual schemas that people have for the material world. At one level, there is what he terms "gut science" which is the kind of tacit and intuitive knowledge we use to make calculations about whether it is safe to cross the road. Then there is the kind of overt knowledge which he characterizes as lay science – the kind of knowledge which is simply a commonsense interpretation of the world such as the idea that heavy things sink, light things float or that a force is needed to sustain motion. Such common sense knowledge is functionally effective for many everyday situations. Finally there is formal scientific knowledge which is the focus of what is taught in school and necessary for working within the scientific community. He argues that individuals use all three forms of knowledge and switch readily between them.

A further critique of Posner et al.'s theoretical framework is that their model is overly rational in focusing on student cognition without any consideration of the way in which students' motivational beliefs might affect the outcome of any learning experiences. Rather, students' cognition is heavily influenced by a set of four general motivational constructs that are their learning goals, the values they hold, their beliefs about their own self-efficacy, and their beliefs about the locus of control. In the case of the latter, for instance, whether they think that intelligence is fixed or mutable and dependent upon the effort they are prepared to make. The failure to consider any of these aspects within the writings on constructivist approaches to teaching is indicative of a theory which has failed to recognize that there is a significant affective component to successful learning.

Perhaps the most substantive criticism of constructivism is that as a theory of learning, it has little to say about teaching beyond the requirement to ascertain students' prior knowledge. Granted its message is that the learner must be active if they are to construct an understanding of scientific concepts, and granted that the argument of social constructivists would be that dialogue with others is essential if ideas are to be developed and comprehended. However, what are the instructional strategies and mechanisms that will generate conceptual change? Most constructivists borrow from Posner et al. and argue that the essential mechanism for generating conceptual change is conceptual conflict. For instance, if students believe that heavier things fall faster, that idea should be challenged by asking them to make a prediction and explain why they believe this. The phenomenon can then be demonstrated with a bunch of keys and a scrumpled piece of paper will both fall at the same rate. The disparity between their prediction and their observation generates conceptual conflict and forces revision of their concepts. Rosalind Driver, in her writings, argued that students should be exposed to conflict situations such as these and then constructed new explanations. But beyond the need to engage in small group work and discuss their ideas, little argument is offered about what might constitute an effective educational strategy. One exception to this is the work of Gunstone and White who developed the notion of predict-observe-explain as an instructional mechanism to generate conceptual conflict. However, even then, while undoubtedly an effective teaching mechanism, it offers no guidance about content. In contrast, neo-Piagetian theory does offer a framework for the selection of content and an argument for the nature of age-appropriate instructional activities. Likewise, those concerned with literacy in science do have a theory which drives what kinds of activities are needed to develop students ability to read and write science – essentially the idea that reading in science must be reflexive which requires tasks which are analytical where the text is summarized in either tabular or diagrammatic form or restructured by reassembling text to make meaning.

In Conclusion: Looking Across the Three Areas of Criticism of Constructivism

What is missing from constructivist writing then is an account of the processes that would support learning and a rationale for their justification. The point that Matthews is making is that if you want an individual to see the world in a new way, then they must be introduced to that way of seeing. Anybody who has tried to get students to observe a specimen down a microscope knows this. Students will not see what you see unless they are given an a priori conception of what to see. The teacher is thus reliant on the use of metaphor and analogy drawn from the familiar world of the student to help them "see" the scientific idea. Ultimately, the failure of constructivism is a failure to recognize the fact that most scientific ideas are unnatural – they do not make sense. Who in their right mind would ever come to the view that atoms are mainly empty space, that day and night are caused by a spinning Earth, or that we look like our parents because every cell in our body contains a chemically coded message about how to reproduce ourselves. Not surprisingly then, it is not immediately obvious how such ideas are fruitful let alone plausible when the standard misconception seems to be a more accurate description of the way the material world behaves.

What the constructivist perspective has been very successful at is challenging the notion that the child is a tabula rasa. The enormous body of research conducted in the last two decades of the twentieth century has shown that students do develop ideas about the material world from simply being in the world and acting on it. In that sense it has undoubtedly been helpful – for to teach any students something about science, constructivism shows that not only is it necessary to know something about science, but we also need to know something about the child. Moreover, in placing the emphasis on the need for learner to be active, it has helped to challenge the notion that simply presenting information in a clear and effective manner is the essential basis of good teaching. Indeed what much of the research in this paradigm has repeatedly demonstrated is that, contrary to the popular view that most communication is a simple act with failure being a rare event, most communication is actually a complex act with *success being the exception*. However, constructivist research has little to say about the selection or sequencing of content, how to build students capability to be metacognitive, or a rationale for any specific instructional strategy and its selection. Any theory which fails to help teachers make rationally defensible professional judgments for what they do is in essence an ideology. For a profession which desperately needs empirically tested theoretical arguments for the instructional choices that teachers make on a daily basis, the argument here is that constructivism is to be found wanting. That is not to say that there is no value in it – rather that the reader should be aware of the limitations as well as its much promoted strengths.

Context of Discovery and Context of Justification

Minwoo Seo and Hasok Chang

Science, University of Cambridge,
Cambridge, UK

Keywords

Context

Introduction

How scientists come up with new ideas, concepts, hypotheses, and theories is usually different from how they present and argue for them in published research articles and textbooks. Philosophers of science have conceptualized this difference into a more rigorous distinction between the context of discovery (for generating novelties) and the context of justification (for validating them). This distinction is also often aligned with the distinction between the descriptive (how science actually works) and the normative (how it ought to work).

History of the Discovery–Justification Distinction

With the development of the new sciences in the early modern period, philosophical discussions on scientific discovery arose in attempts to establish the scientific method. Francis Bacon (1561–1626) and René Descartes (1596–1650) offered the most prominent philosophical models among others to explain and encourage scientific discoveries. Their ideas, inspired by the emerging new scientific practices, in turn prompted groups of natural philosophers to embark on making new findings especially through concerted efforts via newly founded scientific societies. For Bacon, knowledge was gained securely through an inductive process, starting with the collection of unbiased observations and progressing toward more theoretical generalizations. For Descartes secure knowledge could only begin from indubitable foundations, from which the rest was logically deduced. In either the Baconian or the Cartesian view of ideal knowledge, there was no explicit distinction between discovery and justification, as their belief in the existence of the "scientific method" was supported by the conviction that the best method for making new discoveries was at the same time the best justification of the discoveries.

This conviction, however, was put to question starting from the early nineteenth century. An alternative view of scientific discovery, popularly captured by the "Eureka" moment and reinforced by the Romantic image of the scientific genius, made it difficult to conceive that there could be any fixed method for discovery. On the other hand, appreciation of the use of hypotheses in scientific practice paved the way for the rise of hypothetico-deductivism, which argues that the scientific method only concerns the testing of hypotheses, regardless of how they are conceived (Nickles 1980, Chap. 6). These developments drove a wedge between discovery and justification, culminating in the categorical distinction between scientific discovery and scientific justification by leading empiricist philosophers such as Hans Reichenbach (1891–1953) and Karl Popper (1902–1994) in the first half of the twentieth century. According to Reichenbach, the "context of discovery" is subject only to psychology, which deals with the processes of thinking as they actually occur. While any scientific theory consisting of a group of propositions can be justified by being in a correct logical relationship with observational statements, the discovery process was not amenable to this sort of "logic" for philosophers to seize upon. (Thus, there is a great irony in the English title of Karl Popper's masterpiece in the philosophy of science, *The Logic of Scientific Discovery*; there is no similar irony in the original German title, *Logik der Forschung*). Discovery is a subject of all kinds of empirical research, historical, sociological, and psychological. Epistemology is and should be confined to the "context of justification," in which the propositions produced in science are reformulated and rearranged so that their structures and logical relations are made explicit. Epistemology thus considers a rational reconstruction of scientific practice, rather than the actual practice of scientists. The "context distinction" between discovery and justification has exerted a deep influence on philosophers of science through the century (Nickles, Chap. 1).

The terms of debate began to change again, however, with the demise of the orthodoxy in Anglophone philosophy of science that was the legacy of the logical positivism of the Vienna Circle. For post-positivists such as Thomas Kuhn (1922–1996) and Paul Feyerabend (1924–1994), it is theories that give meaning to observations, not the other way around (Chalmers 1999, Chap. 8). Therefore, any truly novel discovery, even of facts, can take place only if it is directly tied to theoretical change. During a phase of "normal science," in which the ruling paradigm is not challenged, facts can pile up more or less cumulatively, and theories are improved only in a trivial way; hence, there is no philosophical problem about justification or discovery. But in the process of a scientific revolution, new theories and facts are discovered together because facts can only be assigned their meaning by underlying paradigmatic theories. Therefore, such discovery, according to Kuhn, is not a matter of a "Eureka" moment, but a difficult protracted process of adjustments of establishing paradigms and their relevant facts together that need to be agreed upon by a whole scientific community and then passed on to the next generation through laborious pedagogical efforts (Schickore and Steinle 2006, Chap. 7). Justification only happens through such processes of negotiation, in which Kuhn famously declared that there is no higher standard of judgment than the assent of the relevant scientific community. Kuhn's stance not only upset the traditional philosophers due to its anti-rationalistic implications even for the context of justification, but it also brought justification and discovery back together, this time in an untidy mix.

The emphasis on the social processes highlighted by Kuhn in his discussion on scientific discovery has been fully adopted and extended by social constructivists. Historians and sociologists of the constructivist bent have offered instructive case studies revealing diverse disagreements and complex negotiations among self-claimed discoverers and their allies or followers, and their political, social, and professional agendas with respect to the "authorization" of discovery. As shown in the classic case of the "rediscovery" of Mendel, scientific discovery in the social constructivist picture is a retrospective affair, a product of a discussion among relevant practitioners in a given discipline; a discovery as an achievement, its meaning, and its discoverer, it is argued, can only be retrospectively evaluated and acknowledged. In these social constructivist construals of scientific discoveries, the scientific realist commitment which implicitly underlay the traditional philosophical discussions has been explicitly problematized and severely attacked. There are various types of antirealists in this debate (Chalmers 1999, Chap. 15; Psillos and Curd 2008, Chap. 21): constructivists often draw on Kuhn's notion of incommensurability, while a majority of antirealist philosophers base their arguments on skepticism or agnosticism about unobservable entities, as in the philosophy of constructive empiricism advanced by Bas van Fraassen (1941–). What these antirealists have in common is that they do not take the notion of discovery for granted, as they reject the realist connotation implied in the term (if something has been "discovered," it must really exist). For them it is meaningless to distinguish sharply between discovery and construction, both being processes of finding a solution to a problem or contriving an empirically adequate theory to save the phenomena.

Discovery and Justification in Practice

With the long-lasting belief that there are some genuine methods for scientific justification (even if no simple logical algorithms), philosophers of science have principally explored its different strategies and procedures largely under the rubric of confirmation theory: inductivism, hypothetico-deductivism, Bayesianism, and value-laden comparative theory appraisal (Psillos and Curd, Chaps. 10, 11, 28, 31, 47). Yet, with the recent rise of a more practice-oriented view of science, it is now generally acknowledged that even justificatory practices are contingent on the context, not captured by either an ahistorical formalism with the belief in a pure observational language or a theory-dominated holism notoriously represented by Kuhn's notion of paradigms. This sensitivity to context leads us to ask in which epistemic situation a knowledge claim is justified and which method of justification can be intelligibly demanded of the knowledge claimant or rationally accepted by the relevant practitioners; this means accepting that an agent attempts to justify a scientific knowledge claim to her relevant epistemic community participating in specific epistemic activities with shared epistemic goals.

Notwithstanding the theory-ladenness of observation, for example, not all observations in practice are on a par. Some are more stabilized and robust in a relevant setting as is the case with middle-level regularities, being relatively independent of high-level theories and their changes, which could function tentatively as an empirical foundation to test and warrant a novel knowledge claim. Yet, these regularities can be made more elaborated and refined in terms of precision, scope, and the like through iterative processes. Moreover, there are various ways of testing a knowledge claim which are to be chosen by the actor depending on the relevant aims, resources, audiences, and even metaphysical values and principles. Even any plausible skepticism of induction could be avoided, for example, in a very well-controlled experimental setting which successfully removes as many extraneous non-observational hypotheses as possible. These, all in all, come down to a self-corrective and pluralistic attitude to scientific justification.

A shift of emphasis to scientific practice is more than welcome in relation to the study of scientific discovery, as traditional philosophical interest in the subject has been meager or just skeptical. Of course, it should be acknowledged that there has been considerable interest in "abduction," often equated with "inference to the best explanation," as a plausible "logic" of scientific discovery (Psillos and Curd, Chap. 18). There are even several automated discovery tools, as is well illustrated by statistical techniques and computer simulation programs to find out from given data abstract correlations or patterns or models, though it is still out of their reach to get at any deep theories or hypotheses. Yet, it would not be a surprise to see that existing philosophical frameworks are helpless when confronted with a sheer diversity of scientific discoveries in practice, given that typical philosophical discussions of scientific discovery pay exclusive attention on the discovery of theories. Therefore, it would be helpful to ask: What sorts of things do scientists discover in practice? A rough taxonomy should include theories and hypotheses, principles and laws, facts and phenomena, observable and unobservable entities, properties and processes, and the like. This again leads to another intriguing question: Are there different patterns in scientific discovery depending on what is discovered? For example, it is argued that discovering unobservable entities like electrons is inextricably interconnected with justifying their existence somehow. Here the complicated link between the contexts of discovery and justification comes up again (Schickore and Steinle, Chap. 12).

The discovery of unobservable entities illustrates that our understanding of scientific discovery would be enriched by a process model of scientific discovery. Anything that looks like a "Eureka" moment should be seen as a nodal point on a long research trajectory in ongoing interaction with the relevant research community; in this sense, the meaning of a discovery is often transformed as it is consolidated, often in ways that are not in accord with the original discoverer's own conception of it. The discovery of unobservables also links up with debates on scientific realism. Here, the descriptive task is to investigate the reason why the actors accept that something is "discovered," not "constructed" or "invented." Yet, normatively, the positions will be divided: entity realists would argue for the discovery of manipulable unobservables, whereas antirealists might recommend a skeptical or agnostic attitude toward them. One of the ways out of this impasse could be to ask again in which context the question of existence or truth is meaningful or useful. That is, we could investigate various ways of accessing reality manifested and developed in scientific practice and evaluate their ontological and epistemological implications.

Implications for Science Education

What does the discovery–justification distinction imply for science education? It seems that the distinction is implicitly but strongly present in ordinary educational settings: students are typically not taught about the process of discovery, though they are usually given some justifications for the theories they spend countless hours learning to apply. In fact they only tend to get told about discoveries if there are striking stories associated with them (e.g., Fleming's penicillin mold, Newton's apple, Kekulé's dream of snakes biting their own tails); these discovery stories are normally used to enhance the "human interest" in science, not especially to teach about real history or methodology.

One may question why we should want to teach students anything substantive about the processes of scientific discovery or justification. On the side of justification, at least many would agree that knowing how scientific justification works is indispensable for acquiring a proper critical appreciation of scientific knowledge; it is difficult to imagine how people lacking a sense of methods of justification can be competent to judge for themselves controversial issues such as policies concerning global warming, the risks associated with vaccination, or the legitimacy of including intelligent design in curricula. But how about discovery? For students who will go on to become research scientists, it is important that their habits and expectations do not become hampered by distorted or overly restrictive notions of how discovery works. Advocates of discovery learning, inquiry-based learning, and problem-based learning would go much farther to argue that going through one's own process of discovery is the best way to learn anything at all (see Schwab (1960) for an early exposition).

Context-Based Science Curriculum Projects

Since the early 1970s, several science courses have been developed which could be labelled "context-based." In some areas of the world, these courses are named Science-Technology-Society (STS). The aims of such courses are usually to make science more relevant to students by linking science to contexts in personal life, local and global situations, and/or practices in science and technology. The course developers expect that this approach is motivating for students due to its focus on familiarity and relevance. Furthermore it might help students to be able to apply scientific knowledge and skills in real-life situations, such as is expected in the OECD Frameworks for Scientific Literacy of the Programme for International Student Assessment (PISA).

In practice a large variety of approaches have been developed, from a short series of lessons to full curricula, with aims which range from simply motivating students to preparing them for decision-making or social action. In some cases materials are monodisciplinary, linking specific science concepts to contexts; in other cases units deal with complex socio-scientific issues (SSI) from areas such as health, climate, and environment. Some projects have remained local, while others have extended to whole countries or have even been adapted across the world.

Most context-based science teaching materials are aimed at students in the age group 12–18. Some efforts have also been made to develop teaching materials for primary and undergraduate education.

Independent research on the effects of the context-based approaches has been limited. Direct comparison of regular and context-based approaches is difficult as aims are partly overlapping and partly different. Available review findings indicate that context-based approaches tend to result in improvement of attitudes to science and to higher quality reasoning and reflective judgments; the understanding of scientific ideas developed seems comparable to that of conventional approaches.

Examples (in Chronological Order) of Context-Based Science Projects

PLON

The PLON project (Dutch acronym for Physics Curriculum Development Project) developed between 1972 and 1986 full, context-based courses (including student's textbooks, teacher's guides, technician's manuals, and even to some extent examination papers) for secondary physics education in three Dutch ability streams. The PLON curricula were context based in the sense that the students' "life world" was taken as a starting point, with an emphasis on technological artifacts and natural phenomena in junior secondary education (grades 8–9, age 13–14), supplemented with an emphasis on socio-scientific issues and the nature of science in senior secondary education (grades 10–12, age 15–17). The aims of physics education put forward by the PLON project have evolved over a number of years into a balance between preparing students, on the one hand, for further education and/or future employment and, on the other hand, for coping with their (future) life roles as a consumer and citizen. An effort was made to find a balance between these two aims by developing teaching/learning units in which basic physics concepts and skills – covering most of the traditional content areas in physics education such as kinematics, mechanics, energy, electricity and magnetism, optics, sound, and matter – are dealt with in a personal, social, or scientific context. Hence the PLON curricula aimed at "physics for all" and not just for future specialists.

IPN Curriculum Physik

In the 1970s, a new curriculum for German school physics (grades 8–10, age 13–15) was designed by the Institute for Science Education (IPN) in Kiel. One aim was to strengthen the link between physics content and students' natural and technological environment. In some modules physics was related to technologies such as bicycles, electric cars, and cameras. Other units dealt with noise pollution, nuclear power stations, automation, and alternative energies, taking into account problems discussed in society.

Science in Society

The Science in Society Project was set up in 1976 by the UK Association for Science Education (ASE). The purpose of this upper secondary school course was to give students (age 17–18) a better understanding of the place of science and technology in the modern world and an awareness of the importance of using them wisely to assure the future of mankind. The developers took this to require an appreciation of the nature of science and a better understanding of industry, involving aesthetic, philosophical, moral, and economic considerations as well as scientific ones. The course was divided into nine units: Health and Medicine, Population, Food and Agriculture, Facts, Energy, Mineral Resources, Industry in the Economy, Land and Water, and Looking to the Future. Much of the work in the course was divergent and required teaching methods that were different from those commonly used in science lessons. Examples are project work, searching out information, reporting to the class, industrial visits, watching films, and decision-making simulation exercises.

Science in a Social Context (SISCON) in Schools

A series of eight books was published in 1983 by the UK project SISCON-in-Schools, an offshoot of the university-level SISCON project. The books provided a course in science and society for general studies at upper secondary school level (age 17–18), specially designed to make scientific problems accessible to nonscientists, as well as explaining the social aspects of science to aspiring scientists. The eight titles were *Ways of Living; How can we be sure?; Technology, Invention and Industry; Evolution and the Human Population; The Atomic Bomb; Energy: The Power to Work; Health, Food and Population;* and *Space, Cosmology and Fiction.*

SATIS

The first Science & Technology in Society (SATIS) project was launched in the UK in 1984. The materials were intended to enrich and enhance the teaching of science and designed to be incorporated into existing science programs. They did not make up a complete course but were a varied set of resource materials, to be used in a flexible manner by teachers to meet their own needs. The units were written by teachers and validated by experts. They included innovative teaching and learning activities such as role play, case studies, and structured discussion. More than 100 SATIS units were published for students aged 14–16 years by the UK Association of Science Education (ASE). In 1987 the SATIS project extended its work to 16–19 year olds with the publication of 100 units, clustered into themes such as materials, energy, environment, health, and ethical issues. More emphasis was placed on guiding the study of students while expecting them to gather the necessary information as a basis for discussion and debate. From 1989 the project also produced some materials for younger students (age 8–14).

Salters Projects

The UK Salters projects (named after an important sponsor of the projects and based at York) started in 1983 with the development of five context-based chemistry units for 13-year-old students. Subsequently a series of courses was developed, covering biology, chemistry, and physics for the high school range (age 11–18) in England and Wales: Chemistry; the Salters Approach (14–16); Science: the Salters Approach (14–16); Salters Science Focus (11–14); Salters Advanced Chemistry (17–18); Salters Horners Advanced Physics (17–18); and Salters-Nuffield Advanced Biology (17–18). Many of these courses have been adapted for use in other countries. Common design criteria for all Salters courses are that they should enhance students' appreciation of how science (1) contributes to their lives or the lives of others around the world and (2) helps them to acquire a better understanding of the natural environment. So units start with aspects of the students' lives drawing on both direct personal experience and ideas encountered through the news media. They introduce scientific ideas and concepts only as they are needed for understanding of the contexts and applications being explored. Units again suggest a range of teaching and learning activities. All courses try to combine a foundation for future studies with providing a satisfying course for those who will take the study of science no further.

ChemCom

The US Chemistry in the Community (ChemCom) project in the 1980s developed a year-long course primarily for students (age 16) who do not plan to pursue careers in science. Its purpose was to help students (1) realize the important role that chemistry will play in their personal and professional lives, (2) use principles of chemistry to think more intelligently about current issues they will encounter that involve science and technology, (3) develop a lifelong awareness of the potential and limitations of science and technology. Each of the eight modules centres on a chemistry-related technological issue, and the setting of each module is a community: school, town, region, or the world. Topics addressed are water needs, conservation of resources, petroleum uses, foods, nuclear chemistry, air and environment, health, and chemical industry. The first (trial) edition was published in 1985 by the American Chemical Society.

Chemie im Kontext

Chemie im Kontext (ChiK) has, since 1997, been a cooperative project involving teams at the Universities of Dortmund, Oldenburg, and Wuppertal and the Leibniz Institute for Science Education (IPN) in Kiel. ChiK is in the tradition of ChemCom and Salters Advanced Chemistry yet distinct from either one. While ChemCom introduces a sequence of topics without much conceptual relationship between them, Salters follows a more stringent line of conceptual development. The approach of ChiK is between these two, using contexts that are not in particularly systematic sequence, yet using them to develop a coherent set of basic chemical concepts.

The core of the project is a conceptual framework for chemistry teaching in grades 8–13 (age 13–18) in the German system of general education. The program provides teachers with guidelines, examples, suggestions, and collections of material that they can adapt to their specific needs in their particular environment by constructing their own lessons within the given framework. After this original framework had been developed by the core group of science educators, a large-scale project was undertaken (funded by the German Federal Ministry of Education) to implement these ideas in classroom practice. Regional teams of teachers were established and accompanied and supported by members of the project staff. Alternating between individual work and group meetings, the teachers produced, tried out, and reflected on teaching units that were then made available to other groups of teachers for adaptation.

The nationwide discussion in Germany in the past decade about science education standards has led to widespread adoption of the notions of basic concepts and context-orientation in the curricula of several German states.

Cooperative Learning

Colette Murphy
Trinity College Dublin, Dublin, Ireland

Cooperative learning is a method of teaching and learning in which students work together in small groups to accomplish a common goal. The goal is reached through interdependent working, although students are also individually accountable for their work within the group. Cooperative learning can be used across a wide range of settings ranging from classroom to lecture, laboratory sessions, and online classes. There are five essential elements of cooperative learning:

- Positive interdependence – group members "sink or swim together"
- Face-to-face interaction – mutual support
- Individual accountability – individual contributions to the task are assessed
- Social skills – include trust-building, leadership, and decision-making
- Group self-evaluation – groups and their teacher reflect on the efficacy of the group

There are many claims from research that cooperative learning results in a higher level of student achievement, as well as social and economic benefits, than when students are engaged in competitive or individually based learning. Theories relating to how cooperative learning "works" suggest that the foundation for cooperative learning success may be explained by a combination of motivational, social cohesion, and cognitive theoretical perspectives. The most commonly reported strategy for developing cooperative learning activity in science classes is "jigsaw." In jigsaw, each group member is responsible for working on a specific task, for example, recording data. All "recorders" in the class are given specific instruction to become "expert recorders." Finally, groups carry out the activity with each member as "expert" in part of the task. Cooperative learning is distinguished from collaborative learning in that cooperative learning is highly teacher directed and more closed ended and has specific answers, whereas collaborative learning is characterized by student empowerment in working together on more open-ended, frequently complex tasks.

Introduction

Historically, science centers and science museums have emphasized cultural heritage through artifacts, collections, object displays, and curiosity cabinets – extolling the wonders of science to the public. Over time, however, exhibitions have evolved to include more hands-on components. Visitors interact with exhibits, by a combination of manipulating, reading, pushing, pulling, and generally using their senses. Information is typically structured through engaging, interactive displays.

A number of different typologies for mapping exhibitions have been proposed by researchers. For example, Wellington (1998) describes two types of exhibits (that are not mutually exclusive) usually found at the science center: experiential and pedagogical. The experiential exhibition allows the visitor to experience, and perhaps interact with, phenomena (e.g, soap bubbles, whirlwinds, water vortices, and air or water movements), while the pedagogical category actually sets out to teach something (e.g., positions of organs in the body, separation of dyes by chromatography, or reflection of light). These two types of exhibitions reflect a more dominant traditional way of (re)presenting science focusing on principles, phenomena, theories, and concepts. Little attention is paid to the status or generation of knowledge or the messiness of science – in other words, science is presented to the public as neutral, authoritative, and void of context. However, in recent years, informal science settings have witnessed increased attention to issues in science and technology and consequently have attempted to develop contemporary science and technology installations with all the social and political trappings of the day. This has led to the emergence of a third category – critical exhibitions (Pedretti 2002).

Critical Exhibitions

Critical exhibitions challenge politically safe, sterile, and authoritative images of science and technology usually encountered in science centers and museums. They acknowledge the tentativeness and purposefulness of knowledge creation and negotiation and view science as a human and social activity (i.e., they address nature of science (NOS) perspectives). For example, the exhibition *A Question of Truth* at the Ontario Science Centre is designed to examine several questions about the nature of science, how ideas are formed, and how cultural and political conditions affect the actions of individual scientists. The exhibition questions the nature of scientific truth and attempts to demonstrate how science is influenced by the cultural, personal, and political backgrounds of the practitioners, qualities that include bias, and points of view.

Most critical exhibitions are issues-based and explore complex relationships across science, technology, society, and environment (STSE), inviting visitors to consider issues from a variety of perspectives with an emphasis on involvement, activity, and ideas. These thought-provoking exhibitions are developed in an effort to represent science in context and to engage the public with issues (such as reproductive technologies, climate change, genetic engineering, and mining) that are important to our lives, to the environment, and to our well-being. For example, consider recent installations such as *Energy Tracker* presented at the Miami Science Museum in Florida that encourages the public to critically reflect on energy use and renewable sources. The Smithsonian Natural History Museum presents evidence for evolutionary theory in The David H. Koch Hall of *Human Origins: What Does It Mean To Be Human?* and von Hagens' travelling exhibition *Body Worlds* pushes boundaries using human cadavers to display issues related to health and well-being. Issues-based (or socio-scientific) exhibitions create possibilities for visitors to explore the intersections across science and society and to engage with the messiness of science that stems from social, political, ethical, and historical factors.

Critical exhibitions share common characteristics: they often cut across science, technology, society and environment (STSE), address nature of science perspectives (NOS), raise public awareness about issues, consider multiple points of view, personalize science, connect science and social responsibility, teach about participation and decision-making, encourage people to be active commentators on matters related to science and technology and to be agents of change, offer a forum for discussing and debating issues in society, provide more robust views of science, and encourage healthy public debate about controversial topics.

Courting Controversy

Critical exhibitions are usually controversial in nature due in part to their interdisciplinary subject matter and the coupling of science and ethics. Consider, for example, reproductive technologies, the use of stem cells, health-related research, space exploration, or evolution. Such issues are typically contentious, fraught with ambiguities, and subject to multiple perspectives. Individuals may interpret the same information differently, and reasoning based on science alone may not be enough to resolve the conflict. Controversial issues draw upon different players; stimulate analysis of the construction and deconstruction of facts and theories; draw attention to the social processes of science and how knowledge is negotiated and utilized; and involve struggles over meaning and morality, distribution of resources, and power and control (Delicado 2009; Macdonald 1998; Nelkin 1995). They often raise tensions between individual needs and community priorities. Controversial issues can spark intense and passionate responses from people and involve problems in which different individuals and groups support conflicting courses of action.

Future Directions

It is widely acknowledged that museums and science centers avoid controversial issues. They are difficult to mount, there is an underlying assumption that public institutions are in the business of transmitting science, issues can change quickly, and funding and patronage concerns arise. Future research agendas include questions such as the following: What kinds of exhibitions are appropriate for public consumption? What ethical concerns are raised? What tale(s) do we tell? Whose stories are silenced? What is the role of advocacy? What is the role of funding? How are different viewpoints presented? Furthermore, research should consider the forms of scientific communication that are most meaningful and valuable to the public and how critical exhibitions encourage and develop meaningful public engagement with complex socio-scientific issues.

Cross-Disciplinary Concepts and Principles in Science, Assessing Understanding of

Audrey B. Champagne
University at Albany, State University of New York, Albany, NY, USA

Assessing Cross-Disciplinary Ideas

Certain ideas expressed as principles or as concepts have explanatory power in all science disciplines. In the science education literature, these ideas are called cross-disciplinary concepts and principles, common themes, unifying concepts, and cross-cutting concepts. These ideas serve two functions, one as frameworks for structuring the science curriculum, the other as a facet of science students are expected to come to understand. The assessment challenge is how to describe these ideas in ways in which they can be measured. An example of a cross-disciplinary idea, expressed as a principle, that is applicable to all the natural sciences is as follows: In a closed system energy is conserved. This principle relates three concepts, system, energy, and conservation. These ideas can be assessed as a principle or separately as one of the three concepts.

Evidence of knowing cross-disciplinary ideas includes the capacity to provide examples of cross-disciplinary ideas or the capacity to select cross-disciplinary principles or concepts from lists of principles and concepts some of which are cross-disciplinary and some of which are not. Evidence of understanding cross-disciplinary concepts is provided by the capacity to illustrate by example how the principles or concepts apply to situations in contexts related to different disciplines. Understanding is also indicated by the capacity to distinguish cross-disciplinary principles or concepts from principles and concepts which are not cross-disciplinary. Examples of tasks to evoke responses to be evaluated are the following: What are three cross-disciplinary ideas? Give an example of an idea that is cross-disciplinary and one that is not. Then explain why one idea is cross-disciplinary and the other is not.

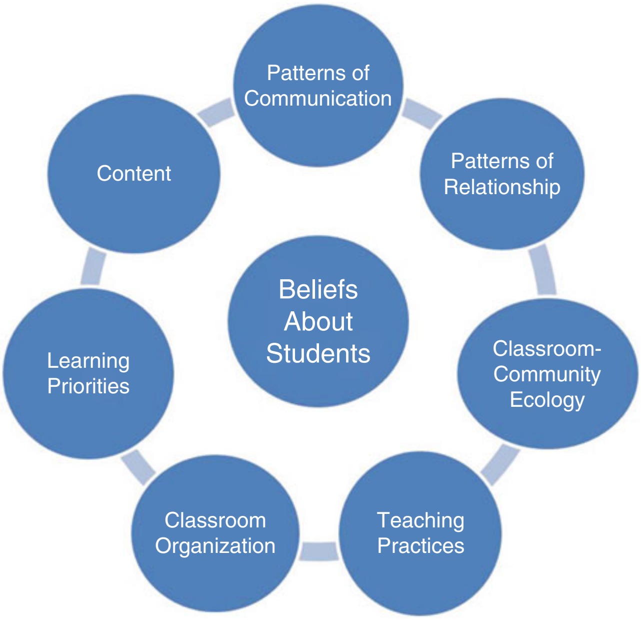
Culturally Responsive Teaching of Science in Canadian Indigenous Settings

Although the science education literature has given attention to the importance of recognizing Indigenous knowledge systems in school science, less attention has been given to the teaching practices that should accompany this knowledge system inclusion and the processes that might accelerate these changes to curricula, including teaching practice. More recent developments in Canada's three most northern territories, the Yukon Territory, Northwest Territories (NWT), and Nunavut, draw attention to how political changes have potential for accelerating practices in education, and science education, specifically, that are responsive to Indigenous people's cultural knowledge systems and practices. In contrast to other provincial jurisdictions in Canada, treaties were historically never negotiated in these northern territories. Over the past three decades, the governments of both Canada and these northern territories have moved toward actualizing policy developments with its Indigenous peoples. These policy developments are commonly referred to as Self-Government Agreements (SGAs). SGAs are complex and wide ranging and include financial compensation, land, harvesting rights, heritage resources, and governance structures in areas like education and justice. The SGAs set out the powers of the government to govern itself, its citizens, and its land.

In the Yukon, the SGAs provide self-governing First Nations (SGFNs) with law-making authority in specific areas of First Nation jurisdiction, including education. For example, the Tr'ondëk Hwëch'in SGA provides for program delivery, design, and implementation of education programs for the Tr'ondëk Hwëch'in First Nation in the Dawson City area with the support and sanction of the Yukon Territorial Government (YTG). With the establishment of SGFNs, each FN with the required cooperation of YTG faces the challenge of reversing assimilation and regaining a sense of identity especially within the processes that influence the education of their children. Typical of most Aboriginal peoples, YFNs presently participate in a school system that has been drawn from the dominant culture, in their case southern Canadian school system models. Because of this, school processes and practices such as decision making in regard to the content of curricula, pedagogical practices and language of instruction have both intentionally and unintentionally denied the inclusion of those aspects of [YFN] culture that have value and are important to [YFN] children (Bishop and Glynn 1999). Consistent with the tenor of SGAs to work toward education practice more responsive to the Yukon's 14 First Nations, "culture-based education" has been more recently identified by YTG and its Education Act as one of the foundational principles for school development in the Yukon. YTG policy requires the activities of organizations in Yukon communities to create, preserve, promote, and enhance their culture, including arts, heritage, and language classrooms. This policy is based upon the principle that culture in all its expression provides a foundation for learning and growth and that YTG should support individuals, organizations, and communities to promote, preserve, and enhance their culture (YTG 2005). The educational experiences should be reflected not only in the management and operation processes of the school but also in the curricula and programs implemented and pedagogies used in classrooms. Although culture-based education may be rhetorically premised as the foundation of northern classrooms, what would classroom environments and teacher practices look like that are, indeed, reflective of YFN students' preferences? From the formal and informal learning of experiences of YFN community members, what would culturally responsive teaching look like, especially in science education?

Over the past decade (2002–2012), we, as researchers, have participated in and continue to participate in several research and development projects in our northern territories that focus on (1) determining Indigenous communities aspirations for education, especially science education; (2) identifying teaching practices, especially in science education, that are responsive to the learning interests, styles, and interests of students and the communities they represent; (3) developing with community members science education resources consistent with these interests, styles, and aspirations; (4) upon implementation, determining the influence of these pedagogies on student learning; and (5) based upon these findings, developing a description of what effective



Cultural Change, Fig. 1 Pedagogical framework for informing culturally responsive teaching of science

Cultural Change, Table 1 Attributes of culturally responsive teachers of science

Category	Description
*What are **my beliefs about students**?*	Students are regarded as culturally located individuals having capacity to learn, like any other, and contribute to my and the entire class' learning. Students expect me to have high expectations for them as learners and as members of a community
*What do I emphasize as the **content** to be learned?*	The formal science curriculum becomes the vehicle for the development of personal attributes deemed as important. Learning is not abstract. It focuses on and is located in local context and connected to students' lives. Science ideas are embedded with contexts, enriched through "working to end" type projects involving tangible end products. Literacy and numeracy development are emphasized as we are learning science. Developing fluency in these areas is a priority. What is learned does not compromise on students' cultural background. Instead it uses this to engage students and support their learning
*What **patterns of relationship** contribute to learning?*	The teachers' role is to cause learning. Establishing a classroom environment that promotes learning is the priority. Manifest in the relationships is a priority on caring. Caring manifests itself in actions – it supports, expects, challenges, affirms and is responsive to each individual and their situation. To do this, classroom routines are very important. Expectations and learning goals are clearly communicated and upheld. There is little compromise on established priorities, especially in regard to learning. Families are on board with these priorities and support these priorities. There is opportunity for students to contribute to decision making. Classroom allows for student voice in establishing consensus, but such that they never compromise on learning
*In what ways does this **classroom ecologically represent the community**?*	The classroom is physically represented through a variety of cultural representations and artifacts. Most importantly local language and community members and their protocols are welcomed and encouraged to be expressed. Learning is promoted through the participation of community members. Much learning occurs outside of the classroom because the community is seen as a contributing resource for fostering learning
*When I am teaching **how do I teach, and what are my practices for causing learning?***	In teaching practice, modeling and demonstrating are common. Visual images are commonly used to inform especially as a pre-reading exercise. Repetition and focus on mastery are emphasized. Time provision is made to gain mastery and think things through. Students show learning in a variety of ways, not just in written form and are given feedback to support next steps in learning. Collaboration and reciprocation in learning are important. The teacher and students must involve each other in a student's learning. It is vital that students are receiving individual attention and are given feedback and affirmation as they learn. Story telling and the use of narratives focusing on local context are frequent. Connections always made between prior learning and new learning across curriculum areas
*How can **classroom organization** say about how we learn and what is important in learning?*	Classroom routines are very important. Expectations are clearly communicated. There is opportunity for negotiation and renegotiation, especially because we are a community of individuals. Organization provides time, opportunity, and support for students to learn and show learning. Working for learning allows for assistance and feedback from peers

(*continued*)

Cultural Change, Table 1 (continued)

Category	Description
What should be the ***patterns of communication*** *when teaching and learning is occurring*	The communication patterns are dialogical rather than univocal, voluntary rather than involuntary. Listening is as important as talking. Sharing circles are a common practice to provide each student time and space to contribute, without interruption. As a teacher, I undertalk more commonly than I overtalk. When I talk with students individually or collectively, I physically situate myself at their level. Students communicate their learning through a variety of modes, not just in writing. The communication patterns are encouraged by a learning environment that focuses on learning as a collective activity
What are the ***learning priorities****?*	Focus is on the development of individuals who believe in themselves as culturally located individuals that are self-reliant, resilient, and contributors to their classroom and community. Although academic knowledge is important, the learning must be broader focusing on the development of life tools such as perseverance and self- sufficiency as well as interdependence and respect. Fundamental literacy and numeracy skills are regarded highly

teaching looks like within our northern schools (Lewthwaite and McMillan 2009; Lewthwaite and Renaud 2009; Lewthwaite and Wood 2009; Lewthwaite et al. 2010). Likely of most consequence from these studies is the understanding of what a culture-based teaching entails.

In Fig. 1 below, we illustrate the various factors that consistently surface as indicators of effective teaching practice in influencing positively student learning. At the center of the visualization are “beliefs about students.” In our experience with effective teachers in Indigenous settings, central to being a responsive teacher of science is a belief in the capability and cultural merits of each student. At the heart of many school systems’ thinking is a belief or, at least, an assumption that Western ways are superior and that Aboriginal culture and specifically students may bring deficits to classrooms, not assets. Such thinking suggests that not only are students’ background experience and knowledge of limited importance to promote learning, but so are their cultural foundations. Deficit thinking or theorizing, as it is called, is the notion that students, particularly low-income, minority students, fail in school because they and their families experience deficiencies such as limited intelligence or behaviors that obstruct learning. In contrast, those that effectively implement a culturally responsive pedagogy believe that students have a whole set of beliefs, skills, and understandings formed from their experience in their world and that their role as teachers is not to ignore or replace these understandings and skills, but to recognize and affirm them.

In Table 1 some more detailed insight into how teacher’s practice can be responsive to students’ cultural backgrounds. The table makes explicit the behaviors we commonly evidence in effective teachers. In brief, the actions of teachers are primarily focused on ensuring that their actions are *reflective* of students’ backgrounds.

At the heart of these effective practices is teachers of science accepting that they are the central players in fostering change, first in themselves by altering their beliefs about students and the cultures they represent and, then, working collaboratively toward an environment where practices reflect the culture in which students and their teaching practices assist students in their learning.

Cultural Imperialism

Derek Hodson
School of Curriculum and Pedagogy, Faculty of Education, The University of Auckland,
Auckland, New Zealand

Keywords

Science Education in the Non-West

While *imperialism* refers to the establishment and maintenance of unequal relationships between countries or societies through conquest and political power, the term *cultural imperialism* is used to identify a form of ideological infiltration that enables some dominant states, organizations, or groups to impose their worldview, values, attitudes, behaviors, linguistic patterns, and lifestyle practices on others, sometimes by deliberate policy, sometimes by means of economic or technological superiority and influence. The term came to prominence in the 1970s through the work of Herbert Schiller (1976) who used it to describe the ways in which multinational companies and the mass media seduce, persuade, force, bully, or bribe social institutions and individuals to act in conformity with, or even to promote, the dominant ideology. Use of the term by scholars in history, philosophy, sociology, anthropology, education, and cultural studies is strongly influenced by the writing of post-structuralists such as Michel Foucault and Jacques Derrida, while in postcolonial discourse it is used to identify and define the cultural legacy of colonialism through forms of social action and organization, language use, and value judgements that contribute to the continuation of western hegemony long after independence.

Whatever the precise definition of cultural imperialism employed, it is apparent that education plays a key role in the establishment, maintenance, and legitimization of the views, beliefs, values, and practices of the dominant group. It does so through two interacting influences: *curriculum experiences*, what students encounter during lessons, and *informal learning experiences*, what is learned via the media (movies, TV and radio, newspapers), Internet sites, advertising, and visits to museums, zoos, aquaria, nature reserves, field centers, and the like. Curriculum experiences are of two kinds: those that are explicitly planned and those that are not. With regard to science education, there are many explicit messages about science, scientists, and scientific practice in textbooks, especially in passages that tell students what science is about and what scientists do when they are conducting investigations; there are explicit references to the nature of science and the history of science in curriculum materials designed for a science-technology-society (STS) approach, and there are references to cutting-edge science and the ethical issues it raises in curriculum materials addressing socioscientific issues (SSI). Teachers often draw explicit attention to features of science and scientific inquiry during laboratory activities and class discussions. Just as frequently, however, messages about the nature of science and scientific practice are not consciously planned by the teacher. Rather, they are implicit messages located in the language used, the kind of teaching and learning activities employed (especially in laboratory work), the examples of science and scientists utilized, the illustrative and biographical material in textbooks, and so on. Many students assume that whatever they do in science lessons, particularly during hands-on activities, mirrors what scientists themselves do as they conduct investigations. Over time, these experiences build into a particular set of messages about science, scientists, and the scientific enterprise. What is at issue here is a very powerful *hidden* or implicit curriculum that conveys messages just as powerful as those of the formal, planned curriculum.

Curriculum decisions (whether consciously or unconsciously made) necessarily reflect the perspectives of the decision-makers. Hence the selection of knowledge for the science curriculum does not reflect a common heritage but one rooted in the knowledge, assumptions, and values of those who have dominated society and educational discourse – in Western society, mostly white, male, and middle class. Further, because many of the individual messages about science are conveyed implicitly via teachers' day-to-day, short-term decisions about the conduct of lessons, the teacher's views constitute a major element of the overall story about science. In many cases, these views are located within a Western tradition, often a positivist tradition that regards science as having an all-purpose, straightforward, and reliable method of ascertaining the truth about the universe, with the certainty of scientific knowledge being located in objective observation, extensive data collection, and experimental verification. Moreover, scientists are seen as rational, logical, open-minded, and intellectually honest people who are required, by their commitment to the scientific enterprise, to adopt a disinterested, value-free, and analytical stance, in conformity with the norms of scientific practice postulated by Robert Merton (1973): universalism, communality, disinterestedness, and organized skepticism.

In making decisions about what to include or exclude from the curriculum, we not only define and limit what counts as science, we erect potential barriers that restrict access or make access to science and science education difficult. It is here that the notion of cultural imperialism can be helpful in focusing attention on the subtext of science education – in particular, on the exclusion of knowledge about the natural world accumulated outside of conventional Western science (variously described as traditional knowledge, Aboriginal knowledge, Indigenous knowledge, and traditional environmental or ecological knowledge); the neglect of ideas drawn from contemporary philosophy of science, history of science, and sociology of science; and the disregard of the perspectives of practicing scientists and the insight provided by commentators on the sometimes harsh realities of contemporary scientific practice – what John Ziman (2000) calls "post-academic science." The notion also raises awareness of the ways in which traditional knowledge and practices in many colonized countries were forcibly replaced by Western science and Western agricultural practices, often with untold damage to local ecosystems and destruction of the social fabric.

Acknowledgement of the role of cultural influences on science education is a relatively recent development, initiated in part by anthropological and sociological explorations of how specific contexts influence teaching and learning. Kenneth Tobin (2006) has written of science education experiencing a "cultural turn" as science education and discourse researchers begin to acknowledge and explore the influence of culture on science education, increasingly scrutinizing and critiquing universal notions of science practices and knowledge production. As a construct, culture owes its existence to the field of anthropology. Other fields, like education, with interests in the production of ideas, processes, and material social practices, have found the construct of culture to be useful for their purposes also.

What Is Culture? Models of Culture

At an abstract level, culture can be thought of as a theoretical category of social life that can be differentiated from other categories of similar stature such as politics, economy, and history (Sewell 1999). Typically, when we talk of culture, we are seeking to differentiate between different groups, identifying bounded entities of beliefs, practices, and ways of knowing as different cultures. Research that initially sought to explore cultural influences on science education was influenced by Clifford Geertz's (1973) notion of cultures as clearly bounded, consensual, and resistant to change. This model supported productive research in science education on student negotiation of "border crossings" between students' lifeworld culture and the culture of science leading Aikenhead to argue that treating science as a cultural enterprise constituted a radical shift in thinking for some science educators (see Aikenhead 1996).

But studies from history and sociology of science and from science education research have challenged this model of culture, leading researchers instead to endorse cultures as fields of material social practice and worlds of meaning that internally are contradictory, contested, subject to constant change, and weakly bounded (see Sewell 1999). The power of this model is that it allows researchers to acknowledge and value contradictions as well as coherences in data of human action, such as that collected from working with learners and teachers in classrooms, rather than try to explain away the contradictions that inevitably exist in all data sources.

Science Education, Cultural Reproduction

Historically, the goal of science education was twofold. First, all students would be assimilated into the culture of science through practice and assessment, a desirable end because of the superiority of science as a way of knowing and being. Second, through education, students would come to adopt and reproduce this superior form of knowing and being, including the norms, values and practices, and acceptance of what is real according to science (Aikenhead 1996). A cultural evaluation of these goals indicates that schooling has a role in ensuring that one vision of what constitutes scientific knowledge and practice is reproduced. However, challenges for this vision emerge in the differences between the everyday culture that students experience, in which they are experts, and the culture of science they are expected to reproduce throughout their educational experience in a school. A nuanced understanding of culture suggests, even more strongly, that the practice of assimilation exerts violence on students who come to science with different understandings. This construction of culture may help researchers to understand why so many students present negative perceptions of science or do not see science as part of their lifeworld and so do not choose to persist in science. Teachers may experience similar cultural disconnectedness from science; Carter (2008) uses the metaphor of science as a cultural story in order to allow beginning primary (elementary) teachers to identify a starting place for themselves in science.

Science as Culture and the Nature of Science

According to Sewell (1999), because cultures are contradictory, contested, and weakly bounded, the powerful (e.g., white, middle class, male in Western cultures) use power, not to establish uniformity, but to organize difference by identifying what is normal or accepted for a culture and marginalizing those that diverge from the norm. Such practices create a map of culture and difference, which tells people where they belong and what fits. However, because cultures are weakly bounded, loosely integrated, and contradictory, their borders are fuzzy and friable, and science education illustrates this issue very well.

What Is Science? In science education, one of the obvious questions that educators are often asked to explore is “What is the boundary of science”; in other words, “What is science and what is non-science?” While some science education researchers may present this boundary as objective and definite, implying that identifying science from nonscience is straightforward, a cultural perspective serves to help us identify the porousness of even this most strongly held belief about this boundary (see Pedynowski 2003). Additionally, cultural perspectives lead researchers and educators to accept that internally, science is heterogeneous and not homogenous as it is often presented in science education resources and in schools. One implication of accepting the porosity of this boundary and the heterogeneousness of the model of what constitutes science is accepting that there is an equally valid place in science for both the observational studies of geological sciences and the explanatory studies of particle physics. Studies within a specific science field also highlight that scientific work is nationally variable (see Fujimura 2000), not universally homogenous.

Traditionally, the development of scientific understanding has been presented as universal; immune to the culture, ethnicity, gender, race, sexual orientation, or religion of the knower; and dependent only on the restrictions of the natural world. However, cultural perspectives reject universal essentialist claims of scientific knowledge, recognizing that the practices, norms, and products of scientific inquiry vary across time and fields (disciplines) and encourage pluralist claims associated with the nature of science. Pluralist models of science education accept that all forms of knowledge exist in a cultural context, so the knowledge must be imbued with the values that are espoused by a culture. A willingness to accept the value-laden nature of knowledge construction is one of the first steps towards developing a richer understanding of a discipline, like science. These perspectives are illustrative of ongoing debates in science education between proponents of pluralist and universalist models of science education and the role of indigenous knowledge in science education (see McKinley 2005)

Beyond Concepts. The notion of culture as material social practices leads researchers to recognize the role of historical context in the development of these practices and associated meanings. For example, in my exploration of the history of understanding the relationship between boiling point and pressure, shows that the development of the thermometer (material practice) was just as important as the conceptual development of an understanding of air pressure and boiling point (social practice) (Milne 2013). Without a way to measure temperature, the conceptual questions could not even be framed. Cultural sensitivity of social practice also leads researchers to acknowledge their cultural stance with respect to the field they are seeking to explore. For example, researchers developing a survey instrument or identifying questions they wish to ask research participants in an interview will always explain in their writings how their understandings, positions, and biases with respect to the concept or construct they wanted to investigate informed and influenced the questions they asked the participants. Typically, this is the practice most ignored by researchers without a cultural perspective.

Belonging to a Culture and Otherness: Categorizing Identity

One other area where culture has influenced science education is in helping us to understand the interaction between individuals and culture in terms of how individuals construct themselves or are constructed; that is their identity. Individual and group identities are culturally and socially constructed around categories such as ethnicity, gender, race, sexual orientation, religion, and occupation, and individual people are categorized in various ways. Identity can be thought of as an objective sense of oneself, which individuals present to others for confirmation. Categories, such as white, Asian, woman, and brainy, can also be inscribed on people as an identifier of belonging to a particular group whether or not they wish to be so categorized. An individual's identity is strongly connected to the cultural production (learning) she has experienced which can be disturbed if someone experiences a culture very different to that with which they are familiar and which they can experience as a form of "culture shock" (see Michie 2011). With greater cultural awareness, researchers and educators are more open to exploring how cultural categories, such as race and gender, are embedded in presentations of scientific knowledge. For example, Bazzul and Sykes (2011) examined heteronormative representations of gender in a biology textbook used with high school students raising the question of why such textbooks represent the constructs of sex and gender as identical and exclusively about men and women to such a vulnerable population.

Generalizing and Otherness. Cultural influences also induce researchers and educators to cast a critical eye on attempts to generalize behavior to a small set of principles. While we can celebrate Galileo's use of idealization to propose the existence of gravity or Piaget's attempt to find universal structures in learning and behavior, cultural perspectives support us to recognize that with this focus on sameness, we lose sight of difference. In many cases, difference becomes identified as otherness. A cultural perspective may prompt researchers to examine critically a catchphrase like, "Science for All," asking, "Whose science? Who is left out?"

Summing Up

This short entry provides just an inkling of how culture influences science education. But hopefully it has communicated how any exploration of cultural influences from coherence and contradictions to identity and instruments offers the potential for a richer, more nuanced understanding of some of the elements that could serve to develop a more humane and inclusive science education. An understanding of cultural influences reinforces the notion that we have a responsibility to look with a critical eye, locally and globally, at how science education and science construct and use knowledge. We must examine not only who is included and marginalized through our stances, but how science education can better support the science learning of all children and youth. Finally, cultural influences support educators to answer one of the most important questions in science education, How does education support learners to see a role for science in their individual identities?

South Africa

Cultural Values and Science Education

Culture is the cumulated experiences of a people group which shape their behavior and overall worldview. Cultural values are attributes that a people group considers to be critical to its survival. Science is a systematic endeavor which attempts to describe, explain, predict, and control nature. Science education is the field of study expressly concerned with two important goals: (1) the development of potential scientific human power and (2) the development of a scientifically (and technologically) literate society. In a world dominated by science and technology, the development of a scientifically literate citizenry is imperative. But in the pursuit of scientific literacy, it is worth noting that certain cultural values differ remarkably from those of science. Also, not all cultural values are associated with science, i.e., there are cultural values which strictly speaking are outside the realm of science. At times, science education must make connections between science and broader cultural values. A contest of values between science and culture serves neither the interests of the students, their communities, nor those of the scientific community.

Culturally-Relevant Pedagogy

Deborah Tippins, Heather Rudolph and
Shannon Dubois
Department of Mathematics and Science
Education, University of Georgia, Athens,
GA, USA

Keywords

Border crossing; Discourse; Funds of knowledge; Hybridity; Third space

A hallmark of science education near the end of the twentieth century was the recognition of the importance of culturally relevant pedagogy (CRP), a term first coined in 1995 by Gloria Ladson-Billings. Since the initial introduction of this concept, a deeper understanding of CRP has evolved through a variety of discourses, particularly in relation to its application in science education. Each of these discourses in some way reflects aspects of Ladson-Billings' (1995) criteria for culturally relevant pedagogy: (1) high expectations for all students to experience success, (2) the development or maintenance of cultural competence, and (3) the construction of a critical consciousness or critical literacy which fosters an analysis of the hidden forces of power which shape our logic, anesthetize our ethics, and even define what we call a problem. In today's twenty-first-century science classrooms, science educators must continue to employ sociocultural consciousness, which draws inspiration from and builds curricula around ways of seeing beyond our differences. Rather than melting difference to make us all the same, we must celebrate the backgrounds of students and make them equally valid in order to provide all learners with the opportunity to experience scientific success.

CRP is especially important considering the increasing diversity due to the mobility of today's world population. Students and families are much more transnational now than ever before due to increased air transportation and Internet. As Carter (2012) points out, our "everyday consciousness is now one of a global imagery, making us feel connected to far-flung places and events" (p. 899). As the world's population mobility continues to escalate, it is likely these changes will endure and increase the diversity in student populations. Thus, it is important to recognize that various conceptualizations or discourses surrounding CRP have, in recent years, been embedded in a larger macro-discourse, the complex sociopolitical-economic context of globalization. An alternative to this is a discourse of "glocalization," whereby a dialectical relationship between local and global practices creates opportunities for a more pluralistic science education.

CRP is an idea which merges conceptions of culture, relevance, and pedagogy in unique ways. From a sociocultural perspective, culture can be viewed as very fluid, lacking coherent boundaries, and ever changing. It is enacted or produced through agency, in which actors, both individually and collectively, consciously appropriate structures in ways that are goal oriented and intentioned. Culture is also created passively in ways that may be aligned to specific goals such that "an actor is aware of culture being created over which she/he does not have complete control" (Tobin 2012, p. 5). In this sense, culture can be depicted as a continuous dialectical relationship between agency and passivity. In contrast to mythical, romantic, and stable myths, pedagogy that is culturally relevant constantly asks the question of whose science and for what purposes are students learning. Pedagogy, often described as the art of teaching, involves the skills, mindsets, beliefs, and knowledge an individual constructs in order to teach subjects such as science. Taken together, CRP emerges as a concept historically described and sometimes used interchangeably with "culturally congruent" and "culturally responsive teaching." It has been compared to a bridge connecting home and school cultures and described as teaching that aims to create democratic and multicultural classrooms that empower students. However, CRP takes on new meaning in light of sociocultural perspectives on science teaching and learning.

In the context of science education, CRP can be viewed through the lens of various discourses, which develop our ability to see from multiple frames of reference. The complexity, integration, and overlap of these various discourses can help us discern further insight into some of the limitations of earlier conceptions of the term. Furthermore, these discourses are beneficial because they represent the ways people have discussed CRP and show how a deeper understanding of how it has evolved in science education.

One of the most often discussed discourses promoting CRP in science education is the notion of "border crossing." This discourse suggests that when students' life experiences differ from the culture of school science, they may feel alienated by science if no attempt is made by the teacher to understand and incorporate their cultures into the science classroom. Non-mainstream students may feel this even more strongly if the examples and topics presented in school are irrelevant to their lived experiences. This discourse further emphasizes the need for educators to use culturally relevant methods and topics to present material in ways that build on students' prior knowledges and experiences, making connections between the known and the unknown. Historically, the concept of border crossing was viewed as unidirectional (i.e., students crossing into school or western science). More recently, Aikenhead (2006) has emphasized the need for science education researchers to view border crossing as occurring in two directions: both into and out of school science. He suggests that Aboriginal peoples, for example, have certain indigenous knowledges that can and should be central to science learning. The discourse of border crossing argues that it is important to change the structures of schools to acknowledge the culture of students.

Another common discourse used in discussing and fostering CRP centers around the idea of community funds of knowledge. Funds of knowledge are the experiences, values, identities, and feelings that comprise a child's life. From the perspective of this discourse, student learning and interest can be maximized when educators build on the funds of knowledge of the learner and his or her community. By building on prior knowledge, language, traditions, ways of knowing, and place-based narratives, important connections can be made between students' everyday lives and science. For example, in many rural areas with a strong sense of community, intergenerational knowledge is passed down and this knowledge includes nutritional choices and values. Students could develop nutritional literacies, by investigating dietary lifestyles of members of the community. In this way, we can build curricula and our ways of seeing by drawing inspiration from individual and community funds of knowledge.

CRP can also be encouraged through a discourse centered around creating a practicing culture of science learners. A practicing culture of science learners is a community of people who are learning about science as they do science in ways that mirror the practice of scientists. A community garden, for example, is a place where students can learn about plant biology by producing science as their garden grows. The garden is a context in which students can come together with local people and share in making decisions about their everyday lives and natural environments. Local people are at the heart of a practicing culture of science learners. Students can practice science outside the classroom and learn by doing, even when new information and experiences may be at odds with students' existing understandings. A community garden grown in an urban setting might feel very foreign to students initially, but by growing some of their favorite foods and sharing with their families and friends, it could become familiar and foster a genuine interest in science.

CRP discourse has also taken a critical stance. It has challenged science educators to think critically about how knowledge can be used to educate students and make social changes rather than fuel social reproduction. This is an idea similar to what Ladson-Billings (1995) described as the critical consciousness tenant of CRP which encourages students to learn to critique and interrupt current and historical social inequities. Critical discussions can encourage and empower students to think individually and not just take for granted mainstream science ideology. Consider, for example, an ecology class in an urban setting where students might read about factories polluting the air of the neighboring countryside where their food is grown. Students could conduct research to become informed about this socio-scientific issue, use this information to make decisions about the health of their community, and take appropriate actions. The challenge is to apply examples in textbooks and other resources to something students might have experienced and give them the tools to make a difference in their lives and those of community members.

More recent discourses surrounding CRP are centered on notions of third space and hybridity. Third space involves the intersections between students' home-community culture and school culture. It is the arbitrary area where culturally relevant teaching connects students' life worlds. Third space is not just accomplished by building bridges between differing cultures, but by using what has been learned about the past and present to facilitate change. For example, Paris (2012) notes that children of migrant farm workers can learn about their culture, where their families came from, where they are now, and the possibilities for their futures. In this way, students join their homes and communities with schools in meaningful ways without devaluing their history and cultures.

Whereas third space is about locating the knowledge in an area, the concept of hybridity is about creating a new type of knowledge. This new knowledge is made by blending students' home culture with the culture of school science and results in a hybridized culture that emphasizes heterogeneity. The additional twist of hybridity, compared to third space, is that students must also come to know and understand the culture of the teacher. In this way, the classroom and participants are constantly embracing multiculturalism. To assist in the cultural blending process, culturally relevant examples are especially important. For example, traditional ecological knowledge (TEK) can be incorporated into science classrooms to facilitate hybridity for all learners. Both teachers and students would simultaneously expand their knowledge on various cultural systems and ecologies.

Moving beyond CRP is the next logical step in thinking about the kind of science education that will be meaningful to the twenty-first-century youth. Science educators are making a point of including relevant material in their classes, but the question "Relevant to what?" continues to be raised. Relevancy as curriculum-centered science and relevancy as community-based science are two concepts proposed as a next step. Curriculum-centered science involves input from various local educational and community sources in developing applicable materials and approaches to teaching science. In this case, the curriculum would be built from the bottom-up using local educational and community sources, instead of top-down from state or national standards. Community-based science changes the curriculum and connects it to the community where students live. It involves meeting students' families, learning about their home life, investigating issues within the community, and developing what is taught from what has been observed and suggested from community members.

Questions have been raised about the implications of CRP for the twenty-first-century learners. Is emphasizing high expectations, cultural competence, and critical consciousness enough to promote CRP and establish sociocultural consciousness and caring? While it is necessary for students to experience a diversity of curriculum materials and pedagogies reflecting a range of ideologies, educators must be cognizant to transcend "tip of the iceberg" conceptions of culture. Many times, curriculum materials and pedagogies are designated as culturally relevant because they include dress, folk dancing, cooking, or music from a variety of cultures. However, while these surface conceptions of culture may promote cultural awareness, they might actually lead to more ridicule and stereotyping of certain students. Besides being relevant and responsive, curriculum and pedagogies should be culturally sustaining. Culturally sustaining pedagogies, such as encouraging the use of student's first language as they communicate amongst themselves during a lab session, will perpetuate and support cultural pluralism. The discourses and educational frameworks that shape our understandings of CRP should be constantly challenged, amended, and extended by "testing out" their theoretical soundness through diverse research methodologies. As demographics change, science education must also evolve to include culturally relevant pedagogies and curriculum that will promote and enhance science achievement for the twenty-first-century learners.

Culture

This entry seeks to summarize our understanding of the processes of science learning that occur within and at the intersection of diverse worldviews and knowledge systems, drawing upon experiences of various indigenous societies. The curricula, teaching methodologies, and assessment strategies associated with mainstream schooling are based on a worldview that does not adequately recognize or appreciate indigenous notions of an interdependent universe and the importance of place in their societies (Kawagley 2006). Many indigenous as well as nonindigenous people have begun to recognize the limitations of a monocultural education system, and new approaches have begun to emerge that are contributing to our understanding of the relationship between indigenous ways of knowing and those associated with western society and formal education. Our challenge is to devise a system of education for all people that respects the epistemological and pedagogical foundations provided by both indigenous and western cultural traditions.

While western science and education tend to emphasize compartmentalized knowledge which is often decontextualized and taught in the detached setting of a classroom or laboratory, indigenous people have traditionally acquired their knowledge through direct experience in the natural world. For them, the particulars come to be understood in relation to the whole, and the "laws" are continually tested in the context of everyday survival (Cajete 2000). Western thought also differs from indigenous thought in its notion of competency. In western terms, competency is often assessed based on predetermined ideas of what a person should know, which is then measured indirectly through various forms of "objective" tests. Such an approach does not address whether the person is actually capable of putting that knowledge into practice. In the traditional native sense, competency has an unequivocal relationship to survival or extinction – if you fail as a caribou hunter, your whole family may be in jeopardy. You either have it, or you don't, and it is tested in a real-world context.

Indigenous people do a form of "science" when they are involved in the annual cycle of subsistence activities. For a student imbued with an indigenous, experientially grounded, holistic worldview, typical approaches to schooling can present an impediment to learning, to the extent that they focus on compartmentalized knowledge with little regard for how academic subjects relate to one another or to the surrounding universe.

To bring significance to learning in indigenous settings, the explanations of natural phenomena are best understood by students if they are cast first in indigenous terms to which they can relate and then explained in western terms (Aikenhead 2001). For example, when choosing an eddy along the river for placing a fishing net, it can be explained initially in the indigenous way of understanding, pointing out the currents, the movement of debris and sediment in the water, the likely path of the fish, the condition of the river bank, upstream conditions affecting water levels, the impact of passing boats, etc. Once the students understand the significance of the knowledge being presented, it can then be explained in western terms, such as flow, velocity, resistance, turbidity, sonar readings, tide tables, etc., to illustrate how the modern explanation adds to the traditional understanding (and vice versa). All learning can start with what the student and community already know and have experienced in everyday life. The indigenous student (as with most students) will then become more motivated to learn when the subject matter is based on something useful and suitable to the livelihood of the community and is presented in a way that reflects a familiar worldview (Kawagley 2006).

There is a growing awareness of the depth and breadth of knowledge that is extant in many indigenous societies and its potential value in addressing issues of contemporary significance, including the adaptive processes associated with learning and knowledge construction (Battiste 2002). The new sciences of chaos and complexity and the study of nonlinear dynamic systems have helped western scientists to also recognize order in phenomena that were previously considered chaotic and random. These patterns reveal new sets of relationships which point to the essential balances and diversity that help nature to thrive. Indigenous people have long recognized these interdependencies and have sought to maintain harmony with all of life. With fractal geometry, holographic images, and the sciences of chaos and complexity, the western thought-world has begun to focus more attention on relationships, as its proponents recognize the interconnectedness in all elements of the world around us. Thus there is a growing appreciation of the complementarity that exists between what were previously considered two disparate and irreconcilable systems of thought (Kawagley and Barnhardt 1999).

The incongruities between western institutional structures and practices and indigenous cultural forms are not easy to reconcile. The complexities that come into play when two fundamentally different worldviews converge present a formidable challenge. The specialization, standardization, compartmentalization, and systematization that are inherent features of most western bureaucratic forms of organization are often in direct conflict with social structures and practices in indigenous societies, which tend toward collective decision-making, extended kinship structures, ascribed authority vested in elders, flexible notions of time, and traditions of informality in everyday affairs (Barnhardt and Kawagley 2008). It is little wonder then that formal education structures, which often epitomize western bureaucratic forms, have been found wanting in addressing the educational needs of traditional societies.

When engaging in the kind of comparative analysis of different worldviews outlined above, any generalizations should be recognized as indicative and not definitive, since indigenous knowledge systems are diverse themselves and are constantly adapting and changing in response to new conditions. The qualities identified for both indigenous and western knowledge systems represent tendencies rather than fixed traits and thus must be used cautiously to avoid overgeneralization (Gutierrez and Rogoff 2003). At the same time, it is the diversity and dynamics of indigenous societies that enrich our efforts as we seek avenues to integrate indigenous knowledge systems in a complementary way with the system of education we call schooling.

Aims; Assessment; Attained; Intended; Policy; Laboratory; Subjects; Taught; Teaching; Theoretic

The word “curriculum” referred originally to the track around which Greek and Roman chariots raced, but its first educational use was at the University of Glasgow in 1824 to refer to the course of study followed by undergraduates. While the word has been defined in a variety of ways, it is almost always associated with formal education (i.e., schools, colleges, and universities) and refers to the content of a student’s educational program. The term is used throughout the English-speaking world, but, despite its Latin origin, it is not commonly found as a cognate in other European languages.

The curriculum, both the overall curriculum and the curriculum of any specific subject, such as the science curriculum, expresses the purposes, goals, or *aims* for education. While informal learning (such as that taking place in play) can be random and aimless, formal education in schools always has aims or purposes that permeate instruction, and these are usually stated in curriculum documents. In addition, the curriculum also has subject-matter *content*. An overall curriculum can consist of any number of subject fields (or they can be integrated), and within each one there are usually topics or themes to be taught at each year or group of years. A curriculum may also contain statements about the processes of teaching and learning, and these are often a logical consequence of the curriculum aims. For example, a curriculum could have, as one of its aims, that students will develop the skills of investigation. Such an aim would imply that the teaching of the subject-matter topics would include providing opportunities for pupils to undertake investigations into those topics. Finally, a curriculum may contain explicit or implicit statements about the assessment that should be carried out in relation to both the aims and content.

But a curriculum is much more than a static statement or document. The curriculum that an individual student actually experiences is the result of decisions made at various levels, some far removed from the classroom. In many jurisdictions, some of these decisions are taken at the government level, where Ministries or Departments of Education set out curriculum policies relating to schools under their control. These may outline, for example, the subjects that students should study at each level of schooling; they may include more detailed lists of topics to be taught at each year or grade; and they may also specify textbooks or published courses that teachers must follow. All such policies exemplify what is called the *intended* curriculum. Regional or local school authorities below those of the national government, examination boards, and even schools themselves may also issue curriculum or syllabus specifications. These are all elements of the intended curriculum, and most teachers develop their instructional activities on the basis of some externally mandated curriculum policies of this nature.

At the classroom level, each teacher delivers what has been described as the *implemented* or *taught* curriculum. This curriculum is based in part on the intended curriculum (or at least on a teacher's understanding or perception of it), in part on resources available and used by the teacher (such as textbooks and other curriculum resources), and in part on the teacher's own philosophy, ideas, and perceptions of the students' needs. As a result of this combination of inputs, the taught curriculum can often differ in significant ways from the intended curriculum, and these differences have been the subject of much empirical research over the years.

Finally, at the level of each individual student, there is what is known as the *learned* or *attained* curriculum. This is obviously related to the taught curriculum but also differs from it. While the taught curriculum is usually delivered to a whole class of students, learning takes place within the mind of each student and is the result not only of the instruction but also of what was known before, of each student's interests and abilities, and of the circumstances of the classroom situation. Sometimes little of what was intended or taught is actually learned. Sometimes, additional, unintended learning takes place (what Dewey called "collateral learnings"). These additional learnings have also been called the "hidden curriculum" because they are not part of the intended curriculum or even an explicit aspect of the taught curriculum.

The curriculum aims, content, teaching processes, and assessment can be thought about and observed at the levels of the intention, teaching, and learning. But the intentions in a given curriculum may not be fully realized in the taught curriculum, and those of the taught curriculum may not be attained in the learned curriculum. These differences have given rise to much curriculum research but also point to one of the central realities of curriculum: while much can be written as policy, as textbook, as advice to teachers, and so on, all of these are *theoretically* based. And ultimately, as Joseph Schwab pointed out, curriculum is *practical* in that it is set in the situations of particular classrooms and the needs of specific pupils. This tension between theoretic and practical lies at the heart of much curriculum discourse.

Curriculum; Values

Links Between Curriculum and Values

As pointed out by Graham Orpwood in this encyclopedia, “The curriculum…expresses the purposes, goals and aims for education” (see curriculum; emphasis in original). Inherent in this statement is some notion of what is judged by experts to be important in education. In developing any curriculum, the belief system underpinning the political, cultural, and economic contexts of the system will be represented. However, such representations are very often implicit and often not even recognized by those developing the curriculum.

Curriculum also consists of subject matter content (Orpwood). This content, science in this case, is also linked to values in three ways (Allchin 1998): values that guide scientific research itself, values that enter science through its practitioners, and values that emerge from science (both product and practice).

Values

There are many definitions that can be used for values (Halman 2010). This may be due to the nature of values as mental constructs; consequently the values people hold can never be observed, but only inferred. Halstead (1996, p. 5) captures the essence of these many definitions in characterizing values as “the principles . . . or life stances which act as general guides . . . in decision-making or the evaluation of beliefs or actions and which are closely connected to personal integrity and identity.” He highlights the more enduring and basic nature of values as compared to beliefs and attitudes. Values also can underpin a disposition or a person’s tendency to act.

Values of Science

It has been quite a common notion amongst some scientists, science educators, and the general community that science is “value-free.” Such ideas have often been perpetuated in the study of science and in science communication, particularly through the focus of science being objective. But objectivity is not really possible as science is a human construction – a way of explaining our natural world.

Science is a way of thinking (and acting) as it is a knowledge-seeking enterprise. It is therefore important to establish the values that underpin this way of thinking (and acting or disposition to acting).

Values in science can be seen as epistemic or sociological in nature. Epistemic values distinguish knowledge that is intrinsically worth knowing and includes the knowledge currently accepted by the scientific community in the form of theoretical explanations for the real world. These values emerge from science as both a product and a practice (see Allchin 1998).

Sociological values include consideration of both external and internal sociological perspectives. External sociological perspectives will include those values that guide scientific research, while internal sociological perspectives include values that enter science through its practitioners. External sociological values of science include the way in which scientists are viewed as experts or possessing some authority within their field of expertise, whether their research should be funded based on decisions about its benefits to society and how scientists communicate their research findings to the public. Internal sociological values of science include the personal values that scientists hold as scientists and consequently as members of the scientific community as well as the personal values a scientist has as a member of society.

Values that underpin science often include curiosity and skepticism, rational thinking, empiricism, parsimony (which could include reliability), robustness, fruitfulness, community practice (as in the community of scientists), interdependence (with other scientists and their research), accuracy, reduction of bias (rather than complete objectivity), open-mindedness, and creativity (which might encompass imagination, innovation, intuition, and informed guesses).

Many of these values may be common to other disciplines such as mathematics and history, but the way in which such values play out in science, both individually and as a collective of values, is very different. For example, while rational thinking is an important value in both science and mathematics, the way it plays out in each of these disciplines can be very different. Rational thinking includes the notions of argument, reasoning, logical analysis, and explanations. It concerns theory, and hypothetical and abstract situations, and thereby promotes universalist thinking. The value can be demonstrated by developing skills in argument and logical reasoning. In mathematics it involves understanding the role of proof and proving, while in science is more about validating the development of knowledge, engaging in discussion and debate, seeking explanations for experimental data, and contrasting alternative hypotheses in terms of available data.

For the individual, then, the interpretation of seemingly the same value has different representations or manifestations in different disciplines, and, while the similarities enable the individual to make sense of the different disciplines, the differences create tensions and can limit their ability to make sense of these disciplines.

Other values such as empiricism (the view that experience, especially of the senses, is the only form of knowledge) are quite unique to science. Science as a way of thinking and acting (or a disposition to act) then is underpinned by the set of values highlighted above that are quite diverse in their nature as they cross epistemic and sociological perspectives.

Values in Science Education

Science as a discipline can be viewed as a particular way of thinking and acting. In science education, experiences of such thinking and acting need to be provided if students are to develop some expertise in the discipline of science. The thinking and acting required in science and science education means that people need to be curious enough to explore their natural environment and try to explain it. In this process of curiosity and/or inquiry, a person needs to engage in some sort of observations (through direct or indirect use of the senses) for some purpose. For example, if you want to know whether you will find a particular bug in a particular place, it is not enough to just look at a bug, but rather you need to look at where the bug is or what it looks like, what color is it, does it have wings, does it have a hard shell, and so on. There is a purpose to your observations, purposes that in essence generate data (which is often uniquely empirical in nature as these are from observations). You then need to look at these data and decide if there are any patterns, ways you can group the data or classify the data (rational thinking). In considering what is the same or different about these data means that you are beginning to place your own meaning (or inferences) on these data. Some of these inferences will be more meaningful than others according to the grouping or patterns. So at this point there are judgments being made about which data are more relevant to the purpose of collecting the data. Those data with the most meaning will contribute to evidence you will use to create an explanation or a model, while data that are less helpful will often be ignored. From here more investigation is required if you are to decide how useful is the explanation or model (often framed as how robust is it) in explaining what I have seen and in enabling me to make predictions about other similar situations/scenarios. If it is useful (or robust) it will explain or fit most situations (not all) – so these explanations or models are useful (plausible, fruitful, and testable). It is also often the case that the simplest explanation/model is the one that suits the most situations (parsimony). If these explanations or models can be combined in ways that build up more complex structures to explore more complex systems, then their use becomes important in terms of understanding how systems will respond if changes are made to them. A fundamental aspect of all of this process is the need to communicate your explanations/models/systems to others to see what they think and to clarify your own thinking (community, collaboration, interdependence, consensus).

The process outlined above is one way that highlights many of the values that underpin science as a way of thinking and acting, many of which are indicated in the brackets in the previous paragraph. The experiences students have in science education must also be inclusive of these values.

Values and the Curriculum

It is rare for curriculum documents to explicitly articulate either the general values underpinning the curriculum or the specific discipline-based values that are included. Nor do curriculum documents highlight the evolving nature of how such values may be interpreted or manifested over time. For example, the recent rapid growth of systems science and interdisciplinary science fields such as biomolecular chemistry and bioinformatics have meant that the thinking and acting needed in these instances are still consistent with the underpinning values but can be represented or manifested in very different ways. Similarly, continued technological developments mean the notion of empiricism has gone far beyond simple observation.

In expressing the purposes, goals, and aims for education, curriculum documents need to also express the values that underpin these purposes, goals, and aims, both in a general sense and in a discipline-specific sense. For science education to provide more authentic experiences of science, teachers and students alike need to be aware of the values that underpin the experiences they engage in and how these contribute to the development of the values that underpin science as a way of thinking and acting.

Curriculum Development

Bat-Sheva Eylon and Avi Hofstein
The Science Teaching Department,
The Weizmann Institute of Science,
Rehovot, Israel

Science curriculum development can involve changes in what is taught, to whom (target audiences), and how (ways of teaching and learning). This entry is concerned with the following questions: *Why* change the science curriculum? *What* should be changed? *How and by whom* is the change process initiated and sustained? The entry discusses various models for initiating and sustaining change.

Why and What to Change? Goals and Driving Factors

Throughout the last 60 years the goals and objectives for science teaching and learning have undergone changes many times, often leading to reforms in the way the science curriculum was developed, taught, and learned. Five key factors influence a change in curriculum goals: the learners (target population), the teachers, the science content, the context of learning and teaching both in and out of school, and the assessment of students' achievement and progress.

The Learners

A long tradition of research on learning and teaching science suggests that learners are

> Goal-directed agents who actively seek information. They come to formal education with a range of prior knowledge, skills, beliefs. In addition, they are directed by their concepts, interest, motivation, and attitudes that significantly influence what they notice about the environment and how they organize and interpret it. This, in turn, affects their abilities to remember, reason, solve problems, and acquire new knowledge. (National Research Council 1999, p. 10)

Studies also indicate that affective (interest, motivation, and attitudes), meta-cognitive, and sociocultural aspects play an important role in the learning-teaching process (Linn et al. 1996). There is agreement among many science educators that the range (or repertoire) of the learners' ideas and ways of making sense of the world should be a key factor in setting curricular goals and in developing teaching strategies and learning materials. Learners' prior ideas and those developed in the process of learning have been researched extensively, indicating that they often depart significantly from the normative ones. The abstract nature of scientific concepts and principles and the need to understand phenomena and interactions that are not directly observable, in particular large or very small spatial and temporal scales, are examples of challenges facing science learners. Some learners' ideas are resistant to change while others may stem, for example, from missing knowledge or confusing use of terms and can be easily remedied. Departmentalization of using science differently in different contexts has been documented extensively (e.g., "school science" vs. out-of-school science ideas or the use of a certain concept differently in different disciplines). Therefore, characterizing the sources of learners' ideas and how they are used has a significant impact on the design of curriculum.

In the process of science learning, learners, either as individuals or as a group studying together, may grapple with a repertoire of ideas that are not necessarily consistent with each other. Science educators hold different opinions regarding the repertoire of learners' ideas. Some regard them as barriers to the process of learning and design strategies to eliminate them, while others regard the repertoire as an essential and useful resource enabling learners to build on their experience and intuitions. Therefore, the curricular goals, the teaching strategies, and the assessments differ in these approaches.

It should be noted that some aspects of learning and teaching science described above hold for all science learners, yet changes in the target population of science learners over the last decade have had a significant impact on science curriculum development. For example, in the USA in the 1960s, the goals were strongly based on the view that science learning should serve students who plan to embark in the future on a career in the sciences, engineering, or medicine. The American Association for the Advancement of Science in 1962 summarized the goals of these curricular initiatives as follows:

- Science education should present learners with a real picture of science, including theories and models.
- Science education should present an authentic picture of scientists and their method of research.
- Science education should present the nature of science (NOS).
- Science education should be structured and developed using the discipline approach (key concepts in each of the subjects).

To attain these goals, a series of science curricula, such as PSSC in physics, BSCS in biology and CHEMStudy in chemistry in the USA, and the Nuffield courses in the UK, were developed. The development teams were led by scientists. All teams included teachers, but the teachers played different roles in the development process. For instance, the development teams in the Nuffield courses consisted mainly of leading teachers. About 20 years later, in the 1980s, there was a shift in many countries toward addressing the needs and abilities of all citizens. For example, an NSF sponsored project, *Project Synthesis*, which analyzed science curricula in previous years, led to a call to change the scope and goals for science teaching and learning, advocating that science education should:

- Include major concerns regarding science as a means of resolving current societal problem.
- Provide a means to attend to the personal needs of students.
- Provide greater awareness of potential careers in science, technology, and related fields.

These goals led, for example, to curriculum projects focusing on science, society, and technology (STS) around the world. Attempts have been made to make science more relevant to learners and adjusted to their backgrounds (e.g., the Chemistry in Context and the Chemcom curricula), attending to characteristics such as equity; gender; students' attitudes, interest, and motivation; conceptual understanding; creativity and curiosity; and knowledge integration.

The Teachers

One of the key factors regarding curriculum change is the teachers. In general, teachers are reluctant to accept radical changes and often do not implement them in accordance with the rationale for the change suggested by the curriculum developers. Such changes may not be aligned with teachers' existing views and practices and may require new knowledge, perhaps content knowledge (CK), or its related pedagogical content knowledge (PCK), or curricular knowledge. Important factors influencing teachers' response to change include personal characteristics, cultural norms (e.g., the role of questioning), the professional status of the teacher, the teacher's understanding of the proposed change and its rationale, and systemic approaches to students' future career opportunities.

The Scientific Content and Organization

The scientific content and the skills or scientific practices to be learned constitute the major fabric of the curriculum. Criteria for choosing scientific core ideas may relate to the importance of concepts within and across disciplines; the provision of key tools for understanding, investigating, and problem-solving; enhancing interest; the relevance to life experiences and the connection to personal and societal concerns; and being teachable and learnable over multiple grades at increasing levels of depth and sophistication (e.g., "learning progressions"). Changes in conceptions about how topics should be organized have also influenced curricular change. For example, "context-based science" (e.g., in the PLON curriculum in the Netherlands and the Salters' projects in the UK) and "knowledge for use" approaches depart significantly from the traditional "structure of the discipline" approach often used for science curriculum development.

Aligning school science with contemporary scientific knowledge is an important consideration in areas that change at a very rapid pace such as molecular biology or nano-science, as well as topics that are interdisciplinary in nature such as brain science and medicine. Changes of this kind in the fields of science and technology are the driving force behind many innovations in school STEM curricula.

Another central issue is the methodologies used for enhancing the acquisition of skills in science curricula. There is a consensus that skills should be developed in the context of content and that in order to develop a generalizable skill (transfer), it must be studied explicitly and practiced in different topics. However, different ways of doing this lead to different curriculum structures.

The Context of Learning and Teaching: The Learning Environment

Learning and teaching science takes place in-school and out-of-school learning environments. Each setting has important benefits as well as limitations. Changes in the learning environment have been shown to influence students' motivation and learning. These changes involve instructional approaches (e.g., inquiry and project-based learning, small group cooperative learning, debates on issues, use of games, and digital simulations) as well as the physical settings in which learning takes place (e.g., outdoors, science museums, authentic research laboratories, and industry). Rapid technological developments and the easy access to information resources in all formats for many of today's students add to the mix of opportunities now available. This proliferation of learning environments raises issues such as: Do students integrate the ideas that they learn in different contexts? Do they have the skills required for autonomous learning, namely, learning to learn skills? What are effective ways and tools to scaffold learners? How can we provide rich opportunities to help socially and culturally deprived students? Responding to these issues influences the goals for learning and teaching and hence influences the design and development of new curricula.

Assessment of Learners' Achievement and Progress

In countries with centralized educational systems, policy decisions concerning the assessment of students may have a radical impact on what and how students learn. Examples of such decisions involve, for example, participation in international testing projects such as PISA and TIMSS; changes in the format of matriculation examinations (e.g., in Hungary and Israel); and decisions made by governments to implement school-based continuous assessment conducted by teachers, allowing more flexibility in the curriculum content and the instructional techniques used. In some countries, as part of educational reforms, alternative assessment methods using tools such as portfolios or e-portfolios are integrated into the curriculum process.

The Curriculum Development and Implementation Processes

Ideally, a curriculum development process should be a holistic, continuous, and long-term endeavor involving several components often carried out in parallel. Key components include initial setting of goals, analysis, and selection of the topics aligned with official syllabi; diagnosis of students' ideas as well as analysis of the inherent characteristics of the science concepts; design of learning, teaching, and assessment materials (e.g., crafting tasks, uses of representations and didactical aids); and small-scale implementation and teacher development cycles accompanied by research (teaching experiments). This process often leads to reconsideration of goals, the pedagogical resources, and the teacher development activities. Advanced stages of the process can lead to large-scale implementation and evaluation studies.

There are many open questions that require further study concerning the ways to enhance the development of useful practical and research-based knowledge relevant to curriculum development in specific topics (Kortland and Klaassen 2010), such as: How can one communicate detailed knowledge about teaching and learning sequences? How can one encapsulate and conceptualize practical knowledge of teachers? How can one develop cumulative research-based knowledge on the development of learning and teaching resources on specific topics?

Models for Curriculum Development: Initiating and Sustaining Change

Over the years, the need for changes in science teaching and learning has been raised by different interest groups such as policy makers, scientists, science educators and curriculum developers, teacher associations, and local initiators (e.g., a school, a school district, or schools networks). Pressure for change has also come from societal or socioeconomic sources.

In recent years, in many countries, curriculum change is often initiated and influenced by national and international standards and frameworks that characterize desirable change and are prepared by national academies, ministries of education (e.g., the Institute of Education in Singapore), and other organizations. Examples of such initiatives include the National Standards in Science Education developed by the US National Research Council in 1996 and revised in 2013 as the Next Generation Science Standards and the Benchmarks of Science for all Americans arising from Project 2061, developed by the American Association for the Advancement of Science. The resulting frameworks have been used for developing curricula and evaluating their quality. Teacher associations have been very influential in initiating curriculum change through the development of frameworks (e.g., the National Science Teachers Association in the USA, the Association for Science Education in the UK, the Irish Science Teachers' Association in Ireland, and the Australian Science Teachers' Association in Australia). Another mechanism for initiating change has been through influential reports discussing goals, methods, and recommendations related to teaching and learning science. Examples of such reports are the ROSE project (Sjøberg and Schreiner 2010) and *Beyond 2000* (Millar and Osborne 1998).

Calls for change have led to two key models of curriculum development efforts that differ in their methods of design and implementation and in the constituents involved in the curricular process: a center-periphery **top-down model** in which a central development group tries to influence those on the periphery and a **bottom-up model**, responding to local needs through school-based (or teacher-based) curriculum development or where change is instigated and implemented by leading teachers and then adopted by others. These two key models often differ in the nature of teacher involvement in the development process, in the activities of implementation, and in the professional development of teachers. The change processes associated with each of these models sometimes differ in the scope of curriculum adoption, in the relationship between the intended and implemented curriculum, in teacher ownership and ways of adaptation, and in the degree of sustainability. In both models, a major concern is how to prepare "educative materials," namely, materials that promote teacher professional growth in addition to student learning, and how to assure effective implementation and sustainability.

Center-Periphery Curriculum Development Models

Big curriculum projects often use a center-periphery model in which a central group develops the curriculum and then tries to disseminate it to the periphery. These groups may include in their teams teachers, science educators, scientists, and other relevant experts (e.g., experts in technology and assessment), who together carry out a comprehensive development and implementation process as described above.

In the past, curriculum change in many countries has been dominated by central governments and/or official stakeholders in charge of curriculum development and implementation, who imposed curricula and assessment methods, sometimes taken from other countries. For example, the *adoption* by developing countries of curricula and assessment methods from developed countries prevailed throughout the 1970s and 1980s and still continues. Unfortunately, these methods often lead to unsatisfactory learning outcomes because they overlook the need to *adapt* the curriculum and assessment methods to the local conditions, taking into account aspects such as the availability of teachers with appropriate CK and PCK to implement the adopted curricula; the local culture and environment (e.g., attempting to introduce advanced open inquiry in a culture where asking questions is not the norm); the availability of laboratory equipment, technology, and lab technicians; conditions for studying at home; and problems of language. Present efforts to adapt new curricula emphasize working with teachers and are more sensitive to local conditions, building on the benefits offered by the local environment and the pedagogical and educational workplace.

Some center-periphery approaches of curriculum development involve intensive ongoing collaborations among school teachers, science educators, scientists, and other relevant professionals. For example, the Salters science curricula in the UK were initiated by a group of concerned teachers, academics, and industrialists whose goal was to make chemistry more relevant to the learner. Teachers were intensively involved in the process of developing the pedagogical ideas and collecting instructional approaches. A similar model is used by the Israeli Center for Science Education in a long-term collaboration between the Israeli Ministry of Education and several academic institutions. In addition to intensive involvement in the development process, lead teachers have a central role in working with other teachers through national centers for science teachers. Learning materials resulting from such intensive teacher involvement have more potential to be adopted in schools. The involvement of leading teachers in the long-term professional development and implementation of new curricula enhances effective customizations aligned with the original rationale of the developers, yet responding to local needs.

School- and Teacher-Based Curriculum Development Models

A growing body of evidence suggests that imposing a curriculum by central professional bodies in what is called "top-down" fashion, whereby teachers are expected simply to implement the developers' philosophy, ideas, and intentions, has proved in many cases to be ineffective in introducing educational and curricular innovations into schools. One conclusion that comes out of decades of studying the success and failure of a wide variety of curriculum innovations is that imposed innovations are generally ineffective and that innovations succeed when teachers feel a sense of ownership of the innovation (Connelly and Clandinin 1988). In general, teachers tend to accept a new curriculum more easily when it is aligned with learning goals they personally value or when they perceive that the innovation provides an effective solution to problems they currently encounter. Several factors seem to be relevant for teachers in adopting curricular changes, such as judgments about the likely success of a new course, the teachers' perceptions of its effects on students' learning and attitudes, teachers' views about students' interest and motivation, perceived learning outcomes, and enhancement of self-regulated learning. The importance of supplementing the curriculum with materials developed by school teachers either in schools or districts, in the context of long-term professional development initiatives, has long been recognized.

School-based curriculum development (SBCD) can be viewed as an endeavor aimed at diminishing dependency on centralized national science curricula, increasing the schools' autonomy, and enhancing teachers' sense of ownership. A central aspect of SBCD relates to teacher professional development and entails the transfer of responsibility or ownership to the teacher. The basic assumption is that SBCD and teacher professional development are two coupled processes. Although ownership by teachers may be high in these models, often the extensive everyday demands on teachers' time and the lack of competence in curriculum development have a negative impact on the quality of change. Another aspect that has to be taken in consideration is the time that is required for the new curriculum to be implemented. Without adequate time for teachers' professional growth, it is unlikely that they will effectively develop and implement new teaching practices.

To sum up, curriculum development and change is a complex endeavor in which many factors need to be considered: the learners, the teachers, the scientific content and organization, the context of learning and teaching, the learning environments, and assessment of students' learning. Years of experience of curriculum development and change provide evidence that it is important to carry out the curriculum development process in a holistic manner that goes beyond writing textbooks and teacher guides. Rather, it should involve cycles of developing innovative learning materials and pedagogical models, implementation, teacher development, and research. There are different models for curriculum development and change that can be roughly grouped into center-periphery models and teacher- or school-based models. No matter which model is adopted, the important role of experienced teachers in the curricular process should not be overlooked. Moreover, the professional development of teachers, and providing them with opportunities and tools to customize instruction to their needs, is essential for effective implementation.

Curriculum Emphasis

Doug Roberts
Faculty of Education, University of Calgary,
Calgary, AB, Canada

The curriculum emphasis concept was developed as a way to understand and distinguish among broadly different educational objectives that have characterized school science programs in recent history. Seven different curriculum emphases were identified originally (Roberts 1982). These were detected through analysis of school textbooks, other high-profile classroom materials, and curriculum policy statements from about –1980 in North America and England especially. A key feature of the methodology was recognizing at the outset that school science programs have two kinds of intended learning outcomes. The more obvious "content" to be learned is selected from within science, i.e., from the concepts, laws, theories, and methodologies that are the basis of scientific explanations for natural phenomena. In addition, there is *context* material that is to be learned *about* science and the reasons for learning it. The latter constitutes the curriculum emphasis. Reasons for learning science are sometimes stated explicitly and are sometimes communicated implicitly by the context.

Curriculum emphases are objects of choice, influenced by societal forces and concerns at different times in history (Roberts 1988). For example, a curriculum emphasis dubbed **Everyday Coping** permeated secondary school science textbooks widely used throughout North America in the 1940s and 1950s. In physics and chemistry textbooks, scientific principles and explanations were presented in the context of having students understand some common mechanical and electrical appliances (e.g., steam shovels, electric motors) and chemical processes (e.g., making steel). In biology textbooks the science was related to understanding aspects of the environment and to personal and public health. Overall, the message this curriculum emphasis communicates to students is that it is important to learn scientific explanations in order to demystify objects and events of fairly obvious personal relevance.

By contrast, **Structure of Science** is prominent in the high-profile classroom materials developed for secondary school science courses in North America and England during the late 1950s and 1960s. Sponsored and funded by the National Science Foundation in the USA and the Nuffield Foundation in England, these materials are silent about demystifying familiar objects and events. Instead, the message to students is about the importance of demystifying science as an intellectual enterprise. The materials concentrate on such matters as the role of mental models in developing explanations, the interplay between observations and interpretation, the reasons accuracy is important, and other aspects of the internal functioning of scientific disciplines. The emphasis remains active in science education today as NoS (nature of science).

Also in the 1960s, AAAS (the American Association for the Advancement of Science) sponsored development of a widely used science program for elementary schools that looked inward to science in another way. Known as "Science: A Process Approach," this program has K-6 students concentrate on the procedures and skills of science in a curriculum emphasis dubbed **Scientific Skill Development**. The materials are carefully sequenced to develop such "basic" skills as observation, measurement, and classification in grades K-3 and more "advanced" skills such as hypothesizing and designing experiments in grades 4–6. The message communicated to students is that the material is to be learned so that appropriate (i.e., scientific) methods can be used for developing proper explanations for natural phenomena. This emphasis is currently recognizable in school science programs (both elementary and secondary) as "scientific inquiry skills."

Two curriculum emphases are much older than those just discussed. Both are evident in school science textbooks from early in the twentieth century, but instances can be found as recently as the 1960s and 1970s. The curriculum emphasis **Correct Explanations** stresses how important it is to learn correct scientific information. The products of science (concepts, laws, and theories) are presented as correct, but very little assistance is given to help students clarify how scientific processes, skills, or reasoning are responsible for the correctness. For example, ideas that have been replaced (e.g., caloric theory of heat) are simply said to be wrong. Closely allied is an emphasis dubbed **Solid Foundation**, in which the message for students (implicitly) is that the purpose of learning the science at hand is that it fits into an overall development and sequence of ideas. In other words, the student needs this in order to get on to the next bit of the sequence. The ideas of science are presented authoritatively, in a style that resembles many university science texts (with appropriately modified language level).

At the time the original study was done, in the early 1980s, there were promising examples in several countries of a curriculum emphasis dubbed **Science, Technology, and Decisions**. This approach brings out the interrelatedness among scientific explanation, technological planning and problem solving, and decision making about practical matters of importance to society. Two high-profile examples are the "Science in Society Project" in England (developed under auspices of the Association for Science Education) and the "PLON Project" in Holland. (PLON is a Dutch language acronym for "Physics Curriculum Development Project.") As discussed below, this emphasis was a prominent component of the developing STS movement in science education.

One more curriculum emphasis was detected in the original study, although it was not very widespread at the time. As the name suggests, the message to students in a **Self as Explainer** emphasis is about the importance of a personal understanding of the process of explanation itself. Using the development and change of theories in physics and astronomy as examples, the "Project Physics" course materials developed at Harvard in the late 1960s introduce students to the influence of intellectual and cultural frameworks on scientists' ways of explaining in their own time and culture. Students can thus become more aware of the influences on their own ways of explaining events. Both constructivism and conceptual change keep this emphasis active in science education today.

Two significant changes related to curriculum emphases have occurred in the 30 years since the original study. Both are at a more general level than a single emphasis. First, science-technology-society has grown into one of the most prominent and successful movements in science education history. STS is not a curriculum emphasis. The movement has obvious roots in environmental education, of course. Indeed, some school programs call it STSE, adding an "E" at the end to call attention to the link. Also, STS/STSE has many aspects, so it is not helpful to think in terms of a single "ordinary" curriculum emphasis. It was noted earlier that **Science, Technology, and Decisions** is a component of STS; so also are portions of **Everyday Coping** and **Self as Explainer**. These three emphases – all of which "look outward" *from science* to the larger world of human affairs – were effectively sidelined in the 1950s and 1960s. The STS movement has rejuvenated them after an era dominated by the prestige of the two scientist-sponsored emphases **Structure of Science** and **Scientific Skill Development** – both of which "look inward" *toward science* (Roberts 2011).

Second, over the past 30 years the slogan *scientific literacy* has been a major topic of discussion about the overall aims and goals of school science. Like STS/STSE, scientific literacy has too many aspects to be usefully discussed as a single curriculum emphasis. Actually, the term has had so many definitions that it has come to incorporate every conceivable objective for school science programs (Roberts 2007). Thus it is tempting to think of scientific literacy as some sort of mega-blend of all seven curriculum emphases, offering students the best of each perhaps. Not so.

Instead, two distinctly different "visions" of scientific literacy have emerged. Since the early 1990s, AAAS Project 2061 has stopped using the term *scientific* literacy, in favor of the term *science* literacy. The shift is significant because, generally speaking, AAAS-type science literacy is inward looking, while scientific literacy as the term has been used historically is outward looking. The two visions have been dubbed, respectively, "Vision I" and "Vision II." The following summary shows the difference starkly (Roberts 2007, 2011).

Vision I: *Science* literacy (AAAS style) incorporates some aspects of four curriculum emphases:

- Structure of Science
- Scientific Skill Development
- Correct Explanations
- Solid Foundation

Vision II: *Scientific* literacy (historically) incorporates some aspects of three other curriculum emphases:

- Everyday Coping
- Science, Technology, and Decisions
- Self as Explainer

This discussion is not intended to suggest that one of these visions is "better" or "more correct" than the other. The visions, like curriculum emphases, are objects of choice for curriculum policy makers. Comprehending the broad array of curriculum emphases in science education history can be helpful in unpacking what is at stake in making such a choice.

[2]University of Minnesota, Minneapolis, USA

Keywords

Program evaluation; Science education evaluation

To understand curriculum evaluation, it is important to first understand what is meant by curriculum and evaluation. Curriculum may be interpreted broadly to mean instructional materials or processes, courses of study, and educational programs or interventions. In other words, curriculum may be considered as anything related to promoting educational growth. Evaluation may be considered a process of delineating, obtaining, and providing useful information for judging decision alternatives. Evaluation is the determination of the merit or worth of something, in this case curriculum. Evaluation can take many forms and follow several different theoretical paths, but it is a process of "valuing" and as such directly related to the perceptions of the stakeholders of the entity being evaluated. In a curriculum evaluation the stakeholders could be the designers of the curriculum, the deliverers of the curriculum, the receivers of the curriculum, and others impacted or having an interest in the curriculum. An evaluation should take the values of all of these stakeholders into account when designing, conducting, and disseminating the evaluation. Evaluation is an applied science; it needs to be used to be effective. Evaluation differs from research in terms of the motivation of the inquirer, the objective of the inquiry, the outcome of the inquiry, the role played by explanation, and the generalizability. Evaluations are almost always conducted at the request of someone and to provide information for decision making, whereas research is conducted to provide reliable information about educational matters, to identify patterns and trends that may be of educational significance, to identify factors that correlate with specific outcomes, and to seek and test explanations for them. For example, evaluation is purposefully tied to a specific object in time and space, while research is designed to span these dimensions.

There are many different approaches to curriculum evaluation. The approach taken is related to the values of the stakeholders or one group of stakeholders and is designed to assess the quality of the program though examination of the

Curriculum Evaluation, Table 1 Possible evaluation questions for curriculum evaluation

Type of questions	Possible evaluation questions
Quality of a curriculum	Are the curriculum developers doing what they said they were going to do?
	Are effective management structures in place to support participants?
	Are communication channels open and operating between providers, participants, and administration?
	Are goals understood and shared by all stakeholders?
	Are the deliverers of the curriculum well qualified?
	Is the delivery of the curriculum well planned?
	Do the participants believe they have benefited from the curriculum?
	Do the participants expect to change their behavior or attitudes as a result of the curriculum?
Outcomes of a curriculum	Has the behavior of the participants (including teachers, students, principals, and others) changed?
	Have others benefited from the changed behavior of the participants?
	Have schools been affected?
	Have student behaviors changed?
	Has student achievement changed?

Curriculum Evaluation, Table 2 Possible curriculum effects and methods of measurement for curriculum evaluation

Possible effects	Methods of measurement
Delivery of curriculum	Observations
	Participant observer
	Participant opinion
Effects on teachers	Discourse analysis
	Phenomenological studies
Effects on classrooms	Classroom observations
	Teacher logs and surveys of what takes place
	Artifact analyses
	Student or teacher opinion, surveys, and environment instruments
	Ethnographies
Effects on students	Pre-post testing of motivation, beliefs, achievement, and behaviors
	Comparison of student outcomes with outcomes from different curricula
Other effects	Case studies
	Policy analyses
	Networking analyses

program processes or the quality of the program outcomes. For example, an evaluation of a new chemistry course might address the needs of students or of their teachers or of the students' parents or any combination of stakeholder groups. Examples of evaluation questions related to the quality of the curriculum or the quality of the curricular outcomes are provided in Table 1.

The first step in a curriculum evaluation therefore is determination of what information is needed. This is a complex step that requires working closely with the commissioners of the evaluation and helping them to articulate the information they will need to make value decisions. For example, if stakeholders are not interested in whether or not students become more cooperative in class, the evaluation should not be designed to gather that information. Evaluators often use logic modeling techniques to help define how the curriculum will produce the desired effects and the consequent underlying needs for data. A logic model is a graphic depiction of the curriculum showing inputs, activities, outputs, and outcomes (Frechtling 2007). Once the desired information is delineated, questions about how best to obtain that information need to be considered. Answers to these questions are based on a variety of criteria, but the amount of time and effort that is available to be applied to the evaluation and the alignment of rigorous methodologies for data collection with the

Curriculum Evaluation, Table 3 Science curriculum examples of Stufflebeam's evaluation models

Model of evaluation	Science curriculum example
Decision/ accountability	Examining the strengths and weaknesses of a science curriculum to make decisions about how to improve the curriculum
Consumer oriented	Rating two science curricula using a set of criteria to determine which curricula is best for students
Accreditation	Evaluating a science curriculum to determine whether the curriculum meets the minimum requirements set by the state or an accrediting agency
Utilization focused	Assessing stakeholders' needs for evaluating a science curriculum and providing them with information they can use to make decisions about the curriculum
Client centered/ responsive	Working with school board members, administrators, and teachers to develop, implement, and evaluate a science curriculum
Deliberative democratic	Involving school administrators and science teachers to be part of the curriculum evaluation through collecting and interpreting the data and discussing the findings to ensure that perspectives and opinions are represented fairly
Constructivist	Partnering with stakeholders in the evaluation process to understand the different perspectives and experiences of different groups of students receiving a science curriculum
Case study	Conducting an in-depth analysis of one science class of several classes to highlight how a science curriculum is being implemented
Outcome/value-added assessment	Analyzing trends in student science assessment data to determine whether results show adequate outcomes and whether changes need to be made to improve a science program

Curriculum Evaluation, Table 4 Three examples of science curricular areas by evaluation method and questions

Curriculum area	Evaluation method	Questions the method addresses
A curriculum about making the school culture more supportive of underrepresented groups pursuing science within a school district	Case study of one or two schools	What is an in-depth description of the institutional culture at one or two schools within the district regarding science and underrepresented student groups?
	Retrospective opinion surveys of those within the school and those who interact with the schools	
	Artifact analysis of policies, procedures, and public statements over a period of time	What do administrators, teachers, staff, students, and parent think the culture of science is within their school? What do people who interact with the schools think the culture is? How has changed the culture changed?
		What changes have occurred in the policies, procedures, and expressed public image during the program?
	Ethnography	What is the culture of the classroom regarding climate change? How is the classroom culture evolving?
	Pre and post assessment of students' perceptions of climate change	How do students perceive climate change before and after participating in the curriculum?
A curriculum about climate change	Observations of the classroom by experts	What are observers' opinions of climate change before and after the curriculum and/or in comparison to other classrooms without the curriculum?
	Phenomenological studies	What are the lived experiences of a few selected students? How are students impacted by the change in implementation?
Effect of changing the implementation of a high school earth science curriculum from face-to-face to online instruction	Assessment of student knowledge and attitude and application of HLM analyses	Which individual student variables are predictive of student achievement and attitude? How much does the type of instruction contribute to the relationship?
	Value-added analysis of student scores over time	What changes have occurred in the longitudinal patterns of student achievement and attitudes since implementing the online instruction?

evaluation questions are primary concerns. Table 2 presents a sample of methods that might be used to evaluate different curricular effects.

The different methodological approaches to evaluation are grounded in different philosophies mainly along two continua: the objectivist-subjectivist epistemologies and the utilitarian-pluralist values. The objectivists rely on reproducible facts, while the subjectivists depend upon accumulated experience. Utilitarians assess overall impact, while pluralists assess the impact on each individual. These can be collapsed into two methodological approaches to curriculum evaluation: positivistic and interpretive. Positivistic methods are hypothesis driven, consider randomized control trials to determine causality as a "gold standard," and include methods such as regression discontinuity, structural equation modeling, path analyses, quasi-experimental techniques, ANCOVAs, and propensity scores. Interpretive methods are more interpretive and inductive philosophically and use methods such as case studies, life history, phenomenography, phenomenology, critical theory, ethnomethodology, symbolic interactionism, hermeneutics, semiotics, and structuralism. It is also possible to mix methods in a variety of ways and at various points of time in an evaluation.

Stufflebeam (2001) describes 22 different approaches to evaluation and recommends nine that best meet the four dimensions of the Program Evaluation Standards of the Joint Committee on Standards for Educational Evaluation (see Yarbrough et al. 2011): utility, feasibility, propriety, and accuracy. These nine approaches include three improvement- or accountability-oriented approaches, four social agenda or advocacy-oriented approaches, and two method-oriented approaches. The models are defined below and listed in Table 3 along with an example of how each could be operationalized in science curriculum education.

There is also a variety of other issues that need to be considered when conducting curriculum evaluation. One important issue is to make sure the evaluation meets all the human subjects Institutional Review Board (IRB) regulations for both the evaluator's institution and for the institutions in which the evaluation is taking place. Additionally, although logic models can be useful, it is critical that they accurately reflect how the curriculum actually operates and that they be revised as changes are made. As with all evaluations, care must be taken to conduct the evaluation in accordance with the Program Evaluation Standards (Yarbrough et al. 2011) and to provide the information to the evaluation stakeholders in a timely and appropriate manner. The evaluation information can be supplied in a variety of formats ranging from a formal report to poems written using participants' voices. The important thing is to present it in a way that the stakeholders receive an accurate picture of what was found in a manner that they find most relevant. Table 4 presents three sample curricular areas along with questions and methods that might be appropriate for a curriculum evaluation.

Curriculum in Play-Based Contexts

Dawn Garbett
Faculty of Education, The University of Auckland, Auckland, New Zealand

What is Play?

The maxim that "children learn through play" is a pedagogical given in early years settings. Teachers and parents recognize that play serves many valuable purposes. It fosters children's physical, intellectual, emotional, and social development. It provides opportunities for high-level reasoning, insightful problem solving, and creative thought. Play-based curriculum is developed from the children's interests and gives rise to their creative explorations of the environment. Despite play traditionally being defined as engaging in activity for enjoyment and recreation rather than a serious or practical purpose, many educationalists have pursued other definitions. For example, Somerset (1995) wrote:

> To children, play is work, hard work, their business in life . . . This self-activated learning . . . is termed merely play perhaps because children choose what they learn, take their own time about it, and enjoy it all. (p. 15)

It has been argued that play has a quality that enables players to transform their world through their active engagement, imagination, flexible thought, and creative storytelling. They can combine and blend ideas into new creative possibilities and reinterpret familiar settings in novel ways. As such, play creates possibilities for learning. It provides a way of framing new ways of knowing, being, and relating to the experienced world. Rather than viewing play as the opposite of work and thereby associating it with limited purpose or value to learning, Davis et al. (2008) have suggested that:

> The opposite of play is… *rigidity* or *motionlessness*. In this sense, a vital quality of all living forms is play and, conversely, a likely indicator of an inert (or dead) form is lack of play. (p. 84)

As the above suggests, play then is a powerful strategy that drives learning in a dynamic, ever-changing world. It is the basis for cultivating imagination and innovation, providing opportunities to take risks, experiment, fail, and continue to play with different outcomes (Thomas and Brown 2011).

Science in a Play-Based Context

Early childhood teachers appreciate that young children are exploring and expanding the way they know about their world in a myriad of ways. They experience an environment where they develop their own workable theories for making sense of the natural, social, physical, and material worlds based on play, observation, and exploration. As Esach and Fried (2005) have argued:

> Whether we introduce children to science or whether we do not, children are doing science. We are born with an intrinsic motivation to explore the world. This means that children will be taking their first steps towards science with or without our help. (p. 332)

To ensure children's first steps toward building their understanding of science concepts are not missteps, teachers have a strategic role in planning for play and engaging in informed scaffolded interactions that create opportunities for the co-construction of knowledge as they emerge from children's interests, curiosity, imagination, and participation. The following examples are designed to illustrate these points in practice.

Example #1

The teacher watches 5-year-old Maddy banging rocks on the Nature Study table. Maddy systematically picks up a rock from the collection, studies it carefully, and then taps it on the table. Each rock is then consigned to one of two piles. "What are you doing?" the teacher asks. Maddy looks up and says "I'm listening to the rocks. These are quiet ones and these are noisy ones." The teacher looks at the two piles and sees that Maddy is classifying the rocks into loud, mostly igneous rocks and metamorphic rocks and quiet, soft, mostly sedimentary rocks. She joins Maddy in tapping rocks on the table. When they are finished, Maddy says "I wonder why these ones were quiet. Do you know?" Before the teacher has a chance to answer, Maddy sweeps the rocks into a single pile and starts sorting them again. "This time," she tells her teacher, "let's put them in their colors."

In this real-life example, the teacher developed the above experience into a project that spanned several sessions. Maddy brought photographs of a family trip to a volcanic area. The teacher took a piece of pumice (volcanic rock) to school, and they discovered that it was the only rock that floated. The teacher and several rockhounds went online together and explored other properties that scientists use to classify rocks.

This example draws attention to the novel perspectives which children can bring to exploring their world. It also illustrates the importance of the teacher's role in fostering and following the children's interests in order to help them construct new understanding. In this situation, children learned about physical properties of rocks and how scientists classify and identify them. Children also learned about floating and sinking as they tested which rocks floated and which did not. Future possibilities coevolve with the children's interest. For example, they could have designed ways to make rocks float, perhaps by building boats or attaching buoyancy devices to them. The teacher's role is to create a playful situation where the children want to learn more about a topic and are active participants in making and taking meaning from the situation. Children who are engaged in knowledge construction are involved in the interpretation of meaning, the reflection of experience, and the reconstruction of the experience to become more knowing. Playing with ideas, reinforced through exploration in practice, builds knowledge.

Example #2

The teacher asked the parents if they had any objection to her burying some bones from a sheep skeleton in the early childhood center's sandpit over the weekend. She assured them the bones were well weathered and clean. On Monday morning, several of the children headed to the sandpit with spades and diggers to start their usual excavations. They were amazed to discover "fossils." The teacher encouraged the students to uncover more bones and then to see if they could fit them together to find out what the mysterious buried creature was. They spent many hours deciding which bones went in which positions and eventually decided that they had discovered a dinosaur. The bones of *Tyranosaurus sheepi* were duly threaded together and hung on the early childhood center's fence for all to admire. It became the backdrop for adventures and the focal point for much storytelling. Indiana Jones was never such an inspiration to become an archaeologist as this teacher!

In this example, the teacher created a rich learning environment in which imagination and narrative became as important to the learning as observation and inquiry. While burying bones in the sandpit had provided an opportunity for the children to create and make meaning, the teacher directed the activity to develop the science experience. She extended the children's play over many hours and consecutive days to establish which bones were part of the skull and which were limbs. What were the functions of the various teeth they uncovered and how did they differ from the teeth the children had in their mouths? In hanging the skeleton together, the children investigated the properties of different threads – wool was too thin and broke too easily. Wire was difficult to work with but sturdy. Nylon fishing line was difficult to knot securely but easier to manipulate. The conversations, trials, and experimentations in this play setting all added to the children's learning about science.

Example #3

David was chasing after a piece of paper that was being blown around the playground. Finally he stamped on it with his foot and stopped it from moving. The teacher asked him what made the paper move. "Naughty Mr. Wind," he replied, mimicking a children's television program.

"Hmm, where's the wind coming from?" the teacher wondered aloud. David was stumped by that question as you can imagine, but by the end of the session, he had flapped his arms like wings and felt the pressure of the air all around him. He had explored running as fast as he could with a piece of newspaper in front of him and made a kite to fly. "Did you know the wind is just moving air?" he asked his mom knowledgeably when she came to pick him up.

In this example, the teacher seized the opportunity to expand David's science understanding through a series of hands-on activities and experiences. She was confident of her own science knowledge and her ability to teach about science in a variety of engaging ways. In the back of her mind was the thought that children spend many hours in front of television or computer screens without social or physical interaction with others. What impact would this have on children's play? One impact could be that technology creates a gap between effort and observable results that may mean that children are reluctant to try tasks that require real effort. Perhaps technology will promote such "magical" virtual experiences when chasing a piece of paper becomes too frustrating in the real world (Bergen 2008). Will tomorrow's children still make a game out of chasing paper in the playground?

Conclusion

Each of these examples highlights the teachers' responsibilities in managing and organizing an environment that offers a wide variety of opportunities to explore and challenge children's developing ideas. Teachers should encourage children to know what is happening and why; they should respond to children's questions thoughtfully to extend their ideas; they should help children problem solve, remember, predict, and make comparisons. An understanding of basic science concepts is important in providing teachers with the flexibility to engage children in learning about science ideas in such play-based contexts.

Curriculum in Teacher Education

Jim Woolnough
University of Canberra, Canberra, ACT,
Australia

Introduction

Curriculum most often refers to the formal documentation designed to provide guidance about what school systems, schools, and teachers should teach. It is generally produced on behalf of governments through sometimes complex processes managed by the appropriate education bureaucracy in an attempt to offer guidance about the content for (and sometimes approach to) teaching. It is, then, a product that reflects the political, cultural, and economic contexts in which it is written. This is sometimes referred to as the "envisaged" curriculum. However, many educators also recognize the existence of an "enacted" (or active) curriculum as something distinct, that is, the reality of what is actually taught, and the range of student experiences, in the classroom.

The enacted curriculum may partially reflect the belief systems and knowledge base of the teacher or local school system delivering it. Teacher education students often receive considerable instruction about the formal curriculum, to some extent because accreditation of teacher education programs is often managed by the same bureaucracy or one closely related to the one that develops the formal curriculum. Teacher education students may receive some exposure to the enacted curriculum, but this may be dependent on the particular philosophies of the teacher educators involved in teaching them in their program.

Curriculum Design

There are a number of different traditions in curriculum design and implementation, varying both with respect to time and place. The 1970s, for example, represented a period of considerable experimentation with a school-based curriculum movement evident across many English-speaking systems. Many teachers involved in this reform found it to be an exciting and challenging experience, which came alongside a number of other educational innovations, such as child-centered curricula and cooperative teaching practices. A decade later, however, there was a resurgence in the development of more prescribed national curricula with a much greater level of political control over curriculum development processes, which now came to regard teachers as agents for the delivery of curriculum. In fact these reforms quite overtly intended to reduce the control of teachers over curriculum decisions (for a thorough and interesting analysis of these historical perspectives in three English-speaking countries, see Guilfoyle (1992)).

Superimposed on these temporal variations are some significant national differences. The German *Didaktik* tradition sees the state curriculum as a broad guide to what should be taught and not as something that could or should explicitly direct a teacher's work. It takes a very "professionalized" view of the role of teachers and encourages them to exercise a degree of self-determination with some limitations on systematic and bureaucratic regulation. The Anglo-Saxon tradition on the other hand, at least over the last 20–30 years, has tended to produce curricula that are designed to be "implemented" by school systems and are intended to provide a significant level of control over how teachers do their work (Westbury 2000). These different traditions can have a significant effect on the relationship between teachers and the curriculum they are responsible for delivering.

Science Curriculum

A significant area of tension in the development of science curricula exists between the knowledge base of science and other aspects of the scientific enterprise, such as the nature of science and the complex interactions between science, society, and culture. The *Science in Society* approach, developed by the Nuffield Foundation in the UK (www.nuffieldfoundation.org/science-society), aims to provide a strong context for science learning through the teaching of important societal issues, such as cloning, genetic engineering, and global warming. *Project2061*, developed by the American Association for the Advancement of Science in the USA (www.project2061.org), includes *The Scientific World View* and *The Scientific Enterprise* as components of its *Benchmarks for Science Literacy* within a Nature of Science strand. A new national curriculum currently being developed in Australia includes *Science as a Human Endeavour* as a learning strand (www.acara.edu.au). These approaches all promise to enrich the science learning of students. However, how teacher education programs can effectively prepare new teachers with the capacity to successfully incorporate these elements into their teaching in a coherent way is still an area of difficulty with which teacher educators continue to grapple.

The resurgence of national curricula in the 1980s also saw the inclusion of laboratory work, often mandated in quite precise ways, in curriculum documentation. Laboratory work and practical experiences in general are a central part of a science teachers' life. At some levels laboratory work is a pedagogical process, designed to enhance the learning experiences of students, and for many teachers, is not seen as necessarily belonging in curriculum documentation. On the other hand, an argument can be made that it is part of the knowledge base and skill set that students should achieve. The problem that remains is the lack of an agreed understanding of what it should involve. A range of terminologies, such as "inquiry," "open-ended and first-hand investigations," "problem solving," and "experimentation," have all been used in the context of laboratory work, and it can be difficult for teachers to decipher what these terms mean in the context of their classroom practice. While the place of laboratory work in teaching, and in curriculum documentation, may seem assured, it is always under some level of scrutiny if only because of the expense of providing it in schools. Implementation of laboratory work will continue to be one of the challenging aspects of a teacher's role in putting science curriculum into action. For a recent review of these challenges in the UK context, see Toplis and Allen (2012).

Conclusion

Curriculum is a complex part of a teacher's life. While individual teachers may not feel that they have much of a role to play in the development of modern curricula, as Smith and Lovat (2003) pointed out in the introduction to their book, for any curriculum "it is the teacher, with the learners, who finally makes it work" (p. xii).

Curriculum; Didaktik; Science for all; Scientific literacy; STS science

The Latin meaning of the word "curriculum" as the race course for athletic sports is a good place to start to describe the use of this word in science education. It conjures up senses of contest and of challenge that have been part of the science curriculum since its earliest beginnings in schooling. Curriculum also had a Latin meaning associating it with the "deeds and events for developing a child to an adult" that also finds resonance in how the teaching and learning of science has in some places and some occasions been conceived. It is this sense of the prescription of an intended curriculum – what is to be taught and learnt in science – that this entry discusses the science curriculum's movement over time. Others in education, and indeed in science education, use the word "curriculum" much more widely to include the pedagogies in classroom practice, the many other explicit and implicit experiences that make up schooling, but this entry uses the more restricted meaning.

The race courses for different athletic events provide some useful metaphors for the contests over the science curriculum. For example, orienteering is a race course with a few checkpoints, but no prescribed route in between. A parallel science curriculum would list a number of big scientific ideas and investigative aspects, but leave it to the science teachers to determine the detailed science they will cover to achieve the learning of these idea and aspects. The German and Scandinavian approach to the science curriculum is somewhat of this type. Again the difference between long jumping and high jumping is breadth of ground coverage versus height upwards (or negatively, depth). Science curricula influenced by the Anglo-American tradition (see below) tend to have science curricula that are quite diffuse, that is, in each year of schooling, a large number of topics are introduced, and these appear again in later years for further development. In other countries, such as Japan and Hungary, the curriculum for each year is more focused on fewer topics, but these are expected to be dealt with more completely. The difference between a long sprint like 400 m and the long distance 10,000 m can be seen in countries like USA and the Philippines which cover a disciplinary science subject in one school year, compared with European countries that devote many years to such a subject.

When the science curriculum is seen as the set of things the learners should learn, it is evident that deciding which set will be a highly contested matter among a number of stakeholders who have an interest in the shape and direction this set of learnings takes. That the science curriculum will be contested stems from many things about science and modern society. These include the strong link between science and technology (S&T) and the national economy, the critical role S&T plays in public health and environmental well-being, and humankind's curiosity about the natural world in which life of incredible variety exists and the expectation that a science curriculum could (and should) provide insights that answer and excite this curiosity. This, in turn, means that the supply and preparation of science-based professionals is of critical interest to academic scientists, who are also well aware that outstanding scientific discoveries are a matter of national pride and international competition. Within schooling there is also tension arising from the fact that science is one of the most expensive aspects of a school's budget because of its specialized laboratories, equipment, and extra professional staff.

An early example of this contest is wonderfully described by David Layton (1973) in his book *Science for the People*. In the mid-nineteenth century, a village school teacher and an educational inspector in England tried to introduce some basic science into the primary education of future agricultural and industrial laborers. There was strong resistance from a number of groups, including scientists, and the contest was lost around two issues – *science as useful knowledge* and *science as moral knowledge*.

Historically, science commonly first entered the curriculum of schooling at the senior levels only. Not surprisingly, it was taught as separate science disciplines, since its main purpose was preparing those students who had an interest in the study of these sciences at university. The contest for the content of these science curricula was dominated by academic scientists, and, as a consequence, the detailed topics for learning changed quite slowly. More scope for new topics arose as some existing ones began to make their way to lower levels of secondary schooling during the twentieth century and eventually in its last decade into the primary years. Even when the school subject in these earlier years had an umbrella title like General Science, its curriculum was usually set out as separate strands of physical, chemical, biological, and earth sciences, maintaining a strong and distinct disciplinary nature.

A major hiatus in this process for changing science content occurred in the 1930s and 1940s because of the great depression and World War II. In the aftermath of the war, during which science played a decisive part and had been developed in many ways, university scientists set about reformulating the science they taught, making it much more conceptual and hence less descriptive. A decade later it was the turn of school science, and substantial national and philanthropic funding was made available on both sides of the Atlantic for curriculum projects that would develop new materials for teaching science in schools. To be consistent and aligned with the conceptual character of university science teaching, the new materials also were to have more conceptual content, and this meant that much of the previous descriptive, applied, and historical aspects of science were deleted. With names like PSSC, BSCS, CBA, and Nuffield, these new approaches to reforming science curricula became known as the Alphabet phase.

Consistent with the view that school science teaching was introductory and preparation for study at university, the first wave of these new materials was for the disciplinary sciences in the senior years. Subsequent projects developed materials for other levels of schooling including the primary years and for nonacademic streams of students. A number of projects followed an interesting division of science and of developmental effort. The projects for the secondary levels of schooling were characterized by their use of science concepts and principles. Those for elementary or primary schooling were much more concerned with scientific processes, probably because it was recognized that many teachers at these levels had very weak science backgrounds. The Science Curriculum Improvement Study (SCIS) was an exception to this division as it did try to include both conceptual science and investigative processes.

No sooner were the new materials from the Alphabet projects available than their relevance as science curricula were challenged by an upsurge in many countries of the idea of comprehensive schooling that should meet the needs of the increasing numbers of young persons who were now in many countries continuing at school for a full secondary education. These "new students" were not attracted to the academically oriented Alphabet courses nor were they content with the alternative nonacademic ones. By the later 1970s the proportion of senior students enrolling in the sciences were declining, and educators and policymakers were looking for new possibilities to attract students to the sciences. A premature example occurred in Victoria, Australia, in 1975 when a new senior project was established to develop a single subject, covering both physics and chemistry. It emerged as *Humans and the Physical World*, where the "and" was meant to emphasize that both the interactions of scientists in producing science, and of nonscientists making use of this science in applications, were to be the source of content. This was an excitingly new conception of science at this final level of schooling, but it was then strongly opposed since, despite attracting new students, it was felt likely to reduce still further the numbers taking the traditional separate subjects. Although failing to be accepted by most schools, some of the ideas in this curriculum were soon included in the curricula for physics and chemistry.

As confusion and disappointment in the 1970s followed the major efforts of the Alphabet projects to produce new materials for school science, there were calls in a number of major reports for a "Science for All," an expression of hope that the school science curriculum would contribute to the needs of a wider population of students (see *Science for All*). As part of preparing the Canadian report, *Science for All Canadians*, Douglas Roberts, from an analysis of the Alphabet projects, introduced the idea of a curriculum emphasis or purpose (see Curriculum Emphasis). He was able to identify and describe seven of these – *Everyday Coping*, *Solid Foundation*, *Structure of Science*, *Scientific Skills*, *Correct Explanations*, *Self as Explainer*, and *Science/Technology Decisions*. He went on to argue that when one of these emphases (or purposes) becomes the criterion for selecting content for science learning, a very different curriculum results, and that if too many of them are intended in 1 year or at one level, some will fail to have an appropriate share of the intended learnings. Roberts went on to contend that as the science content changes to reflect the different emphases, so also should the pedagogy and the forms of assessment (Roberts 1988).

The idea of *curriculum emphasis* made much more explicit the implicit purposes that lay behind the contest for the science curriculum and enabled some stakeholders to be more articulate. The emphasis, *Science/Technology Decisions*, was taken up with enthusiasm in a number of countries in the 1980s, producing exciting materials to support its teaching, such as the *PLON* project in the Netherlands and *Logical Reasoning in Science and Technology* in Saskatchewan, Canada. By the end of the decade, a new movement, Science/Technology/Society (STS), for teaching science had emerged and with it the possibility of setting out the curriculum for science as a set of thematic- or issue-based modules, each occupying a significant amount of a teaching/learning year (Solomon and Aikenhead 1995) (See Science Technology and Society (STS)). This modular format enabled the integration of science content with investigation and the effect of applications, much more easily than did a list of science topics with a separate list of investigative skills.

The heightening concern for the environment during the 1980s, and the need for a hands-on practical science in the early years, meant that several other curriculum emphases became quite well established – *Science for the Environment*, *Science for Technologies*, *etc*.

Soon after, and independently, a number of older subjects like Art & Design, Industrial Arts, and Domestic Science became linked with the emerging computer technologies to be newly defined under the subject umbrella of Technology. This was a setback to the STS type of curriculum thinking since "Technology" was now a curriculum term in its own right, but with a different meaning than it had as "applications of science" in STS, providing the bridge between Science and Society. This, together with the emergence of a new slogan, "scientific literacy" (perhaps to catch some of the priority being given to numeracy and literacy in the primary years), meant that the science curricula of the 1990s were more concerned with establishing science content throughout all the years of schooling using rather traditional approaches, than with giving it a new direction. These later redefinitions of a curriculum for school science, unlike the earlier ones that were just for science at a particular level (or levels), were carried out as part of a total reform of the compulsory school curriculum. A prevailing market view of social practices promoted a template approach to listing each subject's curriculum. The horizontal levels in this template are the years of schooling, and the vertical ones are disciplinary stranded lists of science content and of science processes. Such an expression of the curriculum gives a false air of progression of learning and lends itself to simplified external forms of assessing learning (and of teaching) that are part of the accountability that the market view requires. This approach is, however, at the expense of the intended integration of these strands and of the denigration of those newer goals of the science curriculum that are not accessible to external assessment. Millar and Osborne (1988) provide a helpful critique of this still prevailing approach to the science curriculum in the report, *Beyond 2000*.

"The curriculum" is a familiar term in countries in which education has been primarily influenced by British and American patterns and values of education (the Anglo-American tradition). In countries more influenced by European educational traditions, words like the German, *Bildung* and *Didaktik*, are more familiar. Conversations between representatives of these two traditions in the 1990s helped to clarify some quite significant differences that have a bearing on "what learnings" should be included in science education (Hofmann and Riquarts 1995) (See Didaktik).

In Anglo-American contexts, the curriculum for the sciences has, as its primary goal, been directed to the purpose of introducing students to the basic concepts, principles, and investigative procedures of the various sciences and, in this way, preparing those students who choose to continue science-based studies beyond school. In the European tradition, a primary purpose of school education, and hence of the sciences in this education, is quite explicitly about the maturing of students as whole personalities. Since the various fields of science have developed to serve purposes that are different from this, their bodies of knowledge are not automatically useful in schooling. In the first tradition, the responsibility for the content learning in the science curriculum is usually held centrally, but in the second tradition the individual teacher takes more of this responsibility.

This difference in tradition was very evident in the early 1990s when many countries were redefining their whole school curriculum or their curriculum for science(s). In the Anglo-American countries, there was much concern with identifying Key Learning Areas. Science, as a set of science disciplines, or as combined in some way, was always one of these KLAs. At the same time the Norwegian Government adopted in 1994 the **Core Curriculum** which defined itself not in terms of KLAs or subjects, but as a set of human characteristics that education should strive to develop – *Spiritual Human*, *Working Human*, *Aesthetically aware Human*, *Environmentally responsible Human*, *Social Human* and *Integrated Human*. It is possible to find many learnings in the sciences that would contribute to each of these aspects of a rounded person, but how to structure these into a program for the years of schooling proved very difficult, even in Norway. Nevertheless, the **Core Curriculum** serves as a reminder that a science curriculum should aim to serve educational purposes that are much wider than it often does.

After lying fallow through the 1990s, but again in response to recent evidence from the two international assessment projects TIMSS and PISA of a decline in student interest in science, the ideas of STS are reemerging as science curricula begin to include Context-based Science and Socio-scientific Issues Science. These international projects are conflicting in the sense that TIMSS is concerned with comparing the curriculum content that is common across countries – an inevitably conservative view – whereas PISA, not primarily curriculum oriented, has pushed for students' active use of scientific knowledge in everyday contexts.

In the last decade or so, several of these other emphases have gained strong support among a number of science educators and their innovative teacher colleagues –*Scientific Argumentation*, *Context-based Science*, *Socio-scientific Issues Science* – each of which can also be recognized as developments of the STS movement but in terms of the S, T, and S, respectively. Roberts' early emphases could be accommodated within the teaching of individual science or in more integrated science teaching, but some of these more recent emphases only make sense within an interdisciplinary view of science teaching, since real-world contexts and SSIs rarely involve just a single science discipline.

A recent challenge to the science curriculum has come from stakeholders who see the impact of the digital revolution on society being so great that knowledge is becoming more of a verb than the noun it has formerly been. This Knowledge Society emphasizes skills like *thinking*, *creating*, *communicating*, *problem solving*, *knowing how to learn*, *etc*. These are being described as generic, but they challenge the science curriculum which has hitherto been much more concerned with students acquiring a store of established knowledge and standard procedures than with these more dynamic practices, despite the importance they have in science itself. New science curricula in New Zealand and Australia have been much concerned with how this new challenge is best accommodated.

Curriculum design Curriculum models; Curriculum frameworks

The nature and purpose of science education as a component of the school curriculum have a contested history. For example, DeBoer (2000) identified "scientific literacy" as a common curriculum goal for science education but over time there has not always been a shared meaning of that term. In any event, such a goal can be expressed in curriculum terms in different ways. Curriculum structure is therefore as much a social construct as it is an objective description of the shape and function of a particular curriculum. Disagreements over curriculum structure have often reflected deeper philosophical and political differences about epistemology and the purposes of schooling.

In this entry, curriculum structures will be reviewed paying attention to the multiple senses in which the term is often used: first, as differences in curriculum form; second, as different ways of making scientific knowledge accessible; and third, as an aspect of society's expectations of scientific learning. These different ways of viewing curriculum structure are often underpinned by theories of different kinds and these will also be referred to.

Curriculum Structure as Form

Posner (1974) referred to the many different ways in which the curriculum could be structured: these structures depend on the theoretical disposition of the author, the particular social and political context of the time, and the purposes that a school subject like science is meant to serve. Thus, when the acquisition of scientific knowledge, or learning to "think like a scientist," is seen to be important, the focus of school science subjects will be the science disciplines themselves. This is almost always the case at the senior levels of schooling, but arguments have also been made for younger students to be introduced to science disciplines so they can be adequately prepared to become scientifically literate and have the very real option of taking up a scientific career. The structure of such a curriculum is likely to be topic based, linked to individual science subjects, and characterized as the traditional academic curriculum. Pedagogy is likely to consist mainly of direct instruction.

Psychologists such as Jerome Bruner have suggested that the key concepts of the academic disciplines, whether in science or social science, can themselves form the basis of a school curriculum. Such concepts can be visited and revisited at different stages of schooling so that students can develop a deeper and deeper understanding of them. The resulting curriculum structure is likely to focus on the major concepts in one or more academic subjects and the ways of thinking that characterize that subject. Bruner's views on learning led him to argue that such a curriculum would also highlight students' active engagement with the subject. Thus, while its focus would be the academic disciplines, its pedagogy was more linked to discovery learning.

For other curriculum theorists, such as John Dewey, there needed to be a more integrated approach to knowledge in the school curriculum, and this thinking has had a considerable impact on science education. Integrating knowledge from different science disciplines has been a popular approach to science curriculum development. Key ideas of different kinds can be used as curriculum organizers, such as social issues (e.g., sustainability and environmental degradation) or health issues (e.g., water quality in developing countries) or issues concerning the application of science in society (e.g., the role of nuclear energy). In this form of curriculum organization, scientific knowledge is not abandoned but it is applied in different ways to address important social issues. It is these issues that form the basis of the curriculum. Accompanying pedagogy is likely to be inquiry oriented.

A related curriculum structure to that of the integration of scientific knowledge has been supported by the Salters' Institute for Industrial Chemistry in the United Kingdom. It is based on the identification of everyday contexts, sometimes called authentic contexts, that require both social and scientific knowledge to understand them (Campbell et al. 1994). The importance of such contexts is that they should have particular relevance to the lives of young people. This approach to scientific understanding is reflected in large-scale assessments such as the Programme for International Student Assessment (PISA) but also in curriculum developments in several countries including the United Kingdom and the United States. In a sense, this approach to science curriculum is not so much built on integrating knowledge from different disciplines (although it does this) as bringing together scientific and social explanations for important phenomena influencing young people. Students learn science and its processes but as well and they learn about its social applications in relevant contexts (Solomon and Aikenhead 1994). The curriculum is structured around relevant social contexts that require scientific and social explanations and pedagogy is likely to be inquiry oriented.

Ways of Knowing and Learning Science

It is clear from the above descriptions of different forms of science curriculum that, while they represent different curriculum forms and structures, they are by no means value neutral. Discipline-based approaches assume that scientific knowledge within disciplines should be transmitted exactly in that form to students, and this is why such approaches are usually associated with a pedagogy of direct instruction. Bruner's version of this discipline-based approach both changed the nature of science (from facts to concepts) and saw the need to develop a more engaging and meaningful pedagogy. Integrated curriculum designs did not deny the importance of scientific knowledge but sought to draw on multiple disciplines where they were relevant in addressing particular issues. Authentic context-based approaches went further still by linking the curriculum to daily living and the application of scientific and social knowledge to addressing issues of immediate relevance to students. This trajectory from the disciplines to contexts is not so much about the nature of science as about the ways young people can best access scientific knowledge. If it is assumed that in a democratic society all students ought to have access to key knowledge about science, then different curriculum structures can be seen as different ways to achieve this objective.

It is for this reason that approaches to pedagogy have been referred to alongside each description of a particular curriculum structure. If knowledge is believed to be fixed and static as embodied in the scientific disciplines and only has to be "absorbed" by students, then direct instruction will be the pedagogy of choice. If students themselves need to integrate new knowledge into their existing knowledge structures, then learning processes will need to provide the opportunity for this. There is no single pedagogy that can be prescribed, but, where issues and problems form the structure of the curriculum, then inquiry or problem-based pedagogies will work best. So the "what" and the "how" of science learning are closely related.

Society's Expectations About Science Learning

Schools operate in social and political contexts so it should not be unexpected that what is taught and how it is taught will be of interest to society at large. In the post-World War Two period, the relationship of science to national security led to a focus on the strategic and instrumental purposes of teaching science, and the "race to space" in the 1960s highlighted the need to produce scientists who could assure victory in this race. Thus, the focus on scientific disciplines and Bruner's concept-based curriculum is that students needed to understand "real" science. At the same time, some community groups have often advocated for more “rigor” in the curriculum, and this is generally seen to be achieved with a discipline-based approach to school subjects. It is in this sense that curriculum structure can be said to be socially constructed because it is a response to social pressures.

Yet these social pressures can change. For example, when governments change, there can also be a change in educational philosophy and direction. This can then create spaces for alternative curriculum structures that may be more student focused or more supportive of adopting structures and pedagogies that are known to meet the needs of a broader range of students. Educators themselves can be responsible for promoting these alternative approaches especially where they can show there will be benefits for all students rather than just some. It is important to understand that curriculum structures can be used for important social purposes as well as educational purposes.

Conclusion

Curriculum structures give shape to the form the curriculum takes, but this form may be determined as much by social influences as educational rationale. Choice in curriculum structure ranges from the use of pure science disciplines to the selection of scientific knowledge that addresses issues of immediate relevance to students. Related to this choice are questions of pedagogy and how students can most effectively learn science. Society will always maintain an interest in the form and structure of the science curriculum so that changes can be expected over time and in response to what are seen as key social and political priorities.

Cut Scores

Gabriela Noveanu
Curriculum, Institute for Educational Sciences,
Bucharest, Romania

Keywords

Cut scores; NAEP; Test; TIMSS

Cut scores are points on a distribution of scores representing the minimum scores required for performance at specific levels. They are used to categorize performance on assessments into each of the performance levels. In high-stake tests the cut score becomes the passing score determining either passing or failing the test.

The measured achievements have to be considered as continua. Dividing each of these continua is essentially arbitrary. The result consists in a number of divisions (cut points) that mark the boundaries of the divisions. The establishment of cut scores represents one of the most critical test development issues, especially for test with any consequences for examinees. Standard-setting methods used to determine cut scores require expert judgments about the expected performance at each level. The cut scores determining each level are available with the descriptions because there is a need of reporting student performance not just as scores, but also in terms of content; the usefulness of the data collected can be proved when there is an understanding of what is measured and its connection to what these measures reveal about students.

In Trends in International Mathematics and Science Study (TIMSS), there are selected four cut points, 625, 550, 475, and 400, on the achievement scales. These cut points corresponding to the international benchmarks were selected initially to be as close as possible to the percentile points – 10 %, 25 %, 50 %, and 75 %. The National Assessment of Educational Progress (NAEP) uses a set of cut scores on the scale that defines the lower boundaries of basic, proficient, and advanced levels being determined for each grade through a standard-setting process.

Argumentation; Assessment; Inquiry; Modeling; Rubrics; Scientific Practices

The goal of science is to explain phenomena, reoccurring natural events that happen in the world. As such, scientists strive to understand how and why phenomena occur. All explanations begin with a need to find an answer to a question. A claim is frequently made in response to a question. In order to test these different claims, scientists often design and carry out investigations that allow them to collect data or they may use data that already exists. Scientists also use theoretical ideas to provide justifications for why the evidence supports or refutes these various claims. In constructing these explanations about the natural world, scientists engage in argumentation in which they debate competing claims by evaluating the validity of those claims and the supporting evidence. Here is where evidence and scientific principles play an important role. In science, the claims that best fit with the available evidence and scientific principles move forward in the community. When new evidence emerges that the claim cannot account for, claims are revised, producing a new explanation. As the Framework for *K-12 Science Education* argues, "Deciding on the best explanation is a matter of argument that is resolved by how well any given explanation fits with all available data, how much it simplifies what would seem to be complex, and whether it produces a sense of understanding" (NRC 2012, p. 68). The focus of the framework (NRC 2012) and the Next Generation of Science Standards (NGSS 2013) is for students to construct explanations based on evidence and scientific ideas.

To support students in constructing scientific explanation, McNeill and Krajcik (2011) suggest using a framework that consists of a claim, evidence, reasoning, and rebuttal. The framework supports students in constructing and critiquing explanations. The claim, evidence, reasoning, and rebuttal framework (CERR for short) can be used to develop explanation assessment tasks as well as analyze student explanations. The framework was adapted from Toulmin's (1958) work on argumentation. In writing explanations,

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

students propose claims and support those claims with evidence and reasoning that provides a justification for that link between the data and the claim. They also need to argue why other claims don't fit the evidence as well as the claim they put forth, which is where the rebuttal frequently is incorporated.

The claim is a statement that expresses the answer or conclusion to a question or problem. When a question is posed, information is sought to provide evidence and justification for the claim or an investigation is planned to provide evidence to support the claim. As such, constructing an explanation can engage learners in other scientific practices such as designing investigation, analyzing and interpreting data, and arguing form evidence.

The other components of the scientific explanation framework provide the support and backing for the claim. A central feature of science is its use of scientific data as evidence to understand the natural world (National Research Council 2007). Evidence is scientific data that provided support for the claim. Data can come from observations and measurements from natural settings or from the results of controlled experiments. When constructing explanations, data can either be first or second hand. Firsthand data is data collected and generated by investigations planned by the experimenter. Secondhand data was collected and generated from investigations planned and conducted by other researchers. The accuracy or reliability of scientific data is often checked through multiple trials or by comparing different types of data. Students can either collect data themselves or be provided with data such as data tables, readings, or a database.

There needs to be appropriate and sufficient data to justify the support of a claim. Appropriate data need to be scientifically pertinent and important for supporting the claim. Sufficient data means that enough data has been generated and gathered to support the claim. Typically in science, we collect, analyze, and use multiple pieces of data to answer a particular question or problem.

Reasoning provides a justification that shows a way the data can be used as the evidence to support the claim. The reasoning states why the evidence supports the claim, providing a logical connection between the evidence and reasoning. Reasoning also requires discussing appropriate scientific principles to justify why the data can be used as evidence to support a particular claim. In explaining phenomena, there are multiple plausible explanations for how or why a phenomenon might occur. Often scientists need to provide an argument about which claim is the most appropriate. The rebuttal provides evidence and reasoning to rule out other possible alternative claims and provides evidence and reasoning for why the alternative is not the appropriate explanation for the question or problem. Scientists consider and debate these multiple possible claims.

Construction Scientific Explanation Tasks: How can you design and evaluate tasks to assess students' abilities to construct scientific explanations? How can explanation assessment tasks be designed to align with the key science ideas? Designing and judging assessment tasks that focus on scientific explanations will assess students' understanding of the structure of scientific explanations and disciplinary core ideas (NRC 2012). The claim, evidence, reasoning, and rebuttal framework provides structures for designing and assessing explanation tasks. McNeill and Krajcik (2011) and Krajcik et al. (2008) propose a process for developing scientific explanations assessment tasks. The process consists of seven steps:

Step 1: Identifying and unpacking the science ideas
Step 2: Selecting the level of complexity of the task
Step 3: Developing performance expectations
Step 4: Constructing the assessment task
Step 5: Reviewing the assessment task
Step 6: Using the base rubric to develop a specific rubric

Selecting and Unpacking Science Ideas: The first step entails selecting and unpacking the science ideas. National or state documents that specify what learners should know and that target disciplinary core science ideas addressed in the classroom can be used for selecting the science ideas. Examining documents and selecting the appropriate science ideas can help determine what specific science ideas are key for building scientific understanding necessary for problem solving and explaining phenomena.

After selecting the science idea, the ideas need to be "unpacked." Unpacking has two components. First, a science standard often contains many different science ideas. In order to develop a thorough understanding of the standard, it helps to break it down into related science ideas and to clarify each science idea in terms of its meaning and relationship to the other ideas. Second, it also helps to consider common student nonnormative ideas or challenges in learning the science ideas. The unpacking process helps to clarify what science ideas to target in the item as well as common student difficulties to incorporate into the item.

Selecting the Level of Complexity: The next step in designing scientific explanation assessment tasks is to select the level of complexity. Here, a decision on the level of complexity of the framework as well as difficulties students might experience when constructing explanations needs to be made. Level of complexity refers to the number of components and variations in those components that students will need to incorporate when responding to the task. Students could respond to only the first three components (e.g., claim, evidence, and reasoning), or the fourth component of rebuttal could also be included. Next, the level of difficulty for each component needs to be decided. Typically, the claim is at the simplest level.

Usually, the variation in the difficulty of the components occurs in varying the complexity of the evidence and reasoning. The amount of evidence and reasoning can vary from simple to complex. At the simple level, the evidence supports the claim, and at the moderate level, evidence that is appropriate and sufficient needs to be given. At the complex level, multiple pieces of sufficient and appropriate evidence need to be provided. Reasoning at the simple level provides a justification to support the claim and at the moderate level a justification of why the data can be used as evidence to support the claim using appropriate scientific principles. At the complex level, reasoning requires a justification of why the data can be used as evidence to support the claim using appropriate scientific principles for each piece of evidence. The rebuttal is only appropriate at the complex level and requires that counterevidence and reasoning be given to argue why possible alternative explanations are not appropriate. (See McNeill and Krajcik (2011), for a more complete description.)

Creating Performance Expectations: A performance expectation specifies a learning goal beyond the content knowledge that students are to learn by specifying how they will apply the science ideas (Krajcik et al. 2008; NRC 2012). In this respect, performance expectations specify how students will make use of the science ideas. Although a variety of active verbs can be used to describe how students will use science ideas, the use of scientific and engineering practices – designing an investigation, analyzing and interpreting data, constructing scientific explanations, arguing from evidence, and building models (NRC 2012) – specifies learning goals and what is hoped students will do in terms of important capabilities in science. This discussion focuses on the practice of constructing scientific explanations; however, the construction of other types of assessment tasks can use this process for developing a variety of assessment types.

A performance expectation is developed by crossing the scientific practice of explanation with a science idea of interest. Figure 1 shows a representation and gives an example of this process. Developing performance expectations provides explicit statements of learning goals that guide the design of learning tasks, assessment tasks, and the associated rubrics. Notice that in Figure 1, the performance expectation clearly states the expectations for the claim, evidence, and reasoning. The performance expectation specifies the science idea and how learners should use that knowledge, in this case constructing an evidence-based explanation about pure substances having characteristic properties. The performance expectation specifies the complexity of the evidence and reasoning that needs to be included in the assessment task.

Practice	Science idea from the framework for K-12 science education (NRC 2012)	Performance expectation
Scientific explanation	Each pure substance has characteristic physical and chemical properties (for any bulk quantity under given conditions) that can be used to identify it	Develop a scientific explanation with a claim that a pure substance has characteristic properties, two pieces of appropriate and sufficient evidence and reasoning that a substance has the same molecular composition and structure throughout and that other substances with different properties do not have this same structure and composition

Designing and Assessing Scientific Explanation Tasks, Fig. 1 Creating performance expectations. Scientific practice crossed with science idea to make a performance expectation

Sample	Density	Color	Mass	Melting point
1	1.0 g/ml	Clear	6.2 g	0.0 C°
2	0.89 g/ml	Clear	6.2 g	38 C°
3	0.92 g/ml	Clear	6.2 g	14 C°
4	0.89 g/ml	Clear	10.6 g	38 C°

Designing and Assessing Scientific Explanation Tasks, Fig. 2 Assessment task aligned with performance expectation. John measured the properties of several materials described in the data table below. He was confused because three of the samples had the same mass but different melting points and density. Using the data in the table, write a scientific explanation about whether any of the samples are the same substance. Make sure you include a claim, at least two pieces of evidence, and reasoning to justify your position

Developing the Assessment Task: Developing performance expectations provides specifications for constructing assessment tasks or learning activities to meet performance expectations. Performance expectations help to develop alignment among learning goals (the performance expectation), the learning tasks, and the assessment tasks. Figure 2 provides an assessment task that aligns with the performance expectation in Figure 1.

In writing the assessment task, identification of a context that is accessible to learners must also be taken into consideration. The context includes determining the phenomenon addressed in the task and the data students analyze and interpret to justify their claim. An appropriate context makes the task accessible to students. The assessment task in Figure 2 provides a phenomenon and science ideas that are accessible to middle school learners. The context also is important because scientific explanations are written to makes sense of specific phenomenon. In the example in Figure 2, it is about properties of a specific substance.

The task in Figure 2 would require middle school students to make the claim that samples 2 and 4 are the same substance because they have the same density and melting points. Their reasoning would include that density and melting point are properties that don’t change with the amount of sample. The students would also need to specify that the reason why the density and melting points are the same regardless of amount is because the samples are made of the same types of molecules throughout both samples. Samples 1 and 3 are not the same substance even though the samples have the same mass because mass is not a characteristic that can be used to identify a sample as one type of substance or another. In responding to this item, students also have to engage in interpreting data; as such, this task engages students in a secondary scientific practice of data interpretation.

Review the Assessment Task: Assessment tasks need to be reviewed to check if the science ideas specified in the task are necessary and sufficient for responding to the tasks. The task also needs to be reviewed to assure that the assessment task is comprehensible to learners. The Project 2061 assessment evaluation framework (DeBoer 2005) provides an appropriate process for accomplishing this step. The Project 2061 assessment framework focuses on three criteria: necessity, sufficiency, and comprehensibility. Answering three questions focuses the review:

1. Is the knowledge necessary to correctly respond to the task?
2. Is the knowledge sufficient by itself to correctly respond to the task or is additional knowledge needed?
3. Is the assessment task and context likely to be comprehensible to students?

The necessity criterion examines if students need to apply the science ideas and the scientific practice intend by the assessment task to appropriately respond to the item. In many respects, unpacking the science ideas and specifying the performance expectation helps to ensure if the science ideas and scienttific practice are necessary to provide a response to the item.

The sufficiency criterion considers what other science ideas or scientific practice is included in the assessment task and if that additional knowledge is appropriate to include. As such, the sufficiency criterion provides a check if other science ideas or scientific practices go beyond those specified in the learning goal. If the assessment task includes science ideas or scientific practices that the learners have not developed, then learners are likely to respond inappropriately to the item not because they don't have an understanding of the target goals but because they don't know these additional science ideas or practices used in the task. If learners have previously studied this additional content, it might be appropriate to include. For instance, to respond appropriately to the assessment task in Figure 2, students also need to know that density and melting point are properties of a substance but that mass is not a property of a substance. They also need to know how to read a table and interpret the data in the table. The additional science ideas and the level of data interpretation are appropriate for middle school science.

The comprehensibility criterion considers if the assessment item is appropriately written to meet the experiences and background knowledge of the learners. In the section on developing the assessment task, the appropriateness of the phenomena and science ideas were considered. In determining if the assessment task and context are likely to be comprehensible to students, students' cultural backgrounds and the literacy demands of the task also need to be taken into consideration. If the reading demands are beyond those of the students, the students might know the target learning goals but respond inappropriately because of the language. Consideration of cultural backgrounds is essential as learners from various backgrounds could have difficulty interpreting the context of an assessment task.

Using the Base Rubric to Develop a Specific Rubric: A base explanation rubric (see Appendix 1) provides a general rubric for evaluating scientific explanations for various science ideas (McNeill et al. 2006; McNeill and Krajcik 2011). The base rubric includes the four components of a scientific explanation and provides guidance about developing different levels of student achievement for each of those components in a specific rubric. The specific rubric combines both the general structure of a scientific explanation and the appropriate science ideas and evidence for the particular task. Adapting a base rubric to develop a specific rubric involves aligning the rubric to a particular assessment task. The specific rubric is designed to a particular explanation task and shows what science ideas and evidence the students needs to apply at each level of achievement. The specific rubric includes determining what would count as an appropriate claim, evidence, and reasoning. When applicable, it also needs to include specifying the alternative explanations and the evidence and reasoning to support refuting the alternative claims. To develop a specific rubric, begin by using the base rubric and constructing the ideal student response for each component.

Summary Statement: To support students in constructing scientific explanations, McNeill and Krajcik (2011) suggest using a framework that

Designing and Assessing Scientific Explanation Tasks, Appendix 1 Base Explanation Rubric

	Level		
Component	0	1	2
Claim: A response to the original question	Does not make a claim, or makes an inaccurate claim	Makes an accurate but incomplete claim	Makes an accurate and complete claim
Evidence: Scientific data that supports the claim. The data needs to be appropriate and sufficient to support the claim	Does not provide evidence, or only provides inappropriate evidence (Evidence that does not support claim)	Provides appropriate, but insufficient evidence to support claim. May include some inappropriate evidence	Provides appropriate and sufficient evidence to support claim
Reasoning: A justification that links the data to the claim. Reasoning shows why the data counts as evidence by using appropriate and sufficient scientific principles	Does not provide reasoning, or only provides reasoning that does not link evidence to claim	Provides reasoning that links the claim and evidence. Repeats the evidence and/or includes some scientific principles, but not sufficient	Provides reasoning that links evidence to claim. Includes appropriate and sufficient scientific principles
Rebuttal: Communicates possible alternative explanations and provides evidence and reasoning for why the alternative explanation is not appropriate	Does not communicate alternative explanations exist or makes an inaccurate rebuttal	Communicates alternative explanations and provides appropriate but insufficient evidence and reasoning in making the rebuttal	Communicates alternative explanations and provides appropriate and sufficient counter evidence and reasoning when making rebuttals

Adapted from McNeill and Krajcik (2011)

consists of a claim, evidence, reasoning, and rebuttal. The framework assists students in constructing and critiquing explanations as well as supports teachers and designer in designing explanation learning tasks and explanation assessment items. In writing explanations, students propose claims and support those claims with evidence and reasoning that provides a justification for that link between the data and the claim. They also need to argue why other claims don't fit the evidence as well as the claim they put forth. A six-step process that begins with identifying and unpacking key science ideas and ends with developing a specific rubric provides a technique for developing explanation assessment items that align with the target core science ideas and will help ensure that assessment items are appropriate for the background experiences and prior knowledge of students.

Scientists strive to provide causal accounts that explain and predict phenomena. Scientists use models to represent relationships among components to test and explain complex phenomenon. As such, modeling is an integral and common practice across the science disciplines. Scientists continually form, test, evaluate, and revise models to explain and predict phenomena. By testing models against data, scientists evaluate and revise models to better fit the data. When a model can no longer account for the data, the model is revised.

> Observations of the natural world motivate the construction of models, which in turn motivate further observations and drive the resulting interpretations. In this way, models become explanations: that is, stipulations of possible cause and effect relations in the phenomenon under investigation. (Penner et al. 1998, p. 430)

Defining Scientific Modeling

The practice of scientific modeling differs significantly from the way models are often thought of and talked about in everyday life. For example, a model airplane is usually a smaller version of an actual plane. In this colloquial use of the word, a model is a scale representation of an object. However, scientific modeling is more complex and abstract process. A scientific model does include representations, but it does not it is representing. A model may include invisible components including symbols to indicate the relationships among the components of the model. Although scientific modeling can include representations that look similar to the system that is being modeled, it can also include mathematical representations, graphs, and computer simulations.

All models need to explain and predict phenomena and be consistent with scientific theory; in other words, the model must help explain what, how, or why a phenomenon occurs. Moreover, models need to specify the relationships among components in the system that is being explained to provide a causal account. Scientific modeling is also an iterative process. A scientist will create a model to explain a phenomenon. The model is then used to make predications about related phenomena. Those predications are tested and used to revise the model. The model is refined to design a more robust explanation. The model continually evolves with additional evidence.

One model will not be able to capture all aspects of a phenomenon. In fact, models often simplify the system in order to highlight certain aspects. Thus, different models may be needed to explain different aspects of one particular phenomenon. For example, a lightning strike is a complex phenomenon. One model could highlight movement of particles in the air to explain how large charges build up in thunderstorms. Scientists would use another model to explain why light and sound are observed when the lightning strikes. A different model is needed to predict the likelihood that certain weather systems will lead to lightning strikes. Finally, scientists would use a mathematical model to triangulate locations of strikes using information about where and when they were observed. Scientific modeling is a complex process that requires analyzing a variety of evidence and utilizing theory to explain and predict phenomena.

Modeling in Science Classrooms

Scientific modeling is one of the scientific practices identified in the Framework for K-12 Science Education that should be used in conjunction with disciplinary core ideas and crosscutting concepts to help learners form usable understanding of science (National Research Council 2012). The various scientific practices work together to help build our understanding of the world. For instance, scientists often argue that one model better fits the data than another model. Although developing and using models is central to the practice of science and as such should be an important aspect of what occurs in science classrooms, developing, testing, and revising models are seldom seen in the science classroom.

The models that students develop are concrete artifacts that can be shared and critiqued by others. These artifacts provide a window into students' mental models or their understanding of this area. When students develop and test models to explain and predict phenomena, the process of developing models helps learners form integrated conceptual understanding. Integrated conceptual understanding refers to concepts and connections that students hold and use to represent and explain his or her understanding of phenomenon in the world. Models can be drawings, three-dimensional structures, a set of equations, qualitative descriptions, or a simulation.

Supporting Students in Building Models

Due to the complex nature of the practice of scientific modeling, teachers and curriculum designers need to support students in the process by providing criteria for developing a scientific model. Although models are used in a variety of ways, there are similar elements across models:

1. Identification and specification of the components or variables important for the analysis of the system.
2. Description or representation of the relationships or interactions among the components or variables.
3. The collection of relationships provides a causal account of the phenomena under study.

Even a mathematical model includes these elements. For example, $F = ma$ includes variables to represent the amount of force, mass, and acceleration of an object or system of objects. The equation indicates several relationships among these variables. Finally, the equation serves as a model, when it provides a causal account of the phenomena. The equation alone is a simple algebraic statement; however, it serves as a model if it is used to explain observations or make predictions about the motion of one or more objects.

Designing Assessment Tasks for Scientific Modeling

The Framework for K-12 Science Education (NRC 2012) and the Next Generation Science Standards (Achieve 2013) define science learning expectations as the blending of scientific practices, crosscutting concepts, and disciplinary core ideas to form performance expectations. A performance expectation defines knowledge in use. Assessing scientific modeling requires the use of scientific ideas. A performance expectation for modeling is developed through crossing the practice with disciplinary core ideas and crosscutting concept. Finally, a relevant phenomenon is added so the performance expectation will lead to a rich assessment task.

Clear and specific performance expectations provide guidance in writing an assessment task as they point out important elements that need to be included in the assessment. Table 1 shows an example of a performance expectation. The performance expectation shown in Table 1 contains two critical elements: (1) the scientific practice of developing a model and (2) the use of a disciplinary idea – the structure of an atom. This specificity supports the alignment between the performance expectation and the assessment task. Figure 1 shows an assessment task that aligns to the performance expectation in Table 1. The performance expectation and assessment task are appropriate for ninth or tenth grade physical science.

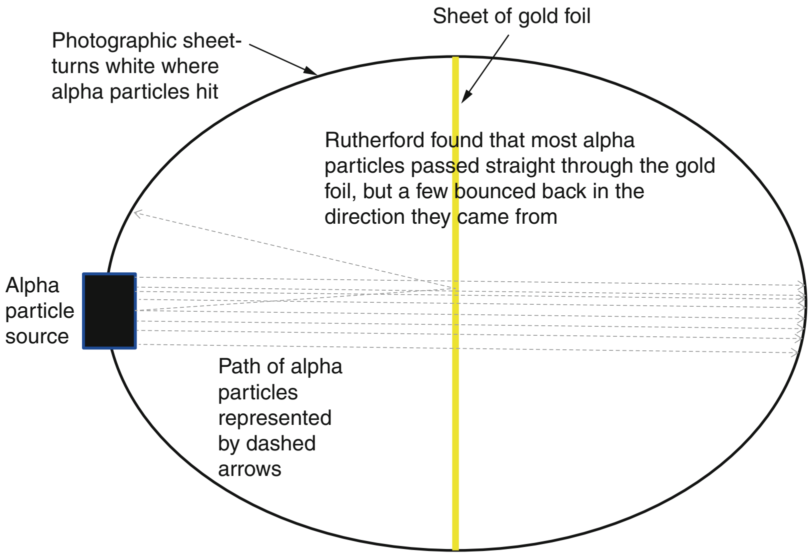
Designing and Assessing Scientific Modeling Tasks, Table 1 Defining performance expectation for modeling

Scientific practice: developing and using models	Disciplinary core idea: “Each atom has a charged substructure consisting of a nucleus, which is made of protons and neutrons, surrounded by electrons” (NRC 2012, p. 107)	Relevant phenomena: Rutherford observed that when alpha particles were shot at a thin sheet of gold foil, most of the particles passed through mostly unaffected, but a few returned close to the direction from which they came	Performance expectation: Develop a scientific model for atomic structure that can account for experimental results related to the structure of the atom

Note that the assessment task requires that students explain in writing how their model is related to the phenomenon; a diagram alone cannot fully assess all key elements of a model and if students demonstrate understanding of the performance expectation.

Assessing Student Responses

Base Modeling Rubric: A base, modeling rubric provides a general rubric for evaluating scientific models that explain a variety of phenomena. The base rubric includes the three elements of a scientific model and provides guidance about assessing different levels of student achievement



Draw (or revise) your model of atomic structure	How does this model explain Rutherford’s observations?

Designing and Assessing Scientific Modeling Tasks, Fig. 1 An assessment task. When Rutherford shot positively charged alpha particles at a thin sheet of gold atoms, he observed that most of the particles passed straight through but was surprised to see some that returned to the direction they came from

Designing and Assessing Scientific Modeling Tasks, Table 2 Base rubric for assessing scientific models

	Levels		
Criteria	0	1	2
Components: Model includes identification and specification of appropriate and necessary components, including both visible and invisible	Diagram shows an image of the phenomenon	Model may include both visible and invisible components, but may be missing key components, or components are not clearly labeled leaving uncertainty in the interpretation of the model	Model highlights all necessary components, including both visible and invisible, that are needed for explaining the phenomena. All components are clearly labeled or identified in description
Relationships: Model includes representations or descriptions indicating how various components within the model are related and interact with each other	Model does not indicate relationships or interactions between components of the model	Model is either missing key relationships or includes some inaccurate relationships between component	Model includes all appropriate relationships necessary for the explanation of the phenomena
The collection of relationships provides a causal account of the phenomena: The model is used to explain or predict phenomena or specific aspects of phenomena	Model is not used to explain phenomena	Model is used to try to explain phenomena, but there are some inaccuracies in the explanation of the phenomena	Model is consistent with available evidence and is used to explain phenomena

for each of the elements. Table 2 provides a general base rubric for assessing students' scientific models.

Developing Specific Rubrics: A specific rubric combines both the general structure of scientific models with the appropriate science ideas and evidence with a particular assessment task. Adapting a base rubric to develop a specific rubric involves aligning the rubric to a particular assessment task. The specific rubric includes determining what would count as appropriate components and relationships in the specific task. To develop specific rubrics, begin by using the base rubric and constructing the ideal student response for each element (Modified from McNeill and Krajcik 2008).

To develop the specific rubric for the Rutherford task, the specific components, relationships, and the connection to the phenomenon need to be identified. Note that these specifics are being defined with respect to the instructional methods used to cover the material in class. In this example, the students learned about Rutherford's gold foil experiment using a simulation where students manipulated the concentration of the positive charges and observed the effect on the electric field and motion of the positive alpha particles. This simulation can be found at http://concord.org/tst/rutherford-model.

Step 1: Identify the object/components: what components need to be specified. The key components needed to explain the results of the Rutherford observations include protons and alpha particles. Additionally, it is necessary to include that these particles are all positively charged. Further, the strength of the electric field around the protons is an important invisible component for explaining how the path of a few of the alpha particles changed so drastically.

Step 2: Specify the specific relationships: what relationships need to be specified. In the Rutherford example, there are two important relationships to include. Since the alpha particles and protons are all positively charged, these particles will repel. An additional relationship that is relevant for explaining Rutherford's observations is the connection between the strength of an electric field and the concentration of charged particles. The electric field is stronger around concentrated charges.

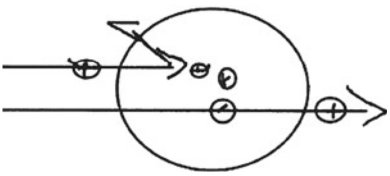
Step 3: Show the connections among the relationships. Do the connections among the

Designing and Assessing Scientific Modeling Tasks, Table 3 Specific rubric for assessing Rutherford modeling task

	Levels		
Criteria	0	1	2
Components: Model includes identification and specification of appropriate and necessary components, including both visible and invisible	Diagram shows an image representing the outcome of Rutherford's gold foil experiment	Model may include both visible and invisible components, but may be missing key components, or components are not clearly labeled leaving uncertainty in the interpretation of the model. Model may not indicate the charge of particles	Model highlights protons and alpha particles and identifies these particles as positively charged
Relationships: Model includes representations or descriptions indicating how various components within the model are related and interact with each other	Model does not indicate relationships or interactions between components of the model	Model is either missing key relationships or includes some inaccurate relationships between component	Model includes repulsive forces between positively charged alpha particles and protons. Model includes relationship between concentration of protons and strength of electric field
The collection of relationships provides a causal account of the phenomena: Model is used to explain or predict a phenomenon or specific aspects of a phenomenon	Model is not used to explain phenomena	Model is used to try to explain phenomena, but there are some inaccuracies in the explanation of the phenomena	Model is consistent with and used to explain the evidence from Rutherford's experiment that most of the alpha particles pass straight through the gold foil but a few are deflected at a large angle

Atomic model to explain Rutherford's observations from the gold foil experiment

Student's representation



Transcript from interview:
This is like the atom and inside of it is both the positive and the-protons and electrons, and when you send out, [an alpha particle] um one woulde either bounce off or go right through depending on what its charge was.
If the alpha particle hits a proton, it will be reflected because they repel; if it hits an electron, it would come right straight through

Designing and Assessing Scientific Modeling Tasks, Fig. 2 Student atomic model to explain Rutherford's observations

relationships provide a causal account for why the phenomenon occurs? Rutherford observed that a few of the positively charged alpha particles returned almost in the direction they originally came from. In order to change the path of the alpha particle this drastically, there must be regions with highly concentrated positive charges. However, the majority of the alpha particles passed almost unaffected through the gold foil. Thus, inside the gold atoms, there must be regions with highly concentrated protons and large regions without protons.

Adding these specifications to the base rubric shown in Table 2 develops the specific rubric. Table 3 displays an example of a specific rubric that would be used to assess students' responses to the task described in Fig. 1.

Example of Assessing Student's Model: Figure 2 provides an example of a student's representation of atomic structure and her

Designing and Assessing Scientific Modeling Tasks, Table 4 Evaluation of sample student model

Criteria	Evaluation	Description
Components	Level 2	Student included protons and alpha particles. Though these are not explicitly labeled in the diagram, the student identified them in the description of the model during the interview. The protons and alpha particles are all labeled with plus signs indicating they are positively charged
Relationships	Level 1	Student included repulsive forces between the alpha particles and protons. However, the relationship between the concentration of positive protons and the strength of the electric field is missing. Instead, the student relates the path of the alpha particles to the interaction with individual particles rather than electric fields created by collection of particles
Connection to phenomenon	Level 2	The student used the model to explain how some alpha particles were reflected and others passed through. Though the student had an inaccuracy in that she related the path of the alpha particles to individual particles rather than a collection of particles, this inaccuracy was captured in the evaluation of the relationship category. The student's description of the phenomenon is accurate and the model provides a causal account to explain the phenomenon

description of how the model related to the phenomenon. The assessment task here is a bit different than the task described above. The students drew representations of atomic structures and then were interviewed about the representations and how they related to a variety of phenomena. The example is provided to illustrate the connection between the base rubric, specific rubric, and a specific example. The example includes the representation the student drew, a selection of the transcript from the interview, and an evaluation of the model using the rubric.

Overview of the analysis of the student model: The model includes appropriate components. Plus and minus signs indicate the charges of the various components. Arrows show a relationship between alpha particle and the path of the alpha particle depending if it interacts with a proton or not. However, the model includes inaccurate ideas: The student's model has alpha particles interacting with an individual proton or electron rather than with the strong electric field due to a concentration of multiple protons. Table 4 displays an evaluation of this student's model based on the criteria described in the base and specific rubrics.

Summary Statement

Scientific modeling engages learners in a complex and essential scientific practice. Teachers need to support students in developing and revising models. This includes providing a structure to develop and evaluate student's models. This structure also helps students to evaluate and revise their own models as they gather additional evidence. Due to the complex nature of the practice of scientific modeling, it is important to describe the three elements of the model to evaluate the components included in the model, relationships between these components, and the connection among the components and relationships in the model to give a causal account of why the phenomena occurs. Additionally, because models explain or predict phenomena, it is important to write assessment tasks that ask students to connect their models to phenomena. Rubrics can monitor students developing conceptual understanding as students continue to build and refine their evolving models. The analyses of students' models provide insights into students' integrated conceptual understanding.

Developmental Perspectives on Learning

Terry Russell
Centre for Lifelong Learning, University of Liverpool, Liverpool, UK

Human curiosity to understand the immediate world and wider universe we inhabit generates a legacy of cultural capital for succeeding generations. Cumulative as well as revolutionary insights spawn a body of knowledge in the form of artifacts, information and communication formats, and centers of research populated by living human expertise. Into this context arrive about 250 births per minute across the world. What do we know about the induction of these new arrivals to the frameworks science offers for making sense of the world? How and where should we begin the enterprise to shape the unknowing dependence of neonates toward scientific literacy for all and a more single-minded commitment for some?

The scientific study of intellectual growth from infancy to maturity is a relatively recent discipline, propelled in the early twentieth century by major contributions from Piaget and Inhelder in Geneva and Luria, Vygotsky, and their circle in the Soviet Union. While the former focused on the developmental construction of knowledge (genetic epistemology) as a "natural" process of intellectual adaptation, independent of instruction, the latter prioritized sociohistorical enculturation processes, especially as mediated by language, with teaching and learning a preeminent interest. Vygotsky's introduction of the term "zone of proximal development" (readiness for the next jump in learning) into educational vocabulary remains important in considering progression.

A number of major disciplines inform thinking about progression in children's developing science-relevant capabilities: cognitive-developmental psychology and curriculum studies complement and supplement science knowledge. The trend in such research has been to extend inquiries to increasingly younger age groups (including pre-birth studies by psychologists) and, on the part of curriculum researchers, an interest in "emergent science" in children from about age three onward. Recent decades have also brought dramatic social contextual changes in the technologies of information and communications environments to which infants and young people in many societies are exposed. This social change is linked to a strong prevailing value position in liberal democracies, manifest in the promotion of attitudes and behaviors consistent with an expectation that, from a very early age, learners should show curiosity and be exploratory, autonomous seekers and evaluators of information. Notwithstanding the enormous body of existing scientific knowledge, active assembly of knowledge is valued by educators, rather than passive receipt of transmitted information. The implication is that a judicious ordering and scaffolding of the salient experiences to be negotiated by learners is essential to achieve a regulated, cumulative progression.

While a senior school and later adult science education specialism may apply to only a minority of students, the underpinning cognitive, affective, and social skills that comprise essential antecedent capabilities to a mature scientific literacy can be identified and nurtured from a very young age. Three aspects describe most of the important foundations for the development of scientific literacy: ideas together with the evidence to support them;

scientific inquiry skills (including variable handling), sometimes referred to as "procedural understanding"; and conceptual development, in the form of knowledge and understanding of the subject matter of science.

Progression with Ideas and Evidence

The area of ideas and evidence – that is, having ideas about what entities exist, how they might be classified, and how such beliefs are justified – has pervasive relevance across the curriculum and as a life skill but is quintessentially important to scientific thinking. While independence of thinking is valued in science, particular times and cultures frequently exert pressure to conform to prevailing beliefs, whether fueled by precedent, folk knowledge, superstition, or simply the weight of orthodoxy (as Galileo's experience confirms most dramatically).

Constructivist research conducted in recent decades confirms that children have ideas, but need an accepting ambience in which to express them. By engaging in a dialogic process, they may gain confidence and be empowered to take ownership of their learning. However, as well as overcoming reticence, the emergence of a "theory of mind" (ToM) is a developmentally significant process. Initially, it seems that young children assume just one reality, which is that which self-evidently exists in their own minds. What is known is assumed to be known by all. The dawning realization that others possess minds of their own opens the awareness that those others also have ideas, though initially in a restricted sense and with an important limitation: the alternative ideas that have come to be accepted are not treated as equally possible alternatives, but as absolutes ("right" or "wrong"), depending on whether they conform to the one known and absolute version of what is. The absolutist (Kuhn 2005) view that "the way things are" is shared by everyone has implications for the development of argumentation skills, because the possibility that others might hold "false beliefs" does not reach the agenda. With increasing experience and corresponding with children's maturation to early adolescence, the appreciation of others' ideas progresses to a "relativist" quality, when alternative beliefs are more readily accepted as genuine options. This tolerance of ambiguity, emerging during adolescence, can be bewildering and may lead many young people, males especially, to seek refuge in the imagined "certainties" of science. Resolution arrives with the development of a value system that allows claims, beliefs, or arguments to be weighed against warrants and evidence, where alternatives are reflected upon by reference to a system of judgment in an "evaluativist" mode. So it is that "argumentation" has become integral to some science education programs, though there is evidence that the evaluative quality of reasoning is not easily achieved. The appreciation that situations may lack sufficient evidence to inform a decision is challenging, and the absolutist and relativist qualities of performance are by no means absent in many forms of behavior in adult life.

The Development of Inquiry Skills

Progression in the manner in which evidence to support claims is gathered has been relatively well researched by science educators. Systematic empirical inquiry is a defining feature of scientific behavior, which in many curricula is prioritized over other considerations (such as science subject matter). Scientific inquiries can be deconstructed into subsets of process skills that contribute to evidence-collecting and hypothesis-testing procedures in which learners gain increasing autonomy and control. These skills (usually encompassing hypothesizing, controlling variables, observing and measuring, collecting data, and interpreting or evaluating results) are called upon in planning and conducting investigations. Each skill is to some degree subject to its own developmental trajectory. For example, hypothesizing can be thought of as the expression of an idea in a form that may be tested empirically, so is dependent on the developments described above in the domain of ideas and evidence. Formally considered, an investigation should assume a null hypothesis, that is, that the outcome of any treatment or independent variable has no effect, but younger learners may seek to conduct an experiment that “proves” their idea.

Observation, quantification, measurement, and the defining of variables develop in a closely related manner. Accurate observation can be encouraged to develop, with stereotypes and theory-laden perception brought to metacognitive awareness and displaced by accurate recording. Children in their early years will be able to handle nominal (categorical) variables, defined by simple observable attributes such as color and shape, moving to ordinal variables defined by relative magnitude; gradually quantification is introduced, allowing interval variables to be handled. This increasing complexity will, in time, be applied to the coordination of both the dependent and independent variables.

Quantification tends to proceed from nonstandard (handspans, arm spans, footsteps, etc.) to standard metrics, starting with the familiar human scale of experience before moving to macroscopic and microscopic scales that require measuring devices. Over time, measurement reliability and precision increase, as well as the complexity of the units used. For example, distance and time are simpler for learners to handle than the relational concept of speed. The recording of outcomes may start with pictograms, moving to tables, bar charts, and line graphs. Causal relationships are observed and described in everyday events from an early age, so that with experience, learners begin to operate the distinction between the independent variable (the cause, such as angle of the sun in the sky) and the dependent variable (the effect, such as shadow length).

Younger children are encouraged to begin their inquiries using “fair testing,” where the teacher encourages consideration of the factors that might influence the outcome in an investigation. This level of development is often characterized by children’s desire to “control everything,” even down to consistency in the clothes they wear. Identification of valid control variables requires a greater understanding of the conceptual system under consideration than is likely to be available to younger children.

Progression in Conceptual Understanding

For science educators, the end of the twentieth and beginning of the twenty-first century was a time of enormous interest and research activity into learners’ conceptual understanding. Piaget’s structuralist epistemology was being increasingly questioned, though stage-developmental interpretations of progression continue to have significant support. By contrast, the Genevan nondirective clinical interview technique, together with classroom variations that have in common the resolve to heed carefully learners’ ideas, to take them seriously as indicators for intervention, is an enduring legacy. This tranche of inquiry shares a concern to understand the ideas pupils bring with them to their science lessons, prior to formal instruction. As a brief example, the evaporation of water from puddles and from washing on the line is an everyday phenomenon experienced by children prior to any formal instruction. Children will make their own sense of these events and we should make no assumptions of a unifying causal mechanism being understood to explain the shift from wet to dry. For children lacking any concept of object permanence, the water in the puddle may be believed to have “disappeared,” its shift to a state of nonexistence being unproblematic. In other contexts, it may be asserted that the water has “soaked in” or traveled to the source of the heat (the sun or a hot radiator) that caused it to move. (Look inside the hot radiator and you will find the missing water.) With experience, conversations, and exposure to secondary sources of information, the macroscopic appreciation of water as existing in three states will be grasped. With formal instruction, a microscopic model that makes sense of matter as particulate will be introduced, though with the salutary reminder for teachers that the model may be filtered or distorted by earlier understandings. With awareness of such possible conceptual milestones, teachers can apply not just science subject matter knowledge but pedagogical content knowledge (PCK) to their instructional strategies.

In the last 30 years, constructivist research has gripped science educators’ imagination for its relevance to daily classroom experience. One outcome is a bibliography of over 8,000 entries compiled at the IPN (Leibniz Institute for Science and Mathematics Education at the University of Kiel) that documents research on teaching and learning science from constructivist perspectives, theoretical and empirical, from leading journals and publications in English and German, covering the period from the late 1970s to 2009, by which time Internet search functionality was felt to have made continuation of the compilation redundant. The research, however, continues, and in a sense will always need to be updated, so long as the broader science endeavor continues with new insights and discoveries, while curricula adapt to changes in priorities and in understanding. The ambitious AAAS Project 2061 (AAAS 2007) is one example of an ongoing program (the start and end marked by the 75 year cycle of the Halley comet's visibility from the Earth) that intends to improve education for 4–19-year-olds by detailing such developmental links and trajectories in the growth of understanding.

The "nature or nurture" debate that preoccupied discussion of development during the first half of the twentieth century, together with questions as to whether intelligence should be construed as global in nature or comprising a range of "factors," has been the subject of a more nuanced form of research benefiting from the tools of neuroscience. Neuroconstructivists suggest multiple and interacting causation and epigenetic plasticity in the functioning of the brain. The digital impact on child development erodes the status of "pre-instruction," yet environmental influences such as social class must be acknowledged as background variables that have a significant impact on progress in learning of individuals and groups. Attempts to uncover, describe, or manage continuity and progression in science learning trajectories must be mindful of the turbulence attributable to such factors, which might help to explain the absence to date of conclusive contributions from the small number of longitudinal studies conducted. An apposite metaphor is that we are more likely to discern "migration routes" than very clearly defined corridors or trajectories. Nonetheless, the case for an evidence-based ordering of curriculum experiences that aim to support continuity and progression and which informs the formative assessment that supports effective teaching and learning is increasingly accepted as indispensible.

Developmental Research

Kees Klaassen and Koos Kortland
Freudenthal Institute for Science and
Mathematics Education, Utrecht University,
Utrecht, The Netherlands

Introduction

Developmental research is a particular way of addressing the basic questions of why and how to teach what to whom. It involves a cyclical process of small-scale in-depth development and evaluation, at a content-specific level, of exemplary teaching-learning sequences. It aims to produce an empirically supported justification of the inner workings of such a sequence, which is claimed to be an important contribution to the expertise of teachers, curriculum developers, and educational researchers.

The Inner Workings of a Teaching-Learning Sequence

Two related elements are involved in the intended justification of a teaching-learning sequence about some topic. First, a detailed description of the desired (by the researcher) development in what students believe, intend to achieve, are pleased about, and so on, in relation to the topical contents. Second, a detailed explanation of why students' beliefs, intentions, emotions, etc., can be expected to develop as described, given such and such learning tasks and when guided by the teacher in this and that way. In this explanation the developmental researcher can rely on what may be called commonsense psychology, i.e., what everybody uses all the time to find out about and influence the mental life of others.

Developmental research tries to improve on the practical wisdom of experienced teachers, both in being more detailed and specific with respect to expectations beforehand and in being more systematic and impartial in evaluating whether or not the expectations have come true. Developmental research also aims at more than what can be achieved by a pretest-posttest research design. Such a design may give an indication *that* a teaching-learning sequence works or fails to work: are the intended learning goals reached, as measured by the progress from pretest to posttest? Developmental research also aims to understand in detail *how* and *why* the teaching-learning sequence works or fails to work: does the teaching-learning process itself proceed as hypothesized? It is precisely this detailed content-specific understanding of the process that promises to offer a worthwhile, evidence-based resource to guide professional practice.

Value-Laden Choices

Separate from the question why a teaching-learning process can be expected to proceed as desired, there is the question of why in the first place it is desirable that there is a teaching-learning process that proceeds in this particular way. Here values necessarily enter the picture. Since the outcomes of developmental research can only be properly communicated and discussed if placed within and judged from the value-laden context in which they are obtained, the developmental researcher will at least have to make explicit his value-laden choices. In particular the choices concern the goals he wants pupils to reach and the tenets or principles underlying the ways in which he wants to make pupils reach the goals (such as that students should be actively involved or that they should know all along what they are doing and why). The goals and principles together set the quality standard against which the developmental researcher himself wishes his outcomes to be measured.

From the value-laden character of learning goals and educational principles, it does not follow that they can be chosen freely. The learning goals cannot simply be decided on in advance. Whether they can be realized with sufficient quality, as measured by the developmental researcher's own principles, will have to be investigated. The connection between the educational principles and empirical investigation is much less stringent, and typically the developmental researcher tends to hang on to his principles. But if again and again he fails to meet the quality standard set by his principles, he may eventually begin to question the principles themselves or the theory from which they were derived.

The Heart of Developmental Research

Whereas commonsense psychology serves to explain why a teaching-learning process can be expected to proceed as desired, there is no theory that serves to actually design the teaching-learning process itself. The developmental researcher will benefit from a deep insight into science, its relations to technology and society, its philosophical foundations and its historical origins, and he may well be inspired by one or another psychological or learning theory. From all of this he may even have derived the goals and educational principles that set the quality standard which the teaching-learning activities he is to generate in the particular case at hand should meet. This standard may function as a checklist, make the developmental researcher receptive to useful ideas, and make him recognize a good idea as such. But the quality standard plays no further facilitating role in actually generating particular teaching-learning activities. The generation of a particular teaching-learning process is an activity sui generis and the very essence of developmental research. In the literature it is variously described as a process in which one's goals and educational principles are applied, implemented, translated, transposed, embodied, given content, or operationalized. But despite all these characterizations, it is a process that refuses to be regularized. Just like any creative process, it is a matter of finding local solutions to local problems. It depends on skill, sweat, talent, persistence, and a good deal of luck. Success or failure may critically depend on details such as the actual wording of tasks.

Vital Methodological Components

One vital methodological component of developmental research concerns the construction of a so-called *scenario* or *hypothetical teaching-learning trajectory*. This consists of the value-laden choices (see section "Value-Laden Choices" above) and the justification of the teaching-learning sequence (see section "The Inner Workings of a Teaching-Learning Sequence"). Simply making explicit the reasons for one's expectations about how the teaching-learning process will proceed may in itself already be sufficient to bring to light quite a lot of wishful thinking. Triangulation in the form of discussing one's scenario with colleagues will make the expectations more realistic by diminishing cases of tunnel vision.

A second vital methodological component is to put the design to the test. This involves the use of the scenario as a theoretical prediction of what will happen. The test then provides the evidence in light of which the scenario is to be evaluated. The comparison of the prediction to what actually happens is not straightforward. What actually happens will have to be interpreted in terms of what, at various stages of the process, students believe, mean by what they say, intend to achieve with what they do, and so on. Here too triangulation, in the sense of coordinating the interpretations of various researchers, is a good methodological advice, if only to avert the danger of seeing what one hopes to see (one's predictions). Proceeding in this way, and relying on commonsense psychology, the researcher can make his interpretation as rigorous, systematic, and objective as can be.

A third vital methodological component consists in reflection on the test, in order to improve the scenario in the face of all the points where the expectations did not come out. In some cases it may be possible to "explain away" a deviation. This may happen if the teacher did not guide the activity as intended, while there are indications that students would after all have done what they were expected to do if the activity had been guided as intended. More frequently the deviations reflect a clear need to make adjustments, though typically it will not be so clear which adjustments will suffice. Since a scenario is a highly interrelated complex, a failure that clearly emerges in one area may just be a symptom of a problem elsewhere. Another aspect of the interrelatedness is that necessary changes in one area are likely to require changes in several other areas. Some further, and deeper, complexity may arise if one decides not to make adjustments to the design in order to better realize the process that one wanted, but instead to make adjustments to what one wants the process to be like. That is, one may feel a need to adjust one's educational principles or learning goals.

Nature and Use of Outcomes

The aim of improving a scenario cannot be to eventually arrive at "the ultimate" scenario – one whose predictions will come out in exactly the predicted way. All that matters is that a scenario can be judged *good enough* to serve as a valuable guideline for understanding and guiding what goes on in actual classrooms. In each actual case the teaching-learning process will without doubt meander in a somewhat different way around the main predicted path. Several revisions are typically needed before one is even willing to consider the question whether or not a scenario can be judged good enough, and the first revisions are likely to require considerable adjustments. But no matter in how many classes or with how many teachers one has tried a scenario, the claim that it is good enough will always be of the following kind. If handled with proper care, the teaching-learning process will proceed more or less as intended, under normal circumstances. Despite the inherently vague nature of such claims, they are worthwhile, evidence-based contributions to the expertise of teachers, curriculum developers, and educational researchers.

The explicit specification of the value-laden choices and the detailed account of the envisioned teaching-learning process allow a teacher to get a feel of how the process appeals to him. In combination with the empirical support, the teacher can form a judgment as to whether or not he can see it work in his circumstances or see himself able to adapt it to his specific circumstances. In this sense a good enough scenario allows a teacher to reach an informed decision about whether or not to make an effort to use it.

Developmental research aims to engender progress in science education research in at least three ways. First, within the quality standard set by a given matrix of learning goals and educational principles, one good enough scenario may arguably better meet the standard than another one. Second, within the quality standard set by fixed educational principles, for a growing number and variety of topics (with associated learning goals), one may be able to produce good enough scenarios. Third, researchers operating with different quality standards can critically discuss the ways in which their respective theoretical perspectives have differently shaped the concrete activities in their respective teaching-learning sequences. At least this may lead to clarification of the educational principles or theoretical perspectives at stake and perhaps even to argumentation about which ones are better. Above all such an exchange will keep theoretical considerations firmly secured to what they are supposed to be relevant for: concrete teaching-learning activities. This is progress too, when compared to the abstract and freewheeling manner in which theoretical frameworks are frequently discussed in the literature.

The developmental researcher does not expect progress in the form of some general body of knowledge by virtue of which curriculum development will be made easier or more efficient. In this respect developmental research may differ from design-based research, in which design principles are often supposed to play such a facilitating or enabling role. It is rather by being exposed to a lot of scenarios, and to empirical tests and critical peer discussions of the scenarios, that curriculum developers are expected to benefit from developmental research.

Drawbacks and Boundaries

There are important educational issues that typically fall outside the scope of developmental research, such as the following: How can one make the value-laden choices of the developmental researcher a major concern of many teachers? What are useful techniques for teachers to make an envisioned teaching-learning process happen in their classrooms? What about large-scale implementation or dissemination?

Developmental research does not sit easy with the current emphasis on quantity of “output.” It takes quite a lot of effort and time to produce a good enough scenario, and because of the formidable complexity of a scenario, it is hard to report concisely its justification and its test. This puts serious pressure on the progress that developmental research aims to engender in what it considers to be the core business of science education research: to construct, critically discuss, and empirically evaluate detailed content-specific justifications of teaching-learning sequences.

Dewey and the Learning of Science

David Wong[1] and Kevin Pugh[2]
[1]College of Education, Michigan State University, East Lansing, MI, USA
[2]School of Psychological Sciences, College of Education and Behavioral Sciences, University of Northern Colorado, Greeley, CO, USA

The connection between John Dewey and science education is enduring, vast, and varied. It would not be much of an exaggeration to say that Dewey had an influence on nearly all aspects of science education. Nevertheless, three influences stand out. First, Dewey proposed that the mind evolved in response to problem-solving situations and, consequently, the mind functions best in practical, problem-solving situations (e.g., Dewey 1916). According to this theory, learning is most effective when undertaking in the context of problem-solving and real-world situations. Second, similar to William James (1890), Dewey (e.g., 1938) firmly believed in the continuity of experience, where past, current, and future experiences were inextricably linked. This view foreshadowed modern constructivism including such principles are the importance of real-world experience and the role of prior knowledge in learning. Third, Dewey (1913) proposed that interest is a necessary component of learning. Interest activates a process of meaningful learning culminating in understanding instead of rote learning. Interest develops from connecting learning to prior experience, and it motivates the application of learning in everyday experience. These three ideas were foundational to the progressive era of education, which DeBoer (1991) identified as spanning 1917–1957. Within the field of science education, progressivism was characterized by dissatisfaction with educational practices that were too teacher centered and with content too far removed from real-world problems and students' prior experiences (DeBoer 1991). Progressive science education sought to contextualize learning in meaningful problems, involve students in experiential learning, and connect science to students' prior experience and interests. These progressivist goals have persisted in science education and are prominent in the twenty-first-century movements emphasizing such things as inquiry or problem-based learning and culturally relevant pedagogy.

Charting Dewey's Influence: Scholarship in Science Education Journals (1992–2012)

Dewey's influence continues to expand. One way of describing the nature and strength of the connection between science education and the work of John Dewey is to examine how his work has been cited in science education journals. We examined the past 20 years of four prominent science education research journals: the *Journal of Research in Science Teaching*, *Science & Education*, *Science Education*, and the *International Journal of Science Education*. We recorded all substantive connections to John Dewey making note of the author and date and, most importantly, assigned a keyword describing the substance of the connection to Dewey. The list below is ordered according to the number of articles making substantive connections to Dewey's work.

Inquiry

Contemporary work by science educators clearly suggests they view inquiry as a distinctive quality of Dewey's work. Indeed, the works of Dewey frequently read by educators – "How we Think" (1933), "Experience and Education" (1938), and "The Child and the Curriculum" (1902), for example – all highlight intelligent activity as a pragmatic process of encountering problems, testing hypotheses, actively engaging with the problem situation, and reflecting on consequences. Science educators focused on inquiry have cited Dewey's work in both philosophical examinations of the nature of inquiry and practical examinations of learning activities and teaching practices.

Pragmatism and Epistemology

Dewey's view of the nature of knowledge and the means by which something becomes knowledge is associated with the philosophical school of pragmatism. In brief, pragmatism holds that the value of a theory or belief lies primarily in its consequences, specifically the success and value of its practical application (Dewey 1929). Areas of science education influenced by Dewey's epistemology and pragmatism include the proper interpretation of Dewey's philosophical views, the nature of science, and the practical implications of teaching science.

Reform

Many of Dewey's works highlight how inquiry – knowing and doing inextricably connected – is central in the proper quest for greater certainty (Dewey 1929). In establishing his view of inquiry and knowledge, Dewey frequently criticized long standing dualisms – such as the separation of mind and body, theory and practice, and reason and experience, to name a few – as artificial and hindering the productive philosophical discourse. Science education reformers have resonated with Dewey's spirit of open-minded liberalism and progressivism, especially his willingness to dissolve categorical boundaries and bring together traditions that have long stood in opposition (Dewey 1902, 1938). Dewey's work has been cited in discussions about the proper role of science education, the importance of authentic inquiry activity, and the vital role of democratic, inclusive processes in science education.

Experiential and Hands-On Learning

Dewey's theory of experience, particularly as articulated in *Experience and Education* (1938) and *Democracy and Education* (1916), states that knowledge comes from experiences with the real world, prior experiences form the basis of new learning experiences, and new learning experiences have the purpose of transforming future experiences in the world. Further, educative experiences involve both an active trying out element (e.g., experimenting) and a passive undergoing element (i.e., experiencing the consequences and developing meaning from them). Science educators have drawn on this theory of experience to advocate the use of direct experience with real-world objects, events, and situations. They have also drawn on this theory to describe the nature of science learning experiences and consider the qualities that make for effective learning experiences (e.g., need for reflection and theory building to accompany hands-on activity).

Aesthetic and Transformative Experience

Dewey's theory of aesthetic experience as best expressed in *Art as Experience* (1934) articulates processes involved in undergoing aesthetic experiences and identifies a particularly meaningful and transformative type of experience, which Dewey termed "an" experience (Jackson 1998). Science educators have drawn on Dewey's theory to identify aesthetic characteristics (e.g., anticipation building toward consummation) and transformative qualities of science learning. Regarding the latter, particular emphasis has been placed on how science concepts (like art) can enrich and expand everyday experience by transforming perceptions of the world. This work also draws on Dewey's construct of an idea from *How We Think* (1933). Models of science instruction focused on fostering aesthetic and transformative experiences have been developed from Dewey's work.

[a] We examined the past 20 years of four prominent science education research journals: the *Journal of Research in Science Teaching*, *Science & Education*, *Science Education*, and the *International Journal of Science Education*. We list only articles judged to make substantive connections to John Dewey's work

Aspects of Dewey's Work Not Prominent in Science Education Journals

In addition to identifying the more common connections science educators have made to Dewey's work in the past 20 years, our review of four major science education journals also reveals aspects of Dewey's work that, perhaps surprisingly, have not received much attention.

The Importance of Subject Matter

In 1902, Dewey wrote "*The Child and the Curriculum*" to address what he perceived to be serious misinterpretations of his earlier works. Dewey felt that educators had taken his recommendations for child-centered education too far and, as a result, educators had neglected the importance of both the subject matter and the teacher. Dewey disagreed that educators must choose between child-centered or curriculum-centered approaches and, instead, argued that such an either/or dichotomy was false and unproductive. Dewey offered an analogy of an explorer (child) using a map (subject-matter idea) to illustrate how intelligent, thoughtful learning required both an active learner and the disciplinary structure of a subject area. The role of the teacher was to facilitate the having of educative experiences by the inquiring student (explorer) with the subject-matter ideas created by disciplinary experts (map). This central role of curricular ideas as well as the teachers' vital role in mediating between the child and curriculum – "psychologizing the subject matter" – received considerable attention in the 1980 and 1990s, largely in connection to Shulman's (1986) construct of pedagogical content knowledge. However, substantial connections in this aspect of Dewey's work seem to be relatively rare in science education research in the past 20 years (Avraamidou and Zembal-Saul (2005) is an exception).

Learning as Social and Cultural

Another important legacy of Dewey's work is an understanding of learning as a social and cultural process. Along with George Mead, Dewey developed a theory of the social origin of mind. He described learning as a process of meaning making through social interaction. This aspect of Dewey's work shares an epistemological foundation with sociocultural perspectives on science education (Lemke 2001). In addition, many of Dewey's writings on pedagogy emphasize democratic forms of education (see, e.g., *Democracy and Education*). Dewey particularly emphasized pluralistic participation believing that schools should give a voice to all and provide a means for even the disadvantaged to shape society. This focus of Dewey's educational philosophy foreshadowed current science education perspectives falling under a critical theory umbrella (e.g., Calabrese Barton 2003). Thus, it is surprising that few references to these aspects of Dewey's work are found in prominent science education journals over the last 20 years (Table 1).

Dialogic Teaching and Learning

Orlando G. Aguiar Jr.

Belo Horizonte, Brazil

Introduction

There is an increasing interest in studies of classroom discourse to inform and analyze the process of teaching and learning science. The reason for that is a theoretical assumption that there is an intrinsic relationship between language and thinking. According to the sociocultural approach inspired by Vygotsky, humans learn by the mediation of signs. According to Bakhtin, language is a system of signs that allows us to share a sense of the world with others, and this process is achieved by joint participation on particular social activities. Thus, language is not a simple way of communicating to others but a means to create and share a sense of the world, a powerful system that allows us to think together. Besides, learning science implies learning the languages of science, which codes a specific worldview, related to the social practices of science in society.

This explains the interest of science education researchers in contributing to the mastering of discursive practices, which allows teachers and students to seek a common knowledge based on scientific concepts. Instead of just claiming that language is a powerful mediational tool, this research agenda seeks to understand which kind of classroom discourse favors the progressive appropriation by the students of scientific concepts and the understanding of science as a cultural enterprise of producing and validating knowledge.

Dialogue is an important aspect of language itself. Based on the Bakhtin work, Wells (2007) suggests that dialogue is the most powerful mediational tool used by children and adults to negotiate meanings in activity. According to this perspective, dialogue is a two-way bridge of sign-based activity that makes it possible for a person to enter into the system of shared meanings in a society. Through dialogue, the child (or adult) can construct her "meaning potential" and thus convert in her own words the words of others, according to her feelings, intentions, and personal understanding of the social and material world. Another reason for the importance of dialogue in science education research agenda is that it allows addressing the problem of how the students' existing informal ideas interact with the new scientific knowledge introduced in the classrooms.

Researchers in education, including in science education, have identified a variety of patterns of classroom talk. The most prevalent pattern of science classroom interactions is a triadic "dialogue" in the form of "initiation-response-evaluation" (or I-R-E) or "initiation-response-feedback" (I-R-F) structures (Mortimer and Scott 2003). These patterns are commonly identified as authoritative (or non-dialogic) as they are centered in the teacher's initiative and power, and it is the teacher who controls the agenda and the contents of talk.

Despite of the effort of many curricular reforms and teaching guidelines, dialogic discourse is still unusual in science classrooms. Results from a range of countries show that even teachers involved with innovative teaching projects (inquiry-based, problem-based, project-based, argumentative teaching sequences, among others) and from a range of school levels (from primary to undergraduate courses) adopt mainly triadic interactions in whole-class discussions. These paradoxical results reinforce the need to review the notion of dialogic teaching (Scott et al. 2006; Littleton and Howe 2010).

Moreover, it is necessary to distinguish teaching science from learning science. The presence of dialogue in the learning practices of the students in a particular subject does not always match the way in which the subject was taught. After all, teaching practices create opportunities for learning but do not determine what and how the students will learn. Thus, to address the topic "dialogic teaching and learning," I start by discussing dialogue in science learning and then exam affordances and constraints of dialogue in science teaching.

Learning as Putting Science into Dialogue

I adopt here a sociocultural approach that conceives learning science as a result of enculturation process. According to this perspective, in school science classes, students are being introduced to the ideas and practices of science and are making these ideas and practices meaningful in a personal perspective.

Learning science is an intrinsically dialogic activity. Meaning making is an interpretative and, thus, a creative activity; faced with new science ideas, each student must create his/her own models to relate these new ideas and tools provided by the teachers to his previous ideas and ways of knowing. For that, she must put the scientific ideas into dialogue to other types of knowledge and, particularly and because of the informal ideas she brings to the class, with the epistemology of everyday life. The world of science being taught often differs deeply from the students' perceived natural world, constructed by direct experience in everyday life.

Following Bakhtin and his circle, dialogism is a feature of human understanding of the world. According to him, any utterance is a link in a chain of human communication. Every utterance is a response to previous ones and seeks an answer to them. It means that there is neither a first nor a final word about any issue. Based on a conception of discourse as language in use in social life, Bakhtin states that any understanding must involve an active response to the words of others.

In the actual life of speech, every concrete act of understanding is active: it assimilates the word to be understood into its own conceptual system filled with specific objects and emotional expressions and is indissolubly merged with the response, with a motivated agreement or disagreement. To some extent, primacy belongs to the response, as the activating principle: it creates the ground for understanding. Understanding and response are dialectically merged and mutually condition each other; one is impossible without the other (Bakhtin 1981, p. 282).

The Bakhtinian concept of responsivity is related to a dialogic stance; this is conceived as a relationship in which the interlocutors perceive themselves to stand with respect to their addresses. The concept of responsivity also helps to conceive dialogic teaching as a cohesive and temporal organization of the students' educational experience, in order to enhance progressive development of their understanding.

What Counts as Dialogue in the Science Classroom?

Below I present four different ways of conceiving of the ideas of dialogism in school science. The first meaning is very popular among teachers and sees dialogue as just teacher talk with the participation of students. However, this is not dialogic in the manner in which Bakhtin conceived it; dialogic relationships do not coincide with conversation replies. Educational research demonstrates that most "dialogues" in [science] classrooms are just recitation scripts in which the students try to complete the desirable answer from the teacher. However, in some cases the teacher does address different points of views and reviews arguments from both sides to compare and contrast perspectives.

A second perspective about dialogic teaching is based on the Bakhtinian distinction between two different forms of discourse, one more open to divergent ideas – what Bakhtin (1986) called "internally persuasive discourse" – and the other more closed, expressing a single perspective and demanding its full acceptance, namely, "authoritative discourse." Based on this distinction, Mortimer and Scott (2003) suggest that the basic feature of dialogic discourse in science classrooms is the consideration of students' points of view, besides the scientific perspective.

Dialogic discourse means, according to this approach, the encounter of different voices. Talk is considered to be more dialogic the more it represents the students' points of view, and the discussion includes both their and the teacher's ideas. This is in contrast with authoritative discourses where just one point of view, the school science perspective, is taken into account. According to the Mortimer and Scott, the consideration of different points of view in the science classrooms is fundamental for making connections between scientific and everyday ways of thinking and talking. The scientific perspective is considered as a social construction among others (religious, esthetical, philosophical, practical constructions), but a powerful one that has some specificity that must be acknowledged and experienced by the students.

The third approach to address the problem of dialogic teaching also comes from the philosophy of language of Mikhail Bakhtin. Contrary to the second approach (above), here dialogism is considered as a general notion of language, not as a particular kind of talk. Whatever kind of talk is being conducted in social life, every utterance is addressed to a listener and seeks to impact on that listener's understanding. One can say that, whatever kind of discourse is used in the classroom, dialogism will be always present, as the students use their counterwords to understand the scientific ideas introduced by the teacher. However, while this idea is very important, it is more closely related to leaning than to teaching; this third approach to dialogic teaching does not help to conceive which kind of discourse would provide best opportunities for learning.

The fourth approach to dialogic discourse emphasizes the distribution of power and control between teacher and students in conducting classroom discussions. From this perspective, attention is to be put on the interactive patterns of discourse, ranging from triadic moves (IRE or IRF) to open discussions. In IRE patterns, the student's participation is limited to giving brief responses to the teacher's questions, searching for the "right answer." However, triadic patterns are not always closed to students' views, as the third move from the teacher may involve not just evaluative statements but encouraging feedback, supporting students' participation (Wells 2007). Even then, the teacher is still in complete control of the discourse. This means that teacher's control may be not the main issue to be considered to address dialogic discourse in classroom settings. In some cases, whereas classroom interactions can be ideologically dialogic, in terms of considering multiple ideas and voices, it can be discursively non-dialogic, in terms of teacher control. So, it is important to note dialogic stances, which involve power and positioning from both students and teachers.

Considering such debate I reinforce the presence of multiple points of view as the main issue concerned with dialogic classroom discourse. However, such discourse may occur in a variety of forms, depending on:

1. Discourse participants (teacher and students or just the teacher)
2. Discourse initiative (power and control, more open or closed to students' initiative)
3. Symmetrical or asymmetrical orientations related to the types of knowledge being addressed
4. Level of interanimation of ideas (low level, when the students points of view are elicited but not further considered; high level, when the scientific perspective is constructed upon – or in opposition to – everyday reasoning)

To understand why dialogic discourse is so rare in educational practices and to develop ways to improve the quality of classroom talk, it is necessary to consider the culture and institution of schooling. Dialogue in the classroom setting must involve a real desire for mutual comprehension and the contrast of perspectives, but the teacher is in an institutional position that reinforces a resolution in the terms of the accepted scientific perspective. So, even in innovative classrooms, dialogic discourse is usually orchestrated by the teacher, who aims to control the flux of ideas in order to achieve, at the end, the scientific perspective as the best alternative.

In one sense, an ideal concept of dialogue in its radicalism has no room in school settings, as the participants of dialogue are not equally open to be convinced by the others. Besides, while there are multiple points of view being considered, they are not equipollent and equipotent in the manner Bakhtin identified in his analysis of the polyphonic novels of Dostoevsky. According to Bakhtin, two voices are considered equipollent and equipotent when they have equal force, power, and significance. In the novels of Dostoevsky, characters are considered from very different perspectives. The author did not take part in the debate; he has just presented the character's worldviews as poles of human understanding in social life. On the contrary, in school science teachers are always committed to the scientific perspective or, in other words, to the resolution of differences according to a certain position for the knowledge to be constructed. Thus, the institution of schooling constrains the ways in which dialogue can be conducted in the classrooms.

Dialogic Teaching Includes Both Dialogic and Authoritative Discourses

Teaching science involves two complementary dimensions that point in opposite directions but are not mutually exclusive. The first dimension relates to cultural heritage. Science, as a public knowledge, allows a picture of the world that often differs significantly from the perceived world of everyday life. Thus, science education demands guided interventions and supports so that the most important scientific ideas can be assessed and reviewed by the new generations. In this sense, teaching science involves a commitment to concepts, models, forms of reasoning, and language stabilized and agreed by scientific communities. Such forms of knowledge point to the past of science and ensure a collective memory for a given community. This is true both for the training of future members of communities of experts and also for ordinary citizens in contemporary societies.

The second dimension concerns personal understanding of science as a way to see and act on the world. Here science may be seen as a process of understanding the world, one that demands critical consideration of knowledge claims, argumentation based on evidences, and a sense of uncertainty faced to the phenomena to be explained. For this to occur, it is essential to design teaching situations in which students are asked to critically examine their views, as well as the scientific views that have been introduced.

Hence, to be implemented in schools, dialogic teaching involves both cultural transmission and meaning making of new ideas, by alternating both authoritative discourse and dialogic discourse. That is to say, scientifically productive classroom dialogue requires instruction that allows not just opportunities to discuss different ideas but also guidance to the new ways of thinking. According to Scott et al (2006), these two forms of discourse are not mutually exclusive, but complementary:

> The tension [between dialogic and authoritative discourse] develops as dialogic exploration of both everyday and scientific views requires resolution through authoritative guidance by the teacher. Conversely the tension develops as authoritative statements by the teacher demand dialogic exploration by students. So, both dialogicity and authoritativeness contain the seed of their opposite pole in the dimension, and in this way, we see the dimension as tensioned and dialectic, rather than as being an exclusive dichotomy (Scott et al. 2006, p. 623).

These two modes of discourse – dialogic and authoritative – accomplish different functions and can be engendered in different moments of a sequence of teaching. On one hand, authoritative discourse, focused on transmission of culturally accepted ways of thinking, allows cultural anchorage and a fidelity to scientific views. On the other hand, dialogic discourse provides opportunities for students both to make explicit their everyday ideas at the start of a teaching sequence and to apply and explore newly learned scientific ideas for themselves.

Ways of Promoting Dialogic Discourse in Science Classrooms

Due to the culture of schooling, dialogic teaching does not happen spontaneously. Therefore, it is important to consider teaching and discursive strategies designed to improve dialogism in science classrooms.

The stronger dialogic teaching design is related to inquiry-based teaching. According to Wells:

> When students pursue investigations, they develop ideas and acquire information that they want to share and debate; at the same time, the problems they encounter call for the joint consideration of alternative possible solutions. In these circumstances, students have reason to learn the skills necessary for engaging in productive dialogue and, over time, they also develop the disposition to approach problem solving of all kinds in this way (Wells 2007, p. 265).

Besides the importance of such approaches, even in countries and schools where educational reforms aim at promoting inquiry-based teaching, there is evidence that dialogic discourse is still rare in the science classrooms. One reason is that teaching materials do not offer necessary support for teachers to change the way language is used in classrooms and to know how to move from students' ideas to abstract scientific concepts.

There are research efforts to design teaching sequences in which the types of discourse around activities are in focus. The interplay between everyday and scientific knowledge involves planning turning points between dialogic and authoritative discourses. The study of such turning points – how and when they happen – is considered a crucial aspect to both understand and promote dialogic teaching.

Among the discursive strategies to improve dialogism in science teaching, there is a strong concern about the type of teacher's feedback. Many studies indicate the need for fewer evaluative statements from the teacher and more prompts and follow-up moves intended to encourage students to come up with new ideas, clarify their positions, and comment on other's points of view. The teacher's types of questioning are crucial to developing more dialogic whole-class discussions. Classroom studies also emphasize teacher's comments to the students' utterances, which allow the continuity of discourse and co-construction of knowledge. In some cases, this is done by "revoicing" the students' previous contributions, thus providing a collective memory to the class and encouraging further developments.

Dialogic discussions, in which students try out ideas and use language to think together, are more likely to occur in peer interactions and group work, free of teacher interventions. Besides, giving students time to prepare their thoughts about an issue or questions prior to a whole-class discussion greatly increases the diversity and quality of contributions. However, successful group work requires preparation, guidance, and supervision, that is to say, a balance between dialogic and authoritative discourse.

Preliminary dialogic discussions in the early stages of a new topic are commonly recommended by educational reforms and highlighted by many science classrooms studies. The purpose of such "exploratory talk" is to explore students' views about the topic and to connect these views to the scientific perspective to be introduced (Mortimer and Scott 2003).

Studies of science classroom discourse show that the move from authoritative to dialogic discussions at the end of teaching sequences, as advocated by Scott et al. (2006), is much less frequent than the use of dialogic discussions in the opening activities. Although teachers around the world are much more willing to explore students' views, the same is not true in respect to giving more space to students to discuss new contexts of use of the recently learned scientific ideas. Another reason is that the commitment of teachers to the scientific correct view is stronger than their belief in the need for responsibility to be transferred to the students in extending the scientific perspective to new contexts.

These activities may involve inquiry tasks in which the students are invited to work within the new scientific ideas. Another possibility is to promote the awareness of conceptual profile by comparing the results of pre- and post tests designed to address the differences between everyday and scientific perspectives on the topic.

Nowadays teachers around the world are facing a dilemma between promoting meaningful learning and being sensitive to the pressure for results in assessments. These assessments always reduce the dialogic space available in the classroom, as the pressure is to prepare students to give the right answer and not to discuss and justify points of view. Besides this, each new trend in the curriculum, instead of relieving this pressure, increases it with new demands on teaching.

Final Comments on the Issue

Based on this review, there is a clear need for more studies in dialogic talk at the end of a teaching sequence, when the students, working together, take the responsibility to use the scientific perspective to construct an explanation to new problems. It is also necessary to develop teaching sequences that use different strategies to link scientific and everyday points of view, highlighting the discursive strategies and communicative approaches to be used along the activities.

Sociocultural approaches in education mean to work in the tension between construction and instruction, discovery and transmission, freedom to explore, and guidelines to follow-up. Dialogic teaching may involve moves between these two types of discourses, dialogic and authoritative, to allow the active reconstruction of existing knowledge.

Today, the challenge is how to incline this balance to the dialogic side. There are many ways to do that: preparing teachers to do dialogic discourse in classrooms, designing teaching sequences in which the students should consider different alternatives to explain a phenomenon, providing links between phases and activities along a teaching sequence, preparing teachers to give feedbacks and prompts that guide the participation of students in dialogic discourse, and being conscious of the need to talk about ways of talking in classrooms. Besides that, there is a need to improve the effectiveness and impact of dialogic discourse in teaching sequences.

Instead of listing ideal features of dialogic discourse or dialogic space, we should understand that dialogue in school is both driven and bounded by predetermined curricular content and objectives. This is a clear constraint for those who think about dialogue as a completely open space for joint construction. However, scientific knowledge has no meaning for students and citizens if there is no interchange and communication between everyday and scientific domains.

Didactical Contract and the Teaching and Learning of Science

Guy Brousseau[1] and Virginia Warfield[2]
[1]LACES, Université de Bordeaux, Laboratoire Cultures Education Sociétés, Talence, France

Introduction

The concept of *didactical contract* provides a powerful way of interpreting aspects of teaching, learning, and the interactions between teachers and learners. This concept has been developed over many years of experimental and theoretical research on didactical situations in mathematics. (Brousseau 1997).

For epistemological reasons, each "didactical contract" is to a large extent specific to the knowledge being taught. This specificity explains why the use of this concept has as yet expanded so little into other disciplines, although it has great potential in these.

In addition, the observation and explanation of various phenomena has led to the extension of the concept of didactical contract to the relationships of all the parties involved in education: parents, society, administration, academic societies, etc., always with respect to a specific (mathematical) concept.

Didactical contract has a great potential for enhancing our understanding of aspects of the teaching and learning of science. In the concluding section of the entry, some ways in which *didactical contract* has this potential are very briefly explored.

Didactical Contract and Mathematics Education

Definitions

The teaching of mathematics is a social project of putting at the disposal of all the members of a society the means of participating in a common mathematical culture and benefitting from it. To each precise notion to be taught, the partners in teaching (i.e., the teacher, the learners, and the other parties mentioned above) associate expectations, obligations that each undertakes and benefits from, and the means by which they envisage (mutually or separately) satisfying these expectations and obligations as well as the consequences of not satisfying them.

A *didactical contract* is, in the broad sense, an interpretation of the set of these expectations and obligations, be they compatible, explicit, and agreed to or not. The study of the didactical contract in any classroom cannot be made solely by direct observation because a large part of these expectations and perceived obligations cannot be made explicit by the partners. Observation must therefore be complemented by modeling and experiments.

The Two Components of the Contract: Devolution to the Students and Institutionalization of Their Results

In mathematics education it is essential to know at every moment who, among the teacher, the students, and the wider *milieu* in which they are embedded, will take the responsibility for each mathematical statement that appears in class.

For example, during *autonomous activity* undertaken by students (such as the solving of a problem or more generally participation in a mathematical situation), the teacher refrains from any specific informative intervention.

This autonomous mathematical activity must be preceded by a phase of *devolution*, in the course of which the teacher provides information (e.g., a "direct" teaching [a lecture], exercises, assignments, etc.) that:

Allows him/her to move epistemological responsibility for what happens during the private

---

The authors would like to express their gratitude to Richard Gunstone for his extremely helpful comments, suggestions, and additions.

or public development of the activity from teacher to student

Allows the students to then take on the responsibility offered to them during the mathematical activity

This mathematical activity of the students is followed by a phase of *institutionalization*, for the students and the teacher, consisting after an autonomous activity of:

Taking note of what has happened, of questions that have been resolved or are still open/unresolved, and of errors uncovered and removed in the course of the autonomous activity

Recognizing the new results obtained by the students if they conform to expectations and standard usage and the progress of routines that are in the course of being acquired

Classifying established pieces of knowledge that are well shared as references that may henceforth be used in class activities

Pointing out the questions that have not been resolved and the challenges to ponder

The nodal point of the didactical relationship is *devolution*. Devolution is the heart of the didactical contract, and is treated in a separate entry. The devolution of the right and capacity to express a personal mathematical thought is the essential act of teaching of this specialty. The study of it reshaped the foundations of the theory of didactical situations in this domain. But every discipline must address the devolution to the student of specific essential powers and rights; the prospects for and reality of devolution in the teaching and learning of any discipline undoubtedly merit studies similar to those already taking place in mathematics education.

Origin

The notion of didactical contract first emerged in 1980 in the course of a statistical and clinical investigation of some students having difficulties in mathematics but not other subjects (1975–1980). One of the cases observed gave a glimpse of certain causes of divergences and natural misunderstandings between the reciprocal expectations and possibilities of the teacher and student (Brousseau and Warfield 1998). Gaël, 8 years old and quite intelligent, responded to a problem involving looking for the unknown term in a sum in the manner of a 4-year-old. He happily refused to accept responsibility for the truth of what he said and thus did not enter into any solution procedure or, especially, a search procedure. This difficulty made starkly apparent the theoretical impossibility of forcing a child to take on a mathematical situation. The case was resolved by a sequence of situations – of "contracts" – to which he gave his agreement. But the theoretical problem remained and revealed profound flaws in the classical conceptions of the teaching of mathematics.

This concept of didactical contract then made it possible to explain observations such as the following (real example). Some teachers posed to their students absurd questions like the following: "On a boat there are 15 goats and 26 sheep. How old is the captain?" The students added up the numbers and said "41 years old!" Some commentators were outraged, claiming positions such as "Teachers are making students more stupid rather than more wise!" Further investigation revealed that the students thought the problem was absurd. When asked why then they answered it, they replied "Because the teacher asked [the problem]!" "And if the captain was 53 years old?" "The teacher didn't give us the right numbers!"

Put in simple terms, the notion of didactical contract provides a most plausible explanation for this student behavior: Past experience had led these students to the intuitive view that the quite implicit "contract" under which their mathematics classroom operated was that whenever the teacher asked a question, their responsibility was to answer the question and no more than this. They were certainly not to query the question, to suggest the question made no sense, or to suggest it was silly, and so on. A similar experiment with teachers in training gave the same results, with the same explanation being once more most plausible.

After its emergence in 1980, the concept of didactical contract was put to the test in the Centre de Recherches sur l'Enseignement Elémentaire des Mathématiques (the Center for Research on the Elementary Teaching of Mathematics – the COREM), which was conceived by G. Brousseau and created by the Institut de Recherche sur l'Enseignement des Mathématiques (Mathematical Education Research Institute – the IREM) of Bordeaux. The COREM functioned from 1973 to 1999 and comprised a scientific laboratory associated with a school with 14 classes of students aged 3-12, set up to permit scientific observation and the realization of long-term experiments on the teaching of mathematics in a controlled and limited context (Davis et al. 1986).

The didactical contract in the classroom depends tightly, but in a complex way, on the conceptions and requirements of various social and cultural institutions relative to each mathematical notion. The numerous phenomena that can only be explained by these interactions constitute the field of *macrodidactique*. This is discussed further in section "Macrodidactique."

Paradoxes of the Didactical Contract

Consider the usual classroom situation where the teacher wants to teach part of what she knows to a student who does not know it. There are a number of paradoxes inherent to this situation, paradoxes that in some contexts are in fact genuine contradictions.

(a) *Fundamental paradox*. The student cannot commit himself to a project about which he does not know the central issue, the precise objective, that is, the essential element of knowledge that is the focus of the project. Nonetheless, his engagement is indispensable – without it the teacher cannot achieve her goal. The teacher's engagement is as well, but she cannot commit herself about the certain success of a designated student. Every didactical contract is in effect a gamble – a necessary illusion.

(b) *Paradox of devolution*. The knowledge and will of the teacher must become the knowledge and will of the student, but what the student knows or does by the will of the teacher is not done or decided by his own judgment (a paradox similar to Husserl's of the master and the slave). The didactical contract finds its success only when it is broken: The student takes on responsibility for what he does or knows, independently of the teacher, and refuses her support.

(c) *Paradox of the said and unsaid* (a consequence of the preceding paradox). It is in what the teacher does not say that the student can find what he can say himself. The unsaid, the inexpressible, the uncertain, and sometimes even the false are the instruments of a living thought that establishes a truth and produces conviction about the reference knowledge.

(d) *Paradox of teleological learning*. A lecture turns the exposition of the conclusions of an historical creation, reorganized to follow deductive logic, into a prerequisite condition for student learning. Thus, the student is supposed to make use of what he will not know until the end of the process to organize first his comprehension and then his learning. He believes that in order to solve a problem, he must first "know" its solution.

(e) *The paradox of the general and the specific*. The teacher can only engage in procedures that are relatively general and common, for example, theorems, whereas the acquisition of a piece of knowledge is an individual and specific adventure of the knowledge in play in the problem.

(f) *Paradox of the actor*. Teaching is a production. The teacher needs to be a professional actor who must feign rediscovery with her students of knowledge that is highly familiar, even an old habit for her. The more she tries to be "natural" and spontaneous, the less credible and effective she will be (Brousseau and Otte 1991).

(g) *The paradox of uncertainty*. Knowledge is manifested and learned by the reduction of uncertainty that it brings to a given situation. Without uncertainty, or with too much uncertainty, there is no adaptation, and no real learning. The optimal development of individual or collective learning is thus accompanied by a normal optimal rate of errors. Global success is not a monotone function of the rate of instantaneous success. Arbitrarily augmenting or reducing it thus impedes and may delay both individual and collective learning (but the latter makes it possible to see to it that it is not always the same students who are doomed to provide the necessary errors.) The result is a new paradox: An increased rate of "instantaneous" success in the course of learning does not prove a better overall effectiveness.

(h) *The paradox of adaptation or lack thereof*. Excessive or premature adaptation to a piece of knowledge in conditions that are too specific can result in a particular piece of knowledge that may constitute an *epistemological obstacle* to the adaptation of this knowledge to new conditions (e.g., the practice of division in the natural numbers is associated to a meaning [sharing] that is an obstacle to its presentation in the decimal numbers when one needs to divide a number by a larger number [e.g., 0.3/0.8]).

(i) *The paradox of rhetoric and mathematics*. In order to construct the mathematical knowledge of students and its logical organization, the teacher uses various rhetorical means to capture their attention. The culture, pedagogical procedures, and even mathematical discourse abound in metaphors, analogies, metonyms, substitutions, figures of speech, etc., of nonmathematical means, against which mathematical concepts are often constructed.

(j) *The paradox of culture and science*. The teacher is thus supposed simultaneously, as a specialist, to cause the rejection of what science has disqualified and, as one who institutes students into a culture, to teach that culture with its historical meanderings.

Division of Responsibilities Between Requesters and Holders of Knowledge

The following types of contract do **not** cause the initiator to engage directly with the initiated, or vice versa:

Esoteric contract. The *client* (i.e., the learner) poses a question and is responsible for the question, its relevance, and the use of the response; the *expert* (i.e., the teacher) provides that response and guarantees its validity without saying how he established it.

Exoteric contract. The *scientist* produces the question and the answer, of which she gives the proof; she shares the responsibility for it with her community. The philistine takes on that of the relevance and use.

Initiatory contract. The *initiator* shows how he conceives of the knowledge. He comments on it, accompanying it with appropriate examples and their solution. He thus guarantees the validity and pertinence of the knowledge presented but takes no responsibility for what the person being initiated does with it.

Contract of instruction. The *instructor* proposes exercises and takes cognizance of the responses of the *learner*. She corrects them and gives the explanations that are asked of her. She makes no guarantees about the learning.

The types of contract where the teacher undertakes to achieve a certain success from the learner are as follows:

- The *strong didactical contract*. The teacher commits himself to initiating a specific protocol, known to make it possible to obtain with a certain frequency the behaviors agreed to be characteristic of some precise piece of knowledge. He thus relies on a custom, a culture, or a science recognized by the partners (parents, society, administration, academic societies, etc.), to achieve an average result agreed to by the partners. The fact that some of the students have succeeded in learning the agreed knowledge suffices to prove that it has been taught. An obligation of the mean has been satisfied.
- The *commercial contract*. If the scientific or cultural references are shared by the partners and only under that condition, teaching may be made the object of a *commercial contract* for collective or individual teaching. Nonetheless, the client would be mistaken to believe, like the Tyrant of Syracuse, that he could thus purchase a nonexistent royal road. It would be an even greater error to believe that random punishments of the students, of their teachers, or of the didacticians could produce improvements that depend in fact only on our shared knowledge. The height of absurdity is reached

when it is the client-students themselves who wish to exercise this type of empirical control over the processes that involve them.

Observation of the Spontaneous Responses of the Teachers and of Their Effects

The reactions of a teacher to an error or a failure of the students are combinations of a finite list of types, depending on:

- Certain criteria of the situation. Whether the error is recognized or not, explicit or not explicitly or implicitly, whether it is partial or global, and corrected or not (abandonment without explanation or, worse, without correction is not well accepted in classical contracts)
- The means used to reduce uncertainty. Identical repetition or metonymic or metaphorical repetition (reformulation, analogy, change of context), decomposition either of the problem (into intermediate questions) or the class (into level groups), analysis at the meta-level (logical, mathematical, heuristic or graphic reminders or comments), etc.

While these types of responses are implicitly fairly well accepted in the strong didactical contract, their properties are very rarely recognized. Sustained observation and theoretical analysis have convinced us that no combination of these types of response is in all cases either better or worse than all the others. None is decisive in all circumstances. Only analysis of the particular situation makes it possible to bring out the optimal choice case by case. Bernard Sarazy has demonstrated experimentally the importance of didactical flexibility: Varying the types of response is the best strategy (Sarrazy B 2002).

Thus, nonspecific pedagogical methods, principally based on the hypothesis of the universality of cognitive processes and hence of methods of learning and hence, a priori, of the existence of valid general methods of teaching, cannot provide optimal teaching. Thus, the use of "universal" responses, theories, and methods may simplify the acceptance by the population of a pedagogical or didactical contract and lower the cost of work and of training teachers, but it cannot under any circumstance be the best response to the expectations for teaching.

Macrodidactic

The above hypothesis led to the study of the influence of the epistemological, scientific, cultural, social, or economic foundations on the didactical contracts currently in operation in different societies. The issue is to explain the expectations, the offers, and the demands of different components of society with respect to this or that specific piece of knowledge and to compare these expectations, offers, and demands with the possibility of responding.

This new field of research has developed over the last decade under the name of "Macrodidactique." It has offered explanations for phenomena like the failure of the reforms of teaching based on mathematical structures in the course of the twentieth century (New Math), that of the teaching of "problem-solving methods," the effects of standardized testing, etc.

By bringing out the effects of the beliefs and inappropriate requirements of various partners in the didactical contracts, this research makes it possible to look into current practices in a more scientific and convincing way. For example, determining which knowledge to teach only on the basis of an explanatory text, without mentioning the actual practices that have produced the knowledge, has contributed to the creation of a didactical fiction which today is an insurmountable obstacle to progress in that domain.

Didactical Contract in Science Education

The word *contract* is most commonly used to indicate an agreement – usually a legal one but sometimes not – between two or more groups or individuals. That use is most certainly pertinent here, although, equally certainly, not "legal" in the usual way. The essence of this construct that there is a "didactical contract" developed over time and very often implicitly between teacher and students is an intriguing and very valuable frame for considering the behaviors and dynamics in any classroom of any subject. It raises a range of critical questions for considering classrooms, for example: What teaching and learning behaviors are expected of each group (teacher and students) in this classroom? Why are these expected? Do students or teacher know that these expectations exist? etc.

Perhaps more significant is that the evolution of the construct in mathematics education has consistently pointed to the impact on the contract of the nature of the content that is the focus of the classroom at a given time.

To what extent are these studies relevant for the teaching of other disciplines, most particularly science (and more generally for education)? Monitoring the meaning of concepts by their use in precise situations is normal in all disciplines and particularly so for mathematics and science. But the heart of the didactical situation is a situation specific to the knowledge in question. Apart from a few general principles and a few methods, each notion poses by definition a problem that is specific to itself.

The interaction between both the teaching and the learning of "X" and the epistemological and ontological nature of "X" has received very occasional attention in the science education literature, but as yet far too little. This is the case even within the branches of science. For example, consider the content of "introductory mechanics" and "introductory DC circuits." At one level one might argue that these are very similar content areas and can be taught with the same broad pedagogical approaches – both involve difficult relationships between concepts and have disarmingly simple formulae that often "hide" the conceptual difficulty in these relationships; both are rich in student alternative conceptions that have profound impact on subsequent learning. But there are profound differences in the nature of the knowledge in each area: In mechanics observations are almost always direct (i.e., we do not need instruments to enable the observation), and analogies and models are almost never used; in electricity, on the other hand, observations are always indirect (can only be made via instruments) and analogies and models are so central that even the language used to talk about the knowledge is totally dependent on analogies and models. To make the point further, consider then the differences they will need to be in the didactical contract between teacher and students in the very specific context of the physics laboratory for investigations of phenomena in mechanics and in electricity.

Keywords

adidactic; Equilibration; Mathematical concepts; Milieu

Imagine a teacher who knows that she/he must miss a class next week and wants to communicate the lesson plan to a replacement colleague. How might the teacher convey the critical features of the lesson so that the colleague can reproduce (1) the same learning outcomes for the students and (2) the same meanings for the knowledge acquired by the students? One of the aims of the theory of didactical situations (hereafter denoted TDS) is to identify the critical conditions for situations that can be presented to students and within which students will carry out activities that will enable them to construct specific meanings and understandings of a given concept.

Several dimensions are intertwined in a teaching situation focused on specific learning outcomes. These dimensions include cognitive, epistemological, cultural, and social concerns. Hence, several theoretical frameworks have contributed to the development of TDS. One such framework is Piaget's theory of "equilibration"; this theory served a pivotal role in the evolution of the idea of "adidactical" adaptation. In this conception, students construct knowledge by becoming directly engaged in solving a novel problem, refining their concepts and strategies in light of feedback from a (material and social) milieu (Brousseau 1997).

Conceiving of knowledge as resulting from a social construction over a long period of time led to the development of the theory of didactical situations, starting from the hypothesis that knowledge cannot be reconstructed in a spontaneous equilibration process. Instead, conditions and environments must be organized to present students with questions or problems that require a reorganization of their thinking. Here, "situation" refers to a collection of problem-solving tasks and environments designed to evoke a particular form of adaptation on the part of students, supporting them in the process of knowledge construction.

A Theory of Relationships Between Situations and Knowledge

Conditions for learning a scientific concept are specific to the content being learned. TDS was originally used to model learning situations in mathematics, but it can be viewed as a theory of the relationship between situations and knowledge so it can be extended to, or reinterpreted in, the sciences. The notions of economy and coherence are central in these relationships. Knowledge in physics, mechanics, or biology provides coherent and unified interpretations of families of phenomena that can be seen as different. As such, the knowledge groupings provide economy in explaining these phenomena. For example, describing two objects at rest as an event involving action facilitates provision of a unified account of the actions of one object on the actions of another object, irrespective of whether there is motion or not (Ruthven et al. 2009).

Identifying this type of economy or coherence for specific mathematical and scientific concepts, therefore, requires an epistemological analysis. This may include an analysis of the genesis and growth of the concepts in the histories of mathematics and the sciences, especially in order to determine the extent to which obstacles are intrinsic to these concepts. The notion of "epistemological obstacle," originating from Bachelard's theorization of the growth of knowledge in the physical sciences, was extended by Brousseau for theorizing the learning of mathematics: "obstacles… from which one neither can nor should escape, because of their formative role in the knowledge being sought" (Brousseau 1997, p. 87).

Adidactical Versus Didactical

The distinction between an "adidactical situation" and a "didactical situation" is key to understanding the distance between Piaget's cognitive equilibration theory and TDS. "Adidactical" does not mean that no teaching intentions underlie the situation; it refers to the perspective of the student. In an "adidactical" situation, the student experiences the problem not as a problem created by the teacher with didactical intentions but as if it were a genuine problem similar to problems that can arise in her/his life outside of school and that she/he must solve.

Although the situation is conceived with didactical intentions, the way the problem is posed and its environment lead the student not to consider the teacher's expectations but rather to take ownership of the problem. The solving processes may include some equilibration processes to overcome cognitive conflicts.

However, although an early assumption in the development of the TDS was that teaching sequences could be organized around adidactical situations alone, it turned out that, when observing their implementation in the classroom, the theory did not take into account "the [inescapable] intervention of the (mathematical [or scientific]) culture through the medium of the teacher" (Brousseau 1997, p. 110). It led to the incorporation of a further stage of "institutionalization" in which the knowledge that students developed from an adidactical situation undergoes a process of socialization and codification through teacher interventions. The asymmetry of the positions of the teacher and the students, with regard to mathematical and scientific knowledge, and the role of language in conceptualization, as laid out in Vygotsky's theory, are also sources of TDS.

As stated above, the guiding epistemological hypothesis in TDS is that a mathematical concept takes its meaning from problems to which it brings an optimal solution. This epistemological hypothesis could be extended to the sciences to the extent that scientific concepts take their meanings in relation to the variety of situations of their fields of applicability. The corresponding cognitive hypothesis within TDS is that learning results from students adapting their thinking in response to some new situation where their existing knowledge does not support an efficient solution strategy. The solution pathways that students find it necessary to devise serve as the sources of new knowledge. Epistemological and cognitive considerations are, of course, not independent: the aim is to identify the conditions for a planned process of learning through which students construct knowledge and use those features which the epistemological analysis has identified as constituting the concept to be acquired.

The teaching sequence is organized around a succession of adidactical situations based on problems. This forms a learning progression in which the question proposed to students at each new stage arises from problems encountered in deriving solutions at the previous stage or from the consequences or developments of these solutions. This succession does not depend only on the prior epistemological analysis, but also on concerns of the local organization and functioning of particular situations within the teaching sequence. Collective sessions, gathering the various solving processes of students under the guidance of the teacher, take place between adidactical situations.

An adidactical situation depends on the problem being one where students have a starting strategy available to them, but this strategy turns out to be unsatisfactory in some way. The ideal is that students, as a result of observing the inadequacy of the initial strategy, will be motivated to look for an alternative strategy and that this will lead them to devise a solution strategy that provides a basis for constructing the intended new knowledge.

Thus, it is of crucial importance that students should become aware of the inadequacy of their tentative solutions and that they should receive information from the situation that enables them to move forward in developing more powerful solutions. The notion of "milieu" has been developed within TDS to refer to that component of the situation that offers possibilities of interaction with students, providing means of gaining feedback to validate or invalidate their solution strategies. Particularly where younger students are concerned, the milieu is often designed to capitalize on a context with which students are already familiar. This familiarity guides the opening exchanges between the situation and the students. Changing the context for each particular situation in the teaching sequence is impractical as it would require students to spend time coming to terms with a new context on each occasion. Moreover, if the same context can be maintained, students' greater familiarity with it facilitates their further exchanges. Finding a suitable context capable of serving over several sessions is therefore a critical issue in the "staging" phase of a teaching process.

The milieu is not only a material milieu but it may develop and incorporate scientific texts, arguments in a classroom discussion, and the prior knowledge of students. This is particularly the case for introducing explanatory models in the experimental sciences. Students cannot themselves elaborate scientific models. The Leeds research group (Ruthven et al. 2009) presented lower secondary school students, learning the behavior of electrical circuits, with a contradiction between their expectations and what happened in the material milieu. The teacher proposed a simple series circuit with a power source at one end of the room and a bulb at the other end with very long wires connecting the circuit together. Many students expected a short delay between connecting the circuit and the bulb lighting. This is not what happened and it was very clear for students; however, students could not build an explanation by themselves. The teacher had to introduce an analogy to the class to explain the behavior of the circuit. Orange (2007) proposed to distinguish between three kinds of milieu for modeling learning situations in experimental sciences like biology: the external milieu, the internal milieu of the student, and the internal milieu of the classroom made of explanations and interpretations socially accepted and shared in the classroom.

In TDS, the social organization plays an important role in the functioning of the milieu. Adidactical situations that aim at fostering the learning of the formulation of mathematical objects and relations are based on exchanges between two students. Student A and Student B build a team and they must solve a problem in a constrained environment. Student B has access to information for solving the problem only through Student A who must convey useful information (verbally or in writing) in a form that is understandable to B. Whereas A and B are partners in a formulation situation, in adidactical situations that aim at the learning of proof, A and B are opponents: Student A needs to win against Student B by formulating arguments that student B can never invalidate.

Didactical Variables

In a task, there are identifiable variables with values that condition the efficiency of specific solving strategies and that make alternative strategies inefficient or tedious. For example, comparing the size of two collections of objects calls for totally different strategies depending on whether the two collections can or cannot be seen simultaneously. If the two collections can be seen together, a counting strategy is not necessary, whereas if it is only possible to have access to each collection separately, counting becomes unavoidable unless the collections have a small number of objects and can give rise to a mental image. Thus, at least two didactical variables can be identified in this comparison task: the size of the collections and the type of access to them. Another variable is the presence or absence of the possibility of manipulating the objects – since the counting process is greatly assisted by the possibility of separating already counted objects from those not yet taken into account. In the previous example about circuits, the length of the wires is a variable that makes visible the erroneous character of a sequential and causal idea about circuits. Such variables are called "didactical variables" because they act as key levers in precipitating and managing the development of the expected trajectory of learning. Identifying such variables starts from analysis of the knowledge available to students, in particular knowledge of the procedures available to them for dealing with the task. Observation of how situations play out with students in the classroom may reveal further variables not identified through prior analysis.

Use of TDS

During its development, the theory of didactical situations gave rise to the design of teaching sequences which, when examined in the classroom context, led to modifications and refinements of the theory. Warfield (2007) offers an introduction to the theory by giving examples of sequences of situations that allow the reader to better understand the use of the theory. For about 20 years now, the theory has also served as a tool for analyzing the design of teaching sequences and their implementation. A notion such as that of the didactical variable can be used independently of TDS to analyze tasks and gain some predictive ideas about the way students would deal with them. Ruthven et al. (2009) interpret TDS as an "intermediate" theory assisted by the "adidactical situation" and "didactical variable" tools. TDS is also used in conjunction with other theories such as the anthropological theory of didactics for analyzing the progress of teaching as a change of positions of students and teachers with regard to knowledge (Sensevy et al. 2005).

Didaktik

Reinders Duit
IPN-Leibniz Institut for Science and
Mathematics Education, Kiel, Germany

The European Science Education Research Association (ESERA) states in its constitution: "*Wherever the English phrase 'Science education' appears in this document, it has a meaning equivalent to 'didactique des sciences' in French, 'Didaktiken der Naturwissenschaften' in German, 'Didáctica de las Ciencias' in Spanish, or the equivalent in other European languages.*" At least in continental Europe, the term "Didaktik" is widely used – however with a number of significantly different meanings that do not only concern subtleties.

The German *Didaktik* tradition (i.e., the tradition that has developed in the German-speaking countries) has been very influential in continental European countries – however to differing extents. In ancient Greek, the word *Didaktik* denotes actions of showing and indicating. While this meaning seems to be quite close to that of the English word "didactical," *Didaktik* as discussed here stands for a multifaceted view of planning and performing instruction. It is based on the German concept of *Bildung* which refers to the formation of the learner as a whole person. It concerns the analytical process of transposing (or transforming) human knowledge (the cultural heritage) into knowledge for schooling that contributes to Bildung. Clearly, this transposition viewpoint is a key feature of thinking about science instruction in terms of Didaktik.

Many recent attempts to improve science teaching and learning have put their major emphasis on changing teaching methods and approaches. But the science content structure *for* instruction should also be given significant attention. This is a key figure of thought within the Didaktik tradition. The *Educational Reconstruction* approach explicitly draws on it. The analytical process of transposing human knowledge into knowledge for schooling is at the heart of this approach. It has become a key concept of German science education and seems to be widely accepted within European science education.

A project was carried out in the 1990s by the German Institute for Science Education (IPN) in Kiel to investigate the differences and commonalities between the European *Didaktik* tradition and the more pragmatic Anglo-Saxon *Curriculum* tradition. Westbury (2000) points out that Wolfgang Klafki (1995), one of the most distinguished scholars in the Didaktik tradition, argues that American curriculum theory and Didaktik are not far apart, as they are concerned with the same set of issues. Westbury points to key differences between the Didaktik and Curriculum viewpoints. He argues that the Curriculum viewpoint is embedded within a pragmatic philosophical position. Accordingly the focus is on *how* things are enabled, while the Didaktik tradition predominantly focuses on the *why*. Hence, he comes to the conclusion that despite the commonalities of the two positions, there are also "fundamental tensions because of their very different culturally embedded starting points" (p. 36).

There have, however, been important developments since Westbury presented his analysis. Globalization of science education research has resulted in close cooperation of science educators around the world. These processes initiated a fruitful international debate on the various science education positions, which have not resulted in a uniform view but more often in the enrichment of national (or regional) views. More recently, in the United States of America, for instance, there have been serious attempts to analyze and discuss critically the European Didaktik position. Duschl et al. (2011), for example, claim "*that didaktik research is a good source for identifying conjectural pathways of learning that can be examined as learning progressions*." This claim is of particular significance as research on learning progression has become a major strand of science education research in the USA.

In order to illustrate the German *Didaktik* perspective discussed above, two key approaches will be briefly presented. The first is Klafki's *Didaktische Analyse* (Educational Analysis) published in 1969. His ideas derive from the concept of Bildung and rest upon the principle of primacy of the aims and intentions of instruction. These frame the educational analysis, at the heart of which are the five questions in Table 1.

Didaktik, Table 1 Key questions of Klafki's (1969) Didaktische Analyse (English Translation: R. Duit)

(1)	What is the more general idea that is represented by the content of interest? What basic phenomena or basic principles and what general laws, criteria, methods, techniques, or attitudes may be addressed in an exemplary way by dealing with this content?
(2)	What is the significance of the referring content or the experiences, knowledge, abilities, and skills to be achieved by dealing with the content in students' actual intellectual life? What is the significance the content should have from a pedagogical point of view?
(3)	What is the significance of the content for students' future life?
(4)	What is the structure of the content if viewed from the pedagogical perspectives outlined in question 1?
(5)	What are particular cases, phenomena, situations, and experiments that allow making the structure of the referring content interesting, worth questioning, accessible, and understandable for students?

Another significant line of thought within the German *Didaktik* tradition is the fundamental interplay of all of the variables determining instruction (Fig. 1) proposed by Heimann et al. (1969). In this model, students' learning processes are of key interest. The aims and intentions of instruction are the starting point for the process of designing instruction. The *interaction* between intentions and the other variables shown in the top row of Fig. 1 is given particular attention. Students' intellectual and attitudinal preconditions, as well as sociocultural factors, significantly influence the interplay of these components. They enable four key questions to be raised that shape the process of instructional planning: Why – What – How – By What.

It seems that attempts to improve science teaching and learning usually put a strong

Didaktik, Fig. 1 On the fundamental interplay of instructional variables (English Translation: R. Duit)

Intentions (aims and objectives)	**Topic of instruction** (content)	**Methods** of instruction	**Media** used in instruction
Why	**What**	**How**	**By What**
Students' intellectual and attitudinal preconditions (e.g., pre-instructional conceptions, state of general thinking processes, interests and attitudes) **Students' socio-cultural preconditions** (e.g., norms of society, influence of society and life on the student)			

emphasis on improving the way science is taught. There is no doubt that this is essential. However, the Didaktik tradition points out that also the science content itself needs to be seen as "problematic." A content structure *for* instruction needs to be developed that addresses students' learning needs and capabilities as well as the aims of instruction.

Digital Resources for Science Education

Angela McFarlane
College of Teachers, London, UK

How you approach the subject of digital resources in science education depends greatly on how you approach science education. Most science educators try to strike a balance between coverage of domain content, the methods of science investigation to establish that body of knowledge, and the skills needed to understand the first and hopefully engage with the second at some level. Perhaps surprisingly, the epistemology of science – sometimes described as how scientists think – is not always addressed, although school science expectations do typically include a broad category concerning the nature of science. At the school level this is commonly reduced to a description of science as a cycle of observation, deduction and testing, though this represents only one form of scientific inquiry, modelled on Baconian principles, and excludes the range of other valid methods used to gather evidence and build knowledge in science. The issues of how we think about science and how we treat the nature of science within science education are dealt with elsewhere in this encyclopedia. However, it is important to hold in mind when reading this entry that how you employ any digital resource, including the learning context and task built around that use, is as significant as the nature of the resource itself.

The range of resources available can support and enrich a wide range of inquiry approaches, as well as more didactic approaches to science teaching. In any classroom there is likely to be a mix of these approaches, with the balance determined by a range of factors including the curriculum and assessment regimes in place and teacher preference. Rather than attempt a comprehensive list of actual sources, which would soon date, the table below summarizes the commonly used types of digital resource in terms of the activities in which they are typically applied and the main affordances they offer.

Activity	Resources	Affordances
Researching/ learning about a topic	Web sites, tutorial programs	Wide range of content available via the Web, structured and interactive presentation to give feedback on learning
Creating an argument	Argumentation environments	Supporting the development of an evidence-based rationale
Developing a model or concept map	Concept mapping tools, argumentation tools	Creating links and building a representation of relationships between concepts
Planning an investigation	Word processing	Writing and editing are tools to aid thinking and improve a plan
Inquiry projects	Scaffolded inquiry learning environments, e.g. Webquests	Carrying out an inquiry-based activity in a supported virtual environment
Investigate a model	Modelling environments	Building and/or experimenting with representations of complex systems
Taking measurements	Data logging and virtual experiments/ models	Ability to collect more data, run more iterations, and capture events too slow or fast for traditional school instruments
Making results tables	Data logging, spreadsheets	Ability to share data and use a class results not just one group
Drawing graphs	Data logging, spreadsheets, databases	Patterns to reveal relationship between variables generated in real time; data can be displayed in a range of ways to achieve most powerful
Doing calculations	Spreadsheets	Ability to work with larger data sets, automate calculation, and investigate relationships
Searching for patterns	Spreadsheets, databases, simulations, modelling programs	Rapid manipulation and larger data sets support an investigative approach to data
Asking "What if?" questions	Simulations, modelling programs	Experimentation can be carried out quickly and easily in simulations and models to prepare for, enhance, or enrich benchwork
Comparing own results with other people's	Social media sites, school learning environment	Larger data sets are more powerful; sharing gives an experience of the social nature of much modern science
Presenting information in a report	Word processing, presentation software	Teachers and students can produce high-quality reports and present these to the class. This process can support students to get feedback on their work and develop their understanding of what they present
Knowledge building	Wiki, knowledge forum, Web 2 tools, online discussion forums	Communicating with peers locally or at a distance, seeking new information and feedback for collaborative knowledge building
Voting or developing social norms	Audience response systems, tagging and voting environments	A particular case of collaborative knowledge building

Digital resources relevant to science learning range from raw, unprocessed data to framework programs which facilitate the management of data, even to the point of building complex simulations of the original systems and processes, and almost all combinations of the two. Whether seeking to present content to be memorized, simulations to support inquiry, or tools to support lab-based experimentation, there are digital resources that can enhance the whole activity or elements of it as shown in the table. Collaboration tools also facilitate the extension of learning beyond the individual, to collaborate with classmates – to compare results or build and test arguments – to connections with learners and experts in online knowledge building fora. Whether the approach is to teach science content or how to think scientifically, or hopefully a mixture of both, there are digital resources to help.

Among the myriad possibilities that digital resources open up for science education is the genuine possibility to join the ranks of scientists who seek out and build new knowledge, not simply to replicate what we already have a solid evidence base to support – important and rewarding though that may be. Perhaps most significant is the opportunity for students to understand the nature of scientific knowledge, that it is built through human endeavor, testable and verifiable, and that even school students can take a crack at it.

The advent of citizen science has seen the growth of Web sites that give students and teachers access to raw data from ongoing scientific research. Perhaps one of the most well known of these has been the Galaxy Zoo project where images captured from fantastically expensive and cutting edge telescopes have been offered to the global population to examine and report on. This is an example of crowd sourcing intelligence. No algorithm can yet match the deductive powers of the human brain to recognize the patterns of a galaxy in an image of a star system, and no science team has the capacity to look at all the images they are capable of capturing. And yet the skills needed to see these patterns can easily be learned – indeed a simple set of questions comparing the image you see to a set of reference diagrams is all you need. And so a situation arises where a school student, with or without the encouragement of a teacher, can become part of a globally significant scientific research project by examining raw data and commenting on it with the very real possibility that they will be the first to sight a new astronomical phenomenon.

Now let us consider how such a resource could be used in a classroom. First, a teacher might use a computer and projector to show a class the Galaxy Zoo Web site, look at a few images, and perhaps show a result of a new sighting made through this project. This could be done in a wide range of curriculum contexts: an example of an astronomical phenomenon in a science topic and an example of the use of the Web in a lesson on digital technology. Alternatively a student may come to school with a presentation she has made based on her experience of working on the site and joining the cohorts of those reporting on new images as part of her project on astronomy. The project may have been spontaneous and her report part of a “show and tell” exercise not even aimed at science. However, an opportunistic teacher might then suggest that all the class look at the site at home, in preparation for a discussion the following week and to contrast this approach to scientific inquiry with the “fair test” model of practical work they are familiar with. There are many options, corresponding to the equally wide range of inquiry approaches and pedagogical designs that may be adopted by science teachers. The resources, however, remain neutral and accessible to many approaches.

Stepping back one stage further from access to raw data or processed digital resources, it is possible for teachers to access scientific instruments so that their students may actually collect data. Although it is unlikely that this will lead to genuinely new discoveries, there is still that possibility, and it certainly gives an authentic sense of the look and feel of working science. The Open Laboratory Web site, launched by the Open University in the UK, in 2013, is one example of access to a range of instruments and simulations of those instruments which students can operate through a computer screen. The site also underscores the notions that many twenty-first-century scientists don't actually work with beakers and test tubes but sit at a computer screen that interfaces with instruments or with massive data sets and complex models built from them and that science is a collaborative activity with many individuals contributing to any breakthrough.

Again, such a resource could be used in many ways with varying levels of control by the teacher or learner, with a learner experience ranging from well defined to open ended. The site could be used to expound certain established areas of content, to explore and discover together or alone, and to experience science as a process or a body of knowledge or any or all of these in combination.

Given that the way the resource is deployed is as important as the nature of the resource in terms of the opportunities it might afford for learning, what then does access to digital resources offer to teachers and learners that transcends the affordances of traditional texts and real-world experiences in the lab or the field? Digital resources offer scale, mutability, and the opportunity to share, revise, and store. Instead of looking at a static data set (e.g., in a table form) or image, it is possible to access many examples, dynamically, comparing and contrasting, looking for patterns, and even gaining an understanding of the variation. For example, when teaching the topic of sound, it can be difficult to make a link between the frequency of a note and its representation on a musical scale. This is not a common approach in textbooks, yet a Web search will quickly unearth a range of descriptions of this relationship that help to build a link across the subjects of physics and music. It will include simulations and animations that help to bring descriptions to life. Once these various sources have been gathered, it is possible to capture elements, add a personal explanation, and make a presentation that explains the phenomenon to yourself (using appropriate citation!) and then to share this with a fellow learner or teacher. Feedback and comments from peers or teacher can then help the student to refine the accuracy and clarity of the end product. Finally, the end result could be shared or simply stored for later review and revision, either for a test or to integrate into further understandings or inquiries into the topic – perhaps in a music class or in a later science course. This example is theoretically possible without digital resources, but in practice could not be achieved easily, or to any level of scale. The essence of digital resources is that they make it realistic to teach and learn in ways that support genuine personal knowledge building rather than rote learning.

There are a few caveats to the use of digital resources in science education. Perhaps most important is that there is a great risk of replacing hands-on, sensory experience with digital alternatives. Just as playing a snowboarding simulation game will never result in one's learning how to snowboard, nor will it ever replace the experience of actually swishing down a mountain, manipulating simulations will never entirely replace scientific lab or fieldwork. Used well, however, such experiences can extend and enhance the student's inquiry into scientific topics. Also, there is a vital element of feedback entailed when a student works to create personal digital records: such products of inquiry must be personal, not simply cut and pasted with little thought, editing, or original commentary. Finally, there remains a gap between the theoretically possible and the achievable when it comes to supplying access to digital resources for students. Having a class of 30 access high-definition video on personal devices over a wireless network is likely to be problematic. So, careful planning and judicious use of resources both in and out of the school environment are required if any of the above scenarios are to be achieved through meaningful hands-on experience for all students rather than teacher demonstration.

Dilemmas of Science Teaching

John Wallace
OISE, University of Toronto, Toronto,
ON, Canada

Keywords

Classroom management; Teaching dilemmas

The term *dilemma* is derived from the Greek (via Latin) terms di meaning two and lemma meaning assumption or proposition. A dilemma is a situation that requires a choice between two options that are, or seem, equally unfavorable or mutually exclusive, hence, the expression, "caught on the horns of a dilemma" – when opting for one choice over another, one is stuck uncomfortably on the horn of that choice and unable to do anything about the alternative option.

In educational contexts, the dilemma idea was explored in Berlak and Berlak's (1981) book *Dilemmas of Schooling*. Here, the authors examine how numerous curriculum and societal dilemmas impact on schooling. These include child as person vs. child as client, content vs. process, knowledge as given vs. problematical knowledge, learning as social vs. learning as individual, common culture vs. subgroup consciousness, equal vs. differential distribution of resources, and equal vs. ad hoc justice. The authors contend that the dilemma language can assist teachers to be critically aware of the consequences of these opposing dispositions and to develop patterns of resolution. They discuss an example of the control dilemma (whole class vs. individual) where a teacher is dealing with inattentive boys during reading time. She intervenes more frequently with the boys than she does with the girls, perhaps indicating an assumption that boys need more control than girls. The authors suggest that this dilemma could be resolved by employing any number of alternative teaching strategies, including differentiated reading materials for boys and girls, or giving both boys and girls more responsibility for choosing their reading matter.

Another take on dilemmas in teaching was presented by Lampert (1985), who paints a picture of the teacher as a dilemma manager. In one of her cases, Lampert describes a grade 4 lesson on the water cycle. One of the students in the case declares that water comes from the ocean, whereas the textbook answer indicates that water comes from clouds. In moderating a class discussion about which is the correct answer, the teacher avoids the dilemma trap by accepting that both answers are correct. In her analysis of this and other cases, Lampert rejects the notion of teacher as a "technical-production manager who has the responsibility for monitoring the efficiency with which learning is being accomplished" (p. 191, original emphasis). Rather, she sees the teacher as a dilemma manager, "an active negotiator, a broker of sorts, balancing a variety of interests that need to be satisfied in classrooms" (p. 190).

In their 2002 edited book, *Dilemmas of Science Teaching*, Wallace and Louden present a series of science teaching dilemmas through teacher-written cases. Accompanying each case is a set of commentaries by distinguished science education scholars and a synthesis by the editors. The cases present a range of dilemmas faced by science teachers, about science itself, about difference, about representation, and about teaching and learning. Three examples from the book illustrate the way in which dilemmas are played out in the science classroom.

The first case, entitled *To tell or not to tell*, involves the dilemma faced by a teacher who wants to encourage students to explore their naïve understandings of science (in this case electrical flow). At the same time, he finds that their understandings fall short of a robust scientific explanation of the phenomenon. According to Wallace and Louden, at the heart of this dilemma is the issue of who has responsibility for learning. "In order to move beyond a reliance on the teacher for the right answer, there is a need for students to accept some responsibility for learning.... Good teachers tread "the 'middle ground' on this issue mediating between the two extremes of telling (and therefore taking on some of the responsibility) and not telling (and encouraging students to take more responsibility)” (p. 203).

The second case involves the use of analogies in science teaching. The teacher in the case described the difficulties she encountered when she used the analogy of a city to explain the structure and functioning of a cell. The teacher found that because students had different understandings and experiences of a city, the analogy was useful to some and unhelpful to others. Moreover, the phenomenon (the cell) comes in different shapes and sizes. The dilemma for the teacher was how far should she push the city analogy before it becomes self-defeating. As the authors point out, managing this dilemma involves a two-pronged strategy of probing into students’ experiences to increase their understanding of the analog *and* helping students understand how analogies are used in science to explain complex and variable phenomena.

In the third case, the authors examine the different responses of girls and boys in activities designed to explore series and parallel circuits. The boys quickly helped themselves to the equipment and adventurously experimented with different arrangements of batteries, wires, and bulbs. The girls were more cautious and soon found themselves falling behind, requiring direct help from the teacher. As Wallace and Louden put it, “The subject matter, the opportunities to compete for resources, the teacher’s different responses to the boys vs. the girls all point towards ‘boy-’ rather than ‘girl-friendly’ science” (p. 84). The teacher is caught in the middle of this dilemma, whether to focus the lesson more on girls’ experiences or boys. Managing this dilemma means attention to both realities, to enable girls as well as boys the opportunity to expand and explore their different experiences and understandings.

To summarize, science teaching is an activity rich with dilemmas. Teachers are required to balance many competing educational demands, for example, between attending to the individual and the rest of the class, between respecting students’ naïve understandings and promoting canonical knowledge, between listening and telling them the answer, and so on. The best science teachers are those who manage their way through these apparently irreconcilable differences with diligence, good humor, and respect for all those involved in the teaching and learning process.

Discourse in Science Learning

Gregory J. Kelly
College of Education, Pennsylvania State University, University Park, PA, USA

Keywords

Conversational analysis; Ethnography of communication; Sociolinguistics

Discourse practices and science learning

Discourse is the use of language in context. In each instance of use, discourse is constructed among people in some context, with some history, projections of future actions, and ideological commitments. As discourse entails more than the ideational communication, the broader contexts of social groups, cultural practices, and interpersonal goals need to be taken into consideration when deciphering meaning in interactional contexts. Social norms, expectations, and practices are constructed through discourse processes and, in turn, shape ways that discourse is evoked in each instance, thus instantiating the symbiotic relationship of discourse and sociocultural practices.

Discourse is central to the ways communities collectively construct norms and expectations, define common knowledge for the group, build affiliation, frame knowledge made available, provide access to disciplinary knowledge, and invite or limit participation. Such communicative processes are central to education. The ways that teachers and students use discourse in educational events have bearing on how learning opportunities are supported or constrained. In science classrooms the ways that teacher talk science, frame communicative norms, and engage students in the range of semiotics of the relevant discipline construct the nature of the scientific knowledge and practices available to be learned (Kelly 2007). Studies of student learning suggest that features of scientific discourse are not mastered as received knowledge through didactic instruction, but rather through participation as a member of a group in a discourse community. Students learn meanings of scientific terms through engagement in discourse and practices.

Scientific discourse includes some unique features, derived from the highly specialized nature of the epistemic communities constructing these discourse processes and practices. In professional and educational settings, scientific discourse is characterized by multiple modes of semiotic communication, including spoken, written, representational, inscriptional, and symbolic, among others. The range of semiotic communicative forms shows wide variation and is often alien to science students' ways communicating in others aspects of their lives. This may pose challenges to learners of science, as the unique linguistic forms of science including the use of passive voice and conditionals, technical vocabulary, interlocking taxonomies, abstraction and nominalization, and complex symbols and notational systems (Halliday and Martin 1993). Studies of classroom discourse have documented ways that it is common for science to be constructed through talk and action in ways often alienating to students, leaving the impression that science is difficult, reserved for cognitive elites, and regimented (Lemke 1990).

A central concern for science educators has been student access to scientific knowledge. Discourse studies have contributed by identifying differences between scientific discourse and students' everyday ways of speaking, knowing, and being in other settings. This concern for equity in science learning has led to studies of the ways that scientific concepts are constructed. In particular, the importance of uses of metaphors and analogies has been identified as a key component to the development of student understanding. Furthermore, there is evidence the variation of students' home discourse with that of science is an important impediment to learning. Students from language backgrounds, often falling along class, race, and ethnic lines, that differ from that spoken by scientist and science teachers face more serious learning challenges than students whose discourse background matches that of science teachers. Taking on a scientific discourse includes building an identity with the discipline and members of the local discourse community, which can be alienating for some students. Thus, studies of educational equity need to account for language variation, specific forms of scientific discourse that pose problems for learners, and ways that affiliation and identity are constructed through language use.

The study of discourse has also been viewed as important for student engagement, including inquiry approaches and student-led group work in laboratory settings. Inquiry teaching often involves students in scientific practices using language such as posing questions, providing explanations, communicating results, evaluating inferences, and critiquing ideas. As these practices are heavily language dependent, discourse analysis provides a way to consider how opportunities for learning are constructed in education events and how the merits of educational practice can be accessed. Inquiry instruction often includes students working with material objects to derive conclusions based on evidence. The processes of discovering how to make inferences, draw conclusions, and communicate results are interactionally accomplished through discourse. Thus, student reasoning can be viewed as a social process, highly dependent on the types of discourse moves available in their sociolinguistic repertoire.

One central practice emerging as relevant to many pedagogical approaches is argumentation. Argumentation refers to the uses of evidence to persuade an audience of the merits of a position. This is particularly relevant to inquiry approaches that place emphasis on evidence and explanation. Building an argument entails understanding the genre conventions for ways of aligning data, warrants, and claims. Furthermore, argumentation is often employed in interactive settings where students are able to make support and defend claims against criticism and counterclaims. Discourse includes the uses of signs and symbols, important for communicating and critiquing scientific models, graphs, and other knowledge representations. Argumentation is thus a learned discourse practice, with particular genre conventions that come to determine what counts as relevant data, a valid argument, sufficient evidence, and so forth.

Learning to teach and learning from teaching involve understanding how to employ, decipher, interpret, and produce discourse in the moment-to-moment interactions of educational events. Teacher education has become increasingly focused on the ways that science teachers learn to reflect on their practice and in particular how to use discourse moves to engage students in reasoning about ideas. As science education reform has increasingly focused on ways to help students understand concepts, models, and epistemic practices, teachers face the challenges of helping students engage with the subject matter in these ways.

Across the range of substantive topics of research and in various educational settings, a number of communicative issues have been observed. Often discussion in science classrooms is directed by teacher talk, following closely science textbooks. Such talk in the interactional context of whole-class discussion falls into a pattern of teacher initiation, student response, and teacher evaluation (IRE). This pattern of talk has implications for what is made available to learn, how the particular science discipline is positioned, and how students develop their identity with science. Yet, educational reformers have argued for a more expansive range of interactional contexts that include opportunities for an active role of students in classroom conversations. Mortimer and Scott (2003) propose a model to examine five important dimensions of classroom discourse: teaching purpose, science content, communicative approach, patterns of discourse, and teacher interventions. This model helps understand the nature of discourse events and provides a basis for designing teacher education with a focus on the centrality of discourse for science learning.

Discourse analysis refers to the study of language in use. To examine the range and types of communicative situations of discourse in science education, analysts have sought to understand how uses of discourse are situated in social practice and over time. Social practices, norms for interacting, and expectations about communicative demands are tied to the ways that language is used. Discourse analysis thus often considers how talk and action is shaped by the norms and expectations of the communicative events. This suggests the need for ethnographic and other research approaches that seek to understand broader cultural patterns of activity governing the uses of discourse. Such studies consider the micro-moments of interaction, the meso-level construction of practices through multiple interactions, and the macro-level analysis of cultural practices. Spoken communication occurs through both verbal and nonverbal channels. To understand meaning in interactional contexts, discourse analysis needs to consider pitch, stress, intonation, pause structures, physical orientation, proxemic distance, and eye gaze, among other paralinguistic features of talk.

The conceptual and epistemic goals of science education entail developing the linguistic repertoire of students. The perspective of discourse analysts suggests that learning concepts means being able to communicate with members of a group in an effective manner. As students come to learn science concepts and engage in scientific practices, they develop more expansive ways of speaking, listening, and interpreting the discourse of science and can be viewed as communicatively competent with members of a relevant community (e.g., other science students, scientists in a particular discipline, member of a community activist group focused on environmental issues). Thus, effective uses of discourse enhances student learning by expanding the range of their repertoire to communicate and learn from others. Such a view is consistent with sociohistorical learning theories that consider cultural tools, signs, and symbols that mediate social interaction as a basis for learning (Vygotsky 1978).

The implications for science teaching of discourse studies in science education are clear. As engaging with science includes working in a range of semiotic fields, teachers need to find ways that students are given opportunities to use words, signs, and symbols to communicate and interpret meaning in a variety of interactional contexts and settings. By providing opportunities for students to learn through speaking, listening, and using concepts in context of use, i.e., while engaging in scientific practices such as observing, reasoning, explaining, or providing evidence in an argument, teachers can engage students in science through active participation where learning is most likely to occur.

Discovery Learning

David Hammer[1] and Richard Gunstone[2]
[1]Department of Education, Tufts University, Medford, MA, USA
[2]Faculty of Education, Monash University, Clayton, VIC, Australia

“Discovery learning” is a label that has been prominent in discussions about education, including science education, since at least the 1940s.

Like all popular terms in education, discovery learning has taken on a range of meanings, but most often it refers to a form of curriculum in which students are exposed to particular questions and experiences in such a way that they “discover” for themselves the intended concepts. The student’s inquiry is usually “guided” by the teacher and the materials, for example, through “Socratic” questions, because no one expects them to arrive on their own at ideas it took scientists centuries to develop.

Many scholars, including the authors of this entry and the editors of this encyclopedia, see the term as having little value today. This is in part because some proponents of “discovery learning” make extreme claims for the benefits they see in student discovery of concepts and in part because the term has become rather debased by its highly inconsistent use in a range of educational debates (including as a pejorative term) (Hammer 1997).

Computational science; Data-intensive science; Information literacy; Scientific computing

Technological advances over the last several decades have disrupted the very nature of our day-to-day lives, as well as scientific research. Grand challenges facing society drive research and education to address questions that require intensive computation and data analysis. Such grand challenges include:

- What is the impact of global and regional climate changes?
- Can carbon dioxide be safely sequestered to minimize the release of greenhouse gases?
- How can we better predict and plan for natural disasters (earthquakes, tsunamis, wildfires, avalanches)?
- How can breakthroughs in genetics be used to cure/fight cancer and other diseases?
- What is the structure of the Milky Way galaxy?

As a result new paradigms of science have emerged. The **empirical method**, the application of experimental data to predict and describe natural phenomena, arrived on the scene 3,000–4,000 years ago and was evident in the lists of Pythagorean triples in Babylonia; in an Egyptian medical textbook (circa 1600 BC) that applies examination, diagnosis, treatment, and prognosis to the treatment of disease; and in charts of planetary motion. The Age of Reason (1400–1700 AD) brought the birth of **theory**: science based on principles that are developed through the use of models and generalizations. Theory was manifest in Galileo's studies of motion; the writings of Hailey, Kepler, Pascal, and Huygens on planetary motion; the development of calculus to explain mechanics by Newton and Leibniz; and Napier's formulization of logarithms. (See *The Fourth Paradigm*: *Data Intensive Scientific Discovery* (Heyet al. 2009) for a detailed discussion of this history.) Until recently, the empirical method and theory were considered the two legs of science. Over the last 20 years, with the advent of powerful computing capabilities, two new science paradigms have arisen: computational science (scientific computing) and data-intensive science (data-centric science).

Computational Science or Scientific Computing

Scientific computing has emerged as the third leg of science, joining theory and experiment. It allows us to attack previously unsolvable problems and make transformational advances in science and engineering to address global challenges in energy, environment, and national security (Wadsworth 2006).

Scientific computing is not computer science per se. Computer science develops technological hardware and software and is a discipline unto itself. Scientific computing is the use of the hardware and software to guide the discovery of new science. Scientific computing is embedded in mathematics, science, and the humanities; it complements experiment and theory, but does not replace them. As others have put it:

> It is both the microscope and telescope of modern science. It enables scientists to model molecules in exquisite detail to learn the secrets of chemical reactions, to look into the future to forecast the weather, and to look back to a distant time at a young universe. (Fosdick et al. 1996)
>
> Scientific computing focuses on simulations and modeling to provide both qualitative and quantitative insights into complex systems and phenomena that would be too expensive, dangerous, or even impossible to study by direct experimentation or theoretical methods. (Turner et al. 2011)

Examples of the use of scientific computing include the study of wind turbines, oil and gas recovery, CO_2 sequestration, seismology, hydrogeology, cloud formation, carbon and water cycles, wildfires, and genetic adaptation.

Data-Intensive Science

The explosive use of personal data, new data collection technologies, and the capabilities and speeds of modern personal and supercomputers has resulted in a wealth of information and data. Simulations of complex models are generated on a 24/7/365 basis and involve multiple scales. The outcome has been the invention of data-intensive science as a fourth paradigm, which has four main activities:

- Capture: How can sensor networks be used to capture geological or ecological data? How can nanotechnology devices be used to gather biomedical data at the individual level?
- Curation: Where and how do we store the data to make it useable?
- Analysis and modeling: How do we mine (i.e., extract useful information) from the data? How can we make inferences without seeing all the data? Can we make models that explain the data?
- Visualization: How does one fully comprehend large data sets? How can we make the human-computer interface more effective?

Computational Science Example

Given these two new paradigms of science, it is important that K-12 educators provide their students with the basic underpinnings of scientific computing and data-intensive science. Let's explore a very simple example to illustrate scientific computing and how technology can give students earlier access to scientific topics than through theory and experimentation alone. The example concerns modeling heat diffusion on a plate using a freely available software package NetLogo. The NetLogo model allows the user to select the plate's material and the temperature conditions on the plate's boundary and then model the diffusion of heat on a plate over time. This allows the user to simulate multiple iterations of the model without knowledge of the heat equation which utilizes partial differential equations (Fig. 1).

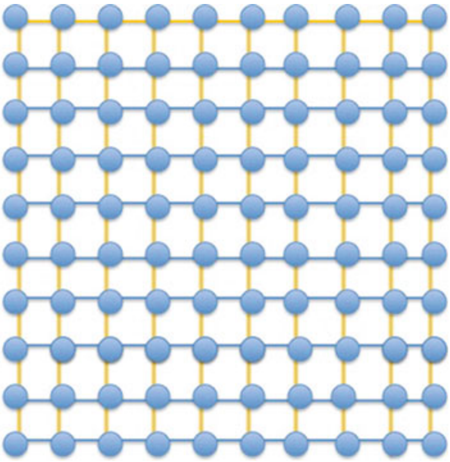
By reducing the example into a discrete model where the plate is represented by a 10 × 10 square (Fig. 1), the concept of heat transfer can be simplified to the level of elementary arithmetic: calculate the average temperature differences around a given node to determine the new temperature of that node. A particle's temperature changes at a rate proportional to the difference between its temperature and the average temperature of its neighbors. For example, if a point P has temperature of 12°, with neighboring points of temperatures 10°, 10°, 20°, and 20°, and the constant of proportionality for heat transfer is 1/3, then point P will have an updated temperature of $12 + 1/3((-2-2+8+8)/4) = 12 + 1/3(3) = 13$. In the 10 × 10 model, finding the new temperature at each point is a matter of four subtractions to determine temperature difference and four additions and two divisions to determine a new temperature, a process that can be completed by hand. However, in a 100 × 100 square, there are 100,000 required calculations per step, and while each step is simple, the number of calculations requires a computer simulation. If we make the grid 1,000 × 1,000 units, the computation requires 100 more calculations per step taking the total number of calculations up to ten million. Expanding this to three dimensions, a cube 1,000 units on each side, requires ten billion operations to calculate the temperature at each node. The necessity of high-performance computers for simulations for even the three-dimensional model is clear.

Education Issues

There are four key elements of why such models are important to student understanding:

1. The dynamic, visual nature of such models
2. The allowance of easy variation of parameters
3. Forced construction of equations out of physical observations
4. Opportunities for a better understanding of orders of magnitude

Computational thinking integrates the power of human thinking with the capabilities of computational processes and technologies. The essence of computational thinking is the generalization of



Discovery Science, Fig. 1 Partial differential equations governing heat transfer on a plate

$$\frac{\partial T}{\partial t} = k\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) = k\Delta T$$

$T(x,y,t)$ is the temperature of the point (x,y) at time t,

k is a constant, and

Δ is the Laplacian operator.

ideas into algorithms to model and solve problems. The new paradigm of scientific computing impacts teaching in four distinct ways:

1. Profoundly – never before have two new paradigms occurred within such a short time frame, and we need to think of scientific computing as a fundamental twenty-first-century skill (Wing 2008).
2. Systemically – not as a separate subject area, but as a paradigm relating the interdisciplinary nature of science, engineering, and the humanities. Scientific computing has a symbiotic relationship with mathematics, science, and engineering; computational thinking requires abstraction and the ability to work with multi-layered and interconnected abstractions (e.g., graphs, colors, time); and it draws on "real-world" problems.
3. Vertically – scientific computing must be developed over many years (Pre-K through college) with a need for experiences to be provided early. Examples of vertical strands are provided in Table 1.
4. Wisely – programming should be incorporated at appropriate times. Computational thinking is not just programming or computer engineering; and much of computational thinking can be developed without programming. The emphasis should be on quality, not quantity of experiences, and the experiences must be tied to the thought processes that arise in utilizing a computer to model a system or mine a data set.

Data-intensive science should also inform our teaching. There is a need to provide basic information literacy skills so that students can be productive members of the twenty-first-century workforce and adapt to an increasingly data-dominant world. Teaching should address the following: How is data mining done? How are inferences drawn from large data sets? What are the pros/cons of models? How can one digest data? Teachers need to make learning more authentic. There are a wealth of resources to connect content areas to "real-world" problems. Curriculum needs to have more depth, less breadth. Project-based and place-based learning pedagogies provide a framework for moving toward in-depth learning experiences for students. We need to change the way we "see" and sense data. This can be done by providing student experiences with multiple interpretations and representations, such as 3D, color graphics, and different scales. Interdisciplinary understandings will be essential, since real-world grand challenges must be approached from multiple perspectives. This calls for more integrated curricula that move away from the silo effect where disciplines in schools are isolated from each other. We must help develop new intellectual tools and learning strategies in our students, such as comprehension of the importance of different scales, the understanding of complex systems, and how does one frame and ask meaningful questions, We also need to provide new experiences for the students

Discovery Science, Table 1 Vertical strands of scientific computing (for more details, see http://www.iste.org/learn/computational-thinking/computational-thinking_toolkit.aspx)

Components	Examples
Algorithms	Importance and qualities of algorithms, binary vs. linear search, finding averages independently and in parallel, basic computational algorithms and their efficiency
Modeling	How we get mathematical observations, addition as counting and multiplication as area or repeated addition, graphs as ways to see change, hands-on dynamical systems, relating physical laws to equations, relating change to slopes of graphs, studying complex, multi-agent phenomena
Probability	Understanding of randomness; basic probability concepts; meaning of average behavior, trends; law of large numbers; geometric probability; sampling through random walks; quantification of uncertainty in simulations (use of ensembles)
Decomposition	Breaking down a task or process, doubling methods to multiply, areas via simple geometric subdivisions, steps for solving different types of equations, areas via integration
Complexity	Understanding of interrelationships and complexity, basic cause and effect, sum of parts can be greater than whole, interpretation of graphs, multiple variable interrelationships
Pattern recognition	Multiples, divisibility, triangular numbers, linear-area-volume dynamic change
Abstraction	Pattern generalization, ability to filter out information, ability to generate information needed, making and verifying conjectures, variables

including collecting and interpreting data from sensors, mining data, collaboration in framing and solving problems, conducting interdisciplinary synthesis, using science to inform policy inferences, use of scientific computing, use of data gathering tools, and practice in visualization. Finally, students must be exposed to statistics, with a focus on data-driven problems and understanding statistical concepts.

Discussion and Science Learning

Lyn Dawes
Cambridge, UK

In memory of Phil Scott

Keywords

Dialogue; Discussion; Exploratory; Interthinking

Learning about science involves asking questions about the world around us and collecting evidence that will help to answer them and then asking further questions. Establishing a theory in science involves people systematically testing their own and other people's ideas to develop robust explanations which fit the evidence. In science, there is never really definitive proof as we might find in mathematics but a gradual working towards a more robust scientific point of view that can explain observations, data, or other evidence. Science learning begins as children question things naturally and draw conclusions from their lived experience. So, a child kicks a ball and notes that it slows as it rolls along the grass and then stops. A reasonable hypothesis for this observation is that the energy put into kicking the ball has been used up. A ball rolling down a hill does not need as much energy because it is easier to go down than up. Similarly a child might notice that the sun is behind nearby trees in the morning, but by lunchtime it is overhead, and that sometimes the sun is yellow, sometimes red. The sun must therefore both move and change color. The use of metaphor, imagery, and imagination in some of our common ways of describing natural phenomena also offers learners a kind of explanation for how things work: for example, "darkness fell," "waves bring the tide up to the top of the shore," "the toy won't work because the battery has run out of electricity."

The outcome of making meaning from a mix of everyday observation and language experiences is that children generate for themselves some work-a-day explanations of the natural world. Such explanations – which may never be articulated – seem to fit what is observed and can last a lifetime. However, assiduous generations of scientists have collected enough information for us to be able to identify some of these ideas as "misconceptions." A ball rolls to a halt under the influence of friction and gravity. Energy cannot be used up. The sun stays in one place while the earth spins; its color is affected by the atmosphere that light passes through to reach us. Batteries contain not electricity but chemicals which can generate electricity. Learning in science must therefore involve eliciting children's already-formed ideas, then providing a range of experience and evidence to help the child to see a different and more scientific perspective if necessary. To consolidate learning, we can enable a child to apply their new knowledge in ways that help them to understand that it is sound and generalizable.

The body of established scientific knowledge, carefully accumulated over the years, is important to us and to the well-being of the earth. It is unnecessary for each child or each generation to repeat the process of finding everything out from scratch. And so an effective education in science involves an intricate mix of activity, discussion, and practical application, including helping children to understand and acquire the relevant skills and the processes scientists go through to ensure that their investigations can be replicated. It involves children in learning both what is established as factual knowledge and the technical language which helps scientists to communicate accurately and concisely with one another. As Jay Lemke puts it, children must become "fluent speakers of science." Science learning necessitates acquiring a collaborative approach and developing the capability to analyze, communicate, and formulate testable questions.

There may be famous scientists who have made strides in establishing science concepts alone; but mostly it is cooperation, discussion, and thinking together that create new ideas. Science is not just factual information and enquiry but also a set of attitudes and values to do with accepting responsibility, being aware of implications of research, and staying open-minded. Einstein, at first completely dismissive of the idea of a Big Bang starting the universe, later gracefully conceded that Hubble's work showed that this was so. Finally, for the teacher, science learning also involves keeping alive the quirky capacity for curiosity and creativity that helps scientists to make the little leaps of imagination – or the seismic shifts – that keep moving human knowledge onwards.

Discussion in Science Learning

Two seminal UK projects in science education of great international influence were the Children's

Learning in Science project (CLIS; University of Leeds) and the Science Processes and Concept Exploration project (SPACE; King's College London and University of Liverpool). The SPACE approach was to "start where the children are," building on the ideas children bring with them to lessons and helping them to develop their understanding of scientific concepts. The CLIS approach involved activity and reflection in which science concepts were tried, tested, and discussed through an imaginative practical approach. Indeed both projects involved science as a practical subject and foregrounded the role of teachers in engaging, motivating, and stimulating the curiosity of children while providing them with a solidly scientific perspective on the world around us. Both have left a valuable legacy of theory and practice for science teachers. In addition another UK project, the CASE (Cognitive Acceleration through Science Exploration) project (King's College, London), was built on a teaching approach involving metacognition, that is, children's reflection on their own thinking. This has been shown to have a marked impact on cognitive development and academic achievement. Primary science education in the UK was given a boost with the introduction of the National Curriculum in 1995 when it was established as a core subject and allocated equal time with English and mathematics. Subsequent revisions of this curriculum have meant that schools have allocated more priority to English and mathematics, at the expense of other subjects. The 2014 National Curriculum highlights the importance of teaching a scientific understanding for our children and strongly suggests that teaching strategies should involve discussion which enables children to ask their questions and talk through tentative ideas.

Both primary and secondary science classrooms in many parts of the world have in the past been characterized by their quietness; teachers were often evaluated by the noise level of their classrooms, silence being highly rated and children's talk being frowned upon. However, the influence of a sociocultural approach to learning has led teachers, particularly primary teachers, to feel that it is quietness that should cause unease rather than noise, at least if it is the dominant mode of the classroom. Learning is today understood to be social. The child's first and best means of communication is through spoken language. The Russian psychologist Lev Vygotsky and the translators and interpreters of his work have helped educators to feel confident that encouraging children to talk in class is of great benefit to their learning. Vygotsky noted that language offers tools with which ideas can be shaped and articulated, then offered for joint reflection. Once aired, ideas can become part of the shared understanding of a group, available for discussion and modification. Being part of a group talking about ideas in science allows individuals to internalize ideas, reflect on them, and bring their modified thoughts to subsequent discussion. Jerome Bruner realized that children in a classroom can be one another's best resource if they can communicate their thoughts through such discussion. Talk offers the chance to share understandings of scientific phenomena and come to a larger consensus or a productive disagreement. Either such consensus or disagreement can help to establish a robust theory or a new line of enquiry.

In his extensive listening to students talking in groups, the educational researcher Douglas Barnes noted that spoken language enables the individual, and the group, to begin to organize ideas. Talk may be hesitant as ideas are proffered and considered; contributions may be incomplete and tentative. Barnes saw that what he termed "exploratory talk" was of great value in aiding understanding and allowed children to express knowledge, opinion, and uncertainty. Importantly, he recognized that if groups of children were to achieve such effective discussion, their talk together must be of a specific quality, a different type of talk than their usual more casual interaction with one another, and so raising their awareness of discussion as a tool for learning would mean that group work became more reliable and effective. He identified a type of talk in which children tentatively try out their own ideas in comparison with the views of others. He suggested that children should be encouraged to contribute ideas from their own experience and to suggest where there seemed to be discrepancy between points of view. In addition, Barnes advocated encouraging children to ask productive questions and noted that it would be invaluable if students were taught how to elaborate on their initial ideas. Discussion in science classrooms should draw on these ideas to ensure that science teaching is inclusive, starts with the child, and develops both science knowledge and understanding.

Every child can communicate, and almost all have a range of talk repertoires at their disposal. Children switch between talking in a range of contexts such as the playground, at home, during competitive sport, in class, and so on. They can also talk to adults appropriately and are able to use their individual accents and dialects to communicate fluently. Each of these types of talk is of equal value as the child functions in their social world. Each type of talk, including classroom science discussion, is based on some implicit, straightforward, but essential "ground rules." Ground rules are the usually hidden ways that people devise to organize themselves so that social harmony is possible. Ground rules for discussion in class are different from the ground rules, for example, of playground talk, talk between children and their parents, or talk between children playing a collaborative game.

Neil Mercer and Rupert Wegerif, in studying children talking about science at computers, found that some children were unaware of the ground rules for exploratory talk. Group work ended in disharmony, and learning fell away as disputes arose which could not be resolved, or groups simply agreed with initial suggestions and did not seek understanding. It was apparent that some children had no experience of a reasoned, exploratory discussion. In learning terms, this is analogous to only having heard traditional stories and never having experienced science fiction, or a ghost story, or a mystery story. It is simply a gap in experience which can be addressed by teaching. Other children were aware of the ground rules which could help them to think and learn together but were unable to apply them. Still others felt that sharing their knowledge and understanding would diminish their personal status – everyone would "know" as much as they did. The ground rules for exploratory talk as later elaborated by Neil Mercer can be summarized as listen to and include everyone, ask questions, challenge what you hear, give explanations with reasons and elaborate on your ideas, and seek to reach a negotiated agreement. The discussion, creation, and use of a class set of "ground rules for exploratory talk" helped children to see that sharing learning does not make individuals poorer but makes the group richer and that exploratory talk could help everyone to articulate their ideas and could help individuals, groups, and the class to establish a joint, robust scientific point of view.

Substantial work elaborated in a number of other entries in this encyclopedia has been able to provide examples which better establish Vygotsky's ideas, left as hypothetical by his untimely death, and thus contributed to educational theory in science learning. For example, Vygotsky saw individual thought as a product of reflection; spoken language he describes as allowing intermental ("between minds") thinking and drawing on intramental ("within the mind") or individual thought. He postulated that adults talking to children in an exploratory way – though he didn't use that term – would be able to influence their thinking. That is, intermental thinking influences intramental thinking; but crucially, that subsequent talk could draw on the newly developed thinking of individuals, contributing to the group's subsequent better understanding. Discussion like this, Vygotsky argued, creates a spiral of learning, as individual development supports group thinking which in turn aids individual understanding and so on. This spiral has been observed, for example, in samples of children's talk about science collected in the Thinking Together project, so confirming Vygotsky's hypothesis. For science learning, this means that children, engaged in a combination of science activity and discussion based on exploratory talk, can learn from and with one another and can construct new knowledge together in a way that is accessible to all of them.

In addition, by engaging in exploratory talk in science, children are learning in effect "how to discuss." They become more adept at listening actively, asking pertinent questions, providing reasons for their contributions, weighing up and summarizing what has been said, and coming to an agreement together or establishing new questions together. This is a transferrable skill and is the basis for rationality, teamwork, and social learning. Neil Mercer has described the joint reflection generated when members of a group engage one another in exploratory talk as "interthinking." Interthinking is a powerful way for groups to proceed during enquiry, problem solving, and understanding new ideas not only in science but across the curriculum. Science learning in classrooms therefore requires carefully organized group work based on the direct teaching of the skills of exploratory talk, the establishment of relevant ground rules for discussion, and in helping children to see how and why to engage in interthinking.

Dialogic Teaching in Science

Relevant science learning involves the teacher enabling children's access to current scientific thinking. Traditionally this has involved such strategies as chalk-and-talk and the completion of "worksheets." More recently the idea of "dialogic teaching" has described how science teachers can engage children in whole-class debate about their ideas in science. Dialogic teaching as described by Robin Alexander involves teacher and class in a searching, cumulative debate, orchestrated by the teacher. During dialogic teaching, children take extended turns, explaining what they know or do not know, and responses are chained together in a meaningful way, stimulating further contributions. It is worth noting that there are clear links between the spoken language structures of dialogic teaching and those of exploratory talk, that is, teachers who generate dialogue are teaching children how to talk effectively to one another in groups.

A distinctive feature of dialogic teaching is that it involves teachers asking authentic questions (as opposed to the common classroom practice in which teachers ask questions to which they already know the answer, in order to involve children or to check knowledge items, for example, *Teacher*: What do we call the ends of magnets? *Child*: Poles. *Teacher*: Yes, that's right).

In dialogic teaching, answers are much less predictable and less likely to be a single word, and any child can answer, not just those who choose to put up their hand. The teacher keeps the discussion open. If the above example of closed and conventional questioning is recast as it would be in dialogic teaching, it would be something like the following:

> *Teacher*: What sort of magnets do you think are strongest?
>
> *Child*: My brother has some you throw up in the air, and they stick and make a funny noise.
>
> *Child 2*: The horseshoe magnet, the red one, it's big, but it's rubbish with the paper clips.
>
> *Teacher*: Anyone else with information about horseshoe magnets?
>
> *Child 3*: The ends both pull together, they – it doesn't mean it's strong, you even get them at playgroup.

In elaborating the idea of dialogic teaching, Phil Scott established that learning in science classrooms proceeds through different episodes of talk as a lesson unfolds over time. He recognized that if children are to have access to a scientific point of view, the teacher must at times establish what is already known by providing an authoritative account of factual information. Phil Scott showed how a timely combination of demonstration, clear teacher explanation, and the active involvement of students provides powerful contexts for classroom learning in science. For example, he showed students a tank of water standing on a table and asked for their ideas about what forces were at work. He asked them to consider whether the table exerts an upward force. Their uncertainty about this was resolved by asking them to take the place of the table and hold up the tank – or holding it up himself and showing what happened if the upward force was removed. He established that science teaching over the time span of a lesson, or series of lessons, proceeds through episodes that are more or less dialogic or authoritative in their nature – his insight being that authoritative episodes, where children are told things directly, are a crucial part of an ongoing dialogue. He recognized that teachers have the professional expertise to create lessons which draw on a range of strategies appropriate to the learning needs of the students, referring to this as "highly skilled guidance" in both discussion and science content.

The concept of "communicative approach" was first introduced by Eduardo Mortimer and Phil Scott to describe how a teacher works with children develop ideas in the classroom. The communicative approach is defined by characterizing the talk between teacher and pupils along each of two dimensions: interactive-noninteractive and dialogic-authoritative.

Interactive teaching involves talk between teacher and students, while noninteractive teaching involves only the teacher's voice. Dialogic teaching involves the teacher asking students for their points of view and explicitly taking account of them, asking for further details, or noting them for further consideration. In dialogic talk, there is always the attempt to acknowledge the views of others, and through dialogic talk the teacher attends to the students' points of view as well as to the scientific explanation.

During science sessions, a shift from dialogic to authoritative approach constitutes a "turning point" in the sequence of episodes. Phil Scott and Jaume Ametller showed how part of a teacher's professional expertise is to recognize key moments and carefully close down dialogic interactions. They could then provide a more authoritative, scientific point of view at times when it was clear that students were ready for an explanation of phenomena or an answer to the questions they had raised. Subsequent discussion in groups enabled students to talk about their new thinking and to examine the fresh perspective they had been given, in order to test its explanatory power, and to use appropriate vocabulary in ways that would support concept formation.

Science Concepts and Concept Formation

A child might know that sand is runny when dry and sticky when wet, without being able to say why. Some may not question this difference. But if asked, "Why do you think wet sand is sticky?" children will create everyday explanations drawing on their current vocabulary, experience, and creative imagination. A scientific explanation involves the concept of surface tension, an understanding of which requires learning about the molecular structure of water, hydrogen bonds, a consideration of particle size, and perhaps some thinking about gravity. Concepts are ideas created in our minds from various items of information and understanding. The label "surface tension" is in essence technical/scientific shorthand for a complicated chemical and physical effect. However complex the phenomenon, its outcomes – making sand sticky, making water droplets form – are easy to access and describe. The child may begin to use the label "surface tension" and only subsequently gradually accumulate the experience and information which deepen understanding. Concept formation is not an instantaneous effect but a gradual reconsidering and reshaping of ideas in the light of experience – and in the light of discussion with others.

This is a perennial dilemma for science educators – whether first to introduce accurate vocabulary so that experience is more readily describable or whether to first provide opportunities and experiences and only later provide the vocabulary necessary for explanation and concept formation. For example, a child might look at plant cells through a microscope and describe them as squares or rectangles. Another child might say bricks or boxes, and so the chance to talk about the three-dimensional nature of plant cells arises. The idea that living things are constructed from cells is fundamental to biology, and children have to start somewhere in learning this by observing cells. Whether we call them that at first seems to be a matter of opinion, based on the teacher's learning aim for their session. It is also important to note the metaphorical power of words – cells were named after the small rooms inhabited by monks. The chance to use the word "cell" aloud and in a science context, with other learners, provides invaluable practice and generates confidence.

The overlap between science terms and everyday uses of the same word can create confusion; for example, the commonly used words *energy* and *force* have particular technical meanings in science. Discussion of what is understood by particular vocabulary can help children to acquire a more scientific perspective as learning proceeds. Another example is the term *liquid*; this has a specific scientific definition, but young children may think that a liquid is sticky (washing up liquid). Similarly they may refer to any colorless liquid (e.g., molten candle wax) as water.

For individuals, science education proceeds both in startling leaps and in lengthy times of reflection and, seemingly, forgetting. But the ideas and words are held in mind and catch on the hooks offered by life – in and out of school. Learners may use new vocabulary in relevant contexts to build up an understanding of some important concepts or draw on their learning in what might seem unrelated contexts. So, if, for example, we consider teaching the concept "Waves have energy," it is possible to consider how a mix of activity, information, and discussion can provide an environment in which learners create this concept in their own minds. Allowing time for the mind to assimilate, try out, and integrate new ideas is crucial. It is also important to note that concepts like this can be taught to learners of any age. Bruner (1960) has written "You can teach any child any subject at any age or stage of development in an intellectually honest way." In primary settings, guided play, purposeful creativity, and chances to talk are the keys to tapping into children's interest in the world around them and helping them establish science concepts.

Analogies are widely used to explain and clarify science concepts, for example, considering current electricity to be analogous to a moving bicycle chain, a hosepipe filled with water, sweets passed around a circle of children, or a loop of rope running through their hands. No one analogy has complete explanatory power – no analogy can logically be exactly the same as the phenomenon it is held or relate to, but a range of analogies gives a concrete anchor for abstract ideas and therefore makes the abstraction more understandable.

With increasing understanding comes the opportunity to develop increasing complexity and to use other modes of communication, further specialized language, mathematics, and a range of ways to present data. Essential to science learning is an ability to communicate understanding to others so that knowledge is shared for further use. Without Newton's mathematical and verbal description of the forces that shape the universe, there would be no basis for Einstein's subsequent review and rethink of what we know about how the planets move. Without Einstein's ability to communicate his ideas to others – in 1905 he published three physics papers on the reality of atoms, the photoelectric effect, and on special relativity – his new explanations would not now be a basis for contemporary science thinking.

Summary

The careful accumulation of science knowledge has enabled us to understand more and more about how the world works. Because of this, we are no longer at the mercy of explanations of the natural world which are to do with imagination, superstition, or magic. The problems that can arise from applications of science, for example, in warfare, food production, human reproduction, and excessive global warming, are to do with human choices about how we use our knowledge, not the science itself. A sound science education is the right of every child. Through their learning of science, young people gain the opportunity to consider facts, issues, and ideas and learn how and why to discuss current causes of concern or interest with others. A discussion-focused approach to science education can support the child's development of concepts while teaching them how to take part in reasoned debate. Asking questions is natural. Science teaching can help young people to learn to collect evidence, to keep their curiosity alive, and to respect the world we all depend on.

Early Childhood Science Teacher Education

Marilyn Fleer
Faculty of Education, Monash University,
Peninsula, Melbourne, VIC, Australia

Introduction

Early childhood education includes the study of children from birth to 8 years of age. Early childhood education has gained increased attention as governments around the world are putting more resources into supporting the quality of teaching and learning of very young children. The expectation is for children to learn more, including learning more discipline knowledge, such as science. Central to these increased outcomes has been the focus on quality provision of early childhood education through highly qualified early childhood teachers. So what do we know about the quality and experience of the graduates of our early childhood degree programs in science education?

A comprehensive search of all published literature into early childhood science teacher education (February 2012) revealed only 16 scholarly works. Thirteen papers were research studies and three were descriptive or theoretical discussions of specific early childhood science teacher education courses. This clearly suggests that early childhood science teacher education is an understudied area in urgent need of research attention.

The first published paper in the area of early childhood science teacher education was written by Margaret Bearlin in 1990 in Australia. Bearlin's paper remains the most insightful and critical analysis of early childhood science teacher education reviewed. Although a brief and multilayered study, it provides a seminal base for all the other papers that followed, where elements of the challenges identified by Bearlin so early on are investigated in a range of different contexts and theorized in different ways. On a macroscale, the problems facing early childhood science teacher education have not changed since 1990. After 24 years, we are no better informed and have made only incremental progress in furthering the findings set out by Bearlin in 1990.

So what did we learn from Bearlin's study, and what have most of the subsequent studies noted? We begin by examining the personal characteristics of early childhood preservice teachers, followed by discussing the institutional challenges and finally the societal and cultural values surrounding what it means to be an early childhood science teacher. Through this analytical framework, it emerges that teacher educators have generally either blamed the students for not having a science background or have designed courses to explicitly change the perceptions of the early childhood preservice teacher to one who can teach science successfully to young children. How the latter is achieved offers the focus for the rest of this entry.

Personal Characteristics of the Early Childhood Preservice Teacher

In all the studies reviewed, a consistent message about the nature of the preservice learner was identified. Early childhood preservice teachers were found to be female, having studied some secondary school science, mostly human biology or biology, with very few having studied chemistry or physics. However, it must be noted that all the studies reviewed were from Australia, New Zealand, and North America (Florida, Georgia, Indiana, Midwest, New York, Ohio); therefore this profile can only be assumed for these European heritage communities. There is no easily accessible profile of early childhood preservice teachers in the Asia-Pacific continents, South American countries, Middle East, Soviet and Baltic communities, African continent, and central and northern Europe. This is specifically an under-researched area. We know most from the North American context.

As would be expected, those studies which assessed students' content knowledge of science showed that students had limited knowledge (Garbett 2003, 2007) and, with the exception of Garbett (2003), also lacked confidence in teaching in this area. Garbett (2003) found that the early childhood preservice teachers she surveyed in New Zealand believed they had sufficient content knowledge to teach young children science. However, her later results (Garbett 2007) showed that student teachers held many misconceptions, impeding their ability to ask appropriate questions or guide young children's investigations in ways that led to conceptual development in science. Here the preservice teachers were identified as not having the necessary background in science. Most studies reviewed, but particularly Garbett (2003, 2007) and Cullen (1999), strongly advocate for a focus in teacher education on building preservice teachers' science content knowledge, with Appleton (1995) arguing for two units of science education, where one unit should be devoted to learning science content knowledge (two units would typically be considered as half of one semester's study in a degree program). However, Appleton (1995) also argued for equal importance being placed upon building preservice teachers' confidence to teach science. Appleton's research which replicated that of Bearlin (1990) found that discipline knowledge needs to be introduced through experiences which support a positive self-image of students as teachers of science, where small group experiences rather than lectures appear to have the greatest impact on preservice teachers' self-image, but at the cost of reducing content coverage. These findings are consistent across all of the studies reviewed. Making sense of these collective findings becomes clearer by reviewing Bearlin's (1990) analytical framework for preservice teacher education.

Bearlin (1990) undertook a survey of practices in the 1980s of in-service and preservice programs, where she found three models for the teaching of science by teacher educators, which she used to inform the development of the Primary and Early Childhood Science and Technology Education Project (PECSTEP) which sought to specifically examine the relations between the historical disciplinary construction of science knowledge and the person. These models conceptualize and name the central problems that have plagued early childhood science teacher education programs since the publication of Bearlin's work in 1990:

Model 1: Subject-centered approaches focus on the body of knowledge that Western science has constructed and found to be a valued form of knowledge. In teacher education programs where this model dominates, educators primarily focus on ensuring that early childhood preservice teachers increase their conceptual knowledge of science concepts. This model tends to privilege the learning of concepts through process approaches devoid of theoretical underpinnings and does not pay attention to gender.

Model 2: Learner-centered approach tends to center on providing practical learning experiences to early childhood preservice teachers that are nonthreatening so as to increase their knowledge of science and gain experience of a range of science activities that are suitable for young children. Low self-confidence to teach science is linked with low science knowledge, and by increasing knowledge of science and science teaching, preservice teachers will increase their confidence and competence in teaching science. Gender issues are noted as not relevant because all children are unique. However, in some programs, specific course work is directed to analyzing the gendered nature of careers in science.

Model 3: Knowledge and person-centered approach is viewed as a gender-sensitive model where both science and gender are seen as constructed. Preservice student teachers are positioned in ways that help them value the knowledge they bring and to recognize the science concepts already understood and used in daily life. Through scientific experiences and inquiry that is based on their own interests (not the interests of children), preservice teachers reflect upon their own scientific learning and their learning about the nature of science as a human construction and not as a body of fixed knowledge. Consciousness about how science knowledge is constructed is the focus leading to the development of self-confidence and competence in science and later science teaching through using pedagogies such as interactive teaching.

Bearlin's (1990) work is noteworthy because the conceptualization and subsequent framing of the PECSTEP model recognized both discipline content knowledge and specifically the constructed nature of science, for what was then, and now, a predominantly female preservice teacher cohort in early childhood education. While the issue of gender has not changed, this highly significant variable in research has become invisible in subsequent years. With the exception of Akerson, Buzzelli, and Eastwood (2010) where issues of power are identified, and Siry and Lang (2010) who specifically created programs for cogeneration of scientific knowledge between the preservice teachers, the children, and the educators, issues of gender have not been further researched in early childhood science teacher education. Further to this is the cultural nature of science, which also remains invisible in early childhood science teacher education research. This too is an under-researched area within early childhood science teacher education.

Institutional Demands and Values (in the Field/in the University) that Shape What Is Possible for the Early Childhood Preservice Teacher

Most of the studies reviewed focused on the relations between the course content and experience of the early childhood student teachers in the university and their experiences on practicum. All science teacher education courses linked their course content explicitly with the practicum. A common problem identified across the studies was the lack of opportunities for preservice early childhood teachers to observe experienced teachers teaching science, and for many, there was also the challenge of not being allowed to teach science while on practicum. Many studies reported that there was never any guarantee that students would be able to practice what they were learning at university with children while on practicum. Consequently, many of the preservice science courses were designed with a range of creative solutions, such as:

1. Being given options for assessment work associated with the practicum just in case students' opportunities for teaching were limited or nonexistent (e.g., designing a science lesson plan and teaching it, designing a lesson plan that integrated science with another curriculum area and teaching it, designing a full unit because they were not able to teach science)
2. Watching videos and CDs of early childhood teachers teaching science
3. Computer simulations of science teaching

Many of these studies reported that literacy and numeracy were a higher priority than science, and consequently early childhood preservice teachers were either not given the opportunity to teach science or they had limited support when teaching science to young children from their supervising teachers in the field (see Lake et al. 2003). Two studies reported innovative ways of dealing with the institutional challenge of field placements being science-free zones. The PECSTEP developed by Bearlin (1990) and her colleagues sought to in-service practicing early childhood teachers in an interactive approach to teaching science. Preservice early childhood teachers were assigned to these same in-serviced teachers for their practicum placements. Siry and Lang (2010) developed a cogenerative dialogue between teachers, early childhood preservice teachers, and the children, where everyone had responsibility for reflecting upon both the pedagogy and the concepts that were the focus of the science lessons. Both approaches increased the quality and quantity of the field experience for the preservice teachers.

Comparing preservice teacher-generated philosophy statements against lesson plans and field practice was undertaken by Gilbert (2009) in order to support teachers with their inquiry-based approach to teaching science. However, changes to practice were still limited due to institutional constraints, such as pressures around assessment.

Garbett (2007) found that assessment practices which sought to encourage student teachers to create conversations with children around night and day in order to elicit scientific thinking were artificial and that conversations would be better if they occurred within everyday activities in which the children were already engaged.

A range of strategies to engage student teachers with scientific concepts have been noted across the studies, with educators trying to create authentic contexts that bring university course and practice in the field together in meaningful ways for students:

1. Models – student teachers reflect on expressed physical appearance of a scientific experience (e.g., volcano erupting) noting conceptual features (i.e., specific science concepts), followed by designing a model to explain what is happening scientifically (e.g., drawing the eruption as a model) which are included within students' lesson plans and used in the field (Kenyon et al. 2011).
2. Slowmation – students research the scientific concepts needed to create a slowmation with children (Fleer and Hoban 2012).
3. Comparing preservice teacher-generated philosophy statements against lesson plans and field practice (Gilbert 2009).

Institutional challenges were also met through the universities themselves. Jones et al. (2003) reported on a study of early childhood science and mathematics where they sought to specifically integrate these cognate areas in order to mirror the integration approach already prevalent in preschools. However, they noted that the traditional three-credit point model structure of teacher education programs made this difficult, as did organizing timetabling for integration and the challenge of transforming existing assessment approaches found within the university sector. While institutional practices directly shape what might be possible in science courses, societal beliefs about science and science teaching also determine how preservice teachers themselves feel about their role as science teachers. Taken together, these studies show that institutional constraints also work against what might be achieved in early childhood science teacher education programs.

Societal Expectations of Early Childhood Science Education

Societies support the learning of our youngest children through resourcing both material and human infrastructure and through the education of early childhood teachers and building and resourcing preschools. Curricula provide directions for early childhood teachers, and preservice early childhood teachers learn about these at university. Curricula are framed around specific theoretical traditions, and these have been noted in some of the studies reviewed. A number of studies from the North American continent draw attention to the interface between general early childhood curriculum which focuses on developmentally appropriate practice (or maturational theory of child development) and science curriculum which draws upon constructivism (Lake et al. 2003; Akerson 2004; Martin et al. 2005). A theoretical discontinuity is also noted in New Zealand where preservice courses link explicitly with their national curriculum – Te Whariki – which uses predominantly sociocultural theory for guiding early childhood teachers and constructivist theory for supporting science curriculum. Having two theoretical masters in the design and delivery of early childhood science teacher education courses is not only a challenge for the educators who teach in these courses but also the preservice students who must bring two different theoretical traditions together in the discipline area of science. This adds another layer of complexity to the design and delivery of early childhood science courses for female preservice teachers who already lack confidence in this area.

Other studies reviewed have drawn upon theory to explicitly develop student self-efficacy, such as Bautista (2011) who used Bandura's social learning theory or Siry and Lang (2010) who used critical theory to problematize power relations and to give agency to children and preservice students alike in the course of furthering scientific knowledge and confidence and competence to teach/learn science content. However, most science educators teaching early childhood preservice teachers science education have used pedagogical content knowledge and constructivism in the design and delivery of their courses. In these studies, no specific reference is made to the early childhood curriculum that the preservice teachers might also be following.

Knowledge traditions in many fields have continued to be developed over time. How science is viewed in society and how it is culturally constructed is important because it influences how preservice students perceive themselves as future educators of science. Akerson et al. (2010) study noted that early childhood teachers who plan and organize science learning do not necessarily reference this as science instruction/concept formation. They argue that because science experiences are not named as science to children or to teachers, early childhood preservice teachers do not necessarily perceive of themselves as science teachers. Their research found that preservice teachers' perceived beliefs about scientists were significantly different to how they perceived themselves. Preservice teachers believed scientists were highly valued and were powerful. In contrast they found that preservice teachers thought of themselves as valuing conformity (constraining action to avoid harming others), benevolence (concerned for others' welfare), and security (safety, harmony, stability of society). It was noted that in teacher education programs, educators should include in early childhood science courses a focus on the perceptions of preservice teachers themselves as teachers of science, rather than as only early childhood teachers. This was also supported by Bautista (2011) who used video observations and social learning theory to specifically improve the self-efficacy of student teachers. In Bearlin's third model of knowledge and person-centered approach to preservice education in science, how science is perceived and constructed in society, and how preserivce early childhood teachers perceive of themselves as teachers of science was foregrounded. Like Siry and Lang (2010), this model acknowledges the background of the student teachers and gives agency, rather than blames them, for the societal positioning of science as a highly valued form of cultural knowledge that represents power and authority to them (Akerson et al. 2010).

The highly valued place of science within society has traditionally been viewed as a body of knowledge to be learned and understood. Some of the programs reviewed reinforce this perspective, and in these programs, survey results suggest that student teachers' knowledge of science and capacity to teach science does not necessarily improve in the ways the educators hoped. However, in the studies reviewed which explicitly show preservice teachers that science is socially and culturally constructed by humans, and where they have the opportunity to create scientific knowledge around their own interests (e.g., Bearlin 1990; Appleton 1995), the survey results show that teacher competence and confidence to teach science significantly improves.

Summary

This entry into the Encyclopedia of Science Education is a limited set of studies which represent

the sum total of what has been researched in early childhood science teacher education to date. A summary of the studies is shown in Table 1 above which shows the range of studies, the details of the courses being taught, and the reliance on surveys for generating data on student experiences of their early childhood science teacher education course.

The work reviewed in Table 1 illustrates that simply giving more content knowledge of science to preservice early childhood teachers does not help them change their own perceptions of themselves as teachers of science. We know that educators of science education may be using a different theory to that which underpins the early childhood curriculum that they must work within their preschools. Many early childhood teachers draw upon one theory to support their work as early childhood teachers and another theory to support their work as teachers of science. We also know that institutional constraints in preschool and the early years of school reduce opportunities for observing and teaching early childhood science. The latter finding has not changed in 24 years. What seems to make the biggest difference to science content learning and confidence to teach science is when knowledge of science is gained through a change in how preservice teachers view the nature of science knowledge and see themselves as having a role in generating scientific knowledge to inform their own scientific thinking. We know some things. But we know very little about how countries other than Australia, New Zealand, and North America design and deliver early childhood science teacher education courses. This review shows that we have much to learn about how to effectively teach science education to early childhood preservice teachers in our current global community. But if the work of Bearlin has stood the test of time for over 24 years, then her research might be a good place to start.

Keywords

Abduction; Earth System; Historical science; Modelling; Multiple working hypotheses; Natural experiments

The philosophy of Earth science is concerned with how humans obtain and verify knowledge of the workings of the Earth system, including the atmosphere, hydrosphere, and geosphere (solid earth). Earth scientists' ways of knowing and habits of mind share important commonalities with other sciences but also have distinctive attributes that emerge from the complex, heterogeneous, unique, long-lived, and non-manipulatable nature of the Earth system (Chamberlin 1890; Frodeman 1995; Ault 1998; Cleland 2001; Manduca and Kastens 2012).

Most Earth processes do not lend themselves to experimental manipulation. Laboratory experiments have provided some important constraints on Earth processes: for example, methodical study of fluid flow in flumes has illuminated hydrodynamic principles essential to understanding rivers and sediment transport. But many first-order Earth phenomena, such as plate tectonics, global atmospheric circulation, biogeochemical cycles, and the structure of the Earth's interior can neither be brought into the laboratory nor manipulated experimentally in situ. As a result, Earth science relies heavily on methodical observation and construction of inference about plausible causal processes that could have led to the observed conditions – in other words on abductive rather than deductive or inductive reasoning.

The object of observation, the Earth system, is inherently complex and heterogeneous in both space and time. Across space, locales differ profoundly depending on whether they are continental versus oceanic; tropical versus polar versus midlatitude; on a tectonically active plate boundary or in a quiescent plate interior; or in mid-continent or mid-ocean versus a coastal setting. As a consequence, no single field area affords the opportunity to study the full range of Earth processes and conditions. Thus, of necessity, Earth scientists who seek answers to big questions are forced to think globally and draw evidence from across the planet (Manduca and Kastens 2012) and in some cases by comparison with other planets. Earth scientists exploit the Earth's heterogeneity by seeking out "natural experiments," circumstances in which an important causal factor or boundary condition varies naturally. For example, by comparing fast-spreading and slow-spreading divergent plate boundaries, geophysicists can isolate out the influence of this factor on volcanic and tectonic processes. Earth scientists favor explanations that cohere across multiple spatial scales (Ault 1998) and work back and forth between consideration of parts and wholes (the "hermeneutic circle" of Frodeman 1995). To reconstruct a complete sequence of a slow process, such as mountain building, Earth scientists "trade space for time" and look at multiple instances in different stages of development (Ault 1998).

Just as no single field locality exhibits the full range of Earth processes, neither does any single slice of Earth history, including the present. Thus, Earth science is an inherently historical science (Ault 1998; Frodeman 1995; Cleland 2002), like cosmology or archeology, but unlike physics or chemistry. To explore conditions when the Earth differed from the present, Earth scientists look to the past: paleoclimatologists examine the hothouse climates of the Cretaceous period and Eocene epoch, and petrologists contemplate the effects of the steeper thermal gradient of the Archean epoch. Observations of the Earth at any moment are typically a consequence of processes that are active at that time superimposed upon traces of past processes (Ault 1998). The historical perspective is most obvious in studies of the solid earth, where active erosion and weathering processes are superimposed upon sedimentary and tectonic processes of the past. But fluid earth processes are also historical, albeit on a shorter timescale; weather systems, for example, develop across time with each moment's configuration an outgrowth of its prior states.

Developing ways to disambiguate the traces of past and current processes and to reconstruct multiple generations of past processes was one of the first epistemological accomplishments of Earth science and remains an active area of research. Early insights include the principle of superposition (sedimentary layers are deposited in a time sequence, with the oldest on the bottom and the youngest on the top) and the principle of crosscutting relationships (the geological feature that cuts another is the younger of the two). Areas of active research involve detecting and exploiting various physical, chemical, and biological traces of past processes in ways that provide constraints on the timing, rate, and/or sequence of past events. Earth scientists care about timing and sequence because sequence constrains causality: if A occurred before B, then A can have caused or influenced B, but B cannot have caused or influenced A. Earth scientists care about rates because rate constrains power: to transport a given volume of sediment or rock or water or air in an hour requires a more powerful causal process than to accomplish the same effort in a day or year or decade or millennium.

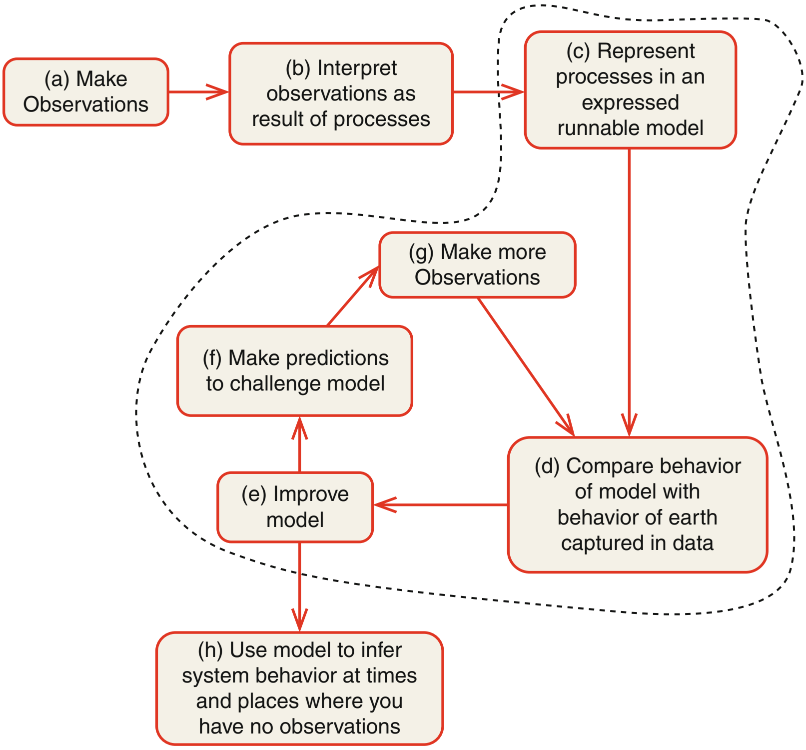
The Earth system exhibits other forms of complexity, in addition to spatial and temporal heterogeneity. Rather than seeking the simplest or most parsimonious explanation, Earth scientists are comfortable with explanatory schemata that invoke emergent phenomena and multiple intertwining feedback loops (Manduca and Kastens 2012). For more than a hundred years, since the writings of Chamberlin (1890), Earth scientists have favored an approach of multiple working hypotheses, rather than a single null hypothesis. Chamberlin used the example of the Great Lakes, which had been hypothesized to be carved, by rivers, or scooped out by glaciations, or deepened by flexure under the weight of ice. In fact all three hypotheses were part of the answer, and Chamberlin used this example to recommend the use of multiple working hypotheses as a habit of mind suited to understanding complex phenomena. To weigh such multiple possibilities, Earth scientists seek distinctive traces of each hypothesized process or event in empirical data. Cleland (2001) calls such decision-supporting traces "the smoking gun," explicitly yoking the reasoning of Earth scientists and detectives.

Progress in modern Earth science is highly dependent on distributed cognition, thinking that is distributed across multiple minds and across human brains working in collaboration with cognitive tools. Because of Earth's complexity, heterogeneity, and fragmentary record, clues to any important Earth science puzzle are likely to be scattered across space, across time, and across disciplines. Thus, important insights in Earth science commonly rely on collaborative merging of lines of evidence developed by different individuals or groups (Manduca and Kastens 2012), any one of which would be unpersuasive but when taken together constitute a sufficient preponderance of evidence to be accepted as a provisional consensus interpretation (Ault 1998). For example, the acceptance of the impact origin for the mass extinction at the Cretaceous/Tertiary boundary relied on evidence from Italy, New Zealand, Denmark, New Mexico, and the Caribbean and from paleontology, stratigraphy, nuclear chemistry, geophysics, isotope geochemistry, marine geology, astrophysics, and paleoecology.

Until a decade or so ago, most Earth scientists thought about the past, either the distant past (e.g., stratigraphers) or the immediate past (e.g., seismologists). Meteorologists thought about the future, but only 3–5 days into the future. In the twenty-first century, however, society is asking the Earth science community tough questions about the future: when will there be another destructive earthquake or hurricane here? How fast will sea level rise? How warm will the climate become? Thinking about the future rather than the past requires a different epistemology (Cleland 2001). In particular, thinking rigorously about the future requires a model. In science education, "model" typically refers to a conceptual model, i.e., an idea or interpretation, and "modeling" typically refers to the process of developing and articulating such an idea. But the computer models used in modern Earth science research are more than simply ideas or representations of ideas. They are cognitive tools, which unload cognitive burden from human scientists' brains and display observable behavior that becomes part of the evidentiary base of science.

Figure 1 sketches the process by which the Earth science community creates new knowledge about the Earth system using models such as global climate models. Scientists make observations (a) of the Earth system and interpret those observations as being the result of processes (b). They represent those processes in a physical or computational device (c), then activate the device (i.e., "run" the model), and compare the behavior of the model with the behavior of the Earth as captured in data (d). Where the model behavior and the behavior of the Earth do not correspond, they improve the model (e). They then use the model to make predictions of how the Earth should behave under a set of non-yet-observed conditions (f). They collect more data (g) and once again compare the behavior of the model with the behavior of the Earth as captured in the new data (d, again). For a complex system, there can be many trips around this circle (d-e-f-g-d), involving many research groups and many data types. Only after a model has been refined by repeated trips around the improvement circle, yielding fewer and smaller areas of non-correspondence between model behavior and Earth behavior, does the model earn the credibility to be used to make inferences about times and places for which no observations are available (h) – such as the future.

In summary, Earth scientists' ways of knowing emerge from the nature of the object of study (Ault 1998; Manduca and Kastens 2012). Because the Earth is not amenable to experimental manipulation, Earth scientists' ways of knowing are characterized by use of spatial and temporal lines of reasoning, lines of reasoning that leverage the Earth's heterogeneity by taking advantage of "natural experiments" in which candidate causal factors have varied over space or changed over time. Because the Earth is a complex system, with multiple interacting subsystems, Earth scientists' hypotheses tend toward complex systemic explanations rather than privileging the simplest



Earth Science, Philosophy of, Fig. 1 Schematic view of how Earth scientists create new insights about the behavior of the Earth system using expressed runnable models such as climate models. The *dashed line* encircles parts of the process that are not often seen by the public or by students (From Kastens et al. 2013)

explanation. Because the record of Earth's past is fragmentary, leaving only scattered clues, Earth scientists tend to construct interpretations collaboratively, drawing from multiple field areas and subdisciplines. In order to think rigorously about times and places for which no observational data are available – including the future – Earth scientists are increasingly relying on distributed cognition not only across multiple research groups but across computational tools as well as human brains.

Ecojustice in Science Education

Ecojustice philosophy merges social and environmental justice theories by emphasizing physical, spiritual, and emotional connections between an environment and the residing social group. It is concerned with environmental issues in a variety of ways including equity in relation to non-Western cultures, abuse of indigenous groups through land exploitation, economic prosperity in conjunction with land use, and modification to the environment in other ways that benefit particular lifestyles. Researchers such as Bowers (2002), Mueller and Tippins (2011), and Sachs (1995) present ecojustice philosophy as a way to make the global more local and encourage decision-making skills across intergenerational contexts. In terms of science education, these researchers maintain that ecojustice philosophy can help in creating democratic environments with learning taking place as a mediated process to encourage participation and action by multiple parties. They further emphasize that it can open the door to learning in different contexts while maintaining a focus on the relationship between society and ecological awareness, preservation, and sustainability.

What Are the Basic Tenets of Ecojustice Philosophy?

Ecojustice philosophy attempts to balance the tensions between cultural systems and environmental systems by analyzing what resources should be conserved and how the use of these resources can be less taxing on ecological and cultural systems. Three distinct components of ecojustice philosophy which make it unique are a focus on cultural assumptions and challenging these, a deeply rooted belief in local action, and an opportunity for the voice of the other to be recognized.

Challenging Cultural Assumptions

A key aspect of ecojustice philosophy is an awareness of cultural assumptions with the recognition of how they influence both thought and action in relation to "others." Foundational beliefs derived from our lived experiences, cultural knowledge, and traditions shape our actions, behaviors, and values. Ecojustice philosophy encourages the uncovering of our cultural ideas and analysis of those assumptions. From this perspective, it is only when value is acknowledged as existing outside of our known that we can begin to enact the actions of promoting justice. In terms of ecojustice, enacting a different mindset comes when what is seen and felt challenges what was thought to have been the ideal. The idea of challenging assumptions is enhanced by the emphasis on local, promoting a view from within which can possibly allow change to occur more readily.

Local Action and Intergenerational Knowledge

Ecojustice philosophy is informed by a belief in the importance of local action and knowledge which can foster responsibility, develop ownership, and encourage involvement and awareness for others. When action represents the "safekeeping" of what is known, the door is then opened for encouraging how individuals might contribute to the protection of the other. At the local level, action allows for familiarity and investment. Sachs (1995) shares several examples of large-scale environmental projects which were implemented and enforced because of a local belief that areas needed protection. When action is implemented by individuals unfamiliar with the community, the cultural use and value of that area are often overlooked. From an ecojustice perspective, local needs should be considered before large-scale decisions are implemented, with an emphasis on involving local citizens to enact policy for their own community. Ecojustice philosophy promotes local action, highlighting contextually specific knowledge that can only be ascertained when there is direct contact with a people and place, with experiences that span generations. A focus on making the local paramount allows for *all* to have a voice; the place, beliefs, customs, and nonhuman inhabitants are heard together with the people.

Empowering the Voices of the Disenfranchised (People or Places)

Inherent within ecojustice philosophy are the personal interactions that promote a voice which is inclusive of living and nonliving, the visible and the invisible. In this sense, ecojustice calls for the equitable sharing of resources between all individuals on the planet, not just humans. This means that when decisions for "progress," "development," and "growth" are considered within a community, society will have to look beyond just the needs of *Homo sapiens* and consider the requirements of other species and ecosystems that will be impacted by such actions. Ecojustice philosophy extends social justice theories to argue that the inequitable distribution of power that ranks humans over nonhuman species or even some humans over others (related to class, race, gender, etc.) is unjust but is passed on through cultural norms such as language. Thus, ecojustice philosophy aims to create an intersection for teaching and environmental equity with science content, process, and pedagogy.

Other Dimensions of Ecojustice Philosophy

Ecojustice philosophy is grounded in uncertainty theory which acknowledges the degradation of Earth's resources as a result of human actions such as consumer-focused lifestyles, overutilization of technology, and the commodification of nature. Bowers (2002) claims that most citizens of Western culture fail to recognize that their consumer-oriented lifestyles, which are explicitly and implicitly encouraged by their society, are directly related to the decline of environmental and/or ecosystem health. Furthermore, according to Bowers, the formal education system is often a powerful force in maintaining the status quo of consumerism and globalization. Ironically, it can also be one of the most promising forces for developing in students a deeper understanding of how these cultural norms are negatively impacting the environment.

What Is the Role of the "Commons" in Ecojustice Philosophy?

In order to embrace a holistic view of sustaining other cultures and the Earth's natural systems, ecojustice philosophy emphasizes the importance of communities working to protect and revitalize their cultural and environmental "commons." The concept of the "commons" is multifaceted in nature. According to Bowers (2002), the commons, historically, were the environmental aspects of the community required for subsistence: pastures, forests, lakes, streams, etc. In other words, the commons were the aspects of the environment that citizens depended upon to provide for their families. More recently our understanding of the commons has expanded to include more intangible items: air, language, narratives, craft knowledge, and technology, to name a few. These are aspects of the community and culture that are common to the majority of individuals of an area even though they are not "owned" by any one person and cannot be bought. What is important from an ecojustice perspective is the way in which human cultural practices and natural systems interact. An understanding of the ways in which the cultural and environmental commons intersect requires teachers and students to develop thoughtful awareness of cultures and traditions that both sustain and oppress social and ecological well-being. In today's world, this is essential as more and more knowledge generated within the commons becomes enclosed and vulnerable to extinction.

Ecojustice Philosophy Framed Within Science Education

Martusewicz et al. (2011) describe the important role that science teachers play in helping their students become "aware of the rich practices and knowledges-the assets-in local communities, involving their students in work that is focused on protecting independent relationships that are part of the intricate living systems" (p. 20). In this way, an ecojustice philosophy argues that educating individuals is a critical aspect of ensuring resource availability for future generations, the revitalization of the commons, and development of a more just society. Of course teachers need to be educated themselves about matters of ecojustice and sustainability in order to teach about them in ways that are embedded in the local community.

In science education, several important pedagogical trends have emerged in recent years that reflect the basic tenets of ecojustice philosophy: place-based education, citizen science, and socioscientific issues and reasoning. Place-based education focuses on grounding learning in local phenomena and students' lived experiences. For teachers, and by extension their students, this means forming meaningful connections to other people and the community or the environment in which they live. These personal connections actively work against the forces of globalization which act to enclose the cultural and environmental commons. Citizen science is another ecojustice pedagogy which is uniquely situated to bridge the growing chasm between professional science and science education. Traditional top-down approaches to citizen science involved local individuals in collecting data for the projects of scientists with little opportunity to participate in the formulation of questions or analysis of data with relevance to local issues. The more recent movement toward the "democratization of citizen science" (Mueller et al. 2011) has provided exciting opportunities for students to view science as something to which all individuals can contribute, for example, through environmental monitoring and habitat restoration projects. This reconceptualized citizen science movement (referred to by some as the public participation in science) repositions teachers and students as producers of scientific knowledge and legitimate members of the extended scientific community. Socioscientific issues and reasoning about these have also been characterized as a pedagogical approach consistent with ecojustice philosophy. Socioscientific issues are social dilemmas with conceptual or technological links to science that require students to engage in a degree of moral reasoning or evaluation of ethical concerns in the process of arriving at decisions regarding possible solutions. Increasingly, as science educators work toward a philosophy of ecojustice which recognizes uncertainty thinking and values cultural pluralism, intergenerational knowledge, and narratives, other pedagogies will be recognized as alternatives to a decontextualized science education.

New Pathways and Directions: The Importance of Mindfulness in Ecojustice Philosophy

How can science educators help students process experiences and question their assumptions in ways that increase awareness and knowledge of others? Research shows that students are more apt to apply knowledge in this way when principles of mindfulness are part of the instructional framework (Frauman 2010). To encourage mindful behavior, hypothetical "what ifs" become especially useful. Rather than promoting a set of rules that will be adopted as second nature, mindfulness research points to the need for increasing the level of thought behind particular actions. In this regard, science educators should propose situations that require student action and allow time and opportunity for dialogue for determining what should happen, rather than presenting things as resolved with little thought as to how they came to be. Mindfulness includes greater exposure to specific settings and consists of higher-order considerations for relationships. Mindful thinking enhances awareness for multiple perspectives, highlights relationships to immediate surroundings for more personally relevant interactions, and includes group responsibility that in turn encourages ownership and greater concern for the local.

Mindfulness is a crucial learning outcome which has been linked to co-generative dialogue. Co-generative dialogue involves multiple stakeholders in conversation that expands the base of knowledge and recognizes the diversity in voices which are intimately associated with creation and recognition of knowledge. Co-generative dialogue encourages mindful behavior and aligns with ecojustice philosophy by increasing awareness of the other and enabling the voice of the disenfranchised to be recognized as equal and valuable, through group dialogue and deliberation. Mindful behavior is an expected outcome of group interaction when there is a moderating voice, but what happens when participants are encouraged to undertake self-analysis and dialogue occurs within rather than between? Within ecojustice philosophy, both self and group encounters play a role in how understanding develops. Yet, mindfulness is more likely to be based on individual perceptions rather than knowledge and beliefs established as truths by the group. Within science education, specifically within the frame of ecojustice, mindfulness can be encouraged by promoting engagement within the familiar and providing the opportunity to question what is often common. Meaningful encounters within the local that include open and continued dialogue, in and about these spaces, enable knowledge of self, the unheard, and the experiences of the communal whole to be further developed.

Implications of Ecojustice Philosophy for Twenty-First-Century Learners: Some Challenges

In a time when youth in industrialized countries are very commonly more disconnected from the natural world than any previous generation in human history, ecojustice philosophy has great potential for making a difference in the way educators frame twenty-first-century science education around principles that may challenge traditional conceptions of scientific literacy. How does one both encourage community involvement in ways that increase the dialogue between partnering groups and multiple generations and decrease vulnerability to outside (and often opposing) forces, forces which deemphasize the value found in locally constructed knowledge?

There are challenges educators often face when attempting to implement reforms informed by ecojustice philosophy.

Challenges

The personal involvement at the heart of ecojustice philosophy makes it very appealing, even when the drawbacks of language, context, and "local" are considered. One of the greatest obstacles involved with ecojustice philosophy is the lack of a shared language, an open dialogue in which all players have equal value and voice to enact change. An open forum for dialogue would provide the common ground necessary for shared knowledge essential to cultivating students equipped to make informed decisions and participate more fully in advocating for Earth's natural systems and other affected parties. Without consistency in the conversation and without the existence of a continued conversation, ecojustice philosophy may never be utilized to its fullest. Learning networks must be built between the school and community as a starting place for conversations which value locally constructed knowledge and experiences.

Ecojustice philosophy is both situational and contextual which poses an additional challenge. It is situational in that opportunities exist in location and relation to something and contextual in that experiences of one event happen within specific parameters that cannot often be replicated. Having an experience and hence beginning understanding of one event may enable meaning to evolve, yet the specific actions are not always replicable elsewhere. These situational and contextual aspects limit transferability and make enactment of ecojustice philosophy challenging. Decontextualized international, national, and state standards, in particular, are troublesome issues for ecojustice and place-based reforms. While ecojustice alternatives are starting to stimulate science education reforms in the directions argued above as appropriate, they may be limited by the significance of how local matters are viewed by policymakers. Teachers and students, in many cases, are often displaced by the priorities of high-stakes tests. This is a predicament which deemphasizes or ignores the responsibility of schools to cultivate students who can participate fully in local decision-making.

Another challenge to using ecojustice philosophy involves its focus on local issues and the emphasis on growing community knowledge so as to avoid being vulnerable to outside influence, such as harmful new industry or economic imperatives that undermine the greater good of the "whole" community. With such interference, knowledge held within a community does not necessarily get passed to future generations. This intergenerational aspect of ecojustice philosophy carries with it the question of how wisdom is imparted to other generations. What relationship must develop between the community and school to encourage solidarity, scientific literacy, and action when outside forces oppose what is best for the local? A continuing challenge in current science education rhetoric is the isolation of school from the local community. While this is not insurmountable, it can prove difficult to connect the voice of the student, local ecosystem, elder, business person, and concerned citizen. Ultimately, for schools in the twenty-first century to capture the meaningful purposes of educational reforms that reflect ecojustice philosophy, teachers and students must be repositioned as producers of science and participants in ecological decisions.

E-Learning

E-learning (electronic-learning) refers broadly to the use of information and communication technologies for the electronic delivery of instructional content and the support of educational processes. Computer-supported learning can vary from being completely "self-paced," with no human instructor, to being highly coordinated, with the instructor interacting with students at a distance. Thus, it is a broad concept that encompasses such phrases as *online learning*, *Web-based learning*, *computer-based instruction*, *Web-based training*, and *virtual education*. E-learning systems have been developed for many different purposes and audiences, for both formal and informal learning contexts. With the rapid growth of the Web over the past decade, the popularity of the term *e-learning* has faded slightly, in favor of the more widely used term, *online learning*. However, both terms still appear regularly in the media, and the phrases e-learning and online learning are often employed interchangeably.

The earliest e-learning systems, developed in the 1960s, explored how computer programs running on mainframe computers could be used to teach children mathematics and reading. This type of learning, which was referred to as *computer-assisted instruction (CAI)* or *computer-based learning (CBL)*, took the form of individualized lessons in which the computer systematically guided the learner though an instructional sequence concerned with a particular topic. In addition to presenting instructional content, these programs often contained a diagnostic or evaluative component that allowed the software to assess student comprehension, provide remedial exercises where necessary, and adjust the sequencing of the material to accommodate the learner's needs. This trajectory of work remains active, within a discipline known as "intelligent tutoring systems."

The notion of e-learning has broadened significantly and is now associated with rich, Web-based multimedia content (e.g., text, images, audio, video, and animation) and a greater level of student control and autonomy. Some e-learning still takes the form of individualized, one-way instruction, such as through video-taped lectures or screencasts, which are widely available on the Web (e.g., Khan Academy). However, other e-learning environments engage learners in online interactions with a human instructor or peers.

Tools like wikis, blogs, asynchronous online forums, real-time chat, instant messaging environments, and many-to-many videoconferences (Webinars) provide supports for group discussions, student collaboration, and the sharing of resources. Some popular e-learning environments, like Moodle and Blackboard, incorporate many of these tools so that instructors can use them in combination. By designing shared online activities and assignments, e-learning instructors can foster a sense of online community in which students work collaboratively to build on peers' ideas and deepen their understanding of the course content.

Current e-learning environments are usually media-rich and Web-based, with some level of support for social interactions and a significant degree of learner control. Screencasts and course management systems like Moodle and Blackboard are widely used. Educational "apps" on handheld devices and desktop computers can also be considered as forms of e-learning. Several modern forms of e-learning are still experimental in nature. For example, the educational potential of immersive virtual environments, like Second Life, is still being studied. Massive open online courses (MOOCS), in which tens of thousands of people may be simultaneously enrolled in a course, represent another relatively new type of e-learning, one that is distinguished by an unusually large number of learners and open access via the Web.

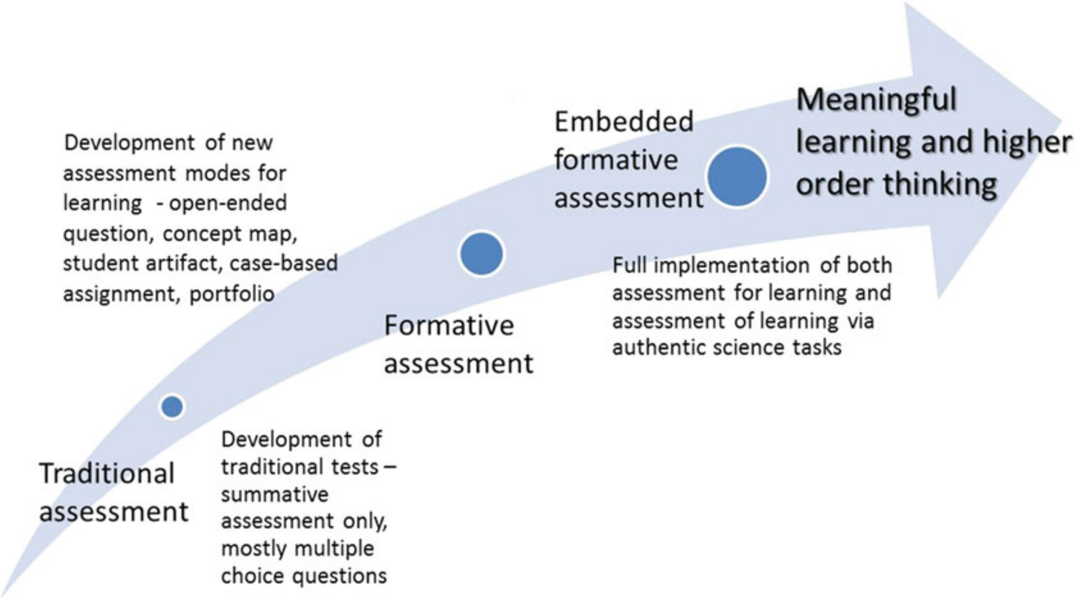
Keywords

Assessment; Assessment methods; Authentic assessment; Authentic science tasks; Curriculum-embedded formative assessment; Formative assessment; Formative embedded assessment

Over the past three decades, western educators and researchers alike have sought for novel ways of assessing students' authentic mastery learning, as well as their understanding of curricular concepts and content continuously throughout a course. Embedded assessments (EAs) aim to assess a broad range of students' abilities and comprehension continuously throughout the learning process (Pellegerino 2002–2003). This ongoing assessment enables teachers to (1) assess students' content knowledge and skills by gathering information on students' abilities to understand and reason, (2) make sense of the information and work towards closing the gap between where students are and where they should be, (3) guide the shaping of teaching plans, (4) make adjustments in response to students' difficulties, and (5) find different ways to attain conceptual understanding and science skills (Furtak et al. 2008).

Valuable EAs constitute authentic, nonroutine, and multifaceted science tasks with no obvious solutions. Often, when teachers implement formal EAs effectively via authentic science tasks in school settings, students achieve higher scores on summative assessments in comparison to students who experienced traditional tests only. More importantly, valuable EAs engage students in active participation and enable them to creatively demonstrate their knowledge of a concept, a process, or a scientific skill while they respond to an authentic assignment in the science classroom (Dori 2003).

Embedded assessment is aimed to serve as formative assessment; thus, it is used as assessment for learning rather than assessment of learning. Ayala et al. (2008) describe five steps for designing and implementing formative and embedded assessments that demonstrate an understanding of topic-specific content, which are linked to the overall goal of the curriculum. EA development may be guided by the "conceptual framework for science achievement" (Ayala et al. 2008), which creates a rubric for science achievement and reasoning with four overlapping types of knowledge: declarative, procedural, schematic, and strategic. It is crucial to specifically place EAs at meaningful points in the learning process, to ask students to reflect on their learning, and to provide them with instant feedback necessary to bridge the gap between students' current knowledge and what they are expected to know (Ayala et al. 2008; Dori 2003; Shavelson et al. 2008). Only then can teachers modify their teaching style accordingly (Dori 2003; Shavelson et al. 2008). These researchers assert that when formative and embedded assessments are combined and implemented, the knowledge acquired by students is elevated and their understanding is improved, thus leading to improved learning outcomes, generally measured by end-of-year standardized, multiple-choice exams. The improvements are seen in students' coherence and comprehension of knowledge while addressing and assessing the broad range of students' learning methods and abilities (Pellegerino 2002–2003). In curricular milestones or junctions, it is important that teachers analyze their task or question choice, quality control of data assessment, and the ways in which science assignments and tasks are assembled and communicated with the students. These kinds of assessments, which are part of the teaching and learning process, provide



Embedded Assessment, Fig. 1 From traditional assessment to embedded formative assessment in science classrooms

every student with an individually constructed opportunity for learning (Shavelson et al. 2008). Although the science assignments may not always have a final grade, they should be well organized, made overtly clear to students, and presented as learning opportunities. These scientific tasks need to be integrated with the students' own conceptual understanding of the topic while they take part in the process of moving towards the ultimate goal of the specific course, on one hand, and gaining scientific and thinking skills, on the other hand (Dori 2003; Pellegerino 2002–2003). Successful implementation of embedded assessment resonates deeply with successful organizational collaboration, that is, teacher-student and teacher-curriculum developer. The two work together best when all parties demonstrate similar and/or compatible philosophies and show awareness of their respective resources, experiences, knowledge, and skills while working together towards a mutual goal. Thus, teachers must take part in an ongoing training and be provided with professional development tools that guide them towards a new conceptualization of the value of assessment, especially EA, compared to summative assessment alone. Through hands-on testing of EAs in a real-world school setting, the main variable in predicting their success was the teachers' pedagogical content knowledge and assessment knowledge as well as their willingness to implement educational reforms (Avargil et al. 2014; Ayala et al. 2008).

Before implementing EAs in actual science classroom settings, teachers should receive an ongoing professional development and mentoring on how to implement EAs, combined with reflection upon their lessons and tasks they developed for their own students (Avargil et al. 2014). This will provide them with the opportunity to reevaluate their approach while teaching a new curricula's material and an opportunity for their students to concretize the scientific concepts, processes, and thinking skills implemented until this particular EA's junctions (Ayala et al. 2008; Dori 2003). As shown in Fig. 1, embedded formative assessment may foster students' meaningful learning and is aimed at developing students' higher order thinking skills, especially in science.

Emotion and the Teaching and Learning of Science

Stephen Ritchie
School of Education, Murdoch University,
Murdoch, WA, Australia

Keywords

Emotion; Emotional climate; Emotional engagement; Facticity; Positive emotional energy

With the exception of extensive research on test anxiety, research on emotions experienced by teachers and students in classrooms is still in its infancy. In particular, little research has explored the emotional arousal of classroom participants in the teaching and learning of specific subject matter such as science (Rosiek and Beghetto 2009). However, overall, it is now clear that emotions have a profound effect on students' and teachers' interest, engagement, performance, and achievement. In short, emotions appear to be central to understanding teaching and learning (Pekrun and Schutz 2007). Moreover, the centrality of emotions to daily life is evident in the realization that every dimension of society is held together or ripped apart by emotional arousal (Turner 2007).

Defining *emotion* has been an elusive challenge because it can be studied from a variety of theoretical perspectives. Emotions can be viewed as the complex of causal effects among four interrelated elements, namely, situational cues (e.g., behaviors relevant to achieving a specific task or goal), physiological changes (e.g., heart rate, blood pressure), emotion labels (e.g., happiness, anger, fear, sadness), and expressive gesture (e.g., facial expressions, hand gestures) (Turner 2007).

Michalinos Zembylas' extensive reporting of his 3-year ethnographic study of science teaching and learning in an elementary teacher's classroom not only reaffirmed the pivotal role of emotions in teaching and learning (e.g., Zembylas 2004) but also showed how emotional practices could be constructed by the teacher and her students. Yet, the social-constructivist perspective underpinning the study is limited because the arousal of emotion is not simply a labeling or socially constructed process but also involves neural transmissions and physiological functions that can be triggered automatically without conscious effort. This suggests that an integrated theory that embraces rather than ignores the biology of emotions, such as Turner's sociology of human emotions, offers a promising way forward to researching emotions in educational contexts (Turner 2007).

Most scholars agree that the four primary emotions are the following: satisfaction-happiness, aversion-fear, assertion-anger, and disappointment-sadness, which Turner (2007) presumes are hardwired in human neuroanatomy. Some scholars add surprise and disgust to this list. These primary emotions can be experienced at different levels of intensity and in various combinations that denote the more complex emotions such as shame and guilt. Interest, boredom, and curiosity are sometimes included on lists of emotions, but other times excluded because they are considered cognitive states (Turner 2007).

A series of studies conducted by Ritchie and his colleagues (see: http://profiles.murdoch.edu.au/myprofile/stephen-ritchie/) in a variety of secondary science and teacher education classroom contexts embraced Turner's theoretical framework that also incorporates related sociological constructs such as *positive emotional energy* generated from successful interactions. They accept that positive emotional energy is a strong steady emotion that affords participants the capacity to act with initiative in the micro-details of interaction that manifest in confident and rhythmically synchronized body movements, eye contact, facial expressions, and vocalizations (Collins 2004). For example, a science class that responds to a group role-play by laughter followed by spontaneous applause demonstrates positive emotional energy. The beginning teacher at the center of one study found *dialogic interactions* were positive and satisfying experiences for her (i.e., she experienced the discrete positive primary emotion of happiness), and she was motivated to reproduce these interactions successfully in different contexts. Both teacher and her students used humor to create a structure for dialogic interactions. In terms of Turner's theory, positive emotional energy was observed during successful interactions between the teacher and groups of her students when the students achieved the teacher's expectations, and the teacher experienced negatively valenced emotions (e.g., disappointment) when the students did not achieve her expectations. In a related study of beginning physics teachers as they implemented inquiry projects, similar results were reported. Teachers experienced positive emotions in response to their students' success during the research projects. When student actions/outcomes did not meet their teachers' expectations, frustration, anger, and disappointment were experienced by the teachers. Over the course of the projects, the teachers' practices changed along with their emotional states and their students' achievements, suggesting that emotions are also important in teacher learning.

This program of research departs from most other studies of emotions in science classes because it explores new and multiple research methods to identify discrete emotions aroused by students and teachers during their classroom interactions as well as to measure the experienced classroom emotional climate. *Emotional climate* of a classroom is the collective state of emotional communion between classroom participants in which the salience of self for individuals decreases as the collective identity of the class is enhanced. Positive emotional climate is related to expressions of happiness and joy and a sense of group belonging and social integration. Similarly, negative emotional climate is associated with expressions of sadness, fear, and/or anger within a group. External raters and classroom participants as internal raters of emotional climate have been employed to explore classroom emotional climate. Students have used audience-response technology (i.e., "clickers," where students record their perception of the emotional climate on a five-point scale by pressing the appropriate key which sends the signal via Bluetooth to a computer) to rate the emotional climate at short intervals such as 3 or 5 min across whole lessons. The results show that the classroom climate varies moment to moment in a series of events represented graphically as peaks and troughs that can be explored microanalytically through conversation analysis of video recordings and analyses of prosody, facial expressions, and gestures.

Audience-response technology also has been used in science teacher education classes where students identify their perceptions of emotional climate and, more recently, their discrete emotions experienced at regular 5-min intervals. The discrete emotions currently being investigated include the following: enthusiasm, happiness, attentiveness, neutral, disappointment, annoyance, and boredom.

The *emotional engagement* of high school science students during activities that focus on socioscientific issues (SSI) has been measured using self-reporting of students' emotions using available affective instruments. This research showed that students were interested in engaging with the SSI topic and writing narratives about the topic. This engagement evoked pride in their work and self-efficacy in completing the task. More recently, student emotion diaries have been used to elicit a wider range of emotional states from students at the end of each lesson. Students identify specific emotions experienced during each lesson, noting when these were experienced so that follow-up microanalyses of video recordings of these events can be undertaken.

Interview studies (e.g., Zembylas 2004) have reported both positive and negative emotions experienced by science teachers. For example, science teachers have reported experiencing such emotions as joy, despair, delight, frustration, and hope. Positive emotional experiences typically were derived from communicating a vibrant, energetic lesson where a sense of humor was maintained. Successful lessons often were those creative and spontaneous lessons that were enjoyable for the teachers and yielded identifiable learning outcomes for the students which collectively strengthened teacher-student rapport (cf. Ritchie et al.). Interview studies also have been helpful in understanding how emotions affect teacher identity. Unsurprisingly, pleasant emotions reinforce a teacher's professional identities and unpleasant emotions destabilize or threaten a teacher's identities. Turner (2007) invokes the theoretical construct of *facticity* to help explain the relationship between emotion and identity. Facticity is the transactional need for people to feel they experience a common world with others in an encounter. When an individual's need for facticity is met, the positive emotions that are aroused reinforce his/her identities, yet negative emotions that threaten identities are experienced when facticity is not realized.

Despite inconsistent outcomes from psychology research investigating possible links between science conceptual change and positive emotions, recent advances in neuroscience have shown that emotions overlap mental processes in controlled laboratory tasks. This blurring between cognition and emotion suggests that learning has as much to do with cognition as emotion. Guided by such an integrated view of learning, teachers are likely to engage students imaginatively where science concepts come to life, where they become real, meaningful, and filled with emotion (Rosiek and Beghetto 2009). As research on emotions matures, innovative methods for measuring emotions could provide much needed insight into learning science in emotionally filled classrooms.

Empiricism

Michael R. Matthews
School of Education, Faculty of Arts and Social Sciences, University of New South Wales,
Kensington, NSW, Australia

Keywords

Analytic/synthetic; Constructivism; Perceptions; Propositional perception; Reductionism; Scientific revolution; Seeing as/seeing that

Empiricism is a part philosophical and part psychological doctrine about the origin (psychology) and evaluation (philosophy) of ideas and concepts. At an everyday level, empiricism maintains that "there is nothing in the mind but that comes from the senses; and ideas or propositions are true in as much as they conforcprm to the evidence of the senses." At a more sophisticated level, empiricism is an epistemological doctrine about the formulation and truth testing of claims, propositions, hypotheses, and theories in all branches of inquiry – mathematics, psychology, social science, history, and so on.

Empiricism has for centuries been an influential doctrine about knowledge-seeking inquiry into the natural world; it has long been an influential philosophy of science since Aristotle's refutation of Platonic rationalism. Understandably, over its 2,500-year history, the doctrine has waxed and waned in response to philosophical challenges. Since the Scientific Revolution its main challenge has been to reconcile itself with modern, post-Galilean science, so much of which seems to contradict its core convictions.

It is important for science teachers to appreciate just what is living and what is dead in the empiricist tradition because debates about it have dominated philosophy of science and thus provide the philosophical background or context for science teachers' own understanding of the discipline they are teaching. Further, empiricism has also had remarkable wider educational and pedagogical impacts. This can be traced from the time of John Locke's 1693 *Thoughts Concerning Education* with its famous (but now mostly infamous) metaphor of the mind as a *tabula rasa*, through to B.F. Skinner's mid-twentieth-century accounts of language learning and subject-matter teaching in which he describes the goal of science teachings as simply "successful behavior in the environment" because such behavior is what is meant by knowledge. And in the current period, the empiricist tradition can also, surprisingly, been seen as providing the psycho-philosophical foundation for much of constructivist pedagogy and theory, especially in the version championed by the late Ernst von Glasersfeld.

Origins

For the pre-Socratics, Democritus, Epicurus, and others, sensory evidence or experience – *empeira* – was a requirement or hallmark of claims to knowledge. Aristotle continued this epistemological tradition with his rejection of Platonism. For Aristotle knowledge was not about the sensory input, or what was seen; it was about universal features or principles, but the senses were the "windows" to the world; they were what enabled knowledge of universals; the senses could not be bypassed.

Thomas Aquinas (1224–1274), the enormously influential medieval theologian and philosopher, despite ecclesiastical warnings, continued and built upon Aristotle's realism and empiricism. Concerning the natural world, the mind could only work with experience, which was constituted by sensation and memory of such sensation. This remembered sensation he labeled a *phantasm*; it is what we might call "experience." The crucial point is that there was already a mental element in experience; the epistemologically significant *phantasm* was both sensation and sensory activation, plus memory's "packaging" of this.

British Empiricists

The eighteenth-century trio of British empiricists – John Locke, George Berkeley, and

David Hume – laid down the foundations of modern empiricism. They were all intimately involved with the epochal Scientific Revolution associated in the first instance with Galileo, Huygens, Boyle, and Newton. Locke famously cast himself as an "under-laborer" in Newton's vineyard and saw his chief philosophical task as "clearing away rubbish and weeds" and making intellectual space for the expansion of the New Knowledge.

Within just a few years of Newton's *Principia* being published, Locke published what was in his view the philosophical underpinnings of the New Science – *An Essay Concerning Human Understanding* (1689). Some 80 years later, David Hume adopted and elaborated Locke's psycho-philosophical account of the origin and testing of ideas. Hume referred to the contents of the mind as "perceptions" and said they are divided into two broad classes: impressions and ideas. The former are sensations, feelings, emotions, and others such primitives; ideas are copies or reflections of these primitives. Some ideas are simple copies or reflections – "red," "heavy," "hard," or "tree"; other ideas are compound or aggregates – "red box," "hard tree," and so on. Some compound ideas are fanciful – "diamond box," "weightless tree," or "unicorn." They are fanciful because although the constituents have their origin in simple ideas, there is no impression that the compound can be traced back to; the mind creates the compound from simples, but it is a fanciful creation.

This distinction and causal mechanism provides Hume with the materials for his "philosophical microscope," for the means of examining and separating among the host of ideas entertained by people and cultures those that are "sensible" and those that are "nonsensible." He writes:

> When we entertain, therefore, any suspicion that a philosophical term is employed without any meaning or idea (as is but too frequent), we need but inquire *from what impression is that supposed idea derived*? And if it be impossible to assign any, this will confirm our suspicion. By bringing ideas into so clear a light we may reasonably hope to remove all dispute, which may arise, concerning their nature and reality. (*Inquiry Concerning Human Understanding*, Section II, #17; Hume 1777/1902, p. 22)

Empiricism and the New Science

It seemed obvious that when Hume's microscope was trained upon Newtonian science, many core ideas would be rendered "nonsensible" or fanciful. So "attraction at a distance," "corpuscules," "gravity," "magnetic fields," and so on all supposedly would be placed in Hume's rubbish bin. And the more that science developed, the greater became the number of "fanciful" and "nonsensible" ideas destined to be put in the bin – atoms, electric fields, electrons, and so on.

Contemporary Criticism

Since the 1950s empiricism has been in philosophical retreat. The bugle was blown by Quine when he wrote in his "Two Dogmas" that:

> Modern empiricism has been conditioned in large part by two dogmas. One is belief in some fundamental cleavage between truths which are *analytic*, or grounded in meanings independent of matters of fact, and truths which are *synthetic,* or grounded in fact. The other dogma is *reductionism*: the belief that each meaningful statement is equivalent to some logical construct upon terms which refer to immediate experience. Both dogmas, I shall argue, are ill-founded. (Quine 1951/1953, p. 20)

Wilfrid Sellars closely followed up this critique with his 1956 *Empiricism and the philosophy of mind* paper. The long paper was originally given as three lectures with the title *The myth of the given*. This title conveys the core of the modern argument against empiricism: there is no given, objective, sensory foundation for knowledge of the world, much less for scientific knowledge of the world. Sellars carefully picked apart the psycho-philosophical theory of sensations and ideas that had been elaborated in such detail by Locke, Berkeley, and Hume. Of the supposed foundation of experience, Sellars wrote that:

> For although *seeing that x over there, is red* is an *experiencing* - indeed a paradigm case of experiencing - it does not follow that the descriptive content of this experiencing is itself an experiencing. (Sellars 1956, p. 282)

Sellars' more general point was that experience has to be articulated, described, and conveyed before it has any role in knowledge creation. Ideas or thoughts have to have names or descriptions; and the link between sensation and verbalized idea is simply not automatic, direct, and given as the founding eighteenth-century empiricist trio, and all subsequent exponents of the tradition, thought that it was. As others noted (Hanson 1958), there is a fundamental distinction between *seeing as* and *seeing that*. The former is a visual sensation. The latter is propositional perception: "I see that the apple is red," "I see that the acid reacts with metal," "I see that the stone weighs two kilos," and so on. The structure of propositional perception is "I see that *p*," where *p* is any verbalized proposition. Propositional perception depends on already having words, concepts, and language being part of a community and culture. You cannot see that the acid reacts with metal unless you know what an acid and a metal is (Mandelbaum 1964).

Engagement with Science

Janice L. Anderson
School of Education, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Within the field of science education, new approaches to teaching and learning science content have emerged (NRC 2012). There has been a shift in the science education community from a focus on supporting the acquisition of formal science knowledge to the current perspective of promoting a culture of scientific literacy through student engagement in scientific inquiry, language, and practices. Student engagement with science in the modern education era emerged primarily from the work of John Dewey. Dewey promoted an approach to learning that allowed students to explore and comprehend their world in ways that fostered deeper understanding. Dewey's move from didactic lectures to participatory models allowed for student engagement in collaborative inquiry practices. His pedagogical approach utilized instructional strategies that embedded content in rich inquiry contexts. This situative learning environment allows the students to gain an appreciation for the content learned in situations where scientific content has value and meaning.

Dewey's notion of participatory practices serves as the basis for situative learning theories such as activity theory (Vygotsky 1978) and situated cognition (Brown 1989). These two theoretical perspectives are premised on the fundamental inseparability of learning and activity from the context in which that activity takes place. This viewpoint stands in opposition to traditional curriculum frameworks where knowledge is separated from experience, therefore fragmenting students' learning. When the student's learning is fragmented by a focus on subject matter rather than on their hands-on experience, a gap is created between the student's interest and the subject matter. If learning is viewed in this fragmented, fixed, and ready-made approach, then too much attention will be directed towards outcomes and the process of learning. By using socially constructed methods and activities, students will be able to connect their interests to their learning in order to create their own authentic engagement with science. What is important for engaged learning, at least in part, is the attention placed on the process. This process can be aided by a diversified curriculum that advocates a problems-based, core-curriculum, or project-based approach. By starting with central, driving questions, students can approach problems in distinct ways that are based upon their own unique interests and needs. This structure creates a learning environment where process and content are not fixed, nor are they an end onto itself. These types of inquiry-based learning methods allow for dealing with changes within the environment or society in a scientific, problem-solving manner, thus developing students who are better prepared and more engaged in the learning of science.

When translating these theories into practice, the affordances of leveraging technology become apparent. Engaging students in complex phenomenon is challenging. The following examples demonstrate the integration of these theories utilizing technologies in rich learning contexts to engage twenty-first-century learners. In the work of Barnett and colleagues (2011), students engaged in a street tree inventory as part of a biodiversity field studies project. By creating an inventory that was continuously updated to reflect changes to the tree canopy of a large urban area, students were able to engage in a scientific inquiry of the natural resources within their own community while learning GIS technology and modeling skills that are utilized by the scientific community. In this instance, science curricula were contextualized in order to meet local needs and create opportunities where not only was science content learned, but the language and ways of inquiry and engagement in science were present. Students become active participants, in projects like this, that can help to set their own learning goals in relation to the challenges embedded within the project. This allows for the development of meaningful engagement as the students are immersed in real-world, complex problems.

Computer simulations and games provide another mechanism to immerse students in the study of abstract, complex scientific concepts (Clark et al. 2009). The affordance of digital technologies allows for the immersion of students in worlds that represent specific scientific phenomenon. The immersive nature of gaming provides students with experiences that allow them to draw upon thinking about scientific concepts, using intuitive knowledge during play to interpret complex problems. By leveraging the affordances of digital gaming environments, educators can increase engagement and foster deeper learning as the students engage in recursive and critical game play, whereby hypotheses are generated, plans and strategies are developed, observations are created, and ultimately hypotheses are adjusted based upon game play (Clark et al. 2009). Games that are well designed allow students to build upon intuitive understandings of this complex physical phenomenon due to the situated and enacted nature of the environment (e.g., Clark et al. 2009); games also have the potential to support students in integrating their tacit conceptual knowledge with instructed knowledge (Clark et al. 2009). This is accomplished through the specific design of the game that allows students to make choices that affect the state of the models being simulated. Complex scientific content that is represented through tangible, experienced, non-textually mediated representations, games, and simulations may serve to engage reluctant learners in the study of science.

Engineering and Technology: Assessing Understanding of Similarities and Differences Between Them

Edys Quellmalz
WestEd, Redwood City, CA, USA

A variety of meanings have been associated with the terms engineering and technology. The definitions for this encyclopedia entry are based on numerous documents produced by national sets of experts. The National Academy of Engineering report, *Standards for K-12 Engineering Education*? (NAE 2010), surveyed standard documents in engineering, technology, science, and mathematics to identify common engineering concepts and skills. The National Assessment Governing Board supported development of the *Technology and Engineering Literacy* (*TEL*) *Framework for the 2014 National Assessment of Educational Progress*. The National Research Council of the National Academies has published the *Framework for K-12 Science Education*, which, along with a draft *Next Generation Science Standards*, integrates engineering ideas and practices with those in science (NRC 2012; Achieve 2012). Definitions of engineering and technology can be culled from these frameworks and standards developed by engineering and science organizations, as well as from standards for engineering and technology for state, national, and international assessments.

The definitions of engineering and technology are the starting points for developing assessments of understanding of the similarities and differences between them. This encyclopedia entry begins with a summary of prominent conceptualizations of engineering and technology. The definitions are followed by descriptions of an assessment framework that can be used to develop and analyze engineering and technology assessments. Descriptions of some potential types of assessment tasks and items to test understanding of the similarities and differences between engineering and technology are provided.

Definitions of Engineering and Technology

Engineering is defined as a systematic and iterative approach to designing objects, processes, and systems to meet human needs and wants. *Technology* is defined as any modification of the natural or designed world developed to fulfill human needs or desires. Technologies, therefore, are products and processes resulting from application of engineering design processes. Technologies also often function as tools and processes used to support engineering design.

Sources of Conceptualizations of Engineering and Technology

Standards for K-12 Engineering Education? The purpose of the National Academy of Engineering report was to survey contemporary frameworks, standards, and practices in engineering to determine if a national set of engineering standards could be proposed (NAE 2010). The report summarized key ideas of engineering and recommended that engineering concepts and processes should be integrated into and linked with contemporary frameworks and standards in science, technology, mathematics, and other disciplines. The report identified a set of the most commonly cited core engineering concepts. The central engineering construct was "design" – understanding and doing it.

Other important concepts included understanding constraints, understanding systems, and optimization. Central skills included modeling, systems thinking, and analysis. In addition, the report emphasized the importance of understanding the relationship of engineering and society and the connections among engineering, technology, science, and mathematics.

Technology and Engineering Literacy (TEL) Framework for the 2014 National Assessment of Educational Progress

The TEL framework is unique in its focus on assessing the interrelationships of engineering and technology. In the framework, technology and engineering literacy is defined as the capacity to use, understand, and evaluate technology as well as to understand technological principles and strategies needed to develop solutions and achieve goals (NAGB 2010). Technology and engineering literacy is divided into three assessment areas, design and systems, information and communication technology, and technology and society. Within design and systems, four subareas of essential knowledge and skills were identified: nature of technology, engineering design, system thinking, and maintenance and troubleshooting.

Principles for the nature of technology expand the scope of common conceptualizations of technology beyond computers and the Internet. The broader view includes every way people manipulate the natural environment to satisfy needs and wants. Therefore, technology includes all the various devices and systems that people make to fulfill some function. The framework lays out key principles for the nature of technology: (1) technology is constrained by the laws of nature; (2) scientists examine what exists in nature, and engineers modify natural materials to meet human needs and wants; (3) technological development involves creative thinking; (4) technologies developed for one purpose may be adapted for other purposes; (5) science, technology, engineering, mathematics, and other disciplines are naturally supportive; (6) the pace of technological change has been increasing; and (7) tools help people to do things efficiently, accurately, and safely. The framework then lays out assessment targets for the nature of technology for grades 4, 8, and 12.

The engineering design subarea in the TEL framework is described as an iterative, systematic process for solving problems. The process begins with stating a need or want and the criteria and constraints of the challenge. Then potential solutions are explored referencing relevant scientific and technical information. Potential solutions are compared, and models and prototypes are constructed, tested, and evaluated to see how they meet the criteria and constraints of the problem. The results of the engineering design process will be technology in the form of either a product or a process. The framework specifies key principles of engineering design and proposes assessment targets for grades 4, 8, and 12. Two additional components of design and systems are systems thinking and maintenance and troubleshooting. For each component, principles are identified and assessment targets for grades 4, 8, and 12 are presented.

The framework also specifies components, principles, and assessment targets for grades 4, 8, and 12 for the prominent technology area of information and communication technology (ICT). ICT is presented as a separate assessment area within technology and engineering literacy because of the central place ICT plays in learning and functioning in school, the workplace, and daily living. ICT subareas to assess include understanding and use of technologies for (1) construction and exchange of ideas and solutions, (2) information research, (3) investigation of problems, (4) acknowledgment of ideas and information, and (5) selection and use of digital tools.

The TEL framework can serve as an important resource for identifying assessment targets relevant for distinguishing between engineering and technology.

Framework for K-12 Science Education and the Next Generation Science Standards

The framework includes engineering and technology as they relate to applications of science. Engineering is used to mean engagement in a systematic design practice to achieve solutions to particular human problems. Technology is used to include all types of human-made systems and processes. Two core engineering ideas are specified. The first is engineering design – how engineers solve problems. The second core idea is understanding of the links among engineering, technology, science, and society. Engineering design is subdivided into three components: (1) defining and delimiting a problem, (2) developing possible solutions, and (3) optimizing the design solution. Links among engineering, technology, science, and society are partitioned into (1) interdependence of science, engineering, and technology and (2) the influence of engineering, technology, and science on society and the natural world. The framework describes grade-band end points for each of the three components.

The *Next Generation Science Standards* provides more specific guidance for assessing engineering design that produces and uses technology (NRC 2013). Performance expectations are presented for the engineering design components. Performance expectations have been developed that integrate the engineering core ideas with cross-cutting concepts such as systems and models and cause and effect and also with science and engineering practices.

Each of the frameworks and standards described above can serve as resources for specifying the similarities and differences between engineering and technology to be assessed. In the following section, the use of a systematic assessment design framework is presented to support the selection or development of assessments.

Evidence-Centered Assessment Design

The focus of this entry in the encyclopedia is on methods for assessing understanding of the similarities and differences between the engineering design processes and the technologies that can both support the design processes and are a result of them. The selection or development of assessments will depend on the purposes of the assessments and the interpretations of the data. An assessment may be intended to provide diagnostic feedback and be used in a formative way to allow adjustments during instruction to improve performance. An assessment may be intended to serve a summative purpose to report on the status of proficiency at a point in time. These purposes will have implications for the criteria used to select, design, or interpret assessments.

A useful framework for understanding the structure of assessments is evidence-centered assessment design (Mislevy et al. 2003). Evidence-centered design is intended to structure an assessment argument. The argument begins with the claim that specified knowledge or skills have been learned. Evidence to support the claim comes from the types of questions or tasks that will elicit observations and performances of the targeted knowledge or skill. Summaries of performances, typically in the form of scores to be reported and interpreted, then complete the argument. Evidence-centered assessment design tightly links the targeted knowledge and skills (student model), with assessment tasks and items to elicit evidence of these targets (task models) and with specifications of how the evidence will be scored and analyzed to report proficiencies (evidence model). The evidence-centered design framework can be used to analyze and evaluate existing assessments or to guide the systematic development of new ones.

The essential first step in assessing student understanding of the similarities and differences between engineering and technology will be to settle on the definitions of engineering and technology and to specify the similarities and differences to be tested. The similar and different features would become the first component of the student model. A second component of the student model would be the cognitive demands or levels of reasoning required. Cognitive demands could range from identifying definitions and lists of similar and different features, to analyzing the features, to evaluating others' identifications of the similarities or differences.

The engineering design process creates plans for developing solutions. Solutions may be tangible artifacts or technologies, such as digital devices or farm machinery. Solutions may also be new or improved technological processes such as more efficient manufacturing procedures or pharmaceutical clinical trials. These solutions are *technologies* that have been developed to address needs in areas of the designed world such as medicine, agriculture, energy, transportation, manufacturing, and construction. Students tend to think of technology in terms of computers and digital technologies, not in terms of the artifacts and solutions engineered in the many other areas of the designed world. Students are expected to understand that there are technologies in all these areas, from pills to plows, plugs, planes, pinions, and pickup trucks. Specifications of the knowledge to be tested will need to decide what students need to understand about the distinctions between the engineering processes, the role of technologies in them, and the technology products. It is likely that such discriminations would be part of a more comprehensive assessment of engineering and technology that would also include understanding of types and functions of representative technologies.

Since engineering is the process, and technology is the product, or a support for the process, the level of cognitive demand is not likely to be very high. Statements of what the student needs to know and the level of reasoning for showing it will become the assessment targets of the student model.

The task model specifies the kinds of contexts, problems, and items that would elicit evidence that the students understood the similarities and differences between engineering design and technology. Simple items could list features of engineering design and technology and have students select the appropriate discriminations. Descriptions of needs addressed by an engineering project producing solutions could include questions to determine that students understood that the solutions, whether new tools or new processes, are technologies. Tasks and items could be designed around scenarios presenting engineering design problems in a range of applied contexts. The overarching problem could be to select and construct engineering processes to use in attempting to solve the problem. Questions about the appropriate supporting technological tools to use and about the resulting solution as a technological advance could be inserted within tasks.

The evidence model would involve determining what kind of scoring and reporting would convey that the student understands the similarities and differences. Specific reports about the similarities and differences assessment target would be needed.

The assessment selection or development can use the framework of evidence-centered assessment design framework to guide analyses of existing tasks and items or to guide the development of appropriate tasks and items. The framework would ask if the knowledge to be tested is clearly specified (student model), if the tasks and items will provide evidence, and if the discriminations have been made, perhaps in a range of applied areas such agriculture, medicine, and manufacturing. The framework would also ask if the scoring and reporting clearly allowed decisions to be made about whether the understanding of the differences between engineering and technology is sufficiently strong. The decisions could then be used diagnostically to inform further instruction or to support a proficiency report. The key to sound assessment is that the assessment argument is clear and supported.

(NAE 2010), surveyed standards documents in engineering, technology, science, and mathematics to identify common engineering concepts and skills. The National Assessment Governing Board supported development of the *Technology and Engineering Literacy (TEL) Framework for the 2014 National Assessment of Educational Progress*. The National Research Council of the National Academies has published the *Framework for K-12 Science Education*, which, along with a draft *Next Generation Science Standards*, integrates engineering ideas and practices with those in science (NRC 2012; Achieve 2012). Definitions of engineering practices can be culled from these frameworks and standards developed by engineering and science organizations, as well as from standards for engineering and technology for state, national, and international assessments.

The definitions of engineering and the design engineering process are the starting points for developing assessments of engineering practices. This encyclopedia entry begins with a summary of prominent conceptualizations of engineering and the outcomes of engineering design – technology. The definitions are followed by descriptions of an assessment framework that can be used to analyze or develop assessments of engineering practices. Descriptions of some potential types of assessment tasks and items to test understanding of the similarities and differences between engineering and technology are provided.

Definitions of Engineering, Engineering Practices, and Technology

In the *Framework for K-12 Science Education*, engineering is defined as the application of science in a systematic design practice to achieve solutions to particular human problems. *Engineering design* is defined as a systematic and iterative approach to designing objects, processes, and systems to meet human needs and wants. The engineering design processes constitute the engineering practices set forth in frameworks and standards documents. Products and processes resulting from application of engineering design practices are technologies. Technologies also often function as tools and processes used to support engineering design practices.

Sources of Conceptualizations of Engineering Practices

Standards for K-12 Engineering Education? (NAE 2010). The report surveyed contemporary frameworks, standards, and practices in engineering to determine if a national set of engineering standards could be proposed. The report summarized key components of engineering and recommended that engineering concepts and processes should be integrated into and linked with contemporary frameworks and standards in science, technology, mathematics, and other disciplines. The report identified a set of the most commonly cited core engineering concepts. The central engineering construct was "design" – understanding and doing it. Other important concepts included understanding constraints, understanding systems, and optimization. Central skills, or practices, included modeling, systems thinking, and analysis.

Technology and Engineering Literacy (TEL) Framework for the 2014 National Assessment of Educational Progress. The TEL framework describes technology and engineering literacy as the capacity to use, understand, and evaluate technology as well as to understand technological principals and strategies needed to develop solutions and achieve goals (NAGB 2010). Technology and engineering literacy is divided into three assessment areas: design and systems, information and communication technology, and technology and society. Within design and systems, three subareas of essential knowledge and skills were identified: nature of technology, engineering design, systems thinking, and maintenance and troubleshooting.

The engineering design subarea in the TEL framework is described as an iterative, systematic process for solving problems. These processes are among the practices of engineering. The process begins with stating a need or want and the criteria and constraints of the challenge. Then potential solutions are explored referencing relevant scientific and technical information. Potential solutions are compared, and models and prototypes are constructed, tested, and evaluated to see how they meet the criteria and constraints of the problem. Two additional components of design and systems are systems thinking and maintenance and troubleshooting. Systems thinking is a way of thinking about devices and situations so as to better understand interactions among components, root causes of problems, and the consequences of various solutions. Maintenance and trouble shooting is the set of methods used to prevent technological devices and systems from breaking down and to diagnose and fix them when they fail. For each of these design and systems components, assessment targets for grades 4, 8, and 12 are presented.

The TEL framework also describes three cross-cutting practices: understanding technological principles, developing solutions and achieving goals, and communicating and collaborating. The framework provides examples of how these practices apply to the engineering design, systems thinking, and maintenance and troubleshooting areas.

Framework for K-12 Science Education and* the Draft *Next Generation Science Standards (NRC 2012; Achieve 2012). The framework includes engineering and technology as they relate to applications of science. Engineering is used to mean engagement in a systematic design practice to achieve solutions to particular human problems. Technology is used to include all types of human-made systems and processes. Two core engineering ideas are specified. The first is engineering design – how engineers solve problems. The second core idea is understanding of the links among engineering, technology, science, and society. Engineering design is subdivided into three components: (1) defining and delimiting a problem, (2) developing possible solutions, and (3) optimizing the design solution. Links among engineering, technology, science, and society are partitioned into (1) interdependence of science, engineering and technology and (2) the influence of engineering, technology, and science on society and the natural world.

The framework also describes the key practices that scientists use as they investigate and build models and theories about the world and the key engineering practices that engineers use as they design and build systems. Science and engineering practices include asking questions and defining problems; developing and using models; planning and carrying out investigations; analyzing and interpreting data; using mathematics, information and computer technology, and computational thinking; constructing explanations and designing solutions; and engaging in argument from evidence. The framework describes grade band endpoints.

The draft *Next Generation Science Standards* provides more specific guidance for assessing science and engineering practices. Performance expectations are provided that integrate disciplinary core ideas, cross-cutting concepts, and science and engineering practices for elementary, middle school, and high school.

Each of the frameworks and standards described above can serve as resources for specifying engineering to be assessed. In the following section, the use of a systematic assessment design framework is presented to support the selection or development of assessments of engineering practices.

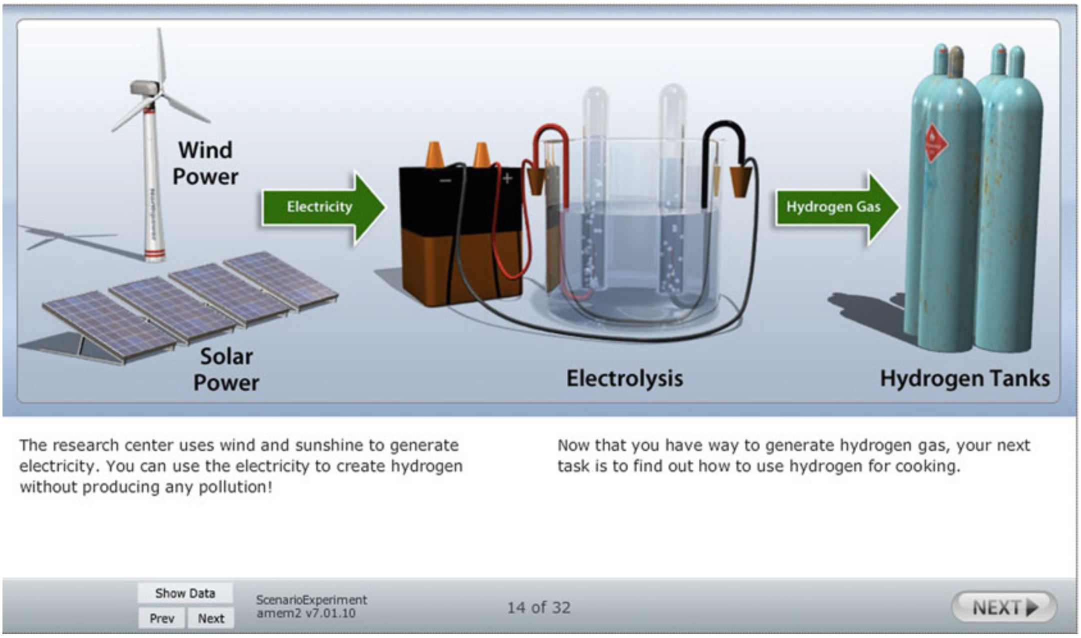
Evidence-Centered Assessment Design

The focus of this entry in the Encyclopedia is on methods for assessing engineering practices. The selection or development of such assessments will depend on the purposes of the assessments and the interpretations of the data. An assessment may be intended to provide diagnostic feedback and be used in a formative way to allow adjustments during instruction to improve performance. Or, an assessment may be intended to serve a summative purpose to report on the status of proficiency at a point in time. These different purposes will have implications for the criteria used to select, design, or interpret assessments of engineering practices.

A useful framework for understanding the structure of assessments is evidence-centered assessment design (Mislevy et al. 2004). Evidence-centered design is intended to structure an assessment argument. The argument begins with the claim that specified knowledge or skills have been learned. Evidence to support the claim comes from the types of questions or tasks that will elicit observations and performances of the targeted knowledge or skill. Evaluations of performances, typically in the form of scores to be reported and interpreted, then complete the argument. Evidence-centered assessment design tightly links the targeted knowledge and skills (student model), with assessment tasks and items to elicit evidence of these targets (task models), with specifications of how the evidence will be scored and analyzed to report proficiencies (evidence model). The evidence-centered design framework can be used to analyze and evaluate existing assessments to determine the coherence of the assessment claims they can support. Evidence-centered design can also guide the systematic development of assessments of engineering practices.

The essential first step in assessing engineering practices will be to specify the practices to be tested. These practices would become the first component of the student model. A second component of the student model would be the cognitive demands or levels of reasoning and complexity of application required. Cognitive demands could range from simple identification of practices being used during an engineering project or selection of practices to be used, to active application of the practices to solve a variety of problems, to evaluating the appropriate use of the engineering practices by others. Importantly, assessment targets would include not only being able to recognize and evaluate practices, but to actually employ them appropriately in a range of engineering contexts in the designed world such as medicine, agriculture, energy, transportation, manufacturing, construction, and academic disciplines.

The assessment task model specifies the kinds of contexts, problems, and items that would elicit evidence that the students understand and can employ engineering practices. For example, in the *Framework for K-12 Science Education* for each of the components of engineering design processes such as defining problems; developing and using models; planning and carrying out investigations; analyzing and interpreting data; using mathematics, information, and computer technology and computational thinking; constructing explanations and designing solutions; and engaging in argument from evidence, the assessment could present tasks and items along a progression from recognition of the components in use, to application of them, to evaluation of their use by others. Tasks and items could be designed around scenarios presenting engineering design problems in a range of applied contexts. The overarching problem could be to select and construct engineering processes to use



The research center uses wind and sunshine to generate electricity. You can use the electricity to create hydrogen without producing any pollution!

Now that you have way to generate hydrogen gas, your next task is to find out how to use hydrogen for cooking.

Engineering Design, Assessing Practices of, Fig. 1 SimScientists problem for engineering design: how to use hydrogen for cooking

in attempting to solve the problem. Within tasks could be inserted questions about the appropriate supporting technological tools and processes to use and about the resulting solution as a technological advance.

Technologies are now available to support the design of innovative tasks that allow students to interact with dynamic systems and actively engage in science and engineering design processes. The SimScientists program, for example, has developed suites of simulation-based formative and summative assessments for middle school science units (http://sinscienitsts.org). The assessments are set in scenarios that present a real-world problem to solve. For example, for the atoms and molecules unit, simulation-based assessments have been developed to embed during the unit. The assessment targets focus on understanding the components, interactions, and emergent behavior of a system and the science and engineering practices for studying them or developing a solution. The embedded assessments provide feedback and graduated coaching on science content and the science and engineering practices as well as progress reports to be used as formative assessment. The end-of-unit simulation-based benchmark assessments present a new scenario and problem to be solved. The benchmark assessments are summative measures of proficiency, so no feedback and scaffolding are provided.

Figure 1 shows a problem set for the atoms and molecules embedded assessments in a research center in Antarctica. Students are given a series of problems around how to make the research center more sustainable given the available resources and tools. For example, students try to figure out the best process for creating hydrogen gas for cooking. The students must apply their scientific understanding about atoms and molecules and their interactions to determine the best cooking method.

The sequence of screens in Fig. 2 focuses on assessing the design of investigations. Students

You need to know what conditions caused a reaction in the flask. You will need to answer the following questions about hydrogen gas.

Does hydrogen react with oxygen if there is a spark?
Does hydrogen react with oxygen whenever they are mixed?
Does hydrogen react with nitrogen if there is a spark?
Does hydrogen react with nitrogen whenever they are mixed?

Review your trials and decide if you have enough information to answer the questions to the left.

- If you want to review one of your trials, click the VIEW button for that trial.
- You can then click RESET to start that trial again.
- If you need to run another trial, click NEW TRIAL.
- When you are satisfied with your trials, click NEXT.

Oxygen and hydrogen do react with a spark. In order to know that you would need to run a trial such as the one shown here.

Click Yes, No, or Can't Tell to show what caused a reaction in the flask.

Hydrogen gas reacts with nitrogen if there is a spark.
○ Yes ○ No ● Can't Tell

Hydrogen gas reacts with nitrogen whenever they are mixed.
○ Yes ● No ○ Can't Tell

are asked to conduct an experiment to determine if hydrogen gas reacts with either nitrogen or oxygen gas, in the presence or absence of a spark, to produce a flame. This is part of the scenario in which students are investigating the use of hydrogen gas as a fuel source for a cook stove. Students can conduct trials by selecting different variables, running the trial, and then saving the trial (top screen). Saved trials can be watched at any point during the task. Once students have completed their trials, they must form conclusions using evidence from their trials. Students are given feedback on their conclusions. If a student makes an incorrect conclusion because they did not run a trial that would have provided the necessary information, then the feedback illustrates what that trial would look like (middle screen). If a student makes an incorrect conclusion based on a trial they did run, then the feedback highlights the trial and coaches the student on how to correct the conclusion (bottom screen).

These formative assessments for atoms and molecules are followed by a simulation-based benchmark assessment to provide a summative report of student proficiency on the assessment targets. The summative assessment presents a new real-world problem, determining potential safety dangers from a chemical spill. Such simulations can support the design of sequences of interactive assessment tasks allowing students to engage in science and engineering practices to solve an authentic problem.

The evidence model of assessments of engineering practices would involve determining what kind of scoring and reporting would convey that the student understands and can apply and critique applications of engineering practices that are employed in a variety of contexts and problems. Assessment reports on progress to be used formatively during instruction would be finer grained than reports of proficiency on the specified assessment targets.

The assessment selection or development can use the framework of evidence-centered assessment design framework to guide analyses of existing tasks and items or to guide the development of appropriate tasks and items. The framework guides asking if the knowledge to be tested is clearly specified (student model), if the tasks and items will provide evidence if the targeted understanding and applications of engineering practices have been made, perhaps in a range of applied areas such agriculture, medicine, and manufacturing. The framework would also ask if the scoring and reporting clearly allowed decisions to be made about whether the understanding and applications of engineering practices are sufficiently strong. The decisions could then be used diagnostically to inform further instruction or to support a proficiency report. The key to sound assessment is that the assessment argument is clear and supported.

The definitions of engineering for this encyclopedia entry are based on numerous documents produced by national sets of experts. The definitions of engineering are the starting points for developing assessments of understanding of it. This encyclopedia entry begins with a summary of prominent conceptualizations of engineering. Descriptions of some potential types of assessment tasks and items to test understanding of engineering are provided.

Definitions of Engineering

Engineering is defined as a systematic and iterative approach to designing objects, processes, and systems to meet human needs and wants. The products and processes resulting from application of engineering design processes are technologies. Technologies also often function as tools and processes used to support engineering design.

Sources of Conceptualizations of Engineering

Standards for K-12 Engineering Education

The report surveyed contemporary frameworks, standards, and practices in engineering (NAE 2010). The central engineering construct was "design" – understanding and doing it. Other important concepts included understanding constraints, understanding systems, and optimization. Central skills included modeling, systems thinking, and analysis. In addition, the report emphasized the importance of understanding the relationship of engineering and society and the connections among engineering, technology, science, and mathematics.

Technology and Engineering Literacy (TEL) Framework for the 2014 National Assessment of Educational Progress

Three main assessment areas were specified: design and systems, information and communication technology, and technology and society (NAGB 2010). Within design and systems, three subareas of essential knowledge and skills were identified: nature of technology, engineering design, system thinking, and maintenance and troubleshooting.

Engineering design is described as an iterative, systematic process for solving problems. The process begins with stating a need or want and the criteria and constraints of the challenge. Then potential solutions are explored referencing relevant scientific and technical information. Potential solutions are compared, and models and prototypes are constructed, tested, and evaluated to see how they meet the criteria and constraints of the problem. The framework specifies key principles of engineering design and proposes assessment targets for grades 4, 8, and 12. Two additional components of design and systems are systems thinking and maintenance and troubleshooting. For each component, principles are identified and assessment targets for grades 4, 8, and 12 are presented.

Framework for K-12 Science Education and the Next Generation Science Standards

The framework (NRC 2011) and standards (NRC 2013) include engineering as it relates to applications of science. Engineering is used to mean engagement in a systematic design practice to achieve solutions to particular human problems. Two core engineering ideas are specified. The first is engineering design – how engineers solve problems. The second core idea is understanding of the links among engineering, technology, science, and society. Engineering design is subdivided into three components: (1) defining and delimiting a problem, (2) developing possible solutions, and (3) optimizing the design solution. The framework describes grade band end points for each of the three components.

The *Next Generation Science Standards* provide more specific guidance for assessing engineering design. Performance expectations have been developed that integrate the engineering core ideas with cross-cutting concepts such as systems and models and cause and effect, and also with science and engineering practices.

Each of the frameworks and standards described above can serve as resources for specifying the engineering concepts to be assessed. In the following section, the use of a systematic assessment design framework is presented to support the selection or development of assessments.

Assessment Methods

Reference to the varying definitions and contexts of engineering can provide the bases for core engineering concepts to be tested. The assessments of understanding engineering concepts may vary the cognitive demands or levels of reasoning required. Cognitive demands could involve simply identifying definitions and lists of engineering design components. More demanding would be to require analysis of the design process components in descriptions of engineering projects occurring in the multiple areas such as agriculture, manufacturing, or medicine. Assessments of understanding could also ask for evaluations of applications of the engineering design processes in multiple contexts. Scoring and reporting of responses to these types of tasks and items would then provide data that could be used diagnostically to inform further instruction or to support a summary proficiency report.

Environmental Education

Over the past half century, environmental education (EE) has evolved as a field of professional practice in response to widespread sociocultural concerns about an increasingly serious array of environmental problems. Historically, public awareness and concern grew in parallel with accumulating scientific evidence of incipient ecological degradation, population-resource issues, and a broadening range of threats to the quality of life and the sustainability of ecosystems. It seems no mere coincidence that ecological science expanded during this time and gained credibility within the academy. In 1969 the first issue of the *Journal of Environmental Education* provided educational coherence to assorted environmental interests in publishing definitional statements for a new interdisciplinary field and in articulating the need for a new environmental ethic and alternative/critical approaches to education, curriculum, and pedagogy based on promoting fundamental changes in human attitudes, relations, and actions. In 1972 a United Nations Declaration on the Human Environment (Stockholm Conference) gave conservation educators, natural resource professionals, and people interested in nature study and outdoor education a common purpose in constructing arguments for inclusion of environmental problems and issues within formal education. On the surface, the history of EE seemed a natural consequence of circumstance.

Less officially, EE has emerged amidst tangled webs of educational responses to environmental issues with perspectives ranging from technical interests concerning appropriate curriculum, pedagogy, and learning outcomes to socially critical approaches promoting interdisciplinary and experiential understandings and practices emphasizing socio-ecological justice. Nothing less than basic reform of the way societies looked at socio-environmental problems and engaged in decision making, it was argued, could alleviate environmental problems of a deteriorating planetary life support system. Whether major responsibility was leveled at the point source of the problem or more generally at societies at large, education systems were targeted as having a key role to play. The mixed rhetoric of environmentalist positionings was reflected in early definitions of EE constructed by the International Union for the Conservation of Nature and Natural Resources (IUCN) and consolidated into a global framework of goals and guiding principles from UNESCO-based conferences in Belgrade and Tbilisi in the mid-1970s. Accordingly, by definition, EE was aimed at producing a citizenry knowledgeable concerning biophysical and sociocultural environments, capable of recognizing values and clarifying concepts concerning those environments, and committed to developing the skills and attitudes necessary for people to work individually and collectively (politically) toward solutions to environmental problems. Many national and regional formulations of EE soon emerged and were adapted to reflect local interpretation of these global goals, all intended to stimulate human responsibility for maintaining and improving the quality of the biosphere (see Palmer 1998).

These official and unofficial activities raised the profile of EE during the 1980s and led to the formation of UNEP (United Nations Environment Programme) thereby establishing a credible international base for dialogue and exchange of curriculum materials. Initially, resources came from rapidly expanding national EE organizations in the USA, Britain, and Australia and these often served as templates for local curriculum development. The importance of international exchanges (via, e.g., the UNESCO CONNECT newsletters) is illustrated by the sharp focus on social processes of community problem solving and decision making that extended beyond the traditional domain and processes of science. In essence, the curriculum and the pedagogy attempted to translate knowledge acquisition into action-oriented processes of change. It was argued that appropriate environmental knowledge, attitudes, and skills could only assume their full significance in contact with real social problems of the environment. It was during this time that forms of behaviorism and instrumental thinking in education were criticized by many within the environmental education community. At international levels, these activities foreshadowed both successes and critiques of EE in the construction of a global environmental component to personal and social ethics in the reform of educational processes and systems (Fensham 1978).

It is important to understand the nature of EE as representing a spectrum of theoretical positions that range from traditional forms of school activities such as schoolyard naturalization, recycling activities, litter patrols, nature walks, and water quality monitoring to forms of critical pedagogy and political activism. Obviously, a -rhetoric-reality gap was to be expected where the socially critical and political action goals of EE could not be realized within existing educational discourse. The spectral tension was reflected in ongoing debate concerning whether or not various forms of EE could find their way into the existing educational systems where whole-scale change seemed unrealistic. Just as there are streams of thought within environmentalism, so EE and EE research have been confronted by different ideologies underlying different currents (Sauvé 2005), visions, and means to change. Several typologies have been constructed to represent the array of arguments for and against development of students' knowledge of political-legal processes in advocacy of particular political positions and/or participation in activist activities. Although EE has often entered the school curriculum through science education, the EE literature has struggled to interpret how the social-political nature of human-environment issues can receive serious consideration among broader social, economic, and political dimensions of science, society, and environment. Thus, it is debates about issues of social and educational values, decision making and action skills, degrees of activism, and interdisciplinarity that have complicated relations within EE itself and between science education and EE.

As EE theory evolved through the 1980s and 1990s, fundamental pedagogical differences between EE and science education became more obvious and created tensions/resistances among contending views about students' active participation in learning, firsthand experiences in natural and built environments, investigation of issues in community and industrial practices, critical thinking, and values clarification skills, as these impacted traditional schooling practices. During this time many curriculum resources were developed promoting environmental issues' investigation, water education for teachers, and animal, plant, and ecosystem studies. Some of these tended toward more formal environmental studies and others the value of aesthetic experiences in natural environments. Differences between science education and EE at curricular levels were articulated within the literature as differences of worldview in intent and practice. Despite impetus from international events, such as the World Conservation Strategy (1980), "Tbilisi Plus Ten" (1987), and Brundtland World Commission on Environment and Development (WCED) (1987), at practical levels, it was the critical self-examination of the goodness of fit between EE (with environment emphasized), ESD (Education for Sustainable Development), science education, and schooling that generated interest.

In each of these discussions, education was considered as a complex construct with stakeholders across many organizations – international and national, governmental and nongovernmental, formal/nonformal, and public and private. Together they formed clusters of interacting systems where relationships varied among cultures, countries, and regions so that any overview is problematic. The educational community whose support the UN was calling for represented those most concerned with inadequacies of environmental science and environmental studies, as well as definitions of environmental learning and environmental literacy (often extending concepts of scientific literacy into the social sciences). The point of all of this was manifest in different conceptualizations of Education for Sustainable Development (ESD) that proved vulnerable to quite diverse interpretations arising from different worldviews, thus presenting practitioners with problems of interpretation and funders with concerns of authentication. Like much of formal education, EE, ESD, and science education have been caught up in a slide away from education's liberal origins toward a vocational-managerial route. Whether this concept of education is enough is the subject of a wider-ranging critique of the current discourse of education. Within EE, Stevenson's (1987) paper perhaps best illustrates persistent major contradictions in purpose and practice between the socially critical and political action goals associated with the contemporary philosophy of EE and traditional practices in schools which emphasized assimilation of factual knowledge as solid foundation for future application.

These concerns, however, mainly trouble people in wealthier, developed countries. In many other places, environmental and socioeconomic factors are inseparable in people's lives. National strategies prepared on Western models offered little to address local needs and give insufficient attention to indigenous life and culture. There are deficiencies that can be ascribed to failure in perception of the whole system, lack of leadership, poor support by societies, and differing points of view to the point where education is an almost-forgotten priority. From the time of the Brundtland Report, ideological conflicts within environmental movements and within EE itself were brought into sharp relief as political debates about direction and practice. Commitments from government officials in many countries revealed a mix of EE and ESD ideas in cross-curricular themes or dimensions of scientific literacy in science education goal statements (e.g., STSE – Science, Technology, Society, Environment). There remains a significant point of contestation within diverse conceptualizations of the relationship of EE and ESD within the literature of EE and science education. While movements toward school-based curriculum, social learning, critical and creative thinking, and community-oriented schooling have been consistent with EE, the confusing rhetoric of ESD was sustained in the 1992 global UN Conference on Environment and Development – the Earth Summit – in Rio de Janeiro, Brazil. The resulting Agenda 21 contained 27 principles for sustainability intended to provide a renewed base for international cooperation and to add legitimacy to and grounding for renewal of EE/ESD in national/local curriculum.

What should be recognized in the activities of the 1990s is how, according to many environmental educators, agencies of the UNEP, IUCN, and WWF changed the language and thus the discourse both in the international goals and in their translation into principles of curriculum development. What should also be recognized is how the parallel forum at the Earth Summit, for representatives of NGOs and educators from around the world, produced guidelines for EE that reaffirmed the values-based and ethical and socio-politico-cultural nature of EE. While ESD retained "official" credibility and provided momentum for public notions of "sustainable development," environmental educators viewed the new discourse of ESD as discursive appropriation of resistance in the politics of environment and development. And so, in spite of these theoretical tensions within the EE/ESD community, in one way or another EE continues to be the "elephant in the room" in debates about the place and value of social-environmental issues in science education.

EE has reached an interesting crossroads. At a time when environmental issues have gone global and are increasingly part of public conversation, government funding is decreasing in both education and environment sectors. And despite credible research from inside and outside the field on the value of EE, changes in daily life are mostly invisible within economies of scale, political hegemony, and the creation of doubt about the certainty of environmental issues, even when grounded in science-based evidence. What is interesting is the persistence of those, both within and outside EE, who continue to challenge the ethics of the status quo in education and in societies from an emerging base in socio-ecological education. The arguments are becoming more thoughtful and philosophically articulate. For example, while many science educators continue to resist forms of values-based political advocacy on grounds of scientific neutrality, environmental educators argue that ethical values are in fact implied by natural facts. Rather than get caught in disputes about scientific evidence per se, they recognize that this naturalistic fallacy may represent the most significant challenge to attempts to ground environmental policy solely within scientific fact. Increasingly many science and environmental educators publicly acknowledge the idea that, while science remains a sound base for knowing about the natural world, it is not sufficient for normative judgments about what best to do. However, the extension of this argument into science teaching remains one of the most vexing problems for environmentalists and environmental educators. Thus, it is this fact-value gap that remains as one of the key challenges in easing the remaining tensions between science education and EE.

EE has come a long way from visions of converting people through behavioral change to inspiring people to expand their thinking, their consciousness, and their ethical positioning; from awareness and understanding of various worldviews to socio-critical forms of action and activism; and from assumptions of language transparency to deconstruction of traditional educational discourses. Much, however, remains to be done. Emerging genres of inquiry have led to a methodological expansion that provides numerous openings, as well as challenges, in both EE and science education. Interdisciplinarity, as a means to the fact-value and aesthetic, ethical, and political "normativities" of the field, remains a challenge. Thinking has broadened as part of larger pedagogical engagements with social and cultural issues and ethico-political processes, but the transition from anthropocentric to ecocentric ethics is incomplete. And while improved theoretical connections to matters of social and environmental justice are evident in the literature of both fields, bringing indigenous and marginalized voices to interface remains inadequate at many levels. Critical socio-ecological educators, ecofeminists, and cultural sociologist and geographers would move further along the path to break free of the discursive limits of sustainable development that seems to privilege business as usual within dominant social models of economic growth and development. Amidst this diverse set of onto-epistemic positions, we find a continuously evolving field where an increasing variety of forms of EE and ESD act separately and in conjunction as socio-ecological and socio-material forms of practice alongside what have become "traditional" embedded practices of EE as "little added frills" to the science curriculum.

In effect we can see why both the practical and theoretical ideas that drive EE have increasingly diverged from those that underpin traditional forms of science education most common in schools. Despite tensions within the field, EE tends toward changing school discourses-practices, whereas the science education literature tends to be less critical of, and thus complicit in, traditional school practice. While exceptions, such as those concerning ecological, cultural, and indigenous knowledge forms, have an increasing presence within the literature of science education, school practice remains the same. Emphases in school science praxis that actively engages the values and ethics of caring, firsthand experiences in natural settings, and interdisciplinary investigation of socio-environmental issues as well as concepts of social and ecological or environmental justice form part of a different onto-epistemic frame than that which currently drives schooling and most school science. Issue-based, problem-centered, community-integrated student activity, conceivable in senior science, goes only part way toward the political action component that has characterized EE goals since its inception. Most environment-related activity seems to depend on the efforts of talented enthusiasts at primary and junior science levels. However, it is also the case that in some countries EE has evolved to fit sociopolitical contexts influenced by ESD frameworks, often governed by national standards. In fact, there is evidence of a widening gap between more traditional liberal approaches to EE/ESD and those EE approaches intended more for purposes of socio-ecological transformation. It seems ironic that even in countries that take environment as a legitimate social concern, when translated into education policy, EE/ESD remains peripheral, as a disjuncture of knowledge forms and pedagogical assumptions concerning those educational qualities that would expand scientific literacy into environmental literacy.

From a science curriculum perspective, science educators who challenge the authority of traditional educational assumptions often align their arguments using dimensions of EE acknowledged as adding relevance and meaning to their programs. Recent literature in science education contains convincing arguments from those who would transform education to align with goals of social (and environmental) justice. Many science educators are beginning to consider how democratic political processes in respect of socio-ecological education may enhance their relevance and credibility with students. Research in science education and EE is increasingly implicated in the evolution of both fields as researchers have learned how to diversify their methodological and theoretical perspectives across a complex of onto-epistemic positions. Research studies from many countries report on the potential of intertwining social and environmental issues of gender, class, race, and colonization within interdisciplinary frames.

In parallel with these transformations in inquiry, both fields are more likely to encourage active engagement of young people in issues that directly implicate crucial sociocultural dimensions of science education and associated research activity. In these transitions sociocultural dimensions of education have become an important theme in research and have come to occupy major strands or themes at (inter)national symposia and conferences.

Beyond these commonalities, critical environmental educators and researchers are currently active in addressing major challenges of this complex of sociocultural and socio-scientific ideas within the curriculum and pedagogy of teacher education. And despite efforts to recast these ideas in goal-change rhetoric, often framed as ESD, EE has developed strands of inquiry in critical pedagogy and activism, ecofeminism, and poststructural perspectives that raise fundamental questions about the role of discourse and power in the formation of identities. Given that social and educational systems are already enacting dominant cultural discourses and that teachers who follow the curriculum cannot avoid inculcating particular values, perhaps the role for critical EE is best performed in creating educational conditions for processes of critical-ethical thought and debate and in encouraging active student learning that encourages and engages young people in critical appraising and valuing multiple perspectives? This, in turn, may help people to work across socio-ecological as well as disciplinary boundaries. The point here is that it takes forms of praxis grounded in views of the social world that cannot ignore human qualities such as embodied emotions, beliefs, and values, as well as insights from a wide range of sensibilities that are crucial to human thought, to transform rather than simply reproduce both educational and socio-ecological conditions. Payne's evolving (Payne 2006) work on a critical ecological ontology for inquiry represents this difficult task in curriculum and pedagogy of sorting and conceptualizing these ideas within deeper overarching frames that can assist the field in making sense of an amalgam of positions. However, without the hard labor of engaging the practical-theoretical gaps that characterize both science and environmental education, EE continually risks fragmentation.

Perhaps because science education is an established school subject, where forms of scientific literacy provide goal structure, there has been less obvious engagement with fundamental (onto-epistemic) challenges to disciplinary structures. It would seem that the time is coming when socially critical and interdisciplinary positions that focus on community problem solving and decision making will need to be addressed as issues of the propositional school curriculum. Potentially there is a strong role for science education here. It is interesting that recent changes proposed in science education (partly in response to young people's interests in technology and media, their patterns of communication, and their concerns about the relevance of science to real-life situations in local environments) tend toward socio-ecological forms of education from a variety of inter- and intra-cultural perspectives. It is in these kinds of spaces, rather than traditional school subjects, that both science and environmental educators can find openings to engage socio-scientific and sociocultural positionings within different forms and levels of curriculum and pedagogy. Just as science education has worked to broaden interpretation of forms of scientific literacy, environmental educators have begun to move, on a somewhat broken front, beyond the sedimented discourse of UNESCO ESD rhetoric, to reengage in critical orientation to change. While this less stable post-critical thinking about curriculum and pedagogy may be disconcerting within traditional sectors of both environmental and science education, it is considered as a state of health by those who value levels of tension within fields where critically reflexive discourses-practices can lead to change.

Recently, within the EE literature, diverse theoretical perspectives confront and complement one another within broad frames of "ecological" sustainability. These perspectives represent a range of philosophical/paradigmatic positionings in respect of both environmental and educational politics and values. For example, many environmental educators now position themselves within sociocultural debates that can accommodate knowledge from various sources, including the social as well as the natural sciences. Knowledge and affect are recognized as useful if not limited in providing insight into the problems of human-environment and culture-nature relations, and as necessary in learning how to understand where and how to focus educationally. Although approaches are increasingly diverse and often reflect the legacy of privileged conceptions, particularly in EE research, the field has moved to engage debates from a wider range of cultural-interpretive, critical, and post-critical perspectives. Beyond these spaces, EE theorists and researchers have begun to explore theoretical perspectives in terms of the process of subjectification, that is, how people have come to construct their environmental identities.

As is now evident within the science education literature, researchers have become aware of the contested nature of ways of knowing (including the scientific) as part of larger onto-epistemic and methodological framings/positionings. Such insight may eventually make it possible for teachers and their students to work with and as inquirers to confront their own notions and ideas about the way the world works and how that implicates reconceptualization of teaching and learning. In reading the hard scholarship found in highly rated journals, we might re-imagine fields of science education and EE in terms of their possibilities in creating conditions for the counternarrative work needed to challenge taken-for-granted cultural discourses and official knowledge. In performing such a postcritical role, each field has attracted a range of scholars and educators who are used to working in uncomfortable spaces. These people accept that they are prone to the kind of critique necessary in pedagogical and theoretical work that crosses traditional boundaries and pushes educators to explore socially critical pedagogies, cultural geographies, and new ways of thinking and doing education.

The kind of critical-thinking and decision-making skills expected of young people today makes it impossible to ignore socio-scientific and socio-ecological justice issues across disciplines and cultural boundaries. If educational goals are intended to engage young people in ways to learn how to participate in democratic processes, it seems appropriate to create educational programs that provide young people with those kinds of experiences that can lead to action. Many environmental educators and a growing number of science educators seem to agree on the importance of expanding or transforming educational practice by invoking new pedagogy arrangements where questions of socio-cultural-political-critical thinking are generated with students as active participants, whether in community or in web-based activity in social media. Whether science education and EE can evolve into a field of professional praxis where people can educationally engage their personal-social-environmental subjectivities in critical explorations of social-environmental issues remains to be seen. Whether, as new pedagogical arrangements are exchanged between educational theory and practice, the old gap may be broached with the potential to make a difference seems to provide a call for compelling action within both fields.

Environmental Education

Introduction

Environmental Teacher Education (ETE) was established as a valid and necessary area of professional preparation and development during the 1970s. Pioneering efforts by UNESCO-UNEP sought to define broad-based educational parameters for environmental education (EE), and as EE was taken up in a range of curriculum development initiatives, implications for ETE were soon drawn out. From the outset, key drivers of ETE have been progressive and constructivist science education projects and action research programs in teacher inquiry and professional learning, e.g., OECD's Environment and Schools Initiatives.

Following the Rio Earth Summit (1992) and Agenda 21, ETE has been largely recast as a key contributor to sustainability education, particularly in preservice contexts (e.g., for early childhood, primary, secondary, tertiary, vocational, and higher education). Subsequent shifts in the focus of ETE can be identified, broadly, away from its roots in preparing teachers to engage students in collaborative, problem-solving inquiries of people-environment relations centered on curiosity and examining conflicts of interest, toward a greater emphasis on campus and community initiatives that address the UN's "mainstreaming" priorities for sustainability throughout education and advance work on the Millennium Development Goals.

Local to international discourses now articulate a wide variety of "ends-in-view" for ETE; commonalities typically include advocating teachers support the greening of institutional policies and practices, facilitate interdisciplinarity and holistic learning, model authentic school and curricular change, and further the democratization of educational goals and partnerships.

Development of Environmental Teacher Education

From its inception, ETE has been advanced to ensure that curriculum, teacher preparation, and professional development address themes of ecological integrity, economic and social justice, sustainable livelihoods, and resilient socio-ecological systems. However, relationships between ETE, science education, and EE remain varied and contested (see, e.g., scholarship from Noel Gough, Martin Ashley, and Irida Tsevreni).

Early contributions to ETE development in science education sought to ensure it was "the servant, not master" in a core of EE (see Peter Fensham), while in response to the claim that education must deliver social change – i.e., education as "*the* solution of the world's ills" – Arthur Lucas voiced pedagogical and philosophical reservations that it would become society's (and politicians') "compensatory mechanism." Lucas also warned science educators against "disciplinary chauvinism," i.e., science education regarded as *the* sole vehicle for EE.

Such concerns have resurfaced in various guises since the 1980s, most notably in debates about the priority and status of discipline-based knowledge in schools and teacher education (e.g., EE largely via geography, biology, and/or civics) and the value and shortcomings of positioning EE as an interdisciplinary and cross-curricular theme. For ETE, key questions concern the adequacy and development of teacher views regarding models for addressing environmental issues within science education and the curricular base for EE and implications for the scope and substance of professional preparation, development, capacity, and priorities. Notable tensions are the value of pursuing "whole school approaches" to EE or broader interpretations and expectations of EE providing an "education outside the classroom."

Important challenges for ETE then emerge around the interplay and tensions between the formal and informal (if not hidden and null) curriculum, as well as slippage and divergence between what is planned, enacted, and received as curriculum (see Elliot Eisner). Compounding this, mounting pressures on the professional and personal lives of teachers have been identified by Paul Hart (among others), in research that highlights the impact of the "structures and effects" of teacher values, beliefs, and experiences on EE and ETE. (Of particular note is teacher narrative research on professional preparation and development identifying "how conservative moral principles guide their behavior as responsible professionals who care deeply about children and their future.")

William Scott has argued that such considerations must equally address the layers and shifts in government policies and support for EE via ETE, while debate continues to ebb and flow as to the value of incorporating ecofeminist, critical realist, and poststructural perspectives in science education, including during ETE (e.g., see contributions from David Kronlid, Heila Lotz-Sisitka, Annette Gough). Here, key questions include how "ecocentric" the principles, processes, and outcomes of any curriculum design can actually be, as well as the benefits and risks of focusing primarily on the pragmatics (including professional standards) associated with ETE, at the expense of philosophical and pedagogical questions and challenges.

Finally, recent scholarship on the public understanding of science and science communication has reopened questions of what constitutes core subject matter, pedagogical content knowledge, and the value of science-based perspectives in curriculum planning and teacher education more broadly. For ETE, this has folded back largely into questions about focus and contribution, for example, on the centrality of inquiries about the "intrinsic value" of nature, "deficiencies" of various "root metaphors" at work in teaching and learning (e.g., education as initiation, socialization, Bildung, world-making, etc.), and appreciating the demands and shortcomings of various "ecological literacy" constructs promoted in or as EE, e.g., related to teaching and learning about climate change, ecosystem services, and biodiversity (see work by David Orr, Chet Bowers, Nicole Ardoin).

An undercurrent in many of these debates is whether ETE is, and can remain, a "hopeful educative practice." This is because while ETE is often imagined to be a vehicle for broadening, enriching, and/or redirecting (science) education via attention to environmental matters, there are few guarantees that EE achieves these qualities in or outwith the classroom. At one level, few dispute the worth of developing teachers' and students' competencies in identifying, understanding, and addressing the impacts of environmental pollution and/or the social inequalities associated with both dominant and alternative socioeconomic development trajectories. Yet research and scholarship identify a significant risk in EE becoming largely associated with practices and thinking that is tinged, if not marked, by a sense of despair or hopelessness. Moreover, "pedagogies of shock and terror" about environmental issues don't square with broader principles of effective educational practice, including productively addressing students' lifeworlds or presuming their readiness and willingness to support the pedagogue's agenda. At issue here are the cases documented in journals such as *Environmental Education Research* and *Journal of Environmental Education*, of students being confronted with apocalyptic scenarios about the future or human-environment relations, typically contained within short bursts or programs of EE that then seem to demand an immediate response and concomitant "overhaul" of lifestyle (e.g., in a lesson, or series, on ecological footprinting). Allied concerns about the strategies and tactics of "poor/bad" educational practice pinpoint the risks of programmatic approaches to EE with crude behavior change foci, marginalization of critical thinking about topics and pedagogy, and "greenwashing" of curricula and campus. Importantly, addressing these concerns in ETE might serve to guard against partisan environmentalist agendas as much as problematic teaching and the co-option of the work and lives of teachers and learners into "uneducational" activities (e.g., as discussed in the work of Bob Jickling, Arjen Wals, Chris Gayford). Equally, questions might also be raised about the spaces and times to address the ways in which education (re)creates the status quo – the charge being that teachers are often heavily constrained by vested interests about curriculum, education, and environment to the extent that the realities of human-environment relations and problems are effectively marginalized as “material” for teachers and students to work with.

The Challenge

In sum, a key issue for the future is: how far should ETE go with the various grains of education, science education, and teacher education, or might we expect ETE to always represent a radical break from any “norms” in these areas?

Epistemic cognition; Epistemological belief; Metacognition; NOS (nature of science); Personal epistemology; Scientific reasoning

One of the major findings from cognitive research during the second half of the twentieth century is that how we reason is strongly influenced by the goals we pursue. Scientific reasoning, broadly speaking, is concerned with establishing causal or predictive explanations of the world and is therefore centrally concerned with what could be described as the coordination of claims and evidence. In science education, this coordination has been viewed primarily either in cognitive terms, as the acquisition and development of knowledge about the world and cognitive processes for claim-evidence coordination, or in sociocultural terms, as the appropriation of communal practices of producing and evaluating claims and evidence. (The term “claim” is used here in a very broad sense to subsume theories, which are typically networks of claims articulated to relate in ways that explain target phenomena, and more specific or granular claims of the sort, “x causes y.”) Within both perspectives, goals are theorized to orient and constrain reasoning. Epistemic goals are those related to efforts to know something.

Epistemic Goals and Scientific Reasoning

Understanding children’s and adults’ competencies at scientific reasoning has been a longstanding concern of psychological research, going back at least to the work of Piaget and colleagues in the middle of the twentieth century examining the logical thinking of children and related work on logical reasoning and hypothesis testing in adults. Piaget’s studies suggested that children did not develop the capacity to think logically, in terms of abstract relations and causal consequences, until adolescence, and related work suggested adults routinely failed to test hypotheses systematically and are biased to confirm hypotheses. A famous example is Wason’s four-card problem, in which subjects are shown a sequence of cards, such as “4,” “A,” “7,” and “D,” and asked which card(s) need to be turned over to disconfirm a rule: “if a card has a vowel on one side, then it has an even number on the other." Most people choose the cards ("A" and "4") that confirm the rule rather than disconfirm it, and this is cited as evidence that most people are unscientific. Recasting such problems in more familiar terms, like "If a letter is sealed, then it has a 20 cent stamp on it," drastically improves performance. Moreover, it appears that performance on these sorts of tasks is not tied simply to prior experience but whether or not the rule at stake has a comprehensible rationale.

Similarly, there is a fair amount of evidence that children, and even adults, often fail to interpret covariation evidence as suggestive of causal relationships. Particularly, Deanna Kuhn has shown a variety of ways in which people seem to fail in coordinating such evidence with claims. One explanation of these findings is that people seek plausible causal mechanisms to explain covariation data and discount the causal import of covariation when a plausible mechanism cannot be generated (Kuhn, 2001). From such tasks and the hypothesis testing work discussed above, we can conclude that people's reasoning is guided by epistemic goals for plausible mechanisms and comprehensible reasons for rules.

Another example from cognitive psychology demonstrates the link between the goals we pursue while reasoning about complex tasks and how we reason. Kevin Dunbar created a computer microworld where college students simulated experiments to discover how gene inhibition works. During a learning phase, subjects learned core concepts to help them use the microworld and biased them toward a wrong hypothesis of gene inhibition. Subjects' success at finding the correct rule varied depending upon whether or not they pursued a goal of finding evidence for their current hypothesis versus a goal of finding a hypothesis that could explain their data. Subjects who pursued a "find hypothesis" goal were much more systematic in their experimentation strategies with the microworld.

These examples illustrate a robust finding from cognitive research into children's and adult's scientific reasoning: the goals one pursues during a complex reasoning task influence how that reasoning occurs. To be sure, it is also the case that a person's prior knowledge about the area of investigation (e.g., how much one knows about genetics or electric circuits) also influences reasoning (Lehrer & Schauble, 2006; NRC, 2007). The influence of goals, over and above prior knowledge, is in how it orients people to such problem-solving activity.

Epistemic Cognition and Goals

Epistemic goals are one aspect of epistemic cognition, a construct introduced by Karen Kitchener in 1983 to account for the kinds of thinking required to solve ill-structured problems. Ill-structured problems are those that have no single correct answer or any single path to a reasonable answer. Science is obviously full of ill-structured problems, and the myriad socioscientific issues (climate change, disease risk, etc.) people encounter are also ill-structured. For Kitchener, epistemic cognition is a specification of the more general process of metacognition. Metacognition involves monitoring one's progress toward solution of a problem and selecting appropriate problem-solving strategies. Epistemic cognition involves reasoning about the nature of an appropriate solution – what counts as an answer – and the criteria of a "good" answer to a problem from the perspective of a given domain or discipline. It is not simply a matter of being metacognitive and asking, "am I making progress?" It also entails some idea of what progress looks like and how it is evaluated (Kitchener, 1983). To design a successful science experiment, for example, requires some understanding of what counts as a good experiment, what experiments are intended to achieve, and so on.

The answers to such epistemic questions are effectively epistemic goals and strategies for achieving them, such as control of variables as a strategy for meeting the goal of isolating causal relationships. This emphasizes the disciplinary specificity of epistemic cognition and highlights that expertise in a discipline, be it science or history or math, entails not simply an understanding of the core concepts of that discipline but also an understanding of its epistemology. The broad epistemic goal of science to construct causal accounts of the natural world leads to an array of epistemic strategies, empirical methods, and inferential strategies for satisfying that goal. Consequently, science learning is now seen to require learning the epistemic practices and standards of science in addition to science concepts. In fact, we can go so far as to say that current views on science education emphasize how science concepts emerge from particular practices of knowledge development, a rejection of the traditional content/process dichotomy (Duschl, 2008; Ford & Forman, 2006).

Epistemic Cognition and Nature of Science

Epistemological concerns in science education have historically been studied under the rubric of nature of science (NOS). NOS research has been concerned with documenting the extent to which students understand the current philosophical characterization of the nature of science. This nature of science is commonly characterized in terms of the nature of scientific knowledge, means for justifying scientific knowledge, and social aspects of science as a human enterprise. NOS research extends back to the late 1950s, a period of time that has seen a great deal of change in philosophical characterizations of science that remain contested to this day. NOS research is treated elsewhere in this volume but bears on epistemic goals in two ways. First, there is some evidence suggesting that learners' views of NOS are associated with how they try to learn science. Learners who see scientific knowledge as interconnected concepts and as historically dynamic appear to pursue deeper learning strategies than those who see science as a collection of static, unconnected facts or ideas. This supports the general finding already discussed that epistemic goals influence reasoning. At the same time, the survey and interview instruments used to assess NOS often fail to characterize clear epistemological perspectives in students, and there is now considerable evidence that students reason about epistemological issues differently in contexts that are familiar to them than when abstract questions are posed to them about science.

The second point to make here is that NOS research has not concerned itself very directly with epistemic cognition. Conversely, the voluminous research on students' experimentation and investigation – ill-structured scientific problem solving – is largely disconnected from NOS research. On the one hand, NOS research does not treat learners' own epistemic goals as an object of study, but asks only whether or not students understand the epistemic goals of science. On the other hand, work on scientific reasoning, including that on students' scientific inquiry, focuses nearly exclusively on how individuals (or small groups) set and pursue epistemic goals without connecting such personal knowledge construction to students' notions of the epistemic goals and practices of professional science. This has meant that the relations between students' own epistemic cognition and their conceptions of the nature of science remain poorly understood (Sandoval, 2005).

Personal Epistemologies

Epistemic goals can be seen as being derived from individuals' beliefs about the nature of knowledge and knowing. The study of such beliefs is known as "personal epistemology" research (Hofer & Bendixen, 2012) and historically has been conducted largely independently of research in science education (or other subjects). Personal epistemology researchers generally argue for a developmental progression across the lifespan from an absolutist stance in early to middle childhood that sees knowledge as simple, knowable with certainty, and justified by trusted authorities, through an unmoored multiplism (or relativism) where knowledge is uncertain, authoritative sources are untrustworthy, and all knowledge claims are equally justifiable. This multiplism is resolved into an evaluative stance that views knowledge as constructed, not knowable with absolute certainty, but asserts that knowledge claims can be justified according to standards of reason and evidence. There are various lines of evidence to support the possibility of such a progression, but a range of findings, many from science education, violate predictions from current personal epistemology models.

Personal epistemology research shares with NOS research the assumption that people develop stable beliefs about knowledge and knowing that directly relate to the epistemic goals and strategies they might pursue. In the last two decades, the evidence for such stability has been sharply questioned in light of findings that the epistemic cognition people engage in appears to vary according to the context of reasoning.

Cultural Perspectives on Goals and Learning

To this point, epistemic goals have been framed solely in individualistic terms: a person's goals for constructing or evaluating knowledge claims influence their processes of construction and evaluation. Yet, in the same way that science studies have shown science to be a culturally and historically situated enterprise, the emergence of sociocultural perspectives on cognitive development and learning frame cognition as socially, culturally, and historically situated. A situated perspective on cognition directs attention away from individual mental processes and toward processes of social interaction, including the ways goals get formulated, interpreted, and pursued. This shift has implications for how epistemic cognition is theorized and how research on epistemic goals and cognition gets carried out.

From a sociocultural perspective on cognition, all knowing is situated in activity. This implies that an individual's epistemic goals within any particular situation emerge in interaction with perceived features of the situation itself and other people involved. Thus, as those features or people change, epistemic goals can change. Furthermore, from this perspective epistemic goals can be considered themselves to be collective and not just individual – individuals' participation in activity is interpreted in relation to their alignment with current goals. From this point of view, then, the forms of epistemic cognition an individual may engage are tied to these interactional, inherently social contexts and thus are not assumed to be stable features of an individual's cognitive structure. One consequence of this perspective is that people's performances on research tasks to assess things like scientific thinking or epistemic belief are themselves seen as particular social contexts instead of neutral means of eliciting stable conceptions or beliefs.

Consider the four-card problem described earlier. A sociocultural (or situated) perspective on that task would interpret "failure" on that task as a misalignment between subjects' goals in the task (e.g., to get course credit for one's participation) and researchers' goals, rather than as a stable indication of a lack of skill. Their improved performance in the contextually grounded versions of the task would be interpreted as such contexts being culturally meaningful, thus triggering epistemic goals relevant to the task.

An example within science education is research on scientific argumentation. It is a common finding that students often fail to justify how particular pieces of data provide evidence for specific claims. A cognitive explanation is that these students lack the skill to justify, whereas a sociocultural explanation is that students do not recognize that justification is necessary (and may not have knowledge of communal, i.e., scientific, standards of justification). The sociocultural perspective treats epistemic goals as socially, rather than individually, generated and therefore tends not to assume that participants in interaction share the same epistemic goals.

This means two things for epistemic goals and their influence on cognition and science learning. One is that learning science necessarily entails learning about the epistemic goals that scientists pursue and how what we casually call "scientific method" has developed in various ways to achieve those goals. This has several implications for science teaching, the most basic being that the epistemic goals of science, as a human enterprise, should become a core part of instruction. Learning the practices of science necessarily entails learning how those practices support specific epistemic goals.

The second implication from the sociocultural perspective is that research on epistemic cognition, including epistemic goals, requires attention to the contexts that individual students may find themselves reasoning in and with whom they are participating. This includes an attention to processes of interaction in ways that can illuminate how epistemic goals are nominated and taken up. It also includes acknowledgment from researchers that the means of eliciting or observing students' epistemic goals are themselves particular kinds of social interactions. Filling out a survey about the nature of science or participating in an interview about one's own inquiry project is assumed, within this perspective, to trigger different goals in participants and thus different forms of cognition. Therefore, cognition cannot be understood independently of the goals pursued by participants.

Current Questions and Issues

To summarize, there is extensive and robust evidence that individual's epistemic goals influence reasoning and learning. Epistemic goals are generated in relation to particular situations of reasoning or problem solving, and there is abundant evidence from both cognitive and sociocultural perspectives on cognition that shifting people's goals within a task shifts their reasoning. The relation between epistemic cognition, including epistemic goals, and the conceptions people have about knowledge and knowing, including scientific knowledge and the nature of science, remains unclear. There has been much research on students' reasoning during investigation, experimentation, and argumentation tasks and also much research on students' conceptions of nature of science. There is as yet relatively little research connecting these two, and epistemic goals may be the connection between the two, to the extent that conceptions of the nature of science may generate epistemic goals that reasoning practices are meant to meet.

Cognitive and sociocultural perspectives on cognition take very different views on these relations, however. Cognitive views posit knowledge and belief as mental structures that generate goals that direct the application of cognitive strategies and that these various mental structures are open to inspection. Sociocultural views theorize knowing as inextricably situated in activity and consequently tend to view observations of practice as the only meaningful indicator of what people know, discounting efforts to elicit espoused beliefs. Hybrid approaches accept the situated nature of cognition while asserting that localized cognitive structures guide reasoning. This somewhat simplistic distinction between what are, in fact, a great variety of specific theories across two broad schools of thought is intended simply to emphasize that the general perspective on cognition and development one takes has a strong influence on how epistemic goals, and epistemic cognition more generally, are conceptualized and studied.

Regardless of the perspective researchers take, several issues related to epistemic goals and their development remain open in science education. One, already mentioned, is the need to develop a better understanding of how learners' epistemic goals during their own efforts to learn science may relate to and be used to develop understanding of the nature of science. Another is how instruction can promote epistemic goals that enhance students' science learning. A third issue is understanding the epistemic goals people pursue in science-related activities outside of school, their strategies for pursuing them, and how such epistemic cognition relates to learning science in school. Epistemic goals have emerged as an important focus of science education research, and there are many avenues of research to clarify their relation to learning science and using science productively in everyday life.

Epistemology is the branch of philosophy that addresses questions involving our ideal cognitive aims and achievements, which include knowledge, justification, explanation, understanding, and wisdom. Epistemology is distinct from the two other branches of philosophy, i.e., metaphysics (which deals with questions of existence, reality, and ontology) and ethics (which deals with questions of moral value and right action). The kinds of questions considered by epistemologists include the following: What are knowledge, justification, explanation, understanding, and wisdom? Can these epistemic aims be attained? If so, how might these epistemic aims be attained? These questions thus concern our cognitive relations and access to the world and so explore the various sources of human knowledge, including perception, memory, reason, testimony, intuition, introspection, revelation, and scientific inquiry. Epistemology also addresses the legitimacy of our claims to know or be justified and so addresses questions of truth and skepticism as part of the effort to develop a coherent theory that specifies the nature, range, and limits of our knowledge.

The scope of the philosophical field of epistemology is very broad. While some philosophers (e.g., Plato) have attempted to develop a philosophical analysis (or definition) of key epistemic concepts by specifying their necessary and sufficient conditions, others (e.g., Rene Descartes) have investigated whether we do, in fact, know what we claim to know and how we are justified in taking what we believe to be knowledge. Still other philosophers (e.g., Aristotle) have focused on delimiting the epistemic virtues, vices, and values which serve to help or hinder the attainment of our cognitive goals of knowledge, wisdom, and understanding. Contemporary epistemologists (e.g., Alvin Goldman) have further focused on the causal, cognitive, social, and institutional processes that underlie knowledge production, including the distinctive methods of scientific and other kinds of inquiry. Contemporary epistemology has thus focused increasingly on both the natural and social dynamics implicated in the construction of knowledge. Naturalist epistemologists (e.g., Philip Kitcher) have thus worked to specify the reliable processes upon which knowledge production depends (including perceptual and testimonial processes), and feminist epistemologists (e.g., Lorainne Code) have explored the ways in which social values and power relations affect the creation and dissemination of knowledge (Moser 2002b).

Many of the core concepts that feature in philosophical epistemology have found a home in the work of psychologists and science educators. However, these researchers have adopted epistemological concepts in order to understand and improve actual human cognition, rather than to advance philosophical inquiry. Research psychologists working in this field have investigated human cognitions relating to knowledge and knowing, including both tacit and explicit beliefs about what knowledge is, how knowledge is obtained, and what kinds and sources of knowledge exist, as well as how that knowledge is justified by both novices and experts across a range of topics and domains. Although the target of this research has been characterized variously as epistemological beliefs, epistemic beliefs, personal epistemology, epistemological reflection, and reflective judgment, the term epistemic cognition has been widely adopted as a unifying description.

There are roughly two (somewhat overlapping) strands of psychological research in which epistemic concepts feature prominently: the developmental and the doxastic traditions. The developmental approach, exemplified in the work of William G. Perry, investigates the epistemic trajectories that characterize cognitive development, from naïve to sophisticated epistemic subjects. Researchers working in this tradition seek to understand cognitive development in terms of a progression through a predictable sequence of successive epistemic stages of increasing sophistication, from epistemic novices who adopt absolutist, dualist, or relativist epistemologies through to epistemic experts who reflectively weigh multiple perspectives (Perry 1999). The alternative doxastic approach, exemplified in the work of educational psychologists like Barbara K. Hofer and Paul R. Pintrich, focuses on a multidimensional set of relatively independent beliefs which characterize the cognition of the epistemic subject, including dimensions of the certainty, simplicity, justification, and sources of knowledge. The doxastic tradition typically uses questionnaires and factor analysis to find correlations between academic variables and scores on measures developed from these multidimensional models of epistemic cognition and to use these correlations in designing effective instruction (Hofer and Pintrich 1997). These two distinct stands of research have grown into a rich and prolific body of research that investigates human psychology using conceptual tools originally developed by epistemologists, with the goal of using psychological models of epistemic cognition to explain and predict variation in the processes and outcomes of learning and reasoning.

In light of the profusion of work in contemporary epistemology, Chinn et al. (2011) have proposed an expanded conception of the dimensions of epistemic cognition, with the goal of developing more sophisticated, fine-grained, and comprehensive psychological models. The expanded conception includes (a) epistemic aims and values (including the interaction between epistemic and non-epistemic aims), (b) the structure of epistemic achievements including knowledge and understanding, (c) the sources and justification of epistemic achievements, as well as epistemic stances including certainty and plausibility, (d) epistemic virtues and vices, and (e) reliable and unreliable processes for achieving epistemic aims. The revised framework includes both individualistic and social features of knowledge production within each component, in order to capture a richer and more fine-grained profile of the full range of epistemic commitments and dispositions of research participants. The framework also emphasizes a dual focus on epistemic cognition, both in terms of the potentially tacit epistemological commitments that people manifest through their behavior (e.g., the degree to which they demonstrate the epistemic virtue of open-mindedness) and in terms of the explicit beliefs they have about a range of epistemic concepts (e.g., their reflective beliefs about the role and value of open-mindedness in inquiry) (Chinn et al. 2011).

Work in philosophical epistemology has particular relevance for science education and research.

This is because an important goal of many science educators (e.g., Norman G. Lederman) is for science learners to develop an understanding of the nature of science, an understanding which is underpinned by an awareness of how scientific methods and processes serve to generate as well as justify scientific knowledge. These science education researchers thus investigate peoples' scientific epistemology, which involves their beliefs about how scientists, scientific processes, and scientific practices are implicated in the production of scientific knowledge.

Disagreements among science education researchers in terms of the epistemological basis of science have influenced the ways in which science education has been pursued. For example, Richard Duschl has critiqued those conceptions of science embodied in science instruction which present scientific knowledge as if it were a completed product, rather than as a tentative set of models and practices that are continually subject to critique and revision. This critique is part of a wider call for a more "epistemologically authentic" science education, in which learners engage in the reasoning and evidential practices of genuine scientists, rather than solely in the memorization of what is considered to be an accepted body of scientific facts. Differences in epistemological beliefs about the nature of science can therefore have a considerable impact on science education policy and practice.

Researchers in science education have also disagreed about the nature and structure of the epistemological knowledge that successful science learners should be able to manifest, as well as the methodology that is best suited for tracing science learners' epistemic commitments with regard to science. For some researchers, science learners' scientific epistemologies consist of relatively stable, coherent systems of explicit and general beliefs about scientific methods and knowledge. These researchers thus tend to rely on questionnaire assessments to trace learners' scientific epistemologies. For other researchers (e.g., David Hammer), the epistemic cognition of science learners tends to be fragmentary, inconsistent, and unstable, which entails that the beliefs articulated in response to questionnaire assessments might not provide much insight into the real underpinnings of a participant's actual epistemic cognition about science. Another locus of disagreement among science education researchers that is epistemologically relevant concerns how a learner's scientific epistemology is manifested in their behavior. For some researchers, like William Sandoval, a person's true epistemic commitments are revealed through their actual inquiry practices, rather than through the traditional pencil-and-paper mass assessments which tend to trace only those epistemic commitments which are subject to conscious reflection and articulation. This is demonstrated by learners (and even scientists) who demonstrate poor insight into the epistemological foundations of good scientific practice, yet who nonetheless engage in sophisticated and productive scientific inquiry. This distinction is thus between a subject's "formal epistemology" of science, involving their explicit beliefs about science and scientific practice, and their "practical epistemology" of science, which involves the often tacit commitments and dispositions that guide their actual inquiry practice. These theoretical and methodological disagreements are thus founded on different conceptions of the role and structure of the epistemic commitments that underlie good scientific reasoning, and resolving them will require grappling with their epistemological foundations.

The philosophical field of epistemology therefore represents an important resource for purposes of science education and research. Epistemologists have uncovered a host of interconnected concepts and issues which are of vital importance in bringing science learners to a sophisticated understanding of the nature of scientific knowledge and practice. In addition, resolving some of the key conceptual and methodological disagreements that characterize the field of science education research requires unpacking the epistemological fault lines that underlie these disagreements.

Ethnoscience

Georgina M. Stewart
University of Auckland, Auckland, New Zealand

Ethnoscience is a one-word conundrum, since its two parts – “ethno” and “science” – are in tension, if not outright opposition. Science is culture-free by definition: science claims to be universal knowledge, which applies equally everywhere. The prefix “ethno” has the meaning of “cultural,” so the word “ethnoscience” literally means “cultural science.” This notion of “cultural science” flouts the criteria of science and is denied by most working scientists.

Ethnoscience is a more technical form of two-word terms such as Indigenous knowledge, Native science, and many versions such as “African science,” “Maori science,” etc. This notion has been influential in education, where programs of reform in a number of countries have been based on incorporating Indigenous knowledge into the school science curriculum (Aikenhead and Michell 2011).

The concept of ethnoscience has two complementary parts: one, recognition of the basis in science of relevant parts of traditional cultural narratives and practices; the other, respect for traditional indigenous philosophies and worldviews, which explained the world in the absence of modern science tools and concepts.

The problem with the word ethnoscience (and its cognates including ethnobiology, ethnochemistry, and ethnophysics) is that its technical form obscures the political issues and philosophical debates inherent within this complex concept. Ethnoscience is of little value to indigenous people when it is understood as an alternative form of science on which culturally relevant science education can or should be based. The concept of ethnoscience reminds science of its basis in culture: as a human form of knowledge, science can aspire to, but never fully attain, the criteria for knowledge that are regarded as its essential characteristics, such as objectivity and universality. This humbling of science is the actual value for science of the vexatious concept of ethnoscience (Boyd 2001).

One example of this use of the concept of ethnoscience is the debate in Aotearoa New Zealand over “Māori science,” which led a local European New Zealand scientist to call into question the coherence of the term “Western science” (Dickison 1994). “Māori science” was concluded by Māori science educators to be, in essence, a protest against the conflation of the term “Western science” with “science” (McKinley 2001). The inbuilt Eurocentrism and elitism in the secondary school science curriculum alienate almost all Māori students, making it the most effective social gatekeeper for the professions. This is not to deny the importance of the ethnic literacy and numeracy gap in explaining the massive underrepresentation of indigenous students among those who successfully study science through to the end of school and beyond. But there is also a scientism rampant within school science, which, over and above the Eurocentric, sexist, and elitist distortions or “myths” of the school science curriculum (Hodson 1999), has “attached itself parasitically to science over the last two hundred and fifty years” (Charlesworth 1982, p. 46). Two aspects of this scientism are, firstly, the amnesia by which school science programs celebrate science’s successes but omit its failures (Benson 1989) and secondly the confusion of the aspiration to objectivity with its attainment (Aikenhead 2008).

Evaluation

Edith Gummer
The National Science Foundation, Arlington, VA, USA

The etymology of the term evaluation is quite clear, and the Old French core provides the foundation of its definition. With “value” at the core, an evaluation is the systematic process by which the value of something is ascertained. Typically, in science education, evaluation focuses on a judgment of the value, merit or worth of a person, product, plan, proposal, program, or policy. Fournier (2005) defines evaluation as an investigation that combines the collection of evidence with synthesis relative to some standard or normative judgment to result in a determination about the condition of an entity. The value element is what makes evaluation differ from assessment and what forms the theoretical grounding by which the evaluation is structured. Evaluations range from an objective, goals-focused process to an examination of the lived experiences of the participants in the context being evaluated. The Joint Committee on Standards for Educational Evaluation has developed a set of standards for student, educational personnel, and program evaluation that describe the attributes of quality evaluation in education (Gullickson 2004, 2008; Yarborough et al. 2010).

An issue of New Directions for Evaluation identified a number of key issues for evaluation in science, technology, engineering, and mathematics (STEM) education (Huffman and Lawrenz 2006). Perhaps the most controversial issue in STEM education evaluation is the premise that evaluation designs that randomly assign participants to a treatment and control group, as the “gold standard” of evaluation, use the only methodology that can determine causality in educational settings, with quasi-experimental studies a distant second. Alternatives include multi- or mixed methodological approaches to evaluation that incorporate randomized designs as an integral part of more comprehensive and methodologically diverse evaluations (Raudenbush 2005). Lawrenz and Huffman (2006) present an evaluation framework for STEM education that includes multiple quantitative and qualitative evaluation designs to examine the efforts of a project or program. These designs range from descriptions and surveys to interpretive designs based on a particular conceptual or theoretical stance, to case studies, to more correlational, quasi-experimental, and experimental designs. Evaluation designs that incorporate multiple methodologies afford the examination of a project or program from multiple dimensions.

STEM evaluation is also concerned with the issue of determining the outcomes of projects and programs on diverse audiences and cultures (Mertens and Hopson 2006; Greene et al. 2006). Evaluation designs might incorporate a perspective of social justice or cultural diversity as the lens by which to examine the value of a project, program, or policy. As new data sources for evaluation, such as local and state data systems, continue to evolve, evaluation capacity becomes an even more important issue (Huffman et al. 2006; Penuel and Means 2010).

Evaluation of Textbooks: Approaches and Consequences

Mansoor Niaz
Department of Chemistry, Epistemology of Science Group, Universidad de Oriente, Cumaná, Estado Sucre, Venezuela

Research in science education has recognized the importance of textbooks for learning science effectively. In many parts of the world, for most science teachers at the secondary, high school, and introductory university level courses, the textbook is the only source of information and guide to classroom practice. Given this widespread use of textbooks in most educational systems, their evaluation for improvement is an integral part of the research agenda.

It is important to differentiate two types of approaches related to the evaluation of science textbooks that can be classified as:

(a) Domain-general: These studies are based on a series of criteria that can be used for evaluating whole textbooks across disciplines (biology, biochemistry, chemistry, earth science, physics, other). Some of the criteria are related to nature of science, scientific literacy, inquiry, analogies, photographs, gender, comprehensibility, readability, vocabulary load, graphical information, and cultural and religious sensibility.

(b) Domain-specific: These studies are based on a historical reconstruction of a given topic of the science curriculum, and the criteria developed can only be used for that particular topic.

Domain-General Studies

Chiappetta et al. (1991) analyzed seven US high school chemistry textbooks to evaluate the following aspects of scientific literacy: (a) science as a body of knowledge; (b) science as a way of investigating; (c) science as a way of thinking; and (d) interaction among science, technology, and society. Authors found that all of the chemistry textbooks analyzed de-emphasize science as a way of thinking and do not stress the importance of how chemists discover ideas and experiment, the historical development of chemistry concepts, cause-and-effect relationships, evidence and proof, and self-examination of scientist's thinking in the pursuit of knowledge. These aspects of the scientific enterprise constitute an important part of scientific literacy.

Nature of science (NOS) as presented in five Turkish secondary school biology textbooks was evaluated by Irez (2009). Based on the literature, the following 11 themes regarding NOS were identified: description of science, characteristics of scientists, scientific method, empirical basis of NOS, tentative basis of NOS, nature of scientific theories and laws, inference and theoretical entities in science, subjective and theory-laden NOS, social and cultural embeddedness of science, imagination, and creativity in science. Based on these themes, the author also generated cognitive maps regarding NOS that provided an overall picture of how science is depicted in each textbook. Results obtained revealed that discussions regarding NOS represented a very small part of the textbooks, and science was generally portrayed as a collection of facts and not as a dynamic process of generating and testing alternative explanations about nature. Of the 11 NOS themes studied, the author considered the following to be particularly misrepresented: scientific method and the tentative nature of scientific knowledge.

Textbook analogies have the potential to become an important learning resource, as some students require alternative presentations of concepts to learn meaningfully and also serve to make the text more user-friendly. Orgill and Bodner (2006) have analyzed the use of analogies in eight US introductory university level biochemistry textbooks. In order to evaluate the textbooks, analogies were classified in the following areas: (1) content of the target concept, (2) location of the analogy in the textbook, (3) analogical relationship between analog and target, (4) presentation format (verbal or pictorial), (5) level of abstraction of the analog and target concepts, (6) position of the analog relative to the target, (7) level of enrichment (How much mapping is explicit? Is the analogy simple, enriched, or extended?), (8) analog explanation (in order to be useful, some degree of explanation is necessary), (9) indication of cognitive strategy, and (10) limitations of the analogy. Results obtained revealed that the use of analogies in biochemistry textbooks is quite similar to that of secondary textbooks in different subject areas. A major finding of the study is that none of the analogies used are completely explained, very few are identified as "analogies," and the limitations of the analogies are rarely mentioned. Of the 158 analogies found in these textbooks, only seven "limitations of analogies" were found, and 23 included a pictorial representation. It is suggested that textbook authors need to improve such aspects in order to make the role of analogies more explicit.

Stern and Roseman (2004) have analyzed nine middle school (grades 6–8, ages 12–14) curriculum materials (textbooks and teacher guides) that are widely used in the USA. These materials were analyzed by educators and scientists trained in the use of the Project 2061 curriculum analysis procedure, based on seven criteria that sought to give a comprehensive and wide in scope approach. The seven criteria are *I: Identifying and maintaining a sense of purpose*; *II: Taking account of student ideas*; *III: Engaging students with relevant phenomena; IV: Developing and using scientific ideas*; *V: Promoting student thinking about phenomena, experiences, and knowledge*; *VI: Assessing progress*; and *VII: Enhancing the science learning environment*. (See the entry *Textbooks: Impact on Curriculum* for detail of the categories.) The following topics in these materials were analyzed: kinetic molecular theory (physical science), flow of matter and energy in ecosystems (life science), and processes that shape the Earth (earth science). Materials were evaluated on the following scale: 0–1.0 = poor, 1.5 = fair, 2 = satisfactory, 2.5 = very good, and 3 = excellent. For the life science topic, on Categories I–VI (Instructional criterion), none of the textbooks were classified as excellent on any category; two textbooks were classified as very good, one on Category I and the other on Category IV; and two textbooks were classified as satisfactory (one on Category I and the other on Categories I and II). In addition to these quantitative results, the authors also provide various examples of how the treatment of photosynthesis and respiration often focuses on naming reactants and products rather than on the idea that matter and energy are being transformed into other substances or other forms of energy. Finally, the authors concluded that currently available materials are not likely to contribute to the attainment of benchmarks related to matter and energy transformations in living systems.

Domain-Specific Studies

When Thomas Kuhn directed the Project “Sources for History of Quantum Physics,” he raised a provocative question: Who first proposed the quantum hypothesis? And he concluded that it was A. Einstein who first recognized that the black body law could not be derived without restricting resonator energy to integral multiples of hν (h = Planck’s constant; ν = frequency). This historical reconstruction shows that Einstein’s formulation of the quantum hypothesis provided greater explanatory power than that of M. Planck. In other words, Planck in 1900 simply introduced an approximate mathematical quantization in doing the calculations. In order to evaluate the inclusion of Kuhn’s thesis, Brush (2000) has analyzed 28 general physics textbooks published in the USA (1990–1997). Results obtained showed that only six textbooks included Kuhn’s hypothesis with respect to the origin of the quantum hypothesis.

Based on a historical reconstruction of the atomic models of Thomson, Rutherford, and Bohr, Niaz (1998) has analyzed 23 general chemistry textbooks published in the USA. All textbooks were evaluated on eight criteria which were validated by inter-rater agreements. Results obtained revealed that most textbooks emphasize experimental details based on observations, leading to the presentation of scientific progress as a *rhetoric of conclusions* based on irrevocable truths. Such presentations in textbooks lack the conceptualizations of *heuristic principles* that led the scientists to design and interpret their experiments. For example, one of the criteria dealt with the Thomson-Rutherford controversy with respect to the single/compound scattering of alpha particles. Both Rutherford and Thomson performed similar experiments on the scattering of alpha particles, but their interpretations were entirely different. Thomson propounded the hypothesis of *compound scattering*, according to which a large angle deflection of an alpha particle resulted from successive collisions between the alpha particles and the positive charges distributed throughout the atom. Rutherford, in contrast, propounded the hypothesis of *single scattering*, according to which a large angle deflection resulted from a single collision between the alpha particle and the massive positive charge in the nucleus. This rivalry led to a bitter dispute between the two proponents. Rutherford’s dilemma was that, on the one hand, he was entirely convinced and optimistic that his model of the atom provided a better explanation of experimental findings, and yet it seems that the prestige, authority, and even perhaps some reverence for his teacher (Thomson) made him waver in his conviction. A science student may wonder why Thomson and Rutherford did not meet over dinner (they were well known to each other) and decide in favor of one or the other model. These issues, if discussed in class and textbooks, could make the presentation of science much more human and motivating. Interestingly, none of the general chemistry textbooks (Niaz 1998) presented this historical episode.

Most general chemistry textbooks consider wave-particle duality as important for understanding atomic structure. After presenting the atomic models of Thomson, Rutherford, and Bohr, textbooks present Einstein’s photoelectric effect and then Louis de Broglie’s hypothesis of wave-particle duality. Based on a historical reconstruction, Niaz and Marcano (2012) have analyzed the presentation of wave-particle duality in 128 general chemistry textbooks (published in the USA). Criteria based on the following historical aspects were evaluated: (1) Einstein and de Broglie suggested wave-particle duality before there was any conclusive experimental evidence; (2) De Broglie suggested how matter waves could be observed experimentally; (3) Importance of Davisson-Germer experiments and their struggle to interpret experimental data; (4) Role of similar experiments by G.P. Thomson; (5) Controversial nature of wave-particle duality and de Broglie's reputation as an obstacle in the acceptance of his theory; and (6) Why was it Schrödinger who developed de Broglie's ideas? Textbooks were classified as Satisfactory (S), Mention (M), and No mention (N). Results obtained revealed that none of the textbooks described satisfactorily criteria 2, 3, 5, and 6. Some textbooks described satisfactorily the postulation of wave-particle duality before there was any conclusive experimental evidence, and very few textbooks referred to similar experiments being conducted by two groups of scientists. In general, historical details are generally ignored or distorted by most general chemistry textbooks. This study provides science teachers with various historically based presentations which provide the necessary background for improving students' understanding of wave-particle duality. It is plausible to suggest that the topic of wave-particle duality can facilitate students' classroom discussions and understanding of how science progresses.

Conclusion

Evaluation of science textbooks is an important guide for their improvement. Textbook authors are generally not aware of research related to evaluation of textbooks. Studies related to both domain-general and domain-specific aspects can provide guidelines for the constant revision of science textbooks. In order to facilitate students' understanding of how science progresses and motivation to study science, the following aspects can be included in textbooks:

(a) Inclusion of scientific literacy themes, nature of science, and analogies
(b) If there is no one way of doing science, which of the following two is more important for scientific progress: experimental evidence or theoretical insight?
(c) When scientists do experiments do they always know beforehand what they are going to find?
(d) If two groups of scientists interpret the same experimental data differently, does that mean that one of them is not being sufficiently "objective"?
(e) Is it possible for two groups of scientists to use different experimental techniques and arrive at the same results and conclusions?
(f) If two theories are proposed to understand the same phenomenon, can the scientific community help to resolve the controversy?

Causal effect; Causal mechanism; Randomized experiment; Scientific research

> The special task of the social scientist in each generation is to pin down the contemporary facts. Beyond that, he shares with the humanistic scholar and the artist in the effort to gain insight into contemporary relationships, and to align the culture's view of man with present realities. (Cronbach 1975, p. 126)

Evidence-based practice in science education is the conscious, explicit, and judicious use of current best evidence to make and implement decisions. The best evidence comes from rigorous empirical research on the efficacy of interventions for improving students' science learning.

Many science education reformers look to evidence-based practice in medicine as a model. Our definition is consistent with Sackett et al.'s (1996) definition of evidence-based medical practice, and there are similarities between the fields. For example, both medicine and education face considerable organizational challenges. Organizations may not seek best practices or support continuous improvement of their processes. However, there are also important differences between medicine and education. For example, "treatment dosage" is better controlled in the former (e.g., pill, inoculation) than in the latter (e.g., curriculum, innovative practice, small class size), especially if teachers "deliver" the treatment in their own particular ways.

Three parts of our definition of evidence-based practice warrant unpacking. First, what counts as rigorous empirical research? Second, what counts in making decisions about practice? And, third, what counts in implementing these decisions? Empirical evidence alone is typically not determinative of what, in the end, is regarded as "best practice." More than empirical evidence should come into play – these include well-grounded values and beliefs; clinical or classroom norms and practices; feasibility of implementing decisions with high fidelity; time, cost, and other practical constraints; and social and cultural processes and structures. Perhaps the label suggested by Hargreaves – "evidence-*informed*" – is more apt than "evidence-*based*" decisions and practice.

Rigorous Empirical Research

Rigorous empirical education research is often translated as "scientific research" on the efficacy of alternative practices, interventions, or programs. These alternatives are typically under consideration by a decision maker (teacher, administrator, policy maker) concerned with student learning (including cognitive, intrapersonal, and interpersonal achievements).

While "scientific research" belies definition, it has a number of defining characteristics that, taken together, circumscribe it (Shavelson and Towne 2002). Scientific research poses questions that can be empirically tested, links these questions to what is already known, uses methods that permit direct investigation of these questions, provides a coherent and explicit chain of reasoning for resulting inferences, is replicable, generalizes across studies, and passes the test of professional scrutiny and critique. In the context of evidence-based practice, such research puts alternative interventions to the empirical test by bringing data to bear, ruling out counterhypotheses as to what works and why, and logically justifying conclusions with data.

Scientific research is not and should not be equated with randomized experiments; research designs should follow from the empirical questions posed. Sackett et al. (1996) made a similar point: "Evidence-based medicine is not restricted to randomized trials and meta-analysis it involves tracking down the best external evidence with which to answer our clinical questions" (p. 72).

Three generic questions might be posed in evaluating alternative practices (Shavelson and Towne 2002). The first is descriptive and asks, "What's happening?" in each alternative. To describe practices, researchers may describe student characteristics with statistical estimates, draw simple relationships between programs and outcomes, or craft rich accounts through case study or ethnographic methods.

The second question, "Is there a systematic effect?", looks for *causal* effects. To answer this question, researchers seek evidence that a given practice produces the expected outcomes and may compare practices to evaluate whether one performs better than the others. In this case, randomized experiments are considered the gold standard, as long as they are authentically, logistically, and ethically applicable, but other designs such as quasi-experimental and observational (e.g., longitudinal surveys) also serve this purpose.

The third question is "Why or how is it happening?" To find evidence of a causal *mechanism* underlying the efficacy of the practice, researchers may use a variety of methods, including in-depth observation and well-controlled experimentation.

Decisions about practice should rely on all three types of evidence although the third type is rare. Realistically only evidence-based description and causal effects are typically available. This said, Cronbach (1975) reminds us that systematic effects are context dependent, facts decay with short half-lives, and even the randomized experiments are case studies. Their generalization to new contexts – student composition, teacher competence, school policy, community characteristics, and expectations – is a matter for judgment in each new setting.

Empirical research, especially social research, is an enterprise of uncertainty. Scientific research, though not perfect (e.g., *Educational Researcher*, 2002, *31*(8), whole), attempts to reduce uncertainty (or at least measure it!) and control bias by its methods. If we are to make decisions about science education practices based on evidence about effectiveness and causal mechanisms, scientific research is the best approach. This said, other scholarly traditions such as philosophy, history, and critical theory inform decisions – making clear what has been learned in the past, what assumptions and values underlie a proposed course of action, and how political and economic power influences choice of alternatives. Evidence-based practice, then, is dominant among multiple factors in determining best practice.

Decisions About Practice

Decisions about educational practice are complex. They involve multiple values and goals; are influenced by interacting social, historical, economic, and political forces; and always require trade-offs. In the best of all worlds, they are rational or at least reasonable. Rigorous empirical evidence is essential, but not sufficient. Education-practice decisions are local and practical, and – perhaps most important – they are made even though there is rarely enough evidence to clearly dictate a specific choice; they are always made with uncertainty.

Nevertheless, evidence has an important role to play in challenging the tendency to rely on familiar experience, popular wisdom, and intuition in decision making. In Michael Lewis's 2003 book *MoneyBall*, rigorous research and data analysis demonstrated that previously undervalued empirical measures ("on-base percentage" and "slugging percentage") were better indicators of success in scoring in baseball than traditionally used indicators such as running speed and bat contact. The team that used these different measures (the Oakland As) found that players with these qualities were cheaper to obtain than those in high demand because of their traditional qualities. And it worked. The As retained some high priced star players while recruiting less expensive but highly productive players to balance out the team. They put together a record winning streak and a winning season. "What works" in baseball subsequently refocused how teams recruit and overcame long-standing traditions rooted in intuition and folk wisdom rather than have an evidence base. The same is likely to apply in many situations in education.

Implementation

Decisions occur at all levels of science education – teachers, administrators, and policy makers. At all levels, empirical data need to be transformed into evidence bearing on alternative practices or interventions. This is no easy step. Even more difficult is transforming evidence into effective action. While teachers may be aware of research "out there," they seldom use it in their own practice; even if they use research, they are rarely adept at transforming scientific statements into practice (Millar and Osborne 2009). Indeed, there is a wide research-practice gap in education, and while a variety of bridging techniques hold promise for teachers, they are mostly untested on a large scale. These techniques include, for example, translating research into teaching materials or activities and testing research locally through lesson study, action research, and design research. Such techniques require expertise, resources, and commitment of a level and type for which American public education is not set up.

Similar challenges confront policy makers and school and district administrators. Policy decisions grounded in evidence-based practice are made at a distance from the classrooms in which they are implemented. Large-scale enactment of evidence-based practice in an education system with wide variation in teaching is vulnerable to inconsistent implementation. Indeed, the apparently same intervention implemented across different sites may actually vary considerably across the sites.

In *Moneyball*, the use of rigorous research came up against institutional realities. Those opposed to the new approach argued against trading star players who were underperforming based on the evidence but were nonetheless considered outstanding by the stakeholders – the fans, team, and baseball generally. Making decisions based solely on the "scientific evidence" would be "hard moves to explain to people." Evidence-based practice – in baseball, medicine, or science education – involves the use of rigorous empirical research in making decisions. Yet, making and implementing decisions is necessarily more complex, taking place in messy realities that demand consideration of practical constraints and other information.

Evidence-Informed Practice in Science Education

John Leach
Centre for Education and Inclusion Research,
Sheffield Hallam University, Sheffield, UK

Many researchers, practitioners, and policymakers share the view that science education research should play a role in improving practice. It is, for example, often claimed that theoretical and empirical research insights ("evidence") have been drawn upon to inform the design and evaluation of curricula, teaching sequences, and activities in science education, as well as the sequencing of content in science curricula and programs ("practice"). In discussing the relationship between research and practice, it is useful to draw a distinction between the contribution of research to the design of instruction and the role of research in the evaluation of instruction (and hence in providing a warrant for recommending an action or approach). The term *evidence-informed practice*, or *research evidence-informed practice*, refers to educational practices where research evidence has been used explicitly to justify decisions. Educational practices include the design of curricula, textbooks, pedagogical activities, teaching sequences, and learning environments. The term *evidence-based practice*, or *research evidence-based practice*, refers to educational practices that have been shown to be in some sense better than other educational practices through empirical research and whose use is therefore warranted by research evidence about its outcomes.

The Historical Development of the Literature and Predominant Themes

Research on the development of people's understanding of physical and biological phenomena as a result of living in the physical and social world, and their understanding of scientific content following deliberate teaching, has been the focus of research at least since the pioneering work of Piaget and Vygotsky in the early part of the twentieth century. From the 1960s, perspectives on science learning were formulated and used to inform curriculum decisions about science, as well as the design of science teaching activities (e.g., Ausubel's *meaningful learning*, various formulations of *constructivism*, models of *conceptual change*, and *sociocultural perspectives on learning*). From the 1970s to the 1990s, a large number of empirical studies of children's, and other learners', explanations for physical and biological phenomena were conducted. These provided empirical evidence about the likely conceptual starting points of science learners when introduced to formal scientific content through teaching and how their understandings developed as a result of teaching.

During the second half of the 1980s and 1990s, the focus of research moved toward considering how empirical evidence about science learners' existing knowledge, as well as theorizations of science learning, might be used to inform decisions about the practice of science education.

Two important considerations are the *focus* of practice that research evidence has been used to inform and the *grain size* at which practice is informed. Research evidence (including both theoretical and empirical insights) has been used to focus upon decisions about the aims of teaching (such as the potential benefits to science learning of direct instruction about aspects of the nature of science), the sequencing of the curriculum and age placement of topics, and overall pedagogical approach in science education. Decisions about these have been at both a *large grain size* (such as the use of "inquiry" as a pedagogical method in science classrooms or the age placement of specific topics in national science curricula) and a *fine grain size* (such as the detailed specification of content aims and pedagogical approaches for teaching a specific science topic to learners at a given age and stage in their education). The same research evidence may be used with more than one focus and in interventions of different grain size.

A Focus on Decisions About Pedagogical Approaches in Science Teaching and Age Placement of Topics (Large Grain Size)

Jean Piaget's account of the development of reasoning in children was very influential in science education in the second half of the twentieth century. Piaget portrayed the development of children's reasoning in many areas, including their reasoning about physical and biological phenomena, in terms of the development of general logic-mathematical reasoning capability (*genetic epistemology*). Piaget proposed broad developmental stages through which all children progressed in a process of intellectual maturation (*stage theory*). Piaget's genetic epistemology and stage theory have been used by science educators with a focus on the age placement of content in science curricula from the 1960s in both North America (e.g., the Biological Sciences Curriculum Study) and the UK (e.g., Science 5–13). The approach used involved analyzing science curriculum content for the logic-mathematical reasoning skills that would be required for comprehension. Content was then placed into the curriculum so it would be taught when most students would be mature enough to learn it, according to Piaget's stage theory. During the 1990s in the UK, the *Cognitive Acceleration through Science Education (CASE)* project drew upon Piaget's genetic epistemology and proposed an approach for developing the reasoning of adolescents by teaching general logic-mathematical reasoning skills in science lessons.

Challenges to Piagetian perspectives on the development of reasoning, and their use to inform decisions about formal education, became prominent following the publication in 1968 of David Ausubel's *Educational Psychology: A Cognitive View*. Ausubel proposed that a learners' grasp of conceptual content, rather than their general reasoning abilities, determined their success or otherwise in learning in a given conceptual area. Drawing upon Ausubel's domain-specific view of learning, perspectives on science learning (e.g., *constructivism*, *conceptual change*) were advanced from the 1970s onwards. These were used to focus on the design of science pedagogy at a large grain size. For example, Posner, Strike, Hewson, and Gertzog portrayed science learning as conceptual change and made suggestions about pedagogy such as how anomalous data could be used to promote conceptual change. Driver and Oldham drew upon a constructivist perspective of science learning to advance a "constructivist teaching sequence." However, in common with much work in the early 1980s, both pieces of work tended to theorize the overall orientation of the teaching rather than details of particular activities at a fine grain size.

More recently, there have been calls to move the focus toward a theory of instructional design, rather than starting with a perspective on learning and then considering its implications for teaching. For example, in 2001 Oser and Baeriswyl proposed a theory of instructional design, based upon the sight structure of lessons (i.e., the concrete activities of students) and basis models of lessons. Basis models refer to activities to promote specific mental processes in learners such as becoming aware of what they already know about a subject. In common with the approaches discussed in the last paragraph, the design of specific teaching sequences at a fine grain size is not addressed.

All of the above research rests upon perspectives that portray science learning as involving the *acquisition* of something (such as scientific concepts or logic-mathematical reasoning skills) in the cognitive system of the individual learner. Perspectives which portray learning as a process where learners become able to *participate* in a social practice have also been drawn upon to inform the overall design of science learning environments. Researchers and designers in North America, working in the field of *the learning sciences*, have been influential in suggesting how theoretical insights about learning can be used to influence the design of science learning environments. The term "learning environment" refers to all aspects of the setting where science learning is to take place, including the resources available and the nature of the tasks that students will undertake. Such work involves or advocates the building up of learning environments over extended periods of teaching lasting for several lessons as a minimum, for the teaching of a range of science content.

Perhaps the most influential proposal for science learning environments arising from sociocultural perspectives on learning is that *inquiry* should be used as a pedagogical approach. Inquiry involves students in learning through activities that are in some sense authentic to the actual practices of professional scientists. For example, learning might take place in contexts where some problem definition is required, as part of teams with shared responsibility for making progress, with accountability to disciplinary norms. In the literature on inquiry as a pedagogical approach, the primary curriculum focus is often upon learning about aspects of the norms and practices of science rather than any particular substantive conceptual content.

The framework of *Productive Disciplinary Engagement* (PDE) was proposed by Engle and Conant in 2002 to specify more precisely how learning environments might be designed to enhance students' science learning. PDE is achieved by promoting 4 principles in the design of science learning environments, namely, ensuring that students have ownership of a scientific problem, giving them authority to address the problem, ensuring that they are responsible to others and to disciplinary norms in coming up with solutions, and making appropriate resources available for students to address the problem. However, there are as yet no published examples of the use of PDE to promote students' understanding of the substantive conceptual content of science.

Around the turn of the new millennium, the National Research Council in the USA brought together a group of experts to provide a bridge for practitioners between the available evidence on learning and the practice of teaching. The products of this work were published in the 2005 book *How People Learn: Brain, Mind, Experience and School* and are summarized in three principles together with a framework of 4 "lenses":

Principles

- Engaging prior understandings
- The essential role of factual knowledge and conceptual frameworks in understanding
- The importance of self-monitoring (i.e., metacognition)

Framework

- The learner-centered lens (encouraging attention to students' existing knowledge and beginning instruction with what students think and know)
- The knowledge-centered lens (focusing on what is to be taught, why it is taught, and what mastery looks like)
- The assessment-centered lens (emphasizing the need to provide regular opportunities for both teacher and students to reflect on the progress of learning)
- The community-centered lens (encouraging a culture of questioning, respect, and risk-taking)

The principles and framework of *How People Learn* were developed by drawing upon both acquisition and participation metaphors for learning and empirical evidence about how individual learners think about particular problems. They provide guidance on the design of learning environments at a large grain size.

A Focus on Decisions About Pedagogical Approaches and the Sequence in Which Ideas Are Introduced in Teaching (Fine Grain Size)

There is also a significant literature on the use of evidence to inform the practice of science education at a finer grain size, including the design of pedagogical approaches to "teach x" to students of a given age and stage in their science education, where x is a specific piece of scientific content. Such research is usually named with some form of the word *didactics* in (non-Anglophone) European languages and addresses questions about what content to teach, why to teach it, who to teach it to, and how ideas should be introduced and built upon in short teaching sequences. During the 1980s, research programs were developed in centers around the world where an important research aim was to develop research evidence-informed practice about "teaching x" (e.g., the works of Fensham, Gunstone, White, and colleagues in Australia; Bell, Freyberg, and Osborne in New Zealand; Lijnse and colleagues in the Netherlands; von Aufschnaiter, Duit, Fischer, Niedderer, and colleagues in Germany; Tiberghien, Séré, Viennot, and colleagues in France; Driver and colleagues in the UK; Arons, Clement, McCloskey, McDermott, Minstrell, and others in the USA). During the 1980s, a number of longitudinal studies of how individual students developed their understanding of scientific phenomena through a program of teaching were also conducted.

These programs of work led to two fundamentally different kinds of product. The first were detailed empirical and theoretical accounts of students' reasoning in various domains of science content learning (together with guidance about practice, including the most appropriate and feasible aims for teaching particular scientific ideas to students of different ages and at different stages of science education, and the most rational approach to introducing linked ideas in teaching sequences). The second product was materials to be used to teach content to students and assess their progress. These research programs were initially developed in several different languages, with the consequence that the development of theory and terminology across research programs was somewhat limited.

From the 1980s until the present day, several approaches to designing and evaluating pedagogical approaches to "teaching x" have been elaborated and refined. The theoretical and methodological basis of approaches has, in some cases, been developed across science and mathematics education. In 2003, a themed issue of the journal *Educational Researcher* presented work from the design-based research and learning sciences communities in which the primary focus was typically to produce sequences of teaching activities together with a domain-specific instructional theory specifically to inform the process of design (Educational Researcher 2003; Leach and Scott 2008). Various authors of papers in the themed issue noted that their approach involved *implementing* an existing design, rather than the process of *generating* the design itself. Authors also noted the difficulty of communicating the outputs of design-based research, with the result that academic outputs targeted at mainstream educational research audiences tended to focus on methodological and conceptual issues rather than substantive products. They also noted that the design process (as well as the designed teaching itself) is always underdetermined by theoretical insights. A more recent collection, edited by Kelly and colleagues (2008), presents further work from the learning sciences community

In the Netherlands, *developmental research* was proposed by researchers in the Freudenthal Institute for Science and Mathematics Education at Utrecht University. The approach involves the production and refinement, through successive iterations of design and implementation, of "teaching scenarios" with the intention that they are progressively improved in "didactical quality." *Educational reconstruction* was developed at the Leibniz Institute for Science and Mathematics Education (IPN) at Kiel University, and at the University of Oldenburg, in Germany. Educational reconstruction involves reconstructing scientific concepts for the purpose of education, by developing links between scientific concepts about phenomena, and learners' everyday reasoning about the phenomena described by those concepts. Educational reconstruction has been used to inform the development of teaching sequences in various content areas of science, as well as to inform the presentation of material in textbooks. Working in Paris, Viennot and her colleagues draw upon empirical evidence about science students' characteristic ways of thinking about a given content domain in physics, as well as the historical development of physics concepts, in the design and evaluation of detailed teaching approaches in physics. Other researchers in France have developed various theoretical tools to inform the design of mathematics and science teaching on the basis of an *anthropological theory of knowledge*. These include the *theory of didactical situations* and *didactical engineering*. These theoretical tools have been used in the design and evaluation of teaching about various scientific concepts, particularly by Tiberghien and her colleagues working in Lyon.

Some work at a fine grain size has focused on assessment as a tool for stimulating changes in teaching, rather than proposing specific teaching interventions. The *Force Concept Inventory (FCI)* in the USA was developed from detailed empirical insights about students' characteristic ways of explaining phenomena, where physicists' explanations draw upon the concept of force. The FCI has been used as both a tool for formative assessment and a stimulus to teaching approaches. Along similar lines, Millar and colleagues in the UK have produced detailed formative assessment items drawing upon empirical evidence about students' explanations in various areas of science.

Much of the evidence used to focus on the design of teaching at a fine grain size has also been used at a larger grain size to focus upon overall design aspects of the science curriculum. For example, many curriculum documents claim that evidence about students' likely conceptual starting points at the beginning of teaching of specific science topics was used to inform curriculum decisions. By the mid-1990s, several studies of the *conceptual trajectories* or *learning trajectories* followed by individual learners had been completed around the world; claims have been advanced that evidence from these has been drawn upon to inform decisions about the age placement of topics. However, due to the fact that examples were produced in various languages, and the length restrictions of academic journals, the details of how this was done tend not to be included in publications.

In a recent paper synthesizing literature on research evidence-informed approaches to teaching science and mathematics content at a fine grain size (included as further reading), Ruthven and colleagues (2009) suggest that three different types of theoretical insights have been used:

- *Grand theories* about learning or epistemology (such as Piaget's genetic epistemology; Bachelard's theory of the development of knowledge) provide an overall orientation to the aims and desired outcomes of educational practice.
- *Intermediate frameworks* (such as the theory of didactical situations or a social constructivist perspective on learning science in formal settings) are developed from grand theory and other influences (such as empirical evidence about students' likely conceptual starting points in a given content domain) to inform an educational practice (such as designing pedagogical approaches to "teaching x" at a fine grain size).
- *Design tools* are developed from intermediate frameworks to inform design decisions at a very fine grain size.

The design tools *knowledge distance* and *modeling relations* were developed by Tiberghien and colleagues to inform decisions about the scientific knowledge to be taught and the relationships between knowledge that need to be made explicit during teaching, respectively. Leach and Scott elaborated an intermediate framework entitled *a social constructivist perspective on science learning to inform science teaching in formal settings*, with the specific aim of informing the design of teaching scientific content at a fine grain size. They developed the design tools *learning demand* and *communicative approach* to inform, respectively, the specification of science content goals for the purpose of teaching and the "staging" of pedagogical activities in the classroom. Research evidence-based teaching sequences have been designed and implemented, with evaluation focusing on both the success of the teaching sequence in achieving its specified aims, and the success of students in understanding the conceptual content that the teaching focused upon, compared to their peers following the school's conventional approach.

The research outlined above was developed in parallel, with few attempts to integrate products of the research cumulatively. When examining the literature on "teaching x," it is striking how many papers state that it is not feasible to specify fully the products of the research in academic papers. There are at least two possible reasons for this. The first is the difficulty of communicating the findings of research on "teaching x" at a fine grain size, particularly when the curricula in different countries include different scientific content at different ages and stages of education. Secondly, insights from the research are often embedded in materials to be used in practice, rather than written down for the purpose of communication between researchers and designers.

Excursions

Jennifer DeWitt[1] and Martin Storksdieck[2]
[1]King's College London, London, UK
[2]National Academy of Sciences, Washington, DC, USA

While excursions can take many forms and extend over a range of time periods, here excursions are defined as one-off school visits, generally lasting a single day or shorter, to informal science settings, particularly locations such as museums, nature and science centers, zoos, aquaria and botanic gardens, local and state parks, planetaria, or science fairs and festivals. The traditional excursions, or field trips, need to be distinguished from other forms of out-of-school learning, such as service learning, citizen science, and ongoing experiences like science clubs or tending a school garden that provide sustained and repeated opportunities for engagement and learning. However, many of the points made below about learning outcomes, factors impacting learning from field trip experiences and the ways in which informal science education experiences during organized excursions can support learning, are applicable to a wider range of settings and types of experiences (e.g., visits to amusement parks).

Excursions offer a range of features that distinguish them from classroom lessons and that may contribute to a range of desired learning outcomes. For instance, they can allow for increased student interaction and responsibility. They also provide exposure to novel experiences and authentic objects. While they can (and oftentimes have to) link to the school curriculum, they also support engagement with new content, contexts, and experiences – and familiar content presented in ways not necessarily possible in the classroom. Put differently, they are not necessarily "better classroom experiences" but rather offer valuable opportunities to complement or extend classroom learning. Indeed, excursions are perhaps most supportive of learning when they are connected to school experiences via pre- and post-visit activities.

Learning Outcomes

Decades of research on school field trips has investigated ways in which these experiences can lead to learning and has explored different types of learning outcomes and conditions that maximize this learning. The original focus of much of this research was on cognitive or conceptual gains, based on perceptions that field trips had to be competitive with classroom instruction in order to be of value. While such experiences can certainly lead to cognitive outcomes, such as understanding and knowledge of facts and concepts, these gains are often quite small and dependent on the degree to which students were readied to engage with content and on designing field trips to focus heavily on specific learning goals. Evidence suggests, however, that school trips are often better suited to reinforcing, or even extending, existing understanding, rather than introducing new concepts. There is also emerging evidence that field trips could provide the foundation for future learning. That is, exposure to a concept during a visit, particularly if experienced directly, can increase the likelihood of deeper learning about this concept when it is reencountered in another environment, such as a classroom.

While major and measurable cognitive gains tied to scientific concepts are difficult to achieve during the short time span of most excursions, other important outcomes are more likely to occur, including exposure to and awareness of ideas or even the trip setting and a range of what are now increasingly being referred to as "21st Century" skills: affective outcomes and social outcomes such as inter- and intrapersonal learning. Indeed, research has documented that school trips can be positive affective and social experiences for students (and teachers), leading many in the field to advocate for the value of these visits in encouraging motivation and sparking interest, as well as supporting exploration and social interaction, both among students and between students and teachers. In addition, extensive research in learning and psychology has highlighted the way in which motivation (especially intrinsic) and interest can lead to conceptual gains. Thus, although school trips may not provide ideal conditions for introducing new concepts to students, they can certainly support even new learning indirectly.

Factors Impacting Learning

There is a variety of factors that can impact the effectiveness of excursions as cognitive, affective, or social learning experiences. For instance, the novelty of a setting can distract from learning as students orient themselves in an unfamiliar environment, highlighting the importance of an orientation prior to the trip. Another important element that can influence what individuals learn, especially cognitively, from a school visit is their prior knowledge about topics and concepts encountered on the trip. When the exhibits and programs encountered connect to and build upon this previous knowledge, learning is enhanced. Making these connections can be difficult, due to the wide range of previous knowledge and experience visitors bring, but teachers can help students to make them if they themselves know what to expect during the field trip and have opportunities to prepare students accordingly.

Another key feature of school trips involves social interactions, among students and between teachers and students (and chaperones, explainers, or docents). This aspect of excursions is memorable and highly valued by students, and interactions – such as small group work and discussions – can contribute significantly to learning, affective, cognitive, and social. Learning is further enhanced when these school visits are responsive to the interests, motivations, and agendas of students.

The Role of Structure

Structure is another key element influencing learning from excursions. Generally, structured experiences (i.e., guided tours, worksheets, specific detailed tasks) can increase cognitive or content learning but often dampen interest or other affective outcomes. However, recent research suggests that well-designed resources, including worksheets, can support both cognitive and affective learning. Worksheets are more effective learning tools when they allow for free-choice exploration; encourage observation, exploration, discovery, and discussion rather than explanations and answers; connect to the curriculum; and focus on objects rather than labels. Field trips are most likely to connect the cognitive, affective, and social domains of students when constructed as opportunities for original experiences and discovery and are least likely to do so when they simply mimic the classroom environment.

Accordingly, a moderate amount of structure seems most likely to maximize the learning potential of field trips. A recent study found that visits offering limited choices to students – involving a structured task but simultaneously allowing some choice and control in exploring a setting – were more engaging than either highly structured or unstructured visits. "Limited choice" trips also seemed to support content learning, encourage deeper involvement, and promote social interactions. Highly structured or mostly unstructured field trips tend to miss building on the opportunities of an out-of-school setting.

The structure of an excursion extends beyond the visit itself to incorporate what happens prior to and following a visit. Although it can be very difficult for teachers to provide extensive preparation and follow-up, research highlights that pre- and post-visit activities in the classroom are critical to maximizing the cognitive, affective, and social learning that can field trips can provide.

Teachers and Schools

Teachers play a critical role in the success of school trips as learning experiences. In order to support learning, teachers have been encouraged to (a) become familiar with the trip setting prior to the visit, (b) orient students to the setting and clarify learning objectives, (c) encourage at least some free exploration during the visit, (d) plan curriculum-related activities that also take advantage of unique features of the trip setting, and (e) implement pre- and post-visit activities to support and reinforce the visit experience.

Although teachers generally want to maximize the learning opportunities offered by school trips, implementation of the recommendations above is curtailed by the contextual and institutional constraints they face, such as time, testing regimes, demands for explicit curricular connections, and other logistical restrictions, and is also hampered by lack of appropriate expectations and pedagogical vision for the affordances that field trips can provide. Consequently, it is argued that informal science institutions have an important role to play in facilitating good practice among teachers, particularly via the provision of resources. Such resources may be constructed in a variety of formats (e.g., web or paper based) and should facilitate behaviors likely to support learning, such as discussion. However, in order to be utilized by teachers in the first place, they should be codeveloped with teachers and with the teacher's context in mind – including their goals or objectives for the visit, their current practices on visits, curriculum requirements, and logistical hurdles. For instance, even when teachers recognize that the trip setting offers unique opportunities for learning, they may be unsure as to the best way to capitalize on those opportunities or to construct rich opportunities for learning and discovery that are clearly tied to the school curriculum.

Nevertheless, there is an ongoing debate in the field as to whether institutions should connect their programs, activities, and exhibits to the curriculum or whether they should focus on their unique affordances. It would seem that, as with the degree of structure, an intermediate solution is most likely to be effective. That is, in order to support teachers in maximizing the learning opportunities, both cognitive and affective, offered by excursions, supporting resources should both highlight the new and connect to the curriculum while respecting the contextual issues faced by teachers and schools. More importantly, rather than recreating school-based learning, out-of-school settings should provide curriculum-relevant experiences that focus on their unique affordances of material, places, or expertise.

Benefits to Science Education

A substantial body of research on school trips has repeatedly indicated that even short-duration excursions can support learning, both cognitive and, especially, affective. Informal educators and teachers alike value these experiences for the opportunities they provide to enhance motivation, spark interest, and encourage social interaction and to access original and authentic settings, objects, and experiences. Learning on and from excursions and field trips is not simply an extension or improvement on classroom lessons, but is an important complement to school instruction and a way to prepare students for future learning experiences. At the same time, in order for the benefits of school trips to be fully realized, it is critical that informal institutions support and scaffold good teacher practices around these experiences.

Finally, although there is considerable evidence of the benefits for science learning provided by excursions, documenting long-term impact continues to be a challenge for the field, though some studies on long-term memory, seeking subsequent reinforcing experiences, or preparation for future learning suggest that field trips can have lasting impacts. Long-term impacts from short-duration field trips are certainly difficult to measure and likely to be idiosyncratic and given the nature of learning as incremental and resulting from the interweaving of many experiences over time, hard to attribute to a specific past experience. Nevertheless, both short- and long-term impacts on learning are most likely when visits are linked to classroom instruction and supported by pre- and post-visit activities.

Experiments

Robin Millar
Department of Education, University of York,
Heslington, York, UK

Keywords

Intervention; Hypothesis testing; Practical work

The word "experiment" is used in different contexts to mean different things. School pupils, in the UK anyhow, often use it to mean any practical activity that they undertake in a science lesson. Teachers and science educators often talk about "experiments" in a similarly general way. Practical activities used in science teaching, however, differ widely in their aims and purposes and not all are "experiments."

The philosopher of science, Ian Hacking (1983), characterizes an experiment as an intervention – where someone (a scientist or a school student) does something in order to create a phenomenon that can then be observed, either qualitatively or quantitatively (by making measurements). This contrasts with situations where data are collected by observing an event or phenomenon that is happening anyhow. In some sciences (physics, chemistry, some aspects of biology), experiments are the dominant form of investigation. In other sciences (astronomy, geology, ecology, paleontology), data are obtained principally (or entirely) by observation; no intervention is necessary (or, indeed, possible) to create the phenomenon of interest.

An "experiment" in this sense does not have to be carried out in a laboratory; it might be undertaken in the field, or in a classroom, or kitchen, or playground. The key criterion is not where it takes place but whether you have to do something to create the phenomenon you are interested in and hence generate data, or can simply observe what is happening, or what exists, anyhow. This usage is quite close to the everyday sense of an "experiment" as "trying something out to see if it works," or perhaps simply "to see what happens."

The word "experiment" is, however, often used with a more specific meaning – as a procedure carried out to test a hypothesis. Carey et al. (1989), for example, used a teaching intervention to encourage middle-school students in the USA to move toward seeing an experiment as a test of a hypothesis. Duveen et al. (1993) similarly sought to encourage students to think of scientists using experiments for "testing explanations," rather than for "making discoveries" or "making helpful things." The principal aim behind this sort of work is to help students appreciate that experiments are purposeful, not simply speculative actions "to see what happens." A hypothesis-testing perspective reflects the centrality of theory and explanation in science and may help to develop students' understanding of the relationships between data and explanation.

Nonetheless, we should perhaps acknowledge that many of the practical investigations which scientists undertake are not designed to test a hypothesis. This is particularly true when a scientist is investigating a new topic or area which is not yet well understood. But it is also the case in more established areas of science. The work of Franklin, for example, to take X-ray diffraction images of DNA that were critical underpinning for Crick and Watson's proposal that the molecule had a double helix structure certainly involved an intervention (the data had to be generated; they were not there waiting to be collected). Taking a diffraction photograph could be regarded, in Hacking's terms, as an "experiment," but could not really be said to be testing any hypothesis. Many other similar examples could be cited.

The word "experiment" also has a rather specific usage in social science – and one which is closer to the "hypothesis-testing" sense of the word. Here an "experiment" means a research study that involves comparing one group that has had a particular experience or "treatment" (the experimental group), with another (the control group). The purpose of an experiment is to provide evidence that a specific factor (the thing which is different for the experimental group as compared to the control group) has, or does not have, an effect on a particular outcome. A classic paper by Campbell and Stanley (1963) discusses the range of experimental designs that can be used in research on teaching and their strengths and weaknesses.

A range of meanings, and nuances of meaning, of the word "experiment" suggest that, in science education research, it may often be better to use a different term (such as "practical work" or "practical activity") to describe the thing we are interested in. If the word "experiment" is used, it may be helpful to say explicitly what it is being taken to mean.

Explainer

Paola Rodari
Trieste, Italy

Explainers, educators, facilitators, mediators, pilots, guides, helpers, science communicators, whatever their name is in the different institutions, these professionals have an essential role in science centers and museums, as well as in the informal learning programs of natural parks, botanical and zoological gardens, aquaria, etc. Often they are the only human, direct interface between the institutions and the public, so being the key element in determining the quality of visitors' experience. Students and young researchers are employed in a similar role in science festivals and outreach activities of research institutes and universities, so that all around the world those human interfaces have a relevant impact on the whole of science and technology public engagement.

Explainers have a wide range of tasks: they greet the visitors; guide them through permanent galleries, temporary exhibitions, open-air promenades, or open-day stands; provide information and help people interpret what they see; and run science shows, scientific demonstrations, and interactive workshops. In hands-on exhibitions, they stand near the exhibits ready to facilitate visitors' interaction and learning. In conservative museums, they help visitors to make sense of the displayed objects. More recently, explainers have also been the facilitators of discussions on controversial scientific issues, in the context of science cafés, board games, role-plays, scenario workshops, or other participatory formats.

But who are they? Is there a clear definition of their role and tasks? How are they selected and trained? Which kinds of contract link them to the institutions? In which kinds of internal organization structures are they placed? And do the answers to those questions differ depending on institutions and/or countries, or are they shared at large?

For many years, explainers' presence has been largely taken for granted and little reflection given to their role in facilitating science and technology public engagement. Institutions such as the Exploratorium of San Francisco have promoted for decades the internal explainers professional development, experimenting with effective and innovative training schemes; but, besides those best practices, only a very small number of studies and surveys has explored their professional role and status. In the last few years, however, greater attention has been given to these practitioners, and the issues related to their professionalization have started to be discussed in congresses and highlighted in papers. More important, reflections and practices are more and more shared among an enlarging, international community.

Most explainers are doing this work as a temporary job while completing their studies or waiting to find another job. The temporary nature of the work determines in many cases the nature of the contracts: many explainers are paid by the hour, generally receiving a low salary (Rodari and Merzagora 2009). This precarious status (young age, rapid turnover, low salaries) is probably the cause, in many situations, of an insufficient investment in their training. But a recent study shows that more and more explainers are on the contrary not so young, have a strong scientific background, and tend to stay in the job for longer periods, if not for their whole working life (Richard and Barrett 2011). On the other hand, the temporary nature of the explainer's position is not necessarily negative. Working as an explainer is an extremely gratifying experience, allowing young people to transmit their passion for science in the direct contact with various audiences (Bailey 2006; Rodari and Merzagora 2009). This experience, and the acquired communication and teaching skills, will be of use in the future when the explainers become researchers, professionals, or teachers, a job's side effect exploited in some international experiences. The Slovenian science center Hisa Eksperimentov, for example, trains and employs university students of the University of Ljubljana, as a recognized part of their degree course. In the USA, the Science Career Ladder program of the New York Hall of Science provides meaningful work experience as explainers to high school and college students, as a way to engage them with science in the perspective of a scientific career. Those pupils and students, acting as explainers, become also science ambassadors for their peers and for “hard-to-reach” audiences, therefore being a precious tool for a better social inclusion.

For those explainers who wish to progress within their institutions, there are rarely well-defined career paths. Possible exceptions are the UK and the USA, where, also in the absence of a clear profession recognition, many people who started to work as explainers are later given major responsibilities in the education or exhibitions departments.

The majority of institutions do not organize a proper training course for explainers when they enter into service, or they merely hold short introductory meetings (Rodari and Merzagora 2009; Richard and Barrett 2011). In most of the cases, the training consists only in the so-called “shadowing,” i.e., the young explainer following and then imitating a senior colleague. Theoretical training in science communication and informal education is almost always missing (Tran and King 2007).

The lack of thorough practical and theoretical preparation makes it difficult to come up with a clear definition of the role of explainers and means that they lack a common language with which to speak about themselves: “It happens ordinarily that someone asks me ‘what is your job?’. I can describe my job but I don’t have the word for my job. There no words: I’m not a teacher, I’m not a researcher, I’m not a guide.” For some, the only way to define themselves is to describe the place where they work: “I work in a science center” (Merzagora and Rodari 2009). In addition, it becomes just as difficult to construct a reference system to assess the performances of explainers and their impact on the public (Tran and King 2007).

Not only the names given to the explainers are various in the different institutions (Rodari and Xanthoudaki 2005), but also the structures in which they are organized can vary. In some institutions people who design activities and people who deliver them are different. In others, the same people are in charge of all tasks.

Despite the local differences, lack of training, and lack of a common theoretical background, explainers identify strongly as a group, even when they come from institutions that are far apart geographically, economically, and culturally (Bailey 2006; Tran and King 2007; Rodari and Merzagora 2009; Richard and Barrett 2011).

The growing awareness of explainers’ importance in the public engagement of science has stimulated many action/research projects aiming at the identification of their training needs (http://www.dotik.eu; http://www.thepilots.eu; http://www.dialogueacademy.org.uk/). The professional profile of the explainers is emerging as incredibly complex.

To work as an explainer requires, besides a good scientific and technological understanding, many and various communication skills, so these skills are prioritized during staff selection. In order to perform demonstrations and science shows, explainers need the body and voice control of an actor and the ability to attract visitors’ attention with meaningful, spectacular experiments organized in well-prepared scripts. In other contexts, such as leading workshops or on-floor dialogues with the visitors, the explainers need considerable flexibility and creativity, to react to changing situations, diverse people, and unexpected events. Being the leaders of the activities, the explainers must be able to leave the stage as much as possible to the public. A good explainer “does not explain” but promotes interaction from the visitors or even, ideally, induces “some kind of ‘scientific behavior’: observation, questioning, manipulation, experimentation, critical evaluation of statements and answers” (Gomes Da Costa 2005). Today, explainers are asked to facilitate *inquiry-based learning* activities that require sophisticated relational and pedagogical skills.

Activities must be adapted to the different audiences, so that the capacity of listening and understanding people is essential, as well as the management of cultural differences (ethnic, religious, ideological, socioeconomic, etc.). Explainers are asked to promote respect and understanding among different cultures, stimulating communication among different communities: “In serving as liaison, cultural broker, and experimenter, the educator is ‘in’ the crossroads of staff and community exchanges that contribute to deepening civic engagement” (Henry 2006). Following a general development of the museums’ mission, the focus of explainers’ work is switching from the centrality of objects, exhibitions, and topics to the centrality of people and their learning needs.

Finally, the explainers should contribute to the promotion of a public *science governance*, becoming facilitators of the dialogue between science and society. This requires for the explainers to acquire new skills, new theoretical awareness, and the knowledge and practice of the new event formats that have been developed in the last years, such as discussion games, role-plays, and scenario workshops (Rodari and Merzagora 2009).

Considering this complexity, is it possible to arrange all these required competences in a professional development scheme, applicable to all institutions? Is it possible, even more, to design and propose a standardized, higher education level, course of studies? The discussion on this point is rich and still ongoing (Bevan and Xanthoudaki 2008; Tran and King 2007; Tran 2008).

The professionalization of explainers would allow them to acquire cultural (and also economic) external and internal recognition. To define its standards of quality and the methods to assess them would be also much easier.

There are two possible interpretations of this professionalization process. With a bottom-up approach to the problem, many European institutions organize international training courses in which sharing of experiences and knowledge gradually leads to an international learning community, still very fluid in practice, but with a growing awareness and reciprocal knowledge. The advantages of this approach are many. An increasing number of explainers are gaining the feeling of being part of a community; they are aware of debates and trends inside the museums or science centers community; they are able to meet people from all over the world and share practices and reflections; they are acquiring new skills and competences. Best practices, always existing, can be finally shared among different institutions, and international training schemes can also be applied locally, so that less experienced institutions can learn from the most experienced.

A “hard” interpretation of the professionalization process, however, leads to a single, complete as possible, training scheme, offered by higher education institutions and largely recognized all around the world. This hard approach presents not only advantages but risks (Bevan and Xanthoudaki 2008). The advantages comprise a stronger external recognition of the explainers’ profession and surely better career opportunities for practitioners. Main risks include:

- Loss of the variety of people now acting as explainers, such as secondary school pupils as well as retired people, with all the richness this diversity offers.
- Loss of the variety of practices, created by institutions with different histories and cultures; a variety that constantly produces new formats of activities.
- Stopping change: because science and technology communication practices (and also theoretical reflections on the field) are changing so fast, it may be difficult for an institutional course to keep pace.
- Reducing the distance from school educators. Many higher education institutions do not have updated competencies in informal learning and science communication; the institutionalization of the explainers’ training would therefore risk bringing their profession too close to the one of school teachers, losing the innovation present in explainers’ informal approach.
- Exclusion of explainers from the definition and development of their own professional profile. In the bottom-up approach, those processes involve explainers as proactive actors, and the peer-to-peer learning is key element of the training best practices. Would be this role guaranteed if universities and higher education institutions take the lead?

The current discussion on the explainers' professionalization, linked as it is to the debates concerning social inclusion and public participation in science and technology governance, is in itself an agent of change, fostering the awareness of this community of people toward a more complex understanding of the role of science and technology in society.

Explaining as a Teaching Strategy

Garry Hoban
Faculty of Social Science, University of
Wollongong, Wollongong, NSW, Australia

Keywords

Argument; Claim; Proposition; Slowmation

An explanation is a statement or set of statements that clarifies the reasons, causes, context, or principles that underpin a particular phenomenon. The word derives from the Latin term explicatus, which means to provide reasoning for. Explanations are central to the discipline of science as one of the goals of the discipline is to provide explanations that lead to a deeper understanding of various phenomena. In plain English, explanations elucidate why things work, what something is, or how things happen. They often provide cause and effect relations, include a time sequence, and use action verbs. An explanation usually has five parts: (i) naming or specifying the concept, (ii) describing elements or components of the concept in an appropriate order, (iii) explaining how the elements relate or connect to each other, (iv) providing an example, and (v) summarizing with a concluding statement.

It is a fundamental expectation in most school science curricula that students should be able to explain science concepts. For example, the Australian National Curriculum states: "Science provides an empirical way of answering interesting and important questions about the biological, physical and technological world. The knowledge it produces has proved to be a reliable basis for action in our personal, social and economic lives" (ACARA 2012, p. 3). Similarly, the US National Science Education Standards calls for more than "science as process," in which students learn such skills as observing, inferring, and experimenting. "Inquiry is central to science learning. When engaging in inquiry, students describe objects and events, ask questions, construct explanations, test those explanations against current scientific knowledge, and communicate their ideas to others. They identify their assumptions, use critical and logical thinking, and consider alternative explanations. In this way, students actively develop their understanding of science by combining scientific knowledge with reasoning and thinking skills" (1996, p. 2).

Types of Explanation

There are many types of explanations, including deductive-nomological, functional, historical, psychological, reasoning, rationalization, consequential, causal, and argumentation. In line with the commonly acceptable deductive-nomological model, a scientific explanation has two parts: (i) the explanandum is the phenomenon that is to be explained and (ii) the explanus is the evidence, reasoning, or details to explain the phenomenon. According to Hempel (1965), "the explanus must be a logical consequence of the explanandum" and "the sentences constituting the explanus must be true" (p. 248). So the explanandum identifies the concept or phenomenon being explained, and the explanus provides the evidence or reasoning. For example, someone may ask a question about a weather phenomenon such as "what is a tornado?" which is an explanandum, and a reply could be "an intense low pressure system that has rapidly rotating air like a spout," which is an explanus.

Another type of explanation is based on the notion of argumentation (Toulmin 1969). An argument has four components: (i) a claim which is an assertion or conclusion about a particular phenomenon, (ii) evidence which is the data that supports the claim, (iii) warrant which is the status of the evidence so that it is adequate and valued by others, and (iv) reasoning which is the line of thought linking the claim and evidence.

Teaching Strategies to Promote Explanations.

Four examples of teaching strategies aimed at promoting explanations:

1. Making the Explanation Explicit

   One way is for teachers to make what is required in an explanation explicit according to a five-step procedure (McNeill and Krajcik 2008): (i) making the framework explicit by being clear to students the type of structure of explanation needed; (ii) modeling and critiquing explanations whereby teachers show students examples of good explanations; (iii) providing a rationale for creating explanations so that students know why they need to be clear about their reasoning; (iv) connecting to everyday explanations meaning that the reasoning is based on common sense; and (v) assessing and providing feedback to students meaning that will only improve their explanations if they get explicit suggestions on the strengths and weaknesses of their reasoning.

2. Writing Scientific Explanations

   It is important that students are provided with frameworks for explaining science concepts. These have been called informative texts and can have the following parts: (i) write an introduction clearly stating the problem or question, (ii) write a sequence of steps or results which may involve providing evidence, (iii) write an implication, and (iv) write a conclusion.

3. PEEL (Project for Enhancing Effective Learning)

   One of the central goals of PEEL (a community of practicing teachers, primarily based in Australia) is to devise and implement practical teaching strategies to support student learning (Baird and Northfield 1992). Many of these strategies relate to improving student explanations, whereby teachers collect and reshape ideas from students, offering a "story" and providing students with new words to be practiced. Some of the suggested strategies are:

   - POE (Predict, Observe, Explain): Students predict what is going to happen when they see a demonstration, observe what happens, and then explain the phenomena individually or in groups.
   - Concept maps: Students summarize a discussion with a conceptual diagram or map. A concept map typically organized around a central term or idea, with other related terms extending from it.
   - Postbox: Group members each write an explanation of a concept on a piece of paper. These are passed around the group or swapped with other groups, and then each group decides which is the best combination of suggestions for the explanation.

4. Digital Representations

   Increasingly students are using their own digital technologies such as mobile phones, iPads, and computers to create digital representations to explain science concepts. They can make podcasts (audio explanation), video (audio and image), as well as animations (see slowmation) to explain science concepts. These can be shared with others by uploading to Internet sites such as YouTube or "60 s Science" or "Scientific American." See www.digiexplanations.com for examples and instructions for how to make five forms of digital explanations.

Conclusion

Explaining how the world works or why something happens is a key feature of the discipline of science. Students at universities and in schools should be encouraged to explain science in their own words as a way to develop conceptual clarity in their own understandings. When students plan for an explanation, they should take into account the purpose, audience, context, and medium so that what they are explaining becomes clearly understandable by others.

Facts, Concepts, Principles, and Theories in Science, Assessment of: An Overview

Audrey B. Champagne
University at Albany, State University of
New York, Albany, NY, USA

Facts, concepts, principles, laws, and theories are components of science information. Inferences are made regarding individuals' knowledge about and understanding of these components based on those individuals' responses to assessment items or teachers' questions.

Measurement of knowledge about and understanding science information is challenging for several reasons. One challenge relates to the difference between knowing about and understanding. A second challenge relates to the fact that knowledge about and understanding always involves the measurement of abilities. A third challenge relates to differences in how these components are labeled and defined in the science education literature.

Knowledge about components of science knowledge typically is measured using multiple choice or constructed response items. For instance, knowledge of the boiling point of water could be measured by requiring an individual select 1,000 °C from five temperatures in response to the question: what is the temperature at which water boils at sea level? Using a constructed response item type, the individual would be required to write 1,000 °C. Knowing about a concept, principle, law, or theory can be assessed in a similar fashion simply by asking individuals to identify the definition of a concept, identify the statement of a principle or a law, or identify the natural phenomena a theory explains. For instance:

Concept: What is the definition of the density of a substance?

Principle: What is Newton's second law?

Law: What are examples of natural phenomena Newton's laws are used to explain?

Theory: What examples of natural phenomena kinetic molecular theory are used to explain?

Demonstrating knowledge of a component is a relative simple task, requiring only recognition or recitation. Demonstrating understanding is more difficult requiring additional knowledge and abilities such as knowing the empirical and theoretical foundations of the fact, concept, principle, law, or theory or the ability to construct, to identify, to evaluate an explanation using the component, or to apply the component to a theoretical or practical problem.

For instance, understanding the fact that water boils at 1,000 °C might be measured by asking why the boiling point of water is different at sea level from the boiling point on Pikes Peak. A measure related to an everyday situation would be to explain why it takes longer for a potato to cook in boiling water on Pikes Peak than at sea level.

As these examples of the measurement of knowing and understanding illustrate, successful performance items designed to measure only knowledge and understanding also measures abilities. Responses to all items require generic

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

abilities such as the ability to read and follow direction. Responses to items also require science-specific abilities such as the ability to identify and evaluate a scientific explanation.

Conversely, items designed to measure abilities such as practices (NAEP and NRC Framework), cognitive skills (TIMSS), or competencies (PISA) also measure knowledge and understanding of components of science information, for instance, the TIMSS cognitive ability assesses reasoning about knowledge related to a content domain (biology, chemistry, physics, or earth science).

Even items designed to measure only what an individual knows or what an individual can do inevitably measure both knowledge and abilities.

A further challenge is that the assessment literature and frameworks for large-scale science assessments typically describe information components using familiar words: fact, concept, principle, law, and theory. However, the words are often used to mean different things. This is especially true of the word "concept." The word "concept" sometimes refers to a single entity, such as energy, organism, or system. Concept may also refer to the relationship between two or more entities. For instance, statements such as energy is conserved in closed systems are sometimes called concepts. In some of the assessment literature, statements of relationships among entities are called principles. The challenge is deciding if the word concept represents a single entity or a statement describing a relationship between or among entities.

While measurement of what individuals know seems relatively straightforward, distinctions between depth of knowledge, conflation of knowledge and abilities in the demonstration of what is known, and differences in how the components of science information are labeled pose challenges to answering the question: what is being measured.

Family Learning

Lynn D. Dierking
Science and Mathematics Education, Colleges of Science and Education, Oregon State University, Corvallis, OR, USA

Defining family learning It is challenging enough to independently define the words "family" and "learning"; understanding the meaning of the two words together only complicates matters. Despite this challenge, the notion of a family learning together makes great sense given that humans learn through group interaction, conversations, gestures, emotions, and watching one another. The very first learning group a person belongs to is her family, and this group is so important that anthropologists, sociologists, and social psychologists refer to the family as an educational institution, without the bricks and mortar.

Family members engage in family learning over their lifetime through the processes of social interaction, collaboration, and sharing among members. Knowledge and understanding is constructed by the family and incorporated into a family narrative, a set of shared experiences and meanings. Interaction, collaboration, and sharing can be direct (a family participating together in an activity or experience) or indirect (the family discussing or doing something together later that builds on an experience a child or adult has had elsewhere).

A Google search of the phrase “family in the 21st Century” reveals an amazing array of responses including links to working families, “Renaissance” dads, stepfamilies, blended families, adopted families, multi-birth families, home-schooling/unschooling families, and so on. The one conclusion that can be drawn is that it is increasingly difficult to define a family. A simple but broad definition is two or more people in a multi-generational group that has an ongoing relationship; they may be biologically related but not necessarily. The general rule is that if a group defines itself as a family, they are one.

Learning can also be defined broadly, including typical notions of remembering facts and concepts, most often expressed in words. However, the definition of learning, particularly for families, also encompasses the development of shared values and beliefs, shifts in attitude, aesthetic understanding, and “learning” in psychomotor ways, such as how to ride a bike or play a group game outside. Learning also includes social/cultural dimensions: learning about how a parent or a child learns, how to think critically and refine one’s learning skills, and how to use the learning resources in a community to the best advantage. This broader definition of learning means that families learn together best when they are naturally engaged in the everyday activities of family life. These activities provide a context for learning about one another as learners and people, for example, how to support and facilitate one another’s interests or the joy of lifelong learning. Also, when trying to understand family learning, the processes of learning are equally important, if not more so, than any products of learning.

Research demonstrates that museums are important settings in which many families spend quality time, learning and building a family narrative as they laugh and learn together. This is an implicit, not an explicit, goal. As a colleague likes to quip, few families wake up on Saturday morning and say, “Hey, let’s go to the aquarium today and learn about teleost fish!” However, interviews with parents in museums demonstrate that they perceive these settings as “good places to take children to learn,” and several studies support the idea that families use museums as socially “mediated” learning environments (Dierking and Falk 1994; Ellenbogen et al. 2007; Falk and Dierking 2013).

Why is it important? By the late 1980s, extensive research provided empirical evidence for what many museum professionals had observed informally for years. Most visitors to most museums, about 60–70 %, were visiting as families (Ellenbogen et al. 2007). Given that families are a major audience, it seems important to support their learning and to use museums as laboratories in which to understand such learning.

Subsequent research also demonstrates that what happens in the home and community is as critical to a person’s success as schooling, suggesting that museums have an opportunity to play an important role in supporting lifelong learning in their communities. After all, less than 1 % of an adult’s life is spent in formal instruction, and even children spend the majority of their waking hours (91 %) outside school.

Research also indicates that visiting museums as a child with one’s family correlates more highly with adult use of museums than visiting with a school group. This further emphasizes the importance of the family audience, both in the here and now, but also as a mechanism for building future audiences. In one study, children indicated that they often prefer to visit museums with their families because they get to look at more things of interest to them personally and can talk to their families about what they are doing and seeing (Jensen 1994). As societies transition into learning societies, with learning opportunities available 24 – 7 – 52 – 80+, museums are positioned well as settings in which families can learn and build identity together.

Research indicates a wide range of factors influencing family learning in museums. Families visit with different expectations, cultural backgrounds, interest levels, belief systems, life experiences, and leisure habits. The visit is viewed by most families as an educational opportunity (with some anticipation of entertainment also – most families do not distinguish between the fun and the learning). The visit is also an important multi-generational social outing (and fortunately we know learning is as much about these social/cultural dimensions as other aspects). These factors influence the visitors' interaction with the exhibition and program material and in turn impact how they respond to the accompanying members of their family. We also know that how they make meaning of these experiences is complex. Some families take time to talk and explore a topic while in the gallery, while others wait until the ride home or 2 weeks later to discuss it over dinner. Also challenging exhibition and program developers working in these settings is that what triggers a family to interact and become engaged has as much to do with why the family is visiting, the understandings and needs they bring to the visit, and the subsequent interactions they will have, as to what exhibitions and programs they may encounter. All complexity aside though, there is evidence that families enjoy engaging and learning in these free-choice, multisensory settings.

Feminism and Science Education

There is no single, coherent recognized "feminism." Rather the feminist movement comprises a range of different schools of thought, organizations, collectives, and loosely formed groups and allegiances, which are often organized around particular foci or theoretical standpoints, which change and develop across time and context. In this sense, it may be more accurate to talk of feminist approaches to science education (or "feminisms" and science education). Examples of different feminist approaches to science education include liberal, radical, socialist, black, and poststructuralist, to name a few. Despite the diversity of theoretical and political lenses and ideologies that feminists bring to science education, feminist approaches do share some common assumptions, namely, the belief that gender inequality is wrong and needs to be challenged, that women are oppressed/dominated by men, and that it is important to advocate for women's rights. In the most recent "second" and "third" waves of Western feminism, feminists have extended these concerns from gender to also include other forms of social inequality, such as social class, "race"/ethnicity, sexuality, disability, and so on.

Within academic fields, such as science education, feminist research is often characterized by a belief in the importance of both theory and practice. Feminists are concerned with not only understanding how and why inequalities are formed, experienced, and perpetuated but also how to bring about change through the practical application of knowledge (referred to as *praxis*).

There is no single feminist methodological approach to science education research, but in line with wider feminist research, the personal is often foregrounded. That is, close attention is given to women's subjective, experiential accounts. In line with the famous feminist slogan "the personal is political," women's and girls' individual stories are seen as shaped by wider structures of power, such that private troubles are revealed as being public issues. Feminist science education research makes use of a wide range of methods, but qualitative methods, such as interviews, ethnography, life histories, and auto/biography, are particularly popular. This is because qualitative methods offer a means for capturing rich data to enable an understanding of the lived reality of girls' and women's lives. While the majority of feminist research has traditionally focused on women (in response to the social and historical dominance by males of knowledge and research), recent years have seen an increased interest in critical feminist approaches to masculinity and education, although this has been relatively slow to spread into feminist science education.

Feminist approaches to science education share a common interest in the operation of power and how practices of power play out within science and science education. Attention has been drawn to the myriad effects, experiences, and implications of power within the practice of science. Feminist science education research has also focused on the intersection of identities and inequalities, for instance, analyzing who can, or cannot, see themselves and be recognized by others as authentic scientific subjects.

Feminist approaches to science education can be loosely classified as falling into three main areas: the epistemology of science, science participation, and science teaching and learning:

1. *Epistemology of science*: Sandra Harding (1986) and Donna Haraway (1985) are two of the key figures associated with the feminist questioning of the masculinist nature of mainstream science. Harding and Haraway were at the forefront of feminist critiques of dominant assumptions about the objective nature of science and developed feminist approaches to the philosophy and practice of science.
2. *Science participation*: Statistics show that girls/women tend to drop out of the science "pipeline" earlier than males and are not equally represented across all areas of science, tending to be underrepresented in the post-compulsory study of the physical sciences and at higher/more senior levels within scientific careers in and beyond academia. Feminist science education research has addressed the reasons for these patterns and inequalities and has documented the experiences of, and issues encountered by, women and girls (from diverse backgrounds) within science, from early years, through formal schooling, and into post-compulsory education, academia, the workplace, and informal science learning environments.
3. *Science teaching and learning*: Feminist approaches to science teaching and learning attempt to show how the culture and practice of science is a socially constructed and located activity. This work attempts to reveal underlying norms, values, and assumptions within science teaching and learning and the ways in which science teaching and learning are socially and historically produced practices, in which particular dominant values, identities, and viewpoints tend to be privileged. Feminist approaches to science teaching and

learning seek to develop and promote new ways of teaching and learning science that are more equitable and inclusive for less powerful groups and communities. This includes promoting more equitable forms of pedagogy, curriculum, and resources.

Feminist Praxis and Science Education: The practice of feminism within science education has not been limited to research and theory. There have been numerous initiatives and intervention programs delivered within and outside schools, which have aimed to improve women's and girls' experiences of teaching, learning, and participating in science. For instance, the Girls into Science and Technology (GIST) project, which ran from 1980 to 1987, was one of the largest and well-known UK action research programs aimed at improving girls' participation in scientific and technological studies at school once these become optional. There are also major national initiatives that continue today; for instance, in the UK, over half of all higher education institutions that are active in STEM (science, technology, engineering, mathematics) subject areas are members of the Athena SWAN Charter, which requires signatories to commit to addressing gender inequalities among their STEM workforce. In the USA, STEM extracurricular programs and initiatives for women and girls abound, and there are some nonprofit organizations that have worked to integrate and coordinate these efforts. For example, the National Girls Collaborative Project is aimed at facilitating collaboration and communication among and between girl-serving STEM organizations and programs. The National Center for Women and Information Technology (NCWIT) is a nonprofit organization with over 450 partners focusing on increasing women's and girls' participation in technology and computing, reforming K-12 computing education, and improving visibility of women in computing. The Women in Engineering ProActive Network (WEPAN) is a nonprofit organization with networks of members on 150 colleges and university campuses, aimed at transforming engineering education to attract, retain, and graduate women engineers.

Field-Based Data Collection

Timothy D. Zimmerman
School of Cognitive Science, Hampshire College, Amherst, MA, USA

Keywords

Mobile data collection; Probeware

Main Text

Field-based data collection is a science education approach that emulates the practices of scientists to evoke ideas of the nature of science through science praxis. During field-based data collection activities, people use genuine (or sometimes science-like) tools and techniques to collect data in settings outside of the classroom. A common goal of these data collection activities is to shift people's understanding of the nature of science by getting them to "think and act like a scientist" through interaction with the real data they collect and the subsequent analysis of those data (e.g., by graphing or reflecting on patterns within the data). By working directly with data they and their peers collect, learners can also construct new understandings about science.

This approach to science education has become increasingly common in middle- and high-school science classrooms, where the tools and techniques have evolved from paper and pencil to approaches that include high-tech automated sensors, mobile computers, and complex, real-time data visualizations. The advent of probeware – small electronic devices attached to calculators or mobile devices for recording environmental parameters such as pH, temperature, salinity, and dissolved oxygen – has enabled scientists to rapidly capture large amounts of field-based data, changing how scientists collect and share data. These devices and techniques also made powerful contributions to field-based data collection in K-12 science. In the mid- to late-1990s, initiatives seeking to connect every classroom to the Internet enabled students to easily share data collected in the field. For example, helping students learn science through the collection and exchange of field-based data concerning their local climate and environmental surroundings was a purposeful design component of Project Globe.

While the use of field-based data collection ostensibly began as a technique for training soon-to-be scientists (i.e., undergraduate and graduate students majoring in science), it has now moved firmly into the K-12 classroom and even into informal learning contexts, engaging people of all ages and disciplinary backgrounds. Smart phones, with their digital cameras, GPS capabilities, and Internet connectivity, have shifted the landscape of field-based data collection, allowing anyone with such a device to participate. Field-based data collection smartphone "apps" (e.g., iNaturalist and Project Noah) have made data collection easier and more accurate, increasing the opportunities for engagement by students and nonstudents alike. The term citizen science is used to describe a project where nonprofessional scientists engage in data collection activities – often field-based data collection. Although little research exists on the science learning that happens during citizen science projects, the recent explosion of citizen science projects has provided opportunities for students or citizens to collect field-based data related to real scientific studies. Research on the use of mobile, technology-mediated field-based data collection tools inside and outside classrooms is on the rise, and early results indicate the immense potential for science learning and instruction provided by this approach.

Formative Assessment

Knut Neumann
Leibniz-Insitute for Science and Mathematics
Education (IPN), Kiel, Germany

Keywords

Assessment; Curriculum; Curriculum-embedded assessment; Feedback; Formative; Formative assessment; Portfolios

Formative assessment refers to assessment that seeks to obtain information about student competence in a particular domain (e.g., science) in order to shape future learning. Typically formative assessment focuses on a specific aspect of student competence (e.g., understanding of the force concept). Teachers use formative assessment prior to beginning a new instructional unit in order to determine students' level of competence and to plan instruction to foster students' progression to the next level of competence. Throughout the instructional unit teachers continuously make use of formative assessment in order to monitor students' progression and adapt instruction where necessary. As such, formative assessment needs to be closely aligned with the curriculum; that is, the formative assessment and the curriculum both need to be based on the same model of student learning. At best, formative assessment is embedded in the curriculum such that learning and assessment become indistinguishable from each other and take place at the same time. When well aligned with the curriculum, formative assessment can provide valuable information not only for the teacher but also for the student. Research has shown that if results from the assessment are fed back to students with respect to which aspects of competence they have mastered and which ones they still have to master, this can be beneficial for students' learning (Hattie 2009). Various sources of evidence may be utilized for formative assessment. In order to monitor student learning, products of student work have been proven most suitable; among them are student worksheets, portfolios, or project documentation. In order to obtain information about students' competence prior to instruction, sources of evidence as they are utilized in summative assessments may be used as well; among them are paper-and-pencil tests based on multiple-choice or open-ended items.

Futures Thinking in Science Education

Cathy Buntting[1] and Alister Jones[2]
[1]Wilf Malcolm Institute of Educational Research, The University of Waikato, Waikato, Hamilton, New Zealand
[2]Deputy Vice-Chancellor, The University of Waikato, Waikato, Hamilton, New Zealand

Futures thinking is aimed at detecting, inventing, analyzing, and evaluating possible, probable, and preferable futures, the deliberate plurality of the name highlighting the range of future possibilities and notions of alternatives (Slaughter 1996). Variously called futures studies, the futures field, futures research, futuristics, prospective studies, or prognostics, it involves a structured exploration into how society and its physical and cultural environment could be shaped in the future. Increasingly, communities are calling on futures approaches to envisage preferred futures and to compare these with current trends and scenarios of other possible futures. Such thinking is regarded as a valuable approach to dealing with uncertainty, the aim being to understand and evaluate alternatives. In science education, socio-scientific issues (SSIs) offer scope for developing students' futures thinking skills. Such skills are increasingly being recognized in curriculum documentation as one of the goals of general education, and as a consequence, areas of study like "citizenship education" are being developed. In this entry we provide a brief overview of futures thinking, where it could fit in science education and how students' futures thinking might be developed.

Futures thinking assumes that the future world will differ from the present world; that the future is not fixed, but consists of a variety of alternatives; that people are responsible for choosing between alternatives; and that small changes can become major changes over time. Most futures work incorporates:

- Input data (observations, raw data, and empirical evidence that are analyzed and synthesized to produce trends)
- Trends (trajectories, extrapolations, projections, and predictions, based on an analysis of the input data; trends tend to be continuous and monotonic, i.e., relating to one aspect only, such as the increasing proportion of the world's population living in developing countries)
- Drivers (groups of trends that share a common theme, e.g., demographics, globalization, economics, science and technology, equity issues and environmental change)
- Wild cards (high-impact, low-probability events, e.g., natural disasters)
- Outcomes (possibilities and scenarios)

The cumulative effect of even small uncertainties in any of these, means that the range of plausible future worlds is very large.

Hicks (2012) differentiates between futures studies and futures education, the former relating to the academic field of inquiry into futures and the latter referring to the translation of futures concepts into learning experiences that are appropriate for school students. Arguments for including futures thinking in education include fostering students' creative, analytical, and critical thinking skills; empowering individuals and communities to envisage, value, and work towards alternative futures; and developing students' values discourse. In science education, futures thinking has the potential to increase student engagement and their perceptions of the relevance of their science learning. It also has potential to develop students' understanding of key scientific concepts, including the nature of science, and to evaluate the positive and negative potential impacts of science and technology on society.

Having a vision of the future is part of being human. In spite of this, futures education is still in a preemergent state with only a limited number of classroom resources. Many of the activities in these resources are based on futures-specific tools, such as futures wheels, environmental scanning, and cross impact matrices, and the contexts for learning tend to be linked with environmental education and education for sustainability. However, there is incipient interest in embedding futures thinking in science education and *socio-scientific issues* offer an accessible context in which to do so.

Although the potential for explicitly including futures thinking in science education has not yet been extensively studied, some initial investigations have been carried out by David Lloyd and colleagues (e.g., Lloyd 2011). Jones et al. (2012) extended some of these ideas to develop a conceptual framework to engage students in a structured exploration of SSIs. Within this framework, students' attention is focused on identifying and analyzing the existing situation, trends, and drivers. Student understandings of these are then used to explore possible and probable futures in a manner that reduces guesswork while still encouraging creativity. A consideration of the social context within which the changes might take place can be considered at a personal, local, national, and global level. The intention is that this will help move students' decision-making from an egocentric activity to one valuing the welfare of the planet and all its occupants. Futures thinking as part of an SSI-focused science program should therefore provide opportunities – through the building of possible, probable, and preferable futures scenarios – for students to reflect on their own as well as others' values. Taking into account multiple perspectives is important for exposing students to some of the complexities and ambiguities associated with SSIs. Also important is an emphasis on the varied interactions between political, environmental, and equity aspects.

As a relatively un-researched phenomenon, the incorporation of futures thinking in science education offers a rich area for further exploration and investigation. Models are needed for how diverse students across different levels of schooling can be supported to develop their futures thinking skills, and what the impacts might be on students' understandings of science and the nature of science, and on their sense of "place" within our world and their ability to contribute to change. There is therefore a range of issues about which little is currently known: What might be appropriate ways to assess students' futures thinking skills? Does futures thinking enhance students' engagement and achievement in science? What does progression in futures thinking look like in the context of science education? What do appropriate, culturally responsive pedagogies look like? What teacher education and support is needed for teachers to plan and implement science education programs that enhance the development of students' futures thinking skills? Beyond this, Gidley and Hampson (2005), in a comprehensive review of futures education, identify a range of areas requiring further research, including psychological dimensions, diverse ways of knowing, cultural diversity, cultural resources, human/social futures, tackling social systems, and developing integral consciousness. Many of the questions that they identify within these themes could profitably be investigated within the context of science education, for example, how can futures in [science] education foster the coexistence of a tapestry of different cultures on a global scale? How has an increase in the use of computers in [science] classrooms affected the teaching of futures? How can futures in [science] education contribute to a reevaluation of roles and expectations in teacher-teacher/teacher-pupil/pupil-pupil relationships? Does the capability of foresight arise from cultural evolution? Is a "scientific" worldview antithetic to foresight?

All students have images of possible futures, and many of these involve scientific and technological advances. Including these futures images and carefully scaffolding the development of students' futures thinking skills when they explore SSIs offers possibilities that are still largely unexplored.

Games for Learning

Mario M. Martinez-Garza and Douglas B. Clark
Peabody College of Teaching, Learning, and
Human Development, Vanderbilt University,
Nashville, TN, USA

Keywords

Educational games; Educational technology; Interactive models; Microworlds; Simulation environments

Main Text

Games for learning is a collective term referring to digital games that are purposefully designed to help players learn about a particular topic. A *digital game* is an interactive form of entertainment in which a player's experience is mediated by computer software. Once limited to desktop computers and young boys, digital games are now popular across genders and ages on a large number of electronic devices, such as mobile phones, tablet computers, and specialized gaming consoles (Kafai et al. 2008).

Traditional classroom approaches to science education, with their focus on explicit formalized knowledge structures, seldom connect to or build upon people's tacit intuitive understandings. Well-designed digital games, however, may serve to help learners build informal yet accurate understandings of certain concepts due to their situated and enacted nature (e.g., Gee 2007). However, most commercial games are not designed to help players articulate, connect, and formalize their intuitive understandings or to transfer knowledge to other contexts. So while games for learning inherit many design elements from their leisure counterparts, they must add an extra set of functionalities intended to support the integration of tacit spontaneous concepts (e.g., notions of force or momentum) with instructed concepts, thus preparing players for future learning.

Investigation into the use of games for learning has grown from a small niche area to a major focus of research over the past decade, supported by a corresponding increase in funding for research on educational games and educational technology more generally. In 2006, the Federation of American Scientists issued a widely publicized report stating that games offer a powerful new tool to support education and encouraging an expansion of funded research into the application of complex gaming environments for learning. In 2009, the transformative potential of games for science education was the focus of a special issue of *Science* (Hines et al. 2009).

Games for Learning and Simulations

Research into games for science learning shares some theoretical and methodological roots with research into learning from simulations. Both of these domains stress the importance of the learner as the central participant, active meaning-maker,

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

and problem-solver. Similarly, both leverage the power of computers to place the learner in contact with a complex system while providing significant affordances for understanding and controlling that system. Digital games share many design characteristics that support learning in simulations, typically featuring similar interactive models that can be explored through manipulation of certain parameters. However, digital games and simulations differ in that games often engender certain levels of play, engagement, and enjoyment as core design characteristics, whereas simulations for learning do not typically include these elements as core characteristics. Games also incorporate rules and explicit goals for players to achieve or progress, often with accompanying scoring or reward systems that relate to a player's skill and progress. In summary, digital games for science education typically feature (a) digital models that allow users to make choices that affect the states of those models, (b) an overarching set of explicit goals with accompanying systems for measuring progress, and (c) subjective opportunities for play and engagement.

Importance of Design: Leveraging the Medium

More than probably any other feature, it is the specific design of a digital game that determines its efficacy for science learning (as is the case for hands-on labs, books, lectures, and many other learning activities). Simply adding game-like elements to an existing instructional platform does not guarantee that the "gameified" software will be effective. To maximize the potential for success, educators and designers must consider the unique affordances of digital games as a medium in light of the learning goals, learners, teachers, and context. Broadly, these affordances can be grouped into six categories: (1) engagement and affective investment, (2) consequential action and meaningful play, (3) implied scientific stance and perspective, (4) approachable entry, (5) guided trajectory, and (6) just-in-time feedback.

Engagement and Affective Investment. The principal quality of digital games, and what makes them attractive to educators, is their ability to engage students. This engagement, though, goes beyond a narrow sense of "having fun." Games cast players into central roles, as protagonists or "heroes" who must prevail against adversity through wisdom, skill, knowledge, and virtue; and thus, games encourage and facilitate the construction of powerful identities and narratives by providing the ideational resources that such identities cluster around. Players of digital games experience designed trajectories of growth and narratives of increasing power that are fundamentally compelling. Learners can gain a sense of control and self-efficacy in the figured universe of the game. Furthermore, players of video games benefit from the goal-centered nature of play. Players expect conflict and resist frustration, so far as they feel that their goals are achievable and that the game is "playing fair." Continued successes in reaching these goals can help increase the player's investment and sense of authorship over the entire experience. A well-designed game provides ample opportunity for a player's goals and decisions to have a visible, lasting impact on the game experience, so that each individual learner's path is reified as an artifact that is visible and valued.

Consequential Action and Meaningful Play. The most effective games are structured so that the embedded system presents a narrative that progresses in accordance with the actions and decisions of the player. Within this narrative, players experience conflict and uncertainty, and their active interpretation and response to these elements creates instances of meaningful play. The player's actions also have an observable effect on the simulation; this *consequential engagement*, in which choices have an impact on the world, is theorized to be an important driver of conceptual understanding. Consequential engagement arises when learners must consider the consequences of their choices, not only in the proximal sense of analyzing their impact on the simulated world but also in the more reflective sense of examining the context in which those choices were made and their appropriateness under the circumstances (Gresalfi et al. 2009).

Implied Scientific Stance and Perspective. Effective games for learning place the player at the center of the action and orient the player toward desirable perspectives and principled attitudes. In digital games that feature models and systems for science learning, these perspectives can help form disciplinary stances and epistemologies, which are equally as important as the learning of specific content matter. Researchers of games for science learning have observed students of various ages thinking and discoursing like scientists, engaging in scientific inquiry, and exhibiting scientific habits of mind.

Approachable Entry. By their nature, games for learning are exceptionally good at providing challenges that are initially simple but that scale gradually and consistently upward in difficulty and complexity. Games have evolved to include varied forms of scaffolding or support for players (e.g., tutorial levels) that successfully guide players in making initial decisions and prepare them for a more complete immersion within the simulated systems at higher levels. These simulated systems tend to be complex and feature-rich, centered on phenomena and relationships that may be difficult for novices to grapple with. The gentle learning curve designed as an intrinsic aspect of good games, coupled with gradually increasing availability of tools to craft and control the simulated environment, allow learners to demonstrate increased expertise as the game progresses. These demonstrations of expertise are sufficiently rewarding that players will persist with the game even in the face of rising difficulty – not the usual pattern educators may expect when students are involved in an independent learning activity.

Guided Trajectory. Another advantage to the structured nature of games is that tools can be provided, as needed, to guide a player along a predetermined path while still maintaining a personalized and flexible experience. Designers of games for learning can readily guide a player through the material and highlight the salient elements of the game without forcing a player to relinquish agency. Players are not marched lockstep through the material, but neither are they left adrift without any cues to tell them when they are ready to proceed to the next segment. Games can be thought of as designed experiences that help learners develop understanding by guiding them through cycles of performance. These cycles act as both a mechanism to present learners with suitably challenging experiences and also to allow increases in difficulty only when the player is ready for them. Few other learning activities have this property.

Just-in-Time Feedback. Games for learning, as fully interactive media, are able to provide direct, frequent, and useful feedback to the player as the game experience unfolds. This form of feedback can be highly engaging and motivating, and it has been found to be a powerful intermediary for learning (Annetta et al. 2009). The expectation of feedback creates a ready channel for presenting information; players will attend to information presented as hints or help when presented in a just-in-time manner that is consistent with their own goals and the current state of the game. The acquired tendency of players to attend to “hints” or “clues” provides excellent opportunities to present material, such as scientific principles or definitions of terms, which would otherwise be difficult to frame in a way that students would willingly digest.

Current Trends, Challenges, and Future Directions

Games for learning are gaining broad acceptance in the larger educational community as a potentially valuable avenue for delivering science education. This follows a growing agreement that today’s learners demand greater levels of engagement, agency, and personal significance in their learning activities to match the fast-paced, networked, interactive environments where today’s students socialize and have fun.

However, along with this greater acceptance comes a demand for (a) a higher quality of evidence regarding the effect of games for learning on student achievement and (b) a tighter integration of games for learning into existing curricula and classroom practices. The former is most frequently framed as a challenge of assessment, which is driven by the complex behavioral and cognitive phenomena that digital games (and play in general) engender. In addition to observational and quasi-experimental methodologies, researchers can now employ sophisticated statistical tools to provide more nuanced accounts of how students learn through games. Although the path to include games for learning in mainstream educational practice is not clear, progress is being made on several fronts. Teachers are becoming more technology-aware and show greater willingness not only to use games in their classrooms but also to advocate for their use and participate in their design. Likewise, researchers and designers of games for learning are now accounting for the administrative and curricular constraints of classrooms, offering a sound approach to the addressing of state and national content standards, including embedded assessments and support materials. The next generation of games for learning (more effective, more accessible, and better integrated into educational practices) will become a more important feature of science education over the next decade.

Gender

Nancy Brickhouse
School of Education, University of Delaware,
Delaware, DE, USA

Keywords

Culture; Generations; Sex/gender

Science education researchers have been interested in the differences between boys' and girls' achievement and participation in science education for decades (Calabrese Barton and Brickhouse 2006). This interest is due in part to a concern regarding the inequitable participation of men and women in science careers and in part to a concern that everyone needs to engage competently in science-related issues in their everyday lives.

Across cultures and across generations, there are patterns of behavior and organization in science and science education that differ by sex/gender. These patterns vary by race, class, nationality, and religion and change over time. For example, over the last 20 years there have been very substantial gains in women and girls participation in science and science education. Most measures of science achievement show few differences between men and women. In the science professions, there have been substantial gains in women's participation in many fields. For example, in the USA, more women than men are now entering medical school, most specifically, in pediatrics. Emerging fields such as biomedical engineering attract women in much higher numbers than more traditional fields of engineering. Nevertheless, in many scientific fields (e.g., computer science, economics, physics), women remain persistently underrepresented.

While patterns of participation vary over time and space, in all cultures the patterns are gendered. Sex/gender remains an organizing principle in all societies, and in most cases those practices and attributes associated as masculine are more highly valued than those associated as feminine. The sciences are typically regarded as more masculine than other pursuits. However, within the sciences there is considerable variation in the gender association of a particular scientific subfield.

The masculine association of the sciences is related not only to male/female participation but also to its epistemology (Lemke 2001). Scientific knowledge, like other forms of knowledge, is gendered. Culturally defined values associated with masculinity (objectivity, reason) are also those values most closely aligned with science. While this association of masculine values with science dramatically oversimplifies the practice of science, it is nevertheless a powerful fiction that may serve to exclude those who do not hold to these values.

Thus, researchers have developed pedagogies of science teaching that focus on engaging a wider range of learners. Rather than teaching a single way of being scientific, these pedagogies instead seek to develop students' scientific competencies by building on existing areas of interest and expertise. Rather than treating science as an elite endeavor available to only a few, science education researchers have developed ways of integrating science learning into the everyday lives of learners from all backgrounds and providing ways for science learning to build stronger connections to the learners' home communities (DeWitt, Archer and Osborne 2013).

Researchers have also studied the ways in which the enactment of gender is quite variable depending on race, class, geography, nationality, sexuality, etc (Brickhouse and Potter 2001). While gender is critically important to understanding how individuals understand themselves and present themselves to others, the meaning of gender in these various instantiations is highly diverse. Thus, for researchers studying science learning as the development of identity, gender is a critical element in understanding how and why learners engage in science learning both at home and at school (Fields and Kafai 2013).

Gender-Inclusive Practices

Jennie S. Brotman
Teaching Matters, New York, USA

Gender-inclusive practices are teaching practices that are explicitly designed to address the learning styles, current and prior experiences, needs, and interests of students of different genders. The concept of gender-inclusive practice has its origin in efforts to address the marginalization of girls from science education. The term "gender-inclusive" originated in the 1980s in Australia with the work of a group of teachers that formed the McClintock Collective (Hildebrand 1989). The use of this term marked a shift in focusing on teaching practice that was "non-sexist" and aimed at eliminating inequity and bias for girls in science to focusing on teaching practice that made central the social construct of gender and its impact on boys' and girls' experiences and learning in science (Harding and Parker 1995).

Reflecting the above history, while one component of gender-inclusive practices is that they aim to minimize bias and sexism in curriculum and teaching, gender-inclusive practices go beyond this to deliberately change and tailor the learning environment, curriculum, assessment, and pedagogy to purposefully include diverse learners across gender lines. While there is some variation in how theorists and researchers describe exactly what this looks like in the classroom, there is a relative consensus that gender-inclusive practices include the following: providing a supportive environment that prioritizes active, collaborative learning; utilizing open-ended assessments that take on a variety of forms and involve diverse contexts; and emphasizing real-life contexts and applications, including the social relevance of science (Brotman and Moore 2008). Furthermore, gender-inclusive practices include challenging how scientific knowledge and practice are defined, since narrow portrayals of the nature and culture of science (such as that science is objective and value-free) can deter diverse learners with regard to gender as well as ethnicity. Finally, in addition to practices at the classroom level, gender-inclusive practices can be considered at the school level as well as at the systemic level (Hildebrand 1989). While gender-inclusive practices involve an explicit attention to issues of gender, they also overlap with practices advocated by general science education reform efforts that aim to articulate what equitable, high quality science education entails (Brotman and Moore 2008).

General Science Teacher Education

Yau Yuen Yeung
Department of Science and Environmental Studies, Hong Kong Institute of Education, Tai Po, Hong Kong, China

General science teacher education typically aims to prepare teachers for teaching of general science (also known as integrated science or science for simplicity in many countries or regions) at the secondary level. It is different from the preparation of teachers for the specialist science subjects, such as physics, chemistry, and biology, but in some instances overlaps with that for primary science (see, e.g., Abell 2000). It is mostly offered as an undergraduate Bachelor of Education degree by a normal university (or education institute/university) or jointly by the faculties of education and science in a comprehensive university to recruit secondary school leavers, and it lasts for 4–5 years. The aims, objectives, and design of such science teacher preparation programs not only depend on the views and experiences of the science educators in the teacher education institution but are also influenced by stakeholders (education bureaucracies/school systems). For example, education policy and national goals of science education, such as "scientific literacy for all," have led to the mounting of teacher education programs to prepare teachers for teaching junior secondary science or integrated science in China and South Korea, following from similar trends in other countries such as the UK, Canada, and Australia.

Contemporary research and international trends pertaining to developments in science education have had an influence of the curriculum of general science teacher education in many countries with issues such as educational values of history and the Nature of Science (NOS), constructivism, misconceptions/alternative conceptions, metacognition in children's science learning, socio-scientific issues, science-technology-society (STS), scientific inquiry/investigation, and informal or community-based science learning and technology (including educational technology and ICT) in science education being strong examples of research that has shaped the nature of the preparation of general science teachers.

In many countries, an emerging issue influencing general science teacher education has been the recent development of national standards/curricula of science education which outline specific science topics, such as NOS, unifying concepts (e.g., systems, forms, changes, and equilibrium as commonly found in various science topics), skills for scientific inquiry, and the use of ICT as well as scientific attitudes that science teachers need to facilitate their students' development at different stages of learning. As a consequence, guidelines, standards, or position statements on science teacher preparation (see, e.g., National Science Teachers Association 2003) may then be advocated by the community or professional society of science teachers to reflect their views and demands for professional conduct, competencies, and practices in science teaching.

Like any other teacher education program, there is an underlying assumption that general science teachers need to develop in three key domains of knowledge, including (i) subject matter knowledge (SMK) in general science, (ii) pedagogical knowledge (PK), and (iii) pedagogical content knowledge (PCK). The general science SMK consists of a balanced combination of courses in both traditional disciplinary courses in physics, chemistry, and biology and interdisciplinary science and technology courses in environmental science, health science, earth science, biotechnology, and/or telecommunications. Such courses tend to stress the conceptual understanding of the SMK at the undergraduate foundation or intermediate level and de-emphasize the analytical/mathematical manipulations, which are often replaced by computer simulation/modeling. The PK refers to those generic instructional principles, classroom management, curriculum development, learning theories, education policy and educational psychology, etc., which are normally taught by other (nonscience) teacher educators. PCK is perhaps the most complex component of any general science teacher education program. Despite variations in its definition (see, e.g., Gess-Newsome and Lederman 1999), it refers to science teachers' subject-specific pedagogical knowledge, consisting of, but not limited to, (i) orientations or views toward science learning and teaching, (ii) characteristics of science learners, (iii) general science curriculum and its trends of development, (iv) a wide variety of science instructional strategies, and (v) science assessment. There is much research to suggest that PCK is difficult to develop in teacher preparation but that concentration of such knowledge development is key to participants' future professional learning (Loughran et al. 2012).

The teaching of general science in teacher education often emphasizes teaching approaches, such as the thematic approach, integrated learning, issues-based inquiry, and STS approach. It also embraces other commonly used science methods, including problem solving, reasoning by analogy, modeling, scientific visualization, theory-evidence coordination, concept mapping, creativity, technology-enhanced learning (in particular, computer-mediated laboratory work), and higher-order thinking strategies, to name but a few.

Based on the above overview, general science methods courses are typically embedded within learning objectives designed to encourage student-teachers to:

- Be aware of children's cognitive processes, affective domain, and difficulties in science

learning as well as their implications for the teaching and learning of general science.
- Understand various NOS perspectives and their sociocultural linkage, as well as their implications for the teaching and learning of general science.
- Understand the unifying concepts of science as well as their implications for the teaching and learning of general science.
- Understand the nature and requirements of national/local general science curricula and assessment guidelines.
- Select, develop, and apply appropriate pedagogical and assessment strategies to facilitate students' science learning.
- Develop the essential knowledge, skills, and attitudes required for the integration of ICT with science education.
- Develop positive attitudes and professional behaviors toward students, science, and the teaching of general science.

For general science teacher education, there has been rather limited research conducted directly on evaluating the effectiveness of such programs, apart from assessing student-teachers' particular general science subject matter knowledge and understanding of NOS. Rather, student-teachers' science learning is often investigated through the lens of the aforementioned PCK, and this may then be interpreted as an indirect inference of science teacher's competence (see, e.g., Russell and Martin 2007). For example, it had been inferred from some TIMSS findings in Hong Kong that junior secondary pupils taught by teachers with general science teacher training outperformed those taught by physics/chemistry/biology teachers.

Gifted Education in Science

Manabu Sumida
Faculty of Education, Ehime University,
Matsuyama City, Japan

Keywords

Acceleration; Domain specificity of giftedness; Enrichment; Special education

Many children show a strong interest in natural phenomena from an early age and demonstrate an outstanding ability to think creatively and in abstract terms. The greater the individual differences in these interests, skills, and ability, the greater is the need for meeting special needs through a high-quality education. In this sense, gifted education is a kind of special education. In the United States, for example, the proportion of children identified as gifted is on average 6 %

nationwide. This is about the same percentage of children that need what is usually brought to mind by the term special education and is therefore not a percentage that can be ignored in ordinary school education activities. Research and practice on gifted education in science could provide a new dimension to the child-centered science education that has spread in the late twentieth century. It is imperative for meeting needs of gifted students in science.

There is no one definition of "gifted," "talented," or "giftedness" that is universally accepted. For convenience, the single word *gifted* is used here to mean *gifted and talented*. To identify a gifted child, a definition of the term is essential. The concept of giftedness is impacted by sociocultural factors. Who is deemed to be gifted can change significantly based on what identification standards are used, along with changes over time, changes in the theories being relied on, and changes in the desired results.

The classical method of identifying a gifted child in many countries has been an IQ test. The IQ test score (e.g., a score of 130 or higher) is still very commonly used as at least a partial basis for identification. In some cases, some upper percentage of a range of scores (e.g., top 10 %) is still used as the standard, based on the notion that a gifted child is someone who performs better than other children of the same age. Researchers and practitioners have come to agree that a more diverse system that incorporates measures other than IQ must be used to identify gifted children.

To identify gifted children, it may be helpful to use general behavioral characteristics of the individual, such as having a large vocabulary, the ability to express themselves well, mental agility, a sense of humor, and concentrate on one thing for a long period of time. However, just because a child can systematically memorize, say, the names and characteristics of hundreds of animated cartoon characters, this does not mean he or she will easily be able to learn and retain the names and properties of the 118 chemical elements or understand the power of the periodic table for organizing these. Similarly, even children who can focus for hours at a time on an activity such as catching insects may not demonstrate any interest in the intricacies of research or the creative arts such as painting or music. It is normal for people to be stronger in some areas and weaker in others. The domain-specific, dynamic nature of science, with its encompassing of a wealth of different fields of study, can accommodate children's varied areas of interest, and for this reason it makes an ideal subject area for children to show their giftedness and in which educators can identify the giftedness. A great deal of attention has recently been paid to science education in research and practice related to domain-specific giftedness.

Taber (2007) discussed gifted education practically from different perspectives in the context of formal secondary school level science education in the United Kingdom. He proposed four clusters of characteristics of what he termed "able science learners" (p. 9): "scientific curiosity," "cognitive abilities," "metacognitive abilities," and "leadership". Sumida (2010) has developed an original behavior checklist that can be used for Japanese primary school children in science classrooms in that non-Western context, including 60 items such as "reports clearly the result of an observation and experiment" and "tries to do things in his/her own way, not according to the instructions given" (p. 2103). As a result of his analysis, three gifted styles in science were identified: "spontaneous style," "expert style," and "solid style."

Among those scientists who have made their mark on history, quite a few are known to have lived with not only outstanding talent and brilliance but also some kind of learning difficulty. Even if a child might be identified as gifted based on multiple criteria, it is possible that the child has special educational needs as well. Unique children who possess both gifts and challenges are referred to as "twice-exceptional" or "dual-exceptional" children. Even when children are identified as gifted, it is inaccurate to view them as perfect children who will demonstrate excellence in every field. Exceptional students will also need support for their unique socio-emotional development.

Gifted Education in Science, Table 1 Two forms and contexts of gifted education program in science

	Formal	Informal
Acceleration	Skipping grade, early entrance, special class, advanced learning in a specific subject, dual enrolment, AP/college credits, differentiation	Dual enrolment, home tutoring, science club
Enrichment	Personal learning, project learning, learning center approach, cooperation with companies or museum/zoo	Saturday/summer/winter science program/camps, science fair/contest, science Olympic, special program in companies or museum/zoo

There are two main forms of gifted education programs. They are "acceleration" and "enrichment." The acceleration is to provide children an opportunity to study the content in the upper grade curriculum and take credits. Skipping grades, special grouping in a specific subject, the forms of advanced placement (AP) courses variously provided in some countries, and dual enrolment are examples of the acceleration. Acceleration does not mean pushing a student beyond their capabilities; it means matching the science curriculum and instruction with the readiness and motivation of the student in order to appropriately extend the student.

Enrichment provides children an opportunity to study interdisciplinary and/or extended content. Forms include personal learning, project learning, center approaches, weekend/vacation programs, and contests. Table 1 summarizes the key characteristics of acceleration and enrichment.

Wai et al. (2010) assessed participation in various educational opportunities such as academic competitions, research apprenticeships, academic clubs, summer programs, and accelerated classes among 1,467 individuals who had been identified as gifted in mathematics at age 13. They found that those who had been involved in more of these educational opportunities (a higher "STEM dose") had, at age 33, a higher rate of notable accomplishments in STEM, such as earning a Ph.D., writing publications, obtaining patents, or securing an academic career.

Several points are proposed for consideration with regard to the development of gifted education in science.

1. There is a need to reevaluate just what young children are potentially capable of doing. At the start of the twenty-first century, various research findings showed that students' scientific competence – even among very young children – exceeded the expectations of the past. When designing formal gifted education, the provision of high-quality education that meets individual needs in early grades is crucial.
2. The second point to be considered is the issue of respect for individuality and diversity in education. In reality, the major issues faced by gifted educators are problems like the students' loss of self-confidence, the pressures related to the perfectionism typical of gifted students, and the underachievement of gifted students in areas outside their interests. An appropriate balance is needed between a focus on acquiring knowledge efficiently and developing skills appropriately within the expected context and on demonstrating independence and collaborative creativity.
3. An appropriate and robust educational model must be developed for gifted students to ensure that their talents are properly cultivated and can blossom fully, and to ensure that these students can actively contribute to society. The development of science curriculum and teaching materials that accommodate the special needs of gifted children and the implementation of related science teaching methods and assessment is relevant to all teaching subjects, school types, and education in general, and can be used in the educational activities of parents and communities as well.
4. The fourth issue to be considered is the need to provide opportunities where all children can demonstrate their giftedness. Support for highly gifted social minorities is an important issue. Opportunities need to be created where all children can develop their giftedness and receive high-quality education.

In conclusion, a model of gifted education must not only cultivate excellent professionals such as scientists and engineers but also must be usable as a model of education that can improve the general literacy of the public. Gifted individuals, even students, should be strongly encouraged to give their maximum effort, just like scientists and athletes. Improving one's own knowledge and raising one's level of thinking and skills is a beautiful process, brings joy and inspiration, and produces educational value that serves as a good model for others. Schools, communities, and families may be able to work collaboratively to clarify their various roles and targets for achieving advancements, diversification, and qualitative improvements in the twenty-first-century science education.

Mobile Learning Technology

At present there are three predominant forms of handheld electronic information and communication device: e-book readers, tablet technologies, and smartphones. However, as the range of features offered by each of these devices is extended, the distinctions among them are becoming less clear. This entry reviews the current state of each kind of device and comments on applications for science education.

E-book readers are portable electronic devices designed primarily for the purpose of reading traditional analogue books in digital form, including newspapers and periodicals. This form of digital device is characterized by its comparative low cost, long battery life, and slow screen refresh rates. Many of the low-cost e-book readers incorporate a display technology which reflects light – referred to as "e-ink" – that is designed to emulate the appearance of ink on paper and is reported to be less tiring to read than luminous LCD displays in a variety of light conditions. A feature of this technology, employed by the popular Kindle, Sony Reader, Nook, and Kobo e-book readers, is the ability to display fixed black and white images and text for long periods with minimal use of battery power. Many of these handheld devices now offer touch-sensitive color screens with SD card readers, Wi-Fi, and/or 3G/4G connectivity to mobile telephone service providers to access content.

Tablet technologies are characterized by thin, touch-sensitive color screens with very fast processors and faster screen refresh rates to enhance user interactivity. Tablets are generally more expensive than e-book readers, and the common use of LCD screens offers greater resolution for the display of high-quality images and multimedia in low-light conditions. Many of these devices incorporate global positioning systems (GPS) for map location and multiple cameras for capturing still images or video. These can also be used for teleconferencing or simple multimedia production. Tablet devices are primarily designed to be connected to the internet via Wi-Fi via local area networks provided by educational institutions, libraries, or local Wi-Fi "hotspots" (e.g., cafes, or airports). More expensive tablets also provide 3G/4G connectivity for seamless connection to the Internet via mobile telephone service providers.

Smartphones are presently comparable in cost to larger tablet devices but arguably have

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

two key elements that differentiate them from the growing suite of features offered by tablets. Firstly, smartphones by design are intended to be highly portable, which puts limits on their physical size and weight. Originally conceived as a mobile phone with "extended" features, smartphones are now rapidly evolving into smaller tablet devices that offer all of the capabilities found in larger tablets (e.g., GPS, internet connectivity via Wi-Fi, e-mail, and videoconferencing), with the addition of 3G/4G connectivity to mobile phone service providers for voice and SMS text. The continued development of new targeted software applications, referred to as "apps," designed to be downloaded to tablets and smartphones allows users new opportunities to customize the device and thus extend their influence in education, entertainment, and the workplace.

The ubiquitous nature of mobile devices combined with the relative low cost of "apps" means that educators and students are realizing creative and exciting ways to investigate the use of digital pedagogies in science education, e.g., apps that allow students to perform motion analysis, manipulate molecules in 3-D, or view star maps of the night sky. Smartphones and tablets allow students to research information with ease and perform simple data-logging tasks using cameras, video, and sound recording for later data analysis. An exciting development is their use by remote students as a communication tool, enabling them to participate in collaborative science projects or to support face-to-face or virtual presentations to peers. Handheld devices also offer engaging ways for students and teachers to develop and record digital portfolios to showcase student learning and encourage the establishment and growth of science learning communities.

Health Education and Science Education

Albert Zeyer
Institute of Education, University of Zurich,
Zurich, Switzerland

Keywords

Health; Health literacy; Health promotion; Medicine; Prevention

Health is a paradigmatic *socio-scientific issue* in science education. Given the current high prominence given to socio-scientific issues in many science curricula, there is a very clear and strong case that health issues and health education should be included more intentionally and prominently than these are at present. Several broad arguments that support this claim can be identified in current literature (e.g., Zeyer and Kyburz-Graber 2012). The *grand challenges of the twenty-first century* consistently involve issues directly or indirectly related to health. Incorporating health issues in science education can help in promoting *scientific literacy* and in fostering *critical discourses* on the role of science in society and the role given to science in school contexts. While these arguments have been recognized for decades in *environmental education* and its relationships with science education, the same cannot be said of health education. Yet evidence is particularly strong that health issues awake *interest and motivation* for science in young people. Indeed, in PISA 2006, the ten science topics students found most interesting were all directly or indirectly related to health and medicine (Bybee 2012), and in the Relevance of Science Education (ROSE) study (Schreiner and Sjøberg 2004), girls' interests were predominately focused on health- and medicine-related topics. This crucial link between health and science education is partially recognized in school biology but widely neglected in other school science subjects, for example, school physics, and also in research in science education.

In particular, *biomedicine*, an infinite source of attractive science topics, is far from being sufficiently recognized.

Health literacy is commonly described as the cognitive and social skills which determine the motivation and ability of individuals to gain access to, understand, and use information in ways which promote and maintain good health (WHO 1998, p. 10). It is a key concept for bridging this persisting gap between health promotion, prevention, medicine, and science education and for establishing a new mutual relationship between these fields. Health issues are typically complex, value laden, and epistemologically disputed. They are a salient opportunity for cultural border crossing (Aikenhead 2000) and hence represent an intrinsic challenge to traditional transmissive science education and research of science teaching and learning.

Heterogeneity of Thinking and Speaking

Eduardo F. Mortimer[1] and Charbel N. El-Hani[2]
[1]Faculty of Education, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil
[2]Institute of Biology, Universidade Federal da Bahia, Salvador, BA, Brazil

Heterogeneity of thinking means that in any culture and in any individual, there exists not one, homogeneous form of thinking, but different types of verbal thinking (Tulviste 1991). This general idea can be also found in other formulations, for example, in the "tool kit" analogy used by Wittgenstein for characterizing his language games. It expresses, also, an acknowledgement that word meanings are essentially polysemous.

The notion of heterogeneity despite genetic hierarchy, discussed by Wertsch (1991), assumes that different forms of thinking can be ranked genetically (in the sense of development or generation), but the latter forms are not assumed to be more powerful. Based on the notion of "spheres of life" mentioned by William James in his description of where common sense, science, and critical philosophy may be adequate and appropriate, and on the "activity-oriented" approach outlined by Tulviste, Wertsch assumes that the development of new forms of activity gives rise to new types of thinking. Nevertheless, since the earlier forms of activity continue to fulfill some role in culture, the old types of thinking employed in these earlier forms are preserved and continue to function well in their appropriate contexts. According to Wertsch (1991), "this position [. . .] can be summarized by saying that although some forms of functioning emerge later than others, they are not inherently better" (p. 97).

Assuming the heterogeneity of thinking implies recognizing the coexistence in the individual of two or more meanings for the same word or concept, which are accessed and used in the appropriate contexts. Science itself is not a homogeneous form of knowing and speaking and can provide multiple ways of seeing the world, which can exist together in the same individual, and be drawn upon in different contexts. For example, the concept of the atom is not restricted to one unique point of view. Chemists deal with the atom as a rigid and indivisible sphere, like the Daltonian atom, in explaining several properties of substances. The structural formulae used by chemists also represent the atoms arranged in molecules in this way. This model is not, however, suitable for explaining several phenomena, including, for example, chemical reactivity, where more sophisticated models, including those derived from quantum mechanics, are used.

A diversity of authors have argued that people can have different ways of seeing and conceptualizing the world. Bachelard, for example, in comment that the concept of mass admitted different meanings, stated that “one concept alone was enough to *disperse* the philosophies and to show that the incompleteness of some philosophies was attributable to the fact that they rested upon one aspect, they illuminated exclusively one facet of the concept” (Bachelard 1968, p. 34). Different ways of knowing and forms of knowledge correspond to the realities of varied social contexts. It can be argued, however, that the concepts and categories available in all the spheres of the world are held in a similar form by a number of individuals, in such a manner that effective communication becomes possible.

These “collective representations,” using the expression of Durkheim, are supra-individual in nature and are imposed upon individual cognition. When Vygotsky pointed to the social dimension of human mental processes, as he did in his general genetic law of cultural development, he was drawing on this position. The fact that those collective constructions are imposed upon individual cognition follows from the development of individual thinking through the construction of an internal plane of functioning by means of cultural tools made available through social interactions. As our social experience is diverse and multifaceted, we do not share only one series of concepts and categories that can be used to signify the world of our experiences. On the contrary, we have at our disposal a diversity of stabilized meanings in different social languages, the weight each of them in our personal way of thinking depending on the extent to which we had opportunities to fruitfully use them throughout our development, in order to face challenges posed by our experiences.

For certain concepts the heterogeneity of thinking and speaking is so overwhelming that each community has its own conceptual ways of dealing with a particular concept in the contextual situations that demand its use. This is the case of the concepts of heat and temperature. Consider two communities for whom these concepts are very important: firefighters and air-conditioning technicians. While for the first community heat is heavily associated with hot things, for the second there are two kinds of “heat,” operating in different contexts: the hot “heat” and the cold “heat.” When installing an air conditioner in a room, members of the second community talk about “avoiding the cold escaping from the room through isolating it.” Thus, these two communities each have a theory for heat that is quite different, and both are quite different from the scientific theory, yet each works very well in the context in which it was developed and specifically applied.

A way of modeling this heterogeneity of verbal thinking is through the theory of conceptual profiles (Mortimer and El-Hani 2014). Conceptual profiles can be seen as models of the heterogeneity of modes of thinking and speaking available for people with a given cultural background to use in a variety of contexts or domains. Modes of thinking are treated here as stable manners of conceptualizing a given kind of experience, by ascribing to it a socially constructed meaning attributed to a certain concept. In our approach, each mode of thinking is modeled as a zone in a conceptual profile, stabilized by ontological, epistemological, and axiological commitments underlying meaning making about a concept. Thus, we are not dealing only with an individual’s conceptual thinking, but with how it comes to be constrained by a set of socially constructed commitments, which in turn grounds the ascription of particular meanings to a concept.

Conceptual profiles are built for a given concept and are constituted by several zones, each representing a particular mode of thinking about that concept, related to a particular way of speaking. Each individual has his or her own individual conceptual profile. It is important to notice, however, that, according to the conceptual profile theory, it is only the relative importance (or "weight") of the zones that varies from person to person, while the zones or modes of thinking themselves are shared by individuals in a given sociocultural background, as maintained by sociocultural approaches to human action. Those differences in relative importance depend on the individual's experience, which offered and offers more or less opportunities for applying each zone in its appropriate contexts. For example, consider the concept of "mass." The empiricist notion of mass, as something that can be determined with a scale, is likely to have a greater importance in the profile of a chemist who works daily in a chemical laboratory weighing samples than a rational notion of mass as the ratio of resultant force and acceleration. The opposite holds true for a physics teacher who teaches Newton's laws every year to several classes. In this sense, each individual has a different conceptual profile for each concept, with different weights in each zone, depending on their everyday school and work experiences.

For example, in a conceptual profile built for the scientific concept of "heat," we find a zone corresponding to the scientific way of thinking about heat as a process of energy transfer between systems at different temperatures and modes of thinking related to the everyday concept of heat which assumes heat as being substantive in nature and proportional to temperature (so that we can speak about "cold heat" and "hot heat"). In the science classroom, students should learn the scientific concept. This amounts to an enrichment of the conceptual profile of heat. In everyday life, they will find, however, discursive contexts that reinforce the idea that heat is a substance and is proportional to temperature. To put it differently, the pragmatic value of everyday language will preserve meanings that are at odds with the scientific view. For instance, in a shop a student will naturally ask for a "warm woolen coat." This mode of speaking is far more appropriate and powerful than the scientific discourse in that context, and, due to the inextricable relationship between thought and language, it is likely to bring with it a corresponding mode of thinking. After all, communication with the salesperson will only be more difficult if the student asked for "a coat made from a good thermal insulator, which prevents the body from exchanging heat with the environment."

This example leads to two important conclusions: (1) scientific modes of thinking and speaking are not more powerful in all contexts of experience, but just in some of them – thus, science education cannot take as a goal the replacement of everyday language by scientific language; (2) the usage of particular language has consequences, since it is closely and importantly related to modes of thinking and plays a central role in how we deal with different problems in our everyday lives. Hence, one should accept the fact that each of everyday language and scientific language tend to be used in different contexts, where each of them shows pragmatic value. One is not really recognizing what is at stake if one says that when the student asked for a "warm woolen coat," she was just using a manner of speaking. All that is consequential in relation to this event concerns the fact that she used a specific mode of speaking!

The Bakhtinian notions of speech genres and social languages can help us find ways to relate different zones of a conceptual profile with different ways of speaking. Bakhtin claims that a national language is not unique, but composed of several different social languages, which "are specific points of view on the world, forms for conceptualizing the world in words, specific world views, each characterized by its own objects, meanings and values. As such they all may be juxtaposed to one another, mutually supplement one another and co-exist in the consciousness of real people" (Bakhtin 1981, p. 292).

In addition, we should consider that to become aware of a multiplicity of meanings and contexts involves, in our terms, the dialogue between new and old zones in a conceptual profile. Any true understanding, or meaning making, is dialogic in nature because we lay down a set of our own answering words for each word of an utterance we are in the process of understanding.

Another interesting question to address is which sequences of communicative approaches (Mortimer and Scott 2003) would be more productive in a teaching/learning context while engaging in a dialogic relationship with students committed to different worldviews and ways of knowing, provided that neither students nor teachers can forget that the main goal is to understand scientific ideas.

Dialogic approaches in the beginning of a teaching sequence offer the opportunity for students to express their views and then later to see how these views relate to a given scientific perspective. In addition, dialogic engagement is potentially motivating of students, drawing them into the problem at hand and legitimizing their expression of whatever ways of talking and thinking they possess. At the same time, dialogic approaches should not be restricted to the initial exploration of students' conceptions. It is important that students have also the opportunity to explore newly learned scientific ideas for themselves through talk and other actions.

Nevertheless, dialogic approaches alone do not ensure meaningful learning. Normal science is played through authoritative discourse, which offers a structured view of the world. It is not possible to be introduced to the tools of scientific reasoning without guidance and assistance. The authority of scientific arguments helps to develop a high degree of intersubjectivity between different people sharing the same scientific paradigm. Thus, if meaningful learning involves making connections between ways of thinking and talking, science teaching should allow for a progressive shifting between authoritative and dialogic communicative approaches, with each giving rise to the other. Thus in a teaching sequence, it is possible to find moments when the teacher encourages dialogic discourse to make students' everyday views available, so as to help students become aware of them. The approach can be shifted to an authoritative one when she aims at introducing the scientific point of view. Then she prompts dialogic discourse as she encourages students to explore and apply the scientific view. Thus, the shifts in communicative approach continue throughout the teaching sequence.

Assuming the heterogeneity of language, meaning, and thinking and the dialogic nature of understanding and learning as theoretical principles that support conceptual profiles, we are in a position to define the basic tasks that should be carried out if we wish to understand how people learn scientific concepts and how these concepts can be taught in terms of conceptual profiles:

1. Determine the zones that constitute the conceptual profile for a number of central concepts.
2. Characterize individual conceptual profiles by investigating how these zones are used in different contexts by individuals belonging to certain groups.
3. Investigate the interplay between different ways of thinking and modes of speaking in the meaning making process in science classrooms.

The conceptual profile notion helps answer the question of what kind of learning should be expected in culturally sensitive science teaching. It preserves the idea that to develop a conceptual understanding in science, it is necessary to establish relationships between scientific and everyday meanings for the same words. But this relationship is not one of subsuming all other forms of knowledge into science; rather it is one of dialoguing between different forms of knowledge in order to clearly distinguish among them and among the contexts in which they can be better applied. In this sense, meanings other than the scientific ones that a word can acquire are not treated as "inferior," but as culturally adequate for the different spheres of life in which we act and talk. This does not mean that one should necessarily avoid being critical about common sense and other culturally based views, but rather that one is entitled to restrict the validity of these criticisms to the domain in which science is valid. In critiquing, for instance, a commonsense view that heat is proportional to temperature and opposed to another form of heat, "cold," a teacher should insist that this latter view is different from the scientific one while also accepting that it is far more convenient to speak about "cold" and "hot" things in everyday life as these have deep cultural roots, are part of our language, and allow for communication in most everyday situations and activities.

Nevertheless, to deal with other everyday life situations, the scientific view of heat as a process of energy transfer is far more convenient than the commonsense view of heat and cold as properties of materials. Consider, for example, a case in which one has to decide which type of container is better to preserve the low temperature of a drink in a warm day, one made of aluminum or one made of glass. The commonsense view would lead us to choose the aluminum, since it is "cold." The scientific view, instead, helps us understand that this coldness is due to the transfer of heat from the aluminum to the liquid, thus making the drink warmer. Since aluminum is a better thermal conductor than glass, the drink will get warmer more quickly in the aluminum than in the glass.

It is in this sense that we claim that the heterogeneity of thinking and speaking helps us comprehend how a student can come to apply a scientific idea she understands in some but not all contexts of her daily life. In the first case, to talk about warm clothes, the commonsense view is far more convenient. In the second, to decide in which type of glass to drink a cold drink in a warm day, the scientific view is much more appropriate. If we help a student to become aware of her conceptual profile of heat and temperature after learning the scientific view, she can comprehend in which contexts of daily life she can apply this scientific view she came to understand.

Finally, it is most important to note that by proposing a theory that holds multiplicity of meanings and dialogue as basic principles, we seek to position the science learner in a place coherent with her pluralist condition of belonging to different communities and dealing with different points of view. This pluralist condition constitutes the rule and not the exception in the lives of most students.

In presenting heterogeneity of thinking and speaking as a cornerstone to learning science, we intend to restate the centrality of conceptual learning for the endeavor of teaching science, while recognizing, at the same time, the importance of culture, language, and context in this process. Even if science curricula today tend to be built around thematic and contextual issues, the essential intent of adopting such approaches includes the learning of scientific concepts, something that is still at the core of the problematic nature of science teaching and learning.

High Stakes Testing

May M. H. Cheng
Department of Curriculum and Instruction,
The Hong Kong Institute of Education,
Hong Kong, China

Keywords

Standardized achievement tests

"High stakes tests" are so labeled because they carry serious consequences for the students and/or educators. They normally take the form of standardized achievement tests and are common tests across a nation, state, or city. The results of the tests impact on students in terms of whether they get a special diploma or certificate for gaining entrance to a higher level of education. There is impact on schools or teachers or educators including financial rewards, funding level provisions, public perceptions, social status, or even sanctions.

As the consequences are serious, parents, students, educators, and the public in general have concerns about these tests, including validity issues and unintended negative consequences. Some researchers are of the view that it will require further studies to establish the positive impact of these tests. They maintain that there is a lack of evidence to show that testing improves student learning or instruction. There are financial implications for the design and administration of the tests. Some educators are concerned about teaching to the test, as less emphasis may be placed on concepts or content which are not tested.

Despite the serious consequences, there are researchers who advocate for the positive impact of high stakes testing. They maintain that students become more motivated or work harder and parents become more involved. There are suggestions that high stakes testing provides fair judgement for progression to higher education. Good scores further motivate student learning, while teachers provide better instruction to students and are motivated to figure out ways to improve student learning outcomes.

There are suggestions to provide alternatives to the large-scale testing approach, e.g., adoption of school-based assessment. These practices have led to discussion and research on teacher judgement. Furthermore, there is research which looks into the impact of high stakes testing on ethnic minorities and ELLs.

History of Science

Josep Simon
Grupo de Estudios Sociales de las Ciencias,
las Tecnologías y las Profesiones (GESCTP),
Universidad del Rosario, Bogotá, Colombia

Keywords

Case studies; History; Interdisciplinarity; Kuhn; Nature of science; Philosophy of science

History of science is one of the reference disciplines in science education research and practice. Science education and the history of science have a long record of interactions, based on the role that history has consistently played in the narratives of science and its teaching. But, in addition, they have lived convergent developments in their making as modern academic disciplines from the

1960s to the present. A good illustration of this special relationship is the large impact that, in the last half century, Thomas S. Kuhn's *The Structure of Scientific Revolutions* has had on both fields. But the lives of history of science within science education are not restricted by the Kuhnian framework. The integration of history of science in science education has been shaped by a wide range of approaches and intellectual traditions. The development of history of science and science education as independent academic disciplines has also contributed to their estrangement, in spite of preserving a fertile common ground for cooperative assessments of the nature of science and its practice.

The history of science has been used as a tool in science education with the aim of providing an accurate view of how science works, a better understanding of scientific concepts and ways of knowing, and a contextual account of the place of science in human culture and society. It contributes to enhance motivation among students with regard to subjects often considered difficult, to provide a sweeping picture of science as culture, and to encourage informed participation in science and technology debates in the context of active citizenship. History of science is able to provide teachers and students with a wider and deeper understanding of science and the natural world. In addition to these large aims, history of science is a strategic resource for the production of pedagogical tools aimed at developing specific educational goals. It has intervened, for instance, in the study of conceptual change, the improvement of scientific literacy, and the dissection of the process of scientific discovery, theory building and experimental evidence uses. Pedagogical actions have made use of elements such as the replication of historical experiments, the use of classic science texts, the analysis of science rhetoric and syntax, and the building of pedagogical narratives by means of biography and key conceptual and experimental developments in historical perspective.

Putting history of science to work in science education is an acknowledgement of the fact that "history" and "science" are not mutually exclusive at all. Past events in science can be productively used to reflect on current problems. Whether leading to standard knowledge still in use, or to knowledge discarded in contemporary views, the past obviously offers the benefit of hindsight. Furthermore, the writing of science's past is supported by a mature discipline, history of science, characterized by a healthy pluralism and constructive criticism, thus able to offer penetrating insights on the making of science.

By engaging with history of science, students can reenact science in the making, according to past experiences, to confront analogous practical and intellectual problems and to deal with comparable debates to those prompted by the original events. Students can gain thus a deeper understanding of the nature and practice of science and in parallel develop their own knowledge and competence. Moreover, research in science education has proved that, in spite of their obsolescence (by current science standards), the conceptual frameworks of past science are useful to reflect on the preconceptions held by current students and the pedagogical processes required to further the learning of new knowledge through conceptual change. Thus, a connection is established between the nature and acquisition of scientific knowledge, past and present, which is of great methodological use in the creation of pedagogical knowledge.

The creation and implementation of this knowledge in the classroom requires a number of techniques of intellectual abstraction and communication which involve turning to several bodies of disciplinary knowledge, including not only the history of science but also pedagogy, psychology, philosophy of science, sociology of scientific knowledge, and science and technology studies. Indeed, the use of history in science education comes usually in the form of integrated history and philosophy of science and case studies. This approach is a reflection of the early development of science education research and history of science as modern academic disciplines in the 1960s. But, in addition, it is a testimony to the pluralism of science education as a research subject.

Like philosophers of science, in the last half century, science education scholars have made a good use of history of science to develop case studies, with the aim of gaining a better understanding of the nature of science and implementing it in the classroom. However, as for historically minded philosophy of science, the use of history of science in science education is not a simple matter of applying knowledge coming from a different field. Instead, it requires a cooperative process of appropriation and integration which involves most reference disciplines within science education.

Aligning history of science with science education requires focusing on specific aspects of science in historical perspective which are potentially useful to confront special problems identified by educationists in contemporary teaching and learning of science. Furthermore, it requires operating under a solid and explicit educational theory, including a coherent integration of pedagogical, philosophical, and psychological elements, among others. The construction of such theory and the integration of history of science within it is obviously a complex endeavor, which often involves tensions between the different disciplinary frameworks involved. The successful resolution of these tensions requires transformation as a new field of knowledge is formed.

The difficulties of such enterprise have partly hindered a larger success of history of science within science education. While history of science occupies a traditional place within science teaching, as a way of humanizing science and illustrating its cultural status, its use as a powerful tool in science education research and practice is less common. Further obstacles arise from the difficulty of providing teachers and educationists with adequate training in an additional discipline, the complexity acquired by history of science as it has developed into a well-established discipline, and the increasing distance that separates historians of science and science education scholars as the two communities have built their own academic niches.

Nonetheless, there is an important community of scholars who have developed during the last half century major work which successfully integrates history of science in science education, and there are important scholarly frameworks for the development of team work aligning science education scholars and historians of science in the production of educational research and pedagogical materials.

Early examples of such initiatives include the *History of Science Cases for High Schools* developed in the 1960s by Leonard E. Klopfer and his collaborators on the model of James B. Conant's *Harvard Case Histories in Experimental Science*; the *Harvard Project Physics* ran between the 1960s and early 1970s by Gerald Holton, F. James Rutherford, and Fletcher G. Watson; and Stephen G. Brush's initiatives in the 1970s and 1980s, leading to contributions such as his *Resources for the History of Physics* and a revised edition of Holton's *Introduction to Concepts and Theories in Physical Science*. Since then, a large number of educational projects have incorporated history of science as a driving agent in their design. It would be impossible to cite all of them, but representative examples are the *Minnesota Case Study Collection* directed by Douglas Allchin; *Mindworks: Making Scientific Concepts Come Alive*, led by Barbara Becker; the *Pavia Physics Project*, coordinated by Favio Bevilacqua; *Project 2061* of the American Association for the Advancement of Science; and the European History and Philosophy in Science Teaching (HIPTS) project. The integration of history and philosophy of science in science education is the driving force behind the International History, Philosophy and Science Teaching Group, established in the late 1980s, and its flagship journal *Science & Education*.

The status of history of science in science education research and practice rests on a solid foundation. However, its consolidation will depend, first, on the production of further studies demonstrating that history of science contributes to significant improvement and increased efficiency in science education and, second, on the willingness of historians of science and science education scholars to cooperate and to fight against the effects of academic fragmentation, caused by disciplinary specialization. This effort could involve, on the one hand, the establishment of more ambitious and updated training schemes in history of science within science education programs, taking into account the major changes that have shaped this discipline in the last decade. On the other hand, it would require a greater acknowledgement by historians of science of the central role that educational research can play in the intellectual and academic development of their own subject and the availability of a large body of expertise in this field in their neighboring faculty of education. Misconceptions on the nature of education and on the nature of history are still frequent on both sides of the divide, but they could be fruitfully overcome with the strengthening and expansion of interdisciplinary programs of intellectual and educational cooperation.

History of Science in the Curriculum

Michael R. Matthews
School of Education, Faculty of Arts and Social Sciences, University of New South Wales, Kensington, NSW, Australia

In the middle of the nineteenth century, the Duke of Argyll, in his presidential address to the British Association for the Advancement of Science, stated that "what we want in the teaching of the young, is, not so much mere results, as the *methods* and above all, the *history* of science." The Duke's exhortation has been more ignored than followed, but there has been a minority tradition in the US, UK, and European science education that has attempted to bring history into science curricula and classrooms. This minority tradition has been energized over the past decade by widespread inclusion of "Nature of Science" goals into national and state curriculum documents and science education standards; the argument of many is that the nature of science cannot be understood apart from its history.

At different times and places, there have been appeals to the following seven reasons for including a historical component in science programs (Matthews 1994):

1. History promotes the better comprehension of scientific concepts and methods.
2. Historical approaches connect the development of individual thinking with the development of scientific ideas.
3. History of science is intrinsically worthwhile. Important episodes in the history of science and culture – the Scientific Revolution, Darwinism, discovery of penicillin, and so on – should be familiar to all students.
4. History is necessary to understand the nature of science.
5. History counteracts the scientism and dogmatism that are commonly found in science texts and classes.
6. History, by examining the life and times of individual scientists, humanizes the subject matter of science, making it less abstract and more engaging for students.

7. History allows connections to be made within topics and disciplines of science, as well as with other academic disciplines; history displays the integrative and interdependent nature of human achievements.

The subject matter, or "disciplinary," arguments for history were well stated by Ernst Mayr in the opening pages of his *The Growth of Biological Thought*:

> I feel that the study of the history of a field is the best way of acquiring an understanding of its concepts. Only by going over the hard way by which these concepts were worked out – by learning all the earlier wrong assumptions that had to be refuted one by one, in other words by learning all past mistakes – can one hope to acquire a really thorough and sound understanding. In science one learns not only by one's own mistakes but by the history of the mistakes of others. (Mayr 1982, p. 20)

"Integrationist" arguments have long been the backbone of liberal approaches to the teaching of science such as those proposed by Percy Nunn, James Conant, Gerald Holton, and others. They were the core of the Harvard Committee Report, *General Education in a Free Society* (Conant 1945), and were prominent in the Harvard Project Physics program. Science has developed in conjunction with mathematics, philosophy, technology, theology, and commerce. In turn it has affected each of these fields, as well as literature and culture more generally. History allows science programs to reveal to students something of this rich tapestry and engender their appreciation of the interconnectedness of human intellectual and practical endeavors. James Conant's two-volume *Harvard Case Histories in Experimental Science* (Conant 1957) embodied these ideals and became a popular university textbook.

The success of Conant's Harvard Case Studies in college courses, and the example of Joseph Schwab's historical text-based science course at the University of Chicago (Schwab 1950), prompted Leo Klopfer to emulate the approach in the teaching of secondary science. He produced a course of *History of Science Cases for Schools* (Klopfer 1969). Each of eight cases was presented in a separate booklet containing the historical narrative, quotations from scientists' original papers, pertinent student experiments and exercises, marginal notes and questions, and space for students to write answers to questions. Teachers' guides and supplementary material were also produced.

In the USA these historically informed courses were marginalized after the 1957 Sputnik shock and the subsequent avalanche of National Science Foundation funded "catch-up-with-the-Russians" curricula – PSSC, BSCC, ESCP, SAPA, and so on. Two prominent exceptions were the Harvard Project Physics course and the Yellow Version of the BSCS *High School Biology* for which Joseph Schwab wrote the Teacher's Handbook.

In the 1980s all of the opening seven arguments for history in school science were made in influential American Association for Advancement of Science (AAAS) publications and working groups that arose from its *Project 2061* study chaired by James Rutherford who was originally involved with Conant at Harvard, then with the Harvard Project Physics course. The project's *Science for All Americans* (Rutherford and Ahlgren 1990) contained one chapter recognizing the importance of philosophy in science education and another arguing for a historical treatment of curriculum topics. The AAAS position was elaborated a year later in *The Liberal Art of Science* where it was said that:

> The teaching of science must explore the interplay between science and the intellectual and cultural traditions in which it is firmly embedded. Science has a history that can demonstrate the relationship between science and the wider world of ideas and can illuminate contemporary issues. (AAAS 1990, p. xiv)

These policy recommendations were embodied in the US Science Education Standards published by the National Research Council in 1996 (NRC 1996), where it was stated that:

> The standards for the history and nature of science recommend the use of history in school science programs to clarify different aspects of scientific inquiry, the human aspects of science, and the role that science has played in the development of various cultures. (NRC 1996, p.107)

In Britain there has also been a long tradition following the Duke of Argyll's exhortation to bring history into science programs. In the interwar years the major figures were Frederick W. Westaway and E.J. Holmyard, both of whom were historians of science, textbook writers, and deeply involved with teacher education. History had a checkered career through the many modifications of the English National Curriculum. Great prominence was given to it in Attainment Target 17 of the first 1988 draft where it was stated:

> Pupils should develop their knowledge and understanding of the ways in which scientific ideas change through time and how the nature of these ideas and the uses to which they are put are affected by the social, moral, spiritual and cultural contexts in which they are developed. (NCC 1988, p. 113.

But as in the USA, these lofty ideals simply did not transfer into classroom practice or examination questions, and progressively the historical and philosophical components of the National Curriculum were whittled away, and with the publication of the Dearing Report (1993), they just about disappeared off the English curricular landscape. One encouraging development has been the introduction in 2007 of the *Perspectives on Science* course for final year students. This curriculum, texts and examination, is explicitly concerned with "The History, Philosophy and Ethics of Science" (Swinbank and Taylor, 2007).

The professional purpose of science education is to introduce students into the conceptual and procedural realms of science. It has been argued that history of science facilitates this introduction. But science education also has a wider purpose which is to help students learn *about* science – its changing methods, its forms of organization, its methods of proof, its interrelationships with the rest of culture, and so forth. Many, as above, have argued that this requires contextual and historical approaches to science teaching.

The integrative function of history is perhaps its fundamental value to science education. History allows seemingly unrelated topics within a science discipline to be connected to each other – Einstein's analysis of Brownian motion to confirm the atomic hypothesis, with Brown's attempts to prove vitalism in biology, and maybe even Brown's botanical work in the early exploration of Australia. History also connects topics across the scientific disciplines – unraveling of the DNA code connected geology, crystallography, chemistry, and molecular biology. Historical study shows the interconnections between different realms of knowledge – mathematics, philosophy, theology, and physics all had parts to play in the development of, for instance, Newtonian mechanics and the conservation laws. Finally, history allows some appreciation of the interconnections of realms of academic knowledge with economic, societal, and cultural factors. Darwinian evolutionary theory was affected by, and in turn affected, religion, literature, political theory, and educational practice. Historical presentation can weave all sorts of seemingly separate topics into strands within disciplines and connect the strands into an intellectual tapestry (Holton 2003). Students having some such picture is a central concern of liberal education (Dressel 1979).

History of Science in Precollege Science Education

History of science (HOS) has long been advocated as a significant curriculum and an instructional emphasis in science education (Conant 1948). Indeed, in the United States, HOS has been systematically integrated into precollege science textbooks and instructional materials since the 1950s, albeit under different modalities. Examples of such integration and contrasting modalities include the *History of Science Cases for High Schools* (HOSC) (Cooley and Klopfer 1963) and *Project Physics Course* (PPC) (Rutherford et al. 1970). A systematic curricular emphasis on HOS in precollege science education continued into the 1990s. For instance, the *Benchmarks for Science Literacy* and *National Science Education Standards* included specific, grade-band HOS learning outcomes under "historical perspectives" and "HOS" standards, respectively.

The *National Science Education Standards* (NRC 1996) HOS standards for grades 9–12 include:

- "In history, diverse cultures have contributed scientific knowledge and technologic inventions. The science that aided the development of modern industrialized societies began to be developed in Europe several hundred years ago. Western, as well as non-Western cultures (e.g., Egyptian, Chinese, Hindu, and Arabic), have developed scientific ideas and solved human problems through technology.
- Usually, changes in science occur as small modifications in extant knowledge. The daily work of science and engineering results in incremental advances in our understanding of the world and our ability to meet human needs and aspirations. Much can be learned about the internal workings of science and the nature of science from study of individual scientists, in their daily work, and their efforts to advance scientific knowledge in their area of study.
- Occasionally, there are advances in science and technology that have important and long-lasting effects on science and society." (pp. 201–204)

Previous to the *National Science Education Standards*, the National Science Teachers Association, as part of its Scope, Sequence, and Coordination of Secondary School Science, (NSTA 1995) listed the following ideas related to HOS:

- In history, diverse cultures have contributed scientific knowledge and technologic inventions. The science that aided the development of modern industrialized societies began to be developed in Europe several hundred years ago. Western, as well as non-Western cultures (e.g., Egyptian, Chinese, Hindu, and Arabic), have developed scientific ideas and solved human problems through technology.

- Usually, changes in science occur as small modifications in extant knowledge. The daily work of science and engineering results in incremental advances in our understanding of the world and our ability to meet human needs and aspirations. Much can be learned about the internal workings of science and the nature of science from study of individual scientists, in their daily work, and their efforts to advance scientific knowledge in their area of study.
- Occasionally, there are advances in science and technology that have important and long-lasting effects on science and society. The following we singled out as important for students to study: Copernican revolution, Newtonian mechanics, relativity, geologic time scale, plate tectonics, atomic theory, nuclear physics, biological evolution, germ theory, industrial revolution, molecular biology, information and communication, quantum theory, technology, galactic universe, and medical and health technology (p. 140).

These outcomes can be summarized into three main reasons for including HOS in curricula and instruction, and they all are closely related to the more well-defined aspects of nature of scientific knowledge (e.g., tentativeness, creativity, subjectivity, and cultural embeddedness) (see Measurement of NOS and Assessment of NOS entries). The first is that HOS provides concrete examples about how the scientific enterprise operates. In this sense, HOS serves to contextualize and facilitate teaching about nature of science and scientific inquiry. For instance, enabling students to develop robust understandings of the stable but tentative nature of scientific knowledge would be difficult without recourse to extended historical episodes of the development of such knowledge. Similarly, students are better positioned to develop a sense of the role of paradigms and theories in the development of claims to scientific knowledge because following the stories and understanding the cultural and theoretical convictions of the scientists through the years can help provide a sense of how, why, and when scientific knowledge was accepted or rejected.

The second reason is that HOS illustrates the human and social aspects of the scientific enterprise and its interface with society. For example, under this dimension, the aforementioned recommendations from the NSTA and NRC emphasized the importance of coming to understand that individuals and groups of collaborators from many cultures and nations across the globe have carried out science. They may do so in culturally distinct ways, and examples from HOS can exemplify the cultural embeddedness of science as well as its collaborative nature.

The third reason stems from the fact that many episodes in the development of science are inextricably intertwined with the cultural heritage of humanity. Specifically, developments in scientific understandings of the natural world have been chiefly responsible for or, at least, closely associated with major shifts in how humans have come to understand their own “place” in the universe and their relationship to each other and their surroundings. Examples of these episodes include the Copernican revolution, which displaced humans from the center of the universe; Newtonian mechanics, which by showing that earthly and heavenly movements are governed by the same set of laws helped erase the pronounced separation of the terrestrial and celestial spheres that had dominated natural philosophy since antiquity; Lyell’s investigations that seeded our currently taken-for-granted conception of deep, geologic timescale associated with the development of the earth’s geologic features; and Darwin’s evolutionary theory, which shattered long-held beliefs about the nature and underlying causes of the diversity and relatedness of life on earth and advanced the mechanism of natural selection, which continues to generate significant discourse and discord at the interface of science, religion, and culture. Other major advances recommended by NSTA include plate tectonics, atomic theory, nuclear physics, germ theory, industrial revolution, molecular biology, information and communication, quantum theory, technology, galactic universe, and medical and health technology.

Assessments and HOS

Interestingly enough, despite the focus on HOS and the affordances for student science learning, this domain has rarely been the focus of assessment as an instructional outcome in and of itself. This state of affairs largely stems from the treatment of HOS in curricula and instructional materials. Indeed, the most prevalent modality for inclusion of HOS in science textbooks amounts to vignettes – both shorter and longer – about scientists who contributed to the development of target scientific concepts and theories. These vignettes often speak both to the scientists' contributions and/or their personal stories. There also are descriptions of historical experiments and the players involved, reproductions of historical images, and illustrations that showcase original publications, instruments, events, and places. Overall, these historical materials are "boxed" in some fashion so as to clearly demarcate them from the rest of the text and most often – though not always – are presented as "contained" or stand-alone additions. A student can go through such textbooks and learn scientific concepts without having to go through these historical materials, which rarely translate into connected historical narratives related to the complex development of scientific concepts and theories. Science textbooks have been criticized for their revisionist and/or over simplistic treatment of HOS. Thus, it is not hard to understand why science teachers rarely accord significance to HOS as a separate instructional outcome, which warrants that they develop HOS-specific assessments. In this regard, it should be noted that there are a few examples of more carefully planned inclusion of HOS in instructional materials, such as the HOSC, that have used what could be characterized as an explicit-reflective approach to effectively use HOS to teach about nature of science and scientific inquiry (Abd-El-Khalick 2012).

HOS as a Context for Formative and Summative Assessments

Instead of HOS-specific assessments, attention to HOS has more often been discussed as a context or instructional approach for students to further develop their understandings of nature of science, scientific inquiry, science as a human endeavor, and the cultural contributions of science. Regarding assessments specifically, many instruments related to nature of science have referenced HOS as a context for questions. Such instruments include the *Conception of Scientific Theories Test* (Cotham and Smith 1981) and *Views of Nature of Science Questionnaire* (Lederman et al. 2002).

As described above, HOS is a way to demonstrate how science is a human endeavor, a way to teach about nature of science through explicit/reflective means. Historical cases demonstrate how knowledge has progressed, been refined, and even dramatically changed through processes of observation, negotiation, and argumentation. Written quizzes, exams, and essays can examine learners' recollection and interpretation of factual events but, more importantly, also can assess learners' understanding of the rationale for how scientific events progressed within the cultural and human context. Historical case studies are useful contexts for teaching but can also be used for assessments, both formative and summative.

Assessments based on HOS can help students explicitly draw connections between those events and scientific inquiry and nature of science. For example, historical episodes such as understanding the structure of DNA provide a context for assessing the details and significance of the scientists and investigations that lead to the creation, rejection, recreation, and eventual acceptance of the DNA structural model. Appropriate assessments based on this historical case include asking learners to explain:

What empirical data were used in the process of developing the model?

What assumption did the various groups of scientists make? How did these assumptions influence their research?

How did inference and creativity play a role in model development and critique?

Who were the scientists involved and what perspectives and methods did they bring to bear on the study of DNA structure?

How, if no one had ever directly seen DNA, could models be created and a single one eventually be accepted within the scientific community as a valid scientific model with explanatory and predictive value?

In these ways, HOS cases can assess learners' understandings of the science concepts and, more importantly for meaningful scientific literacy, can prompt learners to explain how the cases represent various aspects of scientific inquiry and nature of science. Other examples of how HOS can be used to assess nature of science views can be found in the "► NOS, Measurement of" entry in this encyclopedia.

Hobbies

Heather Toomey Zimmerman
Learning and Performance Systems Department, College of Education, The Pennsylvania State University, University Park, PA, USA

Keywords

Leisure pursuits

People's regularly occurring interest-based recreational activities are called hobbies. Hobbies are leisure pursuits, in which adults and children have persistent engagement, outside of work. People who pursue hobbies are called hobbyists. Hobbyists engage in their hobbies because of interests about a topic, to experience design or development challenges, and/or the desire to participate in the hobby's activities or affinity group.

A hobby can include similar activities to a profession, but a hobby can be differentiated from work because a person engaged in a hobby maintains an amateur status. Additionally, while a person may derive a benefit from a hobby, the hobby does not provide a livelihood. However, depending on the hobby, hobbyists can also achieve a material reward or increased social status as a result of their hobby activities, including achieving leadership within affinity organizations, advancing in rank in an informal society, gaining a badge or other external recognition, and giving informational talks about their hobby at societies, museums, schools, or fairs or festivals.

Science hobbies are one kind of free-choice science learning (Falk and Dierking 2002) where people choose to make significant personal investments in a topic of interest. In this way, hobbies are part of a system of everyday science learning opportunities across the lifespan (Bell et al. 2009). Importantly, hobbies are the everyday science activities that are driven by the individual's interests rather than by the objectives of social organizations and institutions. Science-related hobbies can be directly or indirectly connected to subdisciplines of science. Science-related hobbies include bird watching, building model aircraft, stargazing, fossil collecting, gardening, rock collecting, traveling to national parks or international wildlife refuges, reading science nonfiction books, building electronic devices, raising animals, and nature photography.

To support their hobby interests, science hobbyists seek out and learn from a myriad of community and personal resources. A person may take a class or workshop from a university, an association, a community-based organization, a private firm, or a tutor, but hobbies are sustained outside of formal education through personal enthusiasm, curiosity, and interests that align with a set of informal activities. Hobbyists learn from and about various scientific resources: books, online media, specialized language, and scientific equipment. Often, a hobbyist maintains a personal collection of relevant scientific objects or tools to support their activities. Hobbyists gain knowledge about their hobby by attending science cultural institutions (such as zoos or other museums) or by participating in affinity organizations (like the Audubon Society, astronomy societies, or online forums) that overlap their hobby interests. Hobbyists may also learn more through an informal social circle by engaging with events that support increased participation in hobby activities. For example, some science hobbies include participating in engineering or technological practices where people learn to build their own equipment (as in telescopes, model rockets, or ham radios) or create technologies to support their engagement (as in websites, databases, or applications).

Based not only on the nature of the hobby activities but also through the intentions of hobbyists, hobbies have different relationships to biology, chemistry, physics, and other science domains. Science may not start as an aspect of a hobby, but over time, a person may bring in more science as they gain skills in their hobby. The hobby may involve science knowledge and practices, even if the hobbyist is not intending for their hobby to be a science-related hobby. For example, gardening may be started for reasons other than science, such as providing food for a family. But for some hobbyists, gardening overlaps with science as the hobbyist gardeners refine their knowledge of plants, soil, and ecosystem interactions by including beneficial insects instead of a pesticide. For other hobbyists, science may be a driving reason for their engagement, such as reading nonfiction books about the lives of scientists. Similarly, a child's interest in a topic may drive a family to participate together in a shared hobby related to science. A young child's interest in insects may spawn a hobby that becomes a family endeavor with the reading of many books, family trips to museums, watching nature documentaries, attending public programs, outdoor exploration to develop a specimen collection, Internet research at home and the library, and participation in specialized summer camps.

Research has shown that hobbies can provide people with opportunities for learning new science content and practices (Bell et al. 2013). Hobbies also provide access to other key educational outcomes: social development, opportunities to display expertise, enhancement of leadership skills in clubs, communication ability, and the development of identity towards science, education, and or science education.

Humanist Perspectives on Science Education

Glen Aikenhead
Aboriginal Education Research Centre,
University of Saskatchewan, Saskatoon,
SK, Canada

Keywords

Cultural emphasis; Human values; Humanistic policy and perspectives

During and ever since the formal inauguration of an Anglophone school science curriculum in 1867 (England) and 1893 (United States), ideology-based power struggles among science educators and stakeholders have animated school science policy, practice, and research. These struggles have often been identified in terms of two pervasive camps:

- Humanistic perspectives that promote practical utility, human values, and a connectedness with societal events to achieve inclusiveness and a student orientation
- A traditional perspective that promotes professional science associations, the rigors of mental training, and academic screening to achieve exclusiveness and a scientist orientation (Aikenhead 2006, p. 22)

The term "traditional" simply signifies which side won the struggle in 1867 and 1893 and became the status quo, which today is often recognized as science, technology, engineering, and mathematics (STEM) programming, a pipeline to STEM-related professions. This preprofessional training goal contrasts with the humanistic school science goal of students' preparing for responsible savvy participation in their everyday adult lives increasingly affected by science and technology.

The intervening years since 1893 have witnessed a variety of social, economic, political, and educational forces that have promoted various types of humanistic perspectives for school science, thereby, challenging the traditional status quo (Pedretti and Nazir 2011). One such challenge arose from a pluralist multiscience movement (Ogawa 1995; McKinley 2007) that fine-tuned the term "science" into "Eurocentric science" (ES) or "Western science," to make explicit its cultural roots anchored mainly in Euro-American cultures. Humanistic school science has always included scientific content and processes, but it gives significant attention to *the context* of such content and processes and to the context of learners. A humanistic school program encompasses both STEM and humanistic aspects, while traditional STEM programs exclude humanistic aspects, by and large.

Humanistic perspectives have produced such innovations as applied science courses, historical case studies, the nature of Eurocentric science (NOS), science-technology-society-environment (STSE), socio-scientific issues (SSI), citizenship education, cross-cultural or multicultural school science, and political activism. These innovations share a common interest in dealing with values, the social aspects of Eurocentric science (ES), the culture of ES, and the human character of ES revealed through its sociology, history, and philosophy.

No matter what aspects of humanistic perspectives are implemented, research studies clearly show over five decades that measures of students' ES content achievement are either improved or unaffected as a result. A synopsis of research into humanistic perspectives implemented in school science is found in Aikenhead (2006).

School science, whether traditional or humanistic, has been described using various schemes. Three are mentioned here to articulate the meaning of humanistic perspectives of science education. The first scheme is Roberts's (2011) conceptualization of two visions of scientific literacy, that is, two competing purposes for learning ES. Vision I is an inward-looking understanding of scientific disciplines themselves, and it represents a commitment to developing a potential scientist pool. Vision II is an outward-looking understanding of the roles that ES plays in human affairs, and it focuses on the relevance of ES to "a variety of science-related situations that confront adults as parents and citizens" (2011, p. 14). Vision II certainly resonates with humanistic perspectives. Visions I and II are neither dichotomous nor a continuum. A Vision I school science is rather homogenous in the sense that it is consistent enough worldwide to have international assessments conducted and be taken seriously by many governments. A Vision II school science is highly heterogeneous because it will always encompass aspects of Vision I; and its Vision II aspects are multifarious, just as humanistic perspectives are.

Importantly, both Visions I and II are only concerned with *Eurocentric* science for scientific literacy. This eliminates other cultural ways that rationally and empirically describe and explain nature, such as various neo-indigenous sciences and Indigenous ways of knowing nature found worldwide (Aikenhead and Ogawa 2007). Examples of neo-indigenous sciences include Islamic science, traditional Chinese science, a Japanese way of knowing seigyo-shizen, and the long-standing local knowledge of nature held by non-Indigenous farmer-hunters.

The exclusion of an Indigenous understanding of nature from school science is being challenged in a number of countries where Indigenous peoples (e.g., American Indians; the Mäori in Aotearoa, New Zealand; and First Nations in Canada) have suffered colonization in the past and neo-colonization today that bring economic, social, political, and cultural oppression (McKinley 2007). Local place-based ways of knowing nature by Indigenous peoples have a legacy of survival for tens of thousands of years and highlight sustainability and balance in their understanding of nature, in addition to other attributes of Indigenous worldviews (Aikenhead and Ogawa 2007).

A cultural emphasis in school science provides a broader lens for humanistic policy and practice. It considers the culture of ES, the culture of school science, students' cultural self-identities (Indigenous and non-Indigenous), and the community's cultural understandings of the physical world (Indigenous or neo-indigenous). This emphasis produces cross-cultural or culturally responsive school science, which are aspects of humanistic school science receiving widespread attention today. Where culturally responsive school science has been implemented, academic achievement of students tends to rise because of their strengthened cultural self-identities. At the same time, students have access to a richer understanding of nature by being able to draw upon two coexisting, noncompetitive knowledge systems – Eurocentric and Indigenous or neo-indigenous (Aikenhead and Michell 2011). Rather than aiming for *scientific literacy* as Visions I and II do, cross-cultural school science for Indigenous and non-Indigenous students aims for *nature literacy* that embraces both scientific and Indigenous or neo-indigenous ways of knowing nature. When school science combines both ways of knowing nature, it becomes more natural for students to learn other content associated with humanistic perspectives of school science such as NOS.

A second scheme for describing school science focuses on the content to be taught and considers two related principles: relevance of that content and *who decides* what is relevant for students, today and in their future. The issue of who decides will determine the type of ES content taught in school science, as summarized in Table 1. Of the seven categories in Table 1, only one (wish-they-knew ES) describes traditional school science or Vision I. The remaining categories indicate ways of describing humanistic perspectives of science education. (Details of each category are found in Aikenhead 2006.)

A third scheme, which summarizes some of the previous discussions, emerges empirically from five decades of research by science educators who investigated humanistic innovations to traditional school science (Aikenhead 2006).

Humanist Perspectives on Science Education, Table 1 Who decides on relevance and the resulting type of school science content (Modified from Aikenhead 2006, p. 32)

Who decides what is relevant?	Type of school science content
Academic scientists, education officials, and some science teachers, who invariably choose ES canonical content	Wish-they-knew ES
People mainly in ES-related occupations and savvy citizens. Research has identified a wealth of general and specific educational outcomes not normally found in a traditional school science but found in ES-related occupations and everyday events and issues	Functional ES
ES-related experts who interact with the general public on real-life events and who know the problems the public encounters when dealing with these events	Have-cause-to-know ES
The general public who has faced real-life problems or decisions related to ES. What ES content did they need to know to resolve their problem or make a decision?	Need-to-know ES
People who produce the media and internet sites and who draw upon sensational and controversial aspects of ES and technology to achieve motivational value for readers and viewers	Enticed-to-know ES
Students themselves express an opinion on what ES topics would be of interest to study. What are they curious about?	Personal-curiosity ES
Interpreters of culture, who can collaboratively combine aspects of ES culture with local ways of understanding ES and nature, in order to teach features of local, national, and global cultures. This category can simply include a combination of categories above. It is exemplified by, but not restricted to, STSE, SSI, and cross-cultural school science that includes Indigenous or neo-indigenous content	Sciences as culture

A humanistic perspective, however, is not the only researched innovation to have challenged the status quo of school science. But these other innovations (e.g., constructivism, project-based learning, and technology-design courses) rest on more specific educational agendas than the general agendas that guide humanistic perspectives of school science. Any one or combination of the following items identifies a feature of a humanistic school science program, which would not be found in traditional school science to any significant degree:

- Induction, socialization, or enculturation into students' local, national, and global communities that are increasingly shaped by ES and technology
- Citizenship preparation for the everyday world
- Savvy citizens cognizant of the personal, social, economic, political, and cultural dimensions of scientific practice and its consequences
- Attention to several types of Eurocentric sciences, known in the literature as established "core science" versus tentative "frontier science," and/or citizen science
- Pluralistic cultural approaches reflecting understandings of nature held by major cultures worldwide, such as Indigenous and neo-indigenous ways of knowing nature
- Knowledge *about* ES and scientists (contrasted with scientific knowledge)
- Moral reasoning integrated with values, human concerns, and scientific reasoning, where appropriate
- Seeing the world through the eyes of students and significant adults and teaching from that orientation
- Learning by interacting with the everyday world, which results in intellectual achievement, personal change, forming or enhancing one's self-identities, recognizing sociopolitical power, or engaging in practical or social action
- Playing in the culture of ES as an outsider, rather than forming a ES self-identity as an insider
- Acquiring an equity and social justice stance for political activism

One issue may never be resolved: At what point do we label a school science course "humanistic"? In other words, *to what extent* must any of these aspects of humanistic perspectives (or combinations thereof) appear in a classroom in order to characterize a school science experience for students as being humanistic rather than traditional? A school science experience could be superficially, moderately, effectively, or intensely humanistic for students. If we enhanced a traditional science program to be only superficially humanistic, we would not expect it to make a difference to a student's experience. For example, evidence from several recent studies demonstrates the negative impact of traditional school science on students' perceptions of innovations such as SSI: "Students saw the same activities [the SSI innovation] as a simple extension of what ordinarily transpires in science classrooms" (Sadler 2009, p. 36); a conclusion verified by a very extensive study of students' and teachers' perceptions of what transpires in their science classrooms (Wood et al. 2009) and verified in a review of research into students' identity in science learning (Shanahan 2009).

Perhaps a change to the culture of the science classroom or to the culture of school science itself is required before a humanistic innovation causes students to experience their science class as humanistic school science. A defining question would be: Do students understand Eurocentric science as one of several cultural endeavors for understanding nature, which is embedded within a social milieu of society and conducted by various social communities of scientists whose scientific training enculturated them into viewing the physical world according to the subculture of their discipline or paradigm? "Science is a very human activity. It involves human actors and judgments, rivalries and antagonisms, mysteries and surprises, the creative use of metaphor and analogy. It is fallible, often uncertain, and sometimes creatively ambiguous" (Lemke 1990, p. 134).

Hypothetico-deductive Method

Anton E. Lawson
School of Life Sciences, Arizona State
University, Tempe, AZ, USA

The hypothetico-deductive (HD) method, sometimes called the scientific method, is a cyclic pattern of reasoning and observation used to generate and test proposed explanations (i.e., hypotheses and/or theories) of puzzling observations in nature. The goal of the method is to derive useful knowledge – in the sense that causes are determined such that reliable predictions about future events can be made. The term "method" may be somewhat misleading as use of the HD method does not insure success. The method may fail for a variety of reasons, not the least of which is that the "correct" causal explanation may not occur to the scientist, effective ways of testing proposed causes may not occur to the scientist, and proposed tests may not be feasible with available technology or funding. The following seven steps and four inferences are involved:

1. Scientists undertake explorations that lead to puzzling observations. For example, in 1610, Galileo used his newly invented telescope to observe three never-before-seen points of light near Jupiter. Thus, a causal question arose: What caused the three points of light?
2. The scientist then uses his or her store of declarative knowledge and *abduction* (i.e., analogical reasoning) to generate one or more tentative explanations (e.g., like previously seen fixed stars, Galileo thought that perhaps the three points of light were also fixed stars).
3. Next, the scientist uses *retroduction* to subconsciously test the initial explanation against prior observations (e.g., if the three points of light are fixed stars, then their relative positions around Jupiter should be random like other fixed stars. But the points of light appear along a straight line across the middle of Jupiter. Therefore, via retroduction, the fixed stars explanation is contradicted).
4. When retroduction leads to the rejection of an initial explanation, the scientist again uses abduction to generate another explanation (e.g., perhaps, like the Earth's moon, the three points of light are moons orbiting Jupiter).
5. After a successful retroductive test of a prior explanation (e.g., if the lights are orbiting moons, then they should appear in a straight line across the middle of Jupiter; they do appear that way; therefore, the orbiting moons explanation is supported via retroduction), the scientist imagines a test and uses *deduction* to generate one or more expected results (i.e., expectations/predictions) about what subsequent observation(s) should occur – assuming that the proposed explanation is correct and the test is conducted as planned (e.g., if the points of light are orbiting moons and I, Galileo, observe their positions on subsequent nights, then sometimes they should appear to the right of Jupiter, and sometimes they should appear to the left. But they should always appear on a straight line across the middle of Jupiter).
6. The scientist then conducts the imagined/planned test and makes the relevant observation(s) (e.g., on subsequent nights, Galileo

observed the points of light sometimes to the right of Jupiter and sometimes to the left but always on a straight line across the middle).

7. Lastly, the scientist compares expected result(s) with observed result(s) and uses *induction* to draw a conclusion about the veracity of the tested explanation (i.e., if expected and observed results match, then the explanation is supported; if expected and observed results do not match, then the explanation is contradicted). In Galileo's case, his subsequent observations matched predictions deduced from his orbiting moons explanation and its planned test. Therefore, he found support for that explanation and he then proclaimed to the world that he had "discovered" Jupiter's moons. Additional historical examples can be found in Lawson (2010).

Use of the HD method does not result in certainty. In other words, neither proof nor disproof is possible. This is because two or more different explanations may lead to the same prediction; thus, an "incorrect" explanation may appear to be supported – what is called a false positive or what statisticians call a Type I error. On the other hand, a "correct" explanation may appear to be contradicted due to a faulty deduction, a faulty test, or due to invalid evidence – what is called a false negative or what statisticians call a Type II error. Nevertheless, the collective and open nature of the scientific community helps insure that "correct" explanations are eventually found and "incorrect" ones are eventually rejected.

Scientists are not the only people who reason in a hypothetico-deductive manner. All normal adults do, at least in some contexts some of the time. However, the pattern of HD reasoning remains subconscious for most adults. And without a conscious guide to reasoning, several subconscious biases and omissions may derail the process and produce faulty conclusions. These subconscious biases and omissions include cherry picking, confirmation bias, anchoring, outcome bias, wishful thinking, affect bias, and premature closure (e.g., Kahneman 2011). For an example of how these and other biases may derail physicians from correctly diagnosing illnesses, see Lawson and Daniel (2011). Hence, a key goal for science teachers is to help students become more aware of the HD method as well as the biases and omissions that can derail its effective use.

ICT in Play-Based Contexts

Susan Edwards
Faculty of Education and Arts, Australian
Catholic University, Melbourne, Australia

Keywords

Curriculum; ICTs; Play; Technologies

Introduction

Although play-based contexts may be evident across a range of educational settings, they are commonly associated with the provision of early childhood education (defined as education for young children aged birth to 8 years). Play-based contexts in this area of education are focussed on the use of play and play-based experiences as a basis for supporting young children's learning and development. The use of play and play-based learning in early childhood education is highly contentious and involves debates regarding the extent to which children should be able to play without adult intervention, the role of adults in co-constructing knowledge with young children, and issues associated with power and social relationships between peers, adults, and children. Play-based learning also invokes discussion regarding the gender dimensions of play and how these are articulated via curriculum that uses play as a basis for supporting learning. Such debates are informed by a range of theoretical perspectives including sociocultural theory, childhood sociology, critical theory, poststructuralism, and feminist poststructuralism. There is an increasing awareness of the need to understand play relationally in terms of the context in which it is located and therefore experienced by children, families, and educators (Brooker and Edwards 2010).

While ICTs are not commonly discussed in early childhood education in terms of critical or poststructuralist debates about play, they are increasingly evidenced in understandings of play that focus on children's experiences of society and their social and cultural contexts. Understanding ICTs in terms of children's social and cultural experiences has informed a shift in thinking regarding the use of ICTs in play-based contexts. Early debate regarding the use of ICTs in early childhood education suggested that technologies would be damaging to young children's development as they potentially hindered children's opportunities for engaging in the range of active play-based activities that were viewed as important for supporting learning. However, large-scale research identified multiple reference points for young children's technology use within the family context, including the use of mobile technologies, Internet use, television and DVD viewing, and the use of handheld consoles and computers (Vandewater et al. 2007). In the family context, technology use commonly includes interaction with peers and/or siblings, moderation of use by adult-imposed rules, and levels of

R. Gunstone (ed.), *Encyclopedia of Science Education*, DOI 10.1007/978-94-007-2150-0,

access associated with socioeconomic status (Stephen et al. 2008).

Counterarguments against the rejection of ICTs in play-based contexts began to emphasize the role of ICTs in society in general and in children's family and home experiences more specifically. This suggested that ICTs should have a place in play-based contexts as young children were increasingly using technologies in their broader social settings. Some of this discussion was later contextualized in relation to the idea of "digital natives" (Prensky 2001) and the "digital disconnect" (Levin and Arafeh 2002). These propositions suggested that young children were autonomous users of technologies having been born into a digital era and that their home experiences were so technologically orientated that they were increasingly disconnected from their less technologically enriched educational settings. In early childhood education this was considered particularly marked given the emphasis on play-based experiences that valued "active" play over the use of different technologies. However, these views have since been moderated by the suggestion that concepts such as "digital natives" and the "digital divide" more accurately reflect discursive constructions of children in contemporary times based on generational assumptions about how all people use technologies (Selwyn 2009), than they are on a reality necessarily experienced by the majority of the world's young children.

Use of Technology

Comprehensive research into young children's technology use in both family and early childhood education settings in Scotland by Stephen et al. (2008) suggested that young children learned to use ICTs via the same support structures that enabled other aspects of their learning, such as the acquisition of language. This included observational learning (i.e., watching adults or older siblings use a game console), scaffolded learning (i.e., being assisted in turning on the television), and/or exploratory learning (i.e., examining the properties of a computer game). Stephen et al. (2008) also noted a range of similar ICTs appearing in home and early learning settings, resulting in a definition for ICTs in play-based contexts:

> By ICT we mean not only desktop computers, laptops and peripherals but also interactive television, digital cameras, DVDs, mobile telephones, games consoles, electronic keyboards and toys that simulate 'real technology' such as toy laptops or barcode readers (Plowman and Stephen 2008 cited in text). This definition allows us to incorporate technologies that are both interactive and communicative and which are particularly appropriate for preschool age children because they do not rely on using text or a keyboard and are more ergonomically suited for three to five year old children. These technologies are present in many preschool playrooms and represent the range of resources available at home (p. 100)

As this definition (above) suggests, ICTs are increasingly acknowledged as having a functional role in play-based contexts. This includes via the use of "toy" technologies for supporting children's pretend play and/or the use of "real" technologies used for communicative or interactive purposes. Ways in which "real" technologies are used in play-based contexts include using open-ended software on desktop computers, providing children with access to video cameras to make movies associated with their dramatic play, and using applications ("apps") on touch screen tablets to support the development of problem solving, literacy, and numeracy skills. Digital cameras are also commonly employed by educators to document children's learning and are increasingly used in research with young children to help children record their perspectives on their learning environments. Technologies in play-based contexts have also been shown to support pro-social behavior and opportunities for collaborative engagement amongst young children. "Toy" technologies are used in traditional areas of play-based contexts, such as the "home corner" where toy mobile phones and "scanners" are used to create role play experiences for children, such as "going shopping." In literacy corners defunct computer screens and keyboards frequently form part of a role play scenario alongside the use of real and more traditional tools such as pens, paper, and environmental print to support children's emergent meaning making.

The extent to which "real" and "toy" ICTs are effectively integrated within play-based curricula is often dependent on the skills and attitudes of individual educators. Skills are concerned with technological abilities, such as understanding how to operate hardware, use different software, and access the wireless enabled technologies. Attitudes are associated with how educators understand the role of technologies in play-based contexts and what this means for children's learning. A common claim in the early childhood literature is that ICTs would be more widely and effectively used in play-based contexts if educators were provided with better technological support and greater access to professional development about how to use technologies with young children. This argument derives from concerns that many early learning settings do not have access to formalized information technology support services that would allow teachers to respond to problems in using technologies with greater confidence. It is also associated with the idea that teachers require further understanding about how to integrate technologies more fully into play-based contexts. This results in the situation whereby "real" or "toy" technologies may be functionally present in the play-based context, and yet not strongly connected with how teachers use play to support children's learning.

Curriculum

Interestingly, this latter point is evidenced in key international early childhood curriculum documents which tend to separate descriptions of play as a basis for learning from descriptions of technology as an important part of children's lives. For example, the English *Framework for the Early Years Foundation Stage* (Department for Education 2012) describes play as "essential for children's development, building their confidence as they learn to explore, to think about problems, and relate to others. Children learn by leading their own play, and by taking part in play which is guided by adults." (p. 6). In contrast, technology is described as a specific area of learning where children "recognise that a range of technology is used in places such as homes and schools. They select and use technology for particular purposes" (p. 9).

The definition of play does not acknowledge technologies, and the definition of technologies does not incorporate ideas traditionally associated with play, such as exploration, problem solving, and/or social relationships. This situation occurs in other curriculum documents including the *Nurturing Early Learners: A framework for a kindergarten curriculum in Singapore* (Ministry of Education, 2012), New Zealand's *Te Whariki Early Childhood Curriculum* (Ministry of Education 1996), and Sweden's *Curriculum for the Preschool* (National Agency for Education 2006). In some early childhood curriculum documents, play is positioned as having a prominent role in young children's learning and development, while technology and ICTs barely rate a mention. This is the case in the *National Curriculum Guidelines on Early Childhood Education and Care in Finland* (Ministry of Social Affairs and Health 2004) and in the (American) *Developmentally Appropriate Practice Guidelines for Practice* (National Association of the Education for Young Children 2006). Clearly understandings about how technologies relate to play as a basis for learning need further consideration.

Conclusion

While research has established the role of technologies in children's lives (Vandewater et al. 2007) and how children learn to use technologies (Stephen et al. 2008), more research is needed to determine how technologies and play can be understood as an integrated concept in play-based contexts. This includes teachers and curriculum documents being able to talk about and recognize technological activity in play-based terms, rather than continuing to abstract technologies from the core work of play as a basis for learning. This shift in research focus would be significant as it would be more strongly aligned with understanding the nature of children's play in contexts that naturally include technologies, than it would be on either what technologies children commonly use or how teachers can be best supported to use technologies with young children. Understanding the nature of technological play therefore represents a significant aspect of future research associated with the use of technologies in play-based contexts.

Identity

Heidi Carlone and Edna Tan
Department of Teacher Education & Higher Education, The University of North Carolina at Greensboro, Greensboro, NC, USA

Keywords

Beliefs; Formation; Goals; Values

Identity defies one definition; it can be defined legitimately, with rigor, in different ways. Complicating the issue is that theories of identity did not emerge in education or even in educational psychology. Thus, problems arise when science education scholars do not attend to the disciplinary roots, ontological and epistemological assumptions, implied methodologies, and limitations of the ways they use identity. This entry describes two distinct ways of defining and studying identity: (1) individual/developmental and (2) situated/identity in practice.

Perspective #1: Individual/Developmental

Since the early days of psychology, scholars have wrestled with the concept of self. When psychologists focus on identity, some important elements include goals, values, beliefs, self-efficacy, belonging, and/or roles. Erickson's (1968) work on ego identity development, as expanded by Marcia (1980), stressed four developmental stages an individual goes through as one moves from exploration of an identity to full commitment. Failure to reach such a commitment results in either a diffused or foreclosed identity while tarrying in the process of exploration lands one in a state of moratorium.

Underlying Assumptions and Methodological Implications

Some or all of these assumptions are often part of the literature that describes identity from an individual/developmental point of view.

- Identity is something to achieve. With this perspective, the researchers will examine *identity formation*, with the ontological assumption that there is such a thing as an achieved identity. A study that isolates variables affecting identity is one example of how this assumption plays out methodologically. Identity is an established state to which researchers can appeal in order to make causal claims.
- Identity is developmental. One moves toward more and more sophisticated and stable

versions of self, through stages. Scholars researching identity with this assumption use the phrase *identity commitment* and aim to define stages of such development where one's identity in a specific area develops to an advanced or more sophisticated form.
- Identity is a compilation of/affected by personal attributes, internal schemas, and/or psychological processes (e.g., goals, beliefs, and/or values). Though it may be shaped by others, identity is primarily an emic construct. From this perspective, the individual – how one sees oneself and the choices one makes in response to one's environment – is taken to be the primary unit of analysis. Context is studied in as much as it affects the choices one makes and the individual's view of oneself. One methodological implication is that the researchers' role is to uncover or mine individuals' self-understandings, often through surveys and/or structured interviews. This assumes that relevant aspects of identity are reified, with participants able to describe and define these self-understandings.

Critiques

Interestingly, much of the science education literature that claims an identity perspective eschews a purely individual/developmental lens, describing it as too static, decontextualized, and agentic. However, though science educators may not claim this individual/developmental perspective, their methodologies sometimes imply it. One marker of an individual/developmental perspective on identity is operationalizing it as a "thing" to be studied, developed, and/or strengthened. Studies that examine the factors that affect science identity, science teacher identity, or academic identity, for instance, often take up many of the assumptions outlined above.

A primary critique of the individual/developmental lens is that it simplifies the complex ideas of "being somebody" and "defining oneself" to emphasize clean categories of self-understanding and essentialist views of self. The emphasis on achieving a "coherent" identity does not adequately account for performances and understandings of self that shift from context to context and that might involve moments of improvisation and imagination. Units of analysis that prioritize individual mental functioning also means that agency is overemphasized. Processes of "becoming," in this view, seem to be more matters of choice and ignore larger social, cultural, and historical structures that shape individuals' opportunities to take up certain identities. There is not a lot of analytic space, in the individual/developmental views of identity, to examine the ways that structures like race, class, and gender bear down on individuals' everyday practices, enabling and constraining their identities. We have a say in who we become but only a limited say (Holland et al. 2001).

Perspective #2: Situated/Identity in Practice

Those who draw on a situated/identity-in-practice perspective frame identity as a way of being in the world (Wenger 1998) that influences and is influenced by local and global social, political, and historical processes. Identity emerges in practice, through acts of authoring/performances of self and positioning by others and by leveraging historical resources. Authoring involves performing oneself in particular ways and/or intentionally asserting identities in social settings. When people author identities, they perform different behaviors, speeches, and artifacts deemed appropriate in a setting, drawing cultural resources from the past, as well as those available in the immediate, local setting to do so. Successful acts of authoring are constrained by individual imagination and improvisation, accessible local and historical resources, and others' (personal, institutional, societal) positioning. An individual can be an unwitting or unwilling recipient of others' acts and be ascribed an unwanted identity because of her race, class, gender, sexuality, religion, nationality, age, or size.

A primary ontological assumption of a situated/identity-in-practice view, then, is that identity exists, not as a "thing", but in the continual work of making and remaking the self in everyday practice. Some argue that tools one uses to author oneself can be used habitually and, over time and context, can be leveraged for self-control and change (e.g., Holland et al. 2001). In other words, an identity-in-practice view does not have to be inconsistent with a view that assumes some directionality and consistency.

Wenger (1998) juxtaposes an identity-in-practice view with "self-image" by arguing "Who we are lies in the way we live day to day, not just what we think or say about ourselves, though that is of course part (but only part) of the way we live. Nor does identity consist solely of what others think or say about us, that that too is part of the way we live" (p. 151). Though reifications of self, like narratives, categories, roles, and positions, are important in constructing identity, those categories take on meaning in practice. Wenger describes identity as "a layering of events of participation and reification by which our experience and its social interpretation inform each other" (p. 151). Therefore, identities in practice can be stabilized and destabilized over time through the interactions between one's identity authoring and reception by a given community of practice.

Identity in practice has been an important concept in recent science education research because it represents a different way of viewing learning. Instead of defining it as a solely cognitive activity, learning involves new ways of talking, acting, describing oneself, and relating to others. Learning is not separate from identity work; they are inextricably connected. As actors participate in a science learning setting, they are often engaged in identity-related activities to perform themselves as particular kinds of people and make meaning of those performances in certain ways: leveraging resources from past experiences and invoking images of future participation. A situated/identity-in-practice view draws our attention to a learner's increasing participation in a community of social practice.

A situated perspective on identity has its roots in a number of theories, including but not limited to social practice theory (Holland et al. 2001; Lave and Wenger 1991), cultural historical activity theory (Engeström 2001), performance-based notion of identity (Goffman 1959), and Bronfenbrenner's ecological theory (1979). Though each of these perspectives differs slightly, a common thread is that microlevel (local), mesolevel (institutional), and macrolevel (societal) influences enable and constrain one's identity work.

An important shift from the individual/developmental notion of identity to the situated/identity-in-practice notion of identity is that, in the latter case, identity is often examined analytically as a *process* or as *identity work* or as *identity trajectories*. Instead of viewing identity as an achievement, it is viewed as an *ongoing* achievement. The route of such identity trajectories is also not straightforward as identities in the moment along a trajectory can offer different momentum toward or away from a particular recognized identity.

Underlying Assumptions and Methodological Implications

Some or all of these assumptions are often part of the literature that describes identity from a situated/identity-in-practice point of view.

- Identity emerges in everyday practices. Practices (like discourse, ways of acting, and interacting) are locally enacted but have historical longevity, meaning, and political consequence. Methodologically, this means that data collection must involve some acknowledgement and understanding of the taken-for-granted meanings of "science" and "science person" that shape what counts as normal, errant, or extraordinary engagement in practice.
- Identity is a way to account for structure and agency. Identity accounts for individual agency and choice as well as social, political, cultural, and historical structures that constrain individuals' possibilities. People act as both social producers and social products (Holland et al. 2001). This implies an analytic lens that allows for a zooming in and out to understand one's identity work.
- Identity is not simply what an individual says about her relationship to, abilities in, or aspirations regarding science or any other social group. It is not purely an individual achievement, nor is it an entirely emic construct.

It arises out of constraints and resources available in local and global contexts. This means that identity studies must employ multiple methods to understand these multiple perspectives.

- Identity work requires the participation of others (Gee 2000–2001). One cannot pull off being a particular kind of person (enacting a particular identity) unless one makes visible to (performs for) others one's competence in relevant practices and, in response, others recognize one's performance as credible. Since one is often a member of multiple communities of practice, one may have to "code switch" when traversing new cultural contexts, shifting her/his performance to signal cultural membership.

Critiques

The strength of situated identity/identity in practice as an analytic lens in science education – i.e., highlighting the fluid nature of identity work within the confines and affordances of figured worlds – also presents a significant challenge. Since identities are always negotiated and in-the-making, they become impossible to isolate or name. Researchers can observe identities in the moment as evident in performance and engagement in practice, and extensive field time is required to track how students' identity work evolves and which identities in practice are stabilized or destabilized based on available and historical resources and reception/recognition by the classroom community.

Identity of Teacher Educators

Ronnie Davey
College of Education, School of Teacher Education, University of Canterbury, Christchurch, New Zealand

Identity

A professional identity has been variously described as an occupational group's self-image, their sense of place in the world, and their idealized, desired, or valued selves. A professional identity outlines and describes how individuals and groups see themselves being and operating in their work or occupational contexts. It comprises the special occupational beliefs, actions, and knowledge that best defines the "kind" of person that individuals or groups see themselves as being, wanting to be, and acting like in their occupation, and it represents the desired and possible aspects of their occupational lives that they believe make them like or unlike other occupational groups in society.

Characteristics of Teacher Educators

The particular characteristics of a professional identity that have been advanced for teacher educators – those distinctive beliefs, behaviors, abilities, and contexts which distinguish and define them as an occupational group – include:

- A primary responsibility and role as a teacher of other teachers, as distinct, for example, from being a teacher of school children
- A comprehensive and practical knowledge of the theory and practice of teaching and learning and of education generally
- An ethicality of purpose and a strong sense of other-orientedness
- A view of teacher education as multidisciplinary in terms of its methods, but unique in the academy in terms of its "second-order" and recursive nature and content. Teaching about teaching is seen as fundamentally different as a practice to teaching about anything else.
- A commitment to an embodied pedagogy that prioritizes pedagogical method and process over content and involves real-time and ubiquitous modelling and articulation of the pedagogical process.
- A sense of living an occupational life on the margins of the various subcultures of education – a life lived, for example, between and across the cultures of teaching and research, practice and theory, curriculum implementation and policy development, schools and the academy, and so on.

Relevant psychological and social theories of (professional) identity include those of Erik Erikson, Pierre Bourdieu, Etienne Wenger, and James Gee. Recent studies focussed specifically on the professional identity of teacher educators include a special issue of the journal *Studying Teacher Education* dedicated to teacher educator identity (2011), much of the work of the self-study of teacher education practices (S-STEP) Special Interest Group (SIG) of the American Education Research Association, and a number of studies from the United Kingdom and the Netherlands of teacher educators' professional induction and ongoing professional learning.

Studies of professional identity are windows into the professional ideals of an occupational group. They are also studies of professional performance and occupational effectiveness. It has long been acknowledged that professionals' performance and effectiveness is directly influenced, among other things, by the levels of personal commitment that people make to their jobs as a genuinely *professionalized* activity – as vocations, as unique knowledge bases, and as distinct communities of experts. How teachers and teacher educators conceptualize their job as a "professional" activity directly affects how well they do it.

Imagination and Learning Science

Yannis Hadzigeorgiou
School of Humanities, Department of Early
Childhood Education and Educational Design,
University of the Aegean, Rhodes, Greece

Keywords

Creative thinking; Emotional engagement; Narrative thinking; Romantic understanding; Scientific creativity

Imagination is central to human thinking. In induction it is the imagination that helps bring some order to the elements of sense experience and intuition. And in deductive reasoning one has to go, through the use of the imagination (i.e., through suppositions, hypotheses and conjectures), well beyond what is actually present and what is actually noted. Despite its complex nature, imagination can be understood as the ability to form mental images and also to think in terms of possibilities (Egan 1992). The role that these abilities have played in scientific work, although not reported in scientific papers, can be found in the literature where scientists (e.g., Maxwell, Einstein, Planck, Feynman, Polanyi) talk about their own research or the development of scientific knowledge in general. Their views reflect the centrality of the imagination in science, whether the latter is viewed as a creative/artistic activity, that contributes to new ideas or as a daily laboratory practice that involves problem-solving, experimentation, etc. Perhaps it is van't Hoff's metaphor for the imagination as "the building material of science" that best captures the imaginative element inherent in the nature of science itself.

Gerald Holton is one of the very few who have written about the scientific imagination. In stressing the imaginative element of scientific work, Holton talks about three kinds of scientific imagination, namely, the visual, the metaphorical, and the thematic. The visual imagination in particular has played a catalytic role in scientific discoveries and the formulation of new theories and ideas. The history of science testifies to the fact progress in science is made possible because of scientists' ability to visualize and to create analogies. Galileo's and Einstein's thought experiments are perhaps best known for the power to illustrate their originator's ideas, while Young's analogy between sound and light, albeit an unsuccessful one, was decisive for our understanding of the wave nature of light. The role of the imaginative element needs to be acknowledged and recognized even in the thematic imagination, even though the imaginative element is not as evident as in the other two kinds. For as has been observed, it is the thematic imagination (i.e., the scientists' tacit or unconscious preconceptions and presuppositions) that helps shape and even determine scientific ideas, despite available evidence from empirical data or current theory that disagrees with these ideas (Holton 1996, 1998).

Imagination in science, as the ability to form mental images and visualize and/or to think in terms of various possibilities, has been directly or indirectly linked to scientific creativity. Indeed, scientific creativity presupposes the imagination (e.g., one can be imaginative without being creative, but one cannot be creative without being imaginative). This is so whether one considers the scientists' imaginative leaps, like those resulting in original ideas that contribute to scientific progress (e.g., Planck's mental leap to move from radiation itself to the radiating atom), or simply such thinking skills as problem-solving and inquiry, which scientists use in their daily work. The fact that "imagination" and "creativity" have been considered by both scientists and science educators to be two ideas that students should know in relation to the nature of science reflects the importance that science educators attach to imagination. This importance is also reflected in the view that imagination can make scientific creativity more concrete, thus offering more opportunities for a better understanding of the latter in the context of science education.

Scientific creativity, especially in the form of thought experiments through which knowledge can be acquired through mental manipulations alone, provides support for the central role of the imagination in conceptual change in science and contradicts the epistemology of empiricism that dominated the philosophy of science for the most part of the past century. Thus the recognition of the importance, if not the centrality, of the imagination in science education, came with the epistemological shift from empirical inductivism that took place during the last three decades of the twentieth century. Although some scientists and philosophers had long argued that scientific ideas (e.g., concepts, hypotheses, theories) are mental constructions and therefore they are not directly derived from observation data but are invented in order to account for these data, the role of the imagination in science education was acknowledged with the rise of constructivism, that is, an epistemology which criticized the standard, positivist, empirical view of science (see "▶ Constructivism").

Jerome Bruner's hypothesis concerning two distinctive but complementary modes of thinking, that is, the paradigmatic (or logico-mathematical) and the narrative, was decisive for the rediscovery of the importance of the imagination in thinking and learning. While the paradigmatic mode is concerned with the formation of hypotheses, with the development of arguments, and with rational thinking in general, the narrative mode is concerned with "verisimilitude," that is, lifelikeness, and the creation of meaning. It seeks explications that are context sensitive and particular (not context-free and universal), is entirely divergent, and employs literary devices, such as stories, metaphors, and hyperboles, in order to evoke meaning. Both modes of thinking are "natural," in the sense that under minimal contextual constraint, they come spontaneously into being (Bruner 1986).

The narrative mode of thinking has been considered central to science and science education. Metaphors and analogies (see "▶ Analogies in Science", "Mataphors for Learning") rely on the narrative mode. Even thought experiments are not simply visualizations (e.g., riding on a beam of light, free falling inside an elevator); they do have a narrative form (i.e., when one narrates the thought experiment), and through the listener's or reader's imagination, the situation that the narrative describes, no matter how realist or unrealistic that might be, becomes understood. In short, a thought experiment is always conveyed in a narrative form. What should be pointed out though is that the narrative mode is not as imaginative as one might think, since the paradigmatic mode tests ideas through the use of available evidence and logical arguments. And it is in this sense that the two modes of thinking are considered complementary.

The hypothesis concerning the existence of the narrative mode of thinking captures the notion of "possibility thinking" and supports the argument that imagination cannot and should not be linked only to imagery and visualization (e.g., Medawar's view that central to the scientists' work is "the ability to imagine what the truth might be" does point to a conception of the imagination as the ability to think in terms of possibilities). In science education both the ability to visualize and the ability to think of the possible rather than the actual are considered crucial (see "▶ Visualization and the Learning of Science").

More specifically, imagination is required for the generation of analogies and metaphors, for the construction of thought experiments, and for problem-solving and scientific inquiry (see "▶ Problem Solving in Science Learning"). In the context of science education, with the exception of thought experiments, in which the imagination is stimulated and used regardless of whether those experiments are teacher or student generated (with the creative imagination necessarily present in the process of generation), the above mental activities are not necessarily imaginative. In the case of analogies, helping students understand a science idea (e.g., teaching Coulomb's law as an analogue to Newton's law of universal gravitation) is not as imaginative as is the generation of the analogy, notwithstanding the misconceptions that can arise sometimes from their generation and use. Problem-solving and inquiry can be imaginative activities too but their implementation in a step-by-step fashion, or generally in ways that restrict students' freedom and imagination (e.g., through guidance toward an accepted solution or idea), does not make them imaginative.

As well as the construction and/or use of thought experiments, other imaginative teaching/learning activities are (a) open inquiry, (b) storytelling, and (c) artistic/creative activities (e.g., poetry, drama). All three activities require the stimulation and use of the imagination, through the search of various possibilities (e.g., possible factors that might affect the growth of a plant or the illumination of a room, possible combinations of words to write a poem, possible actions in role playing) and imagery (e.g., Newton under the apple tree, Archimedes in a tub, the trial of Galileo). All three can be meaningful, in the sense that they can encourage engagement with science. Such engagement can be explained by the emotional element (see "▶ Emotion and the Teaching and Learning of Science"), particularly present in storytelling and the artistic/creative activities, thus providing support for the link between emotion and imagination. This link is extremely crucial in the case of young children who role-play and pretend play in order to learn science.

The power of storytelling to stimulate the imagination can be enhanced by encouraging a "romantic understanding" of science. Based on Egan's notion of "romantic understanding," a romantic understanding of science can be defined as a narrative kind of understanding which enables students to become aware of the human context of the science content that they are supposed to learn, by associating, at the same time, such content with heroic human qualities, with the extremes of reality and experience, with a contesting of conventional ideas, and also by experiencing a sense of wonder. This definition of romantic understanding, while different from that of conceptual understanding, nevertheless relates to the content of science in that science is full of extremes, can evoke a sense of wonder, and provides ample opportunities for associating the concepts of science with people and even things that have heroic qualities. Moreover, scientific content can be associated with the contesting of convention if such content is associated with scientists who struggled against conventional and prevailing ideas and beliefs (Hadzigeorgiou et al. 2012).

The notion of "romantic understanding," which can be traced to the romantic conception of science, is in line with the view that the stimulation of the imagination facilitates thinking, and this can take place through strange and unfamiliar situations and also through the elements of paradox, mystery, and wonder. The power of wonder, in particular, to stimulate the imagination and facilitate thinking is central to the so-called "aesthetic" approach to science teaching and learning. This approach is based upon Dewey's notion of "aesthetic" experience, that is, an experience in which reason, imagination, emotion, and action are united (see "▶ Dewey and the Learning of Science").

Although the extent to which science education can stimulate students' imagination has not been specifically researched, evidence from studies on the role of thought experiments, storytelling, romantic understanding and drama in science education (see "▶ Role-Plays and Drama in Science Learning"), and the ways these approaches encourage engagement and learning is quite promising.

Immersive Environments

Michelle Lui
Ontario Institute for Studies in Education,
University of Toronto, Toronto, ON, Canada

Keywords

Immersive simulations; Virtual reality environments; Virtual worlds

Definition

Immersive environments are digitally mediated learning environments designed to engage users in an artificially created, make-believe "world." Immersive environments may take on a broad range of forms, with affordances for varying degrees of sensory immersion and awareness of the user's physical self or the presence of others. Types of immersive environments extend from massively multiplayer online role-playing games (MMORPGs; e.g., World of Warcraft) and multiuser online virtual worlds (e.g., Second Life) to surround-screen projection-based virtual reality environments (e.g., Cave Automatic Virtual Environments, CAVE).

In MMORPGs, users log into the game from a computer or a game console and assume the role of a character to accomplish the goals of the game – often collaborating and competing with other distributed players who log in from their own computers. Multiuser virtual worlds are similar to MMORPGs in the sense that each user accesses the immersive environment through their own individual computer, acts through an avatar, and interacts with other distributed users who log into the same environment. However, virtual worlds tend not to have game mechanics or goals built into the environment. Rather, users decide for themselves what they wish to accomplish in the virtual world. In the case of both MMORPGs and virtual worlds, the perception of immersion is characterized by cognitive immersion rather than spatial-motor or sensory immersion.

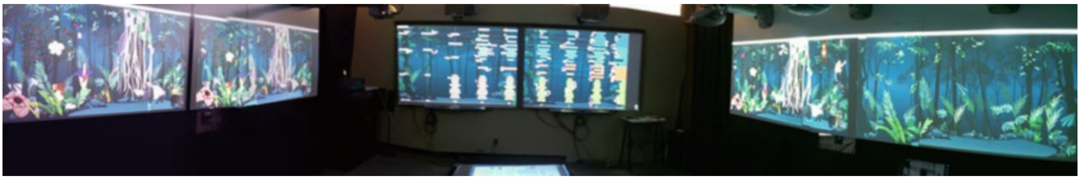
With surround-screen, projection-based virtual reality environments, users are presented with multiple-linked representations, shown on large displays that surround them (e.g., projected on several walls or into the corner of a room). Audio elements may be used to augment users' experiences, enhancing the "immersive" aspect. Characterized by sensory immersion, CAVE environments have been used for training purposes, such as submarine operation and flight simulation.

Immersive Environments for Science Education

For purposes of science education, immersive environments provide students with opportunities to visualize settings that are not otherwise accessible to them and to conduct inquiry within such an environment. In River City, a multiuser online virtual environment, students are immersed in a nineteenth-century city, where they collaborate in distributed teams of three or four to discover why people are getting sick and how they can resolve disease transmission issues (Dede 2009). Using River City, students learn scientific knowledge and inquiry skills.

Another example of immersive environment for learning takes advantage of *both* sensory immersion *and* colocated participants, allowing for collaboration opportunities, to provide a scientific inquiry experience for groups of students in a room-sized immersive environment. EvoRoom, a room-sized immersive simulation of a rainforest ecosystem, allows students an interesting way to investigate evolutionary biology and understand biodiversity. They can walk into the "rainforest," listen to sounds, observe animated plant and animal species, and then "rewind" or "fast-forward" the room through its evolutionary development over 200 million years. Collaborative inquiry activities are designed to guide or complement students' interaction with immersive simulations. Depending on the size of the room used for the immersive simulation, several small groups of students work together on different inquiry tasks. Technology supports, as accessed with tablet computers or other mobile devices, are designed to provide further support for students during the inquiry process (Lui and Slotta 2014; Fig. 1).

Taken together, immersive learning environments such as River City (i.e., a game-like environment where students are cognitively engaged) and EvoRoom (a room-sized simulation in which students are immersed physically and cognitively) offer a promising avenue for science education. New technologies, including projectors, touch screens, and computer vision and sensing



Immersive Environments, Fig. 1 EvoRoom, an immersive simulation for teaching biodiversity and evolution, which consists six projected displays (three on each side) and two interactive whiteboards (*middle*)

(e.g., Microsoft Kinect), are making it easier to develop powerful new ways for students to interact with materials and peers in a variety of learning environments.

Immersive Exhibitions

Marianne Achiam
Department of Science Education, University of Copenhagen, Copenhagen, Denmark

The immersive exhibition is a specialized exhibition genre in museums, which creates the illusion of time and place by representing key characteristics of a reference world and by integrating the visitor in this three-dimensionally reconstructed world (Mortensen 2010). A successful representation of the reference world depends on three criteria: whether the exhibition is staged as a coherent whole with all the displayed objects supporting the representation, whether the visitor is integrated as a component of the exhibition, and whether the content and message of the exhibition become dramatized as a result of the visitor's interaction with the exhibit.

Immersive Exhibition Types

Immersive exhibitions may be classified by how they represent their reference world. An immersive exhibition that is based on an *exogenous* logic reconstitutes a reference world that is real or fictional and reconstitutes this reference world as authentically as possible. This type of immersive exhibition is therefore based on a model of *reconstitution*. Examples are life-sized environments such as a forest clearing or Sherlock Holmes' study, which incorporate authentic objects such as taxidermied animals or real furniture. The layout of such exhibitions is thus governed by a logic that exists outside of (exogenously to) the exhibit, namely, the logic which characterizes the reference world (Montpetit 1996).

An immersive exhibition that is based on an *endogenous* logic is an exhibition that refers to a world that neither exists nor has existed. The world represented in the exhibition is created ad hoc to serve the needs of the exhibition objectives and follows only the rules and logic which it itself generates (which are endogenous to it). This type of immersive exhibition is therefore based on a model of *creation* (Montpetit 1996). An example could be a "sensory tunnel" in which the intent is to let the visitor explore their five senses one by one as they proceed through a tunnel.

The layout of such an exhibition is governed by the objective of providing visitors with an experience of their five senses and does not correspond to any existing reference world.

Finally, an immersive exhibition that employs a combination of exogenous and endogenous logics is an exhibition that utilizes interpretation. This is often the case when the knowledge to be exhibited is not associated with a representable human-scale realm, or the significant experiences of the reference world are abstract. Interpretative immersion exhibitions thus combine the exogenous logic of an existing reference world with the endogenous logic generated by their own setting-in-scene. This type of immersive exhibition is therefore based on a model of *interpretation* (Montpetit 1996). An example could be a walk-through scale model of the human digestive tract. The morphology of such an exhibition would be based on the exogenous logic of an existing reference world (the human digestive tract) interpreted by exhibition engineers to create an analogical representation according to an endogenous logic.

Immersive exhibitions that are based on an endogenous logic diverge from the basic analogy of resemblance that characterizes *reconstitution* immersive exhibitions. Instead of physically resembling their reference worlds, *creation* or *interpretation* exhibitions must rely on an indicative or symbolic relationship with their reference worlds. Common to all types of immersion exhibitions, however, is the fact that they consist of self-contained systems of meaning and symbols designed by the exhibition engineers for the purpose of creating a *microculture* for the museum visitor to enter into (Mortensen 2010).

The Role of the Visitor

Immersive exhibitions usually specify a role for the visitor. Depending on the model of representation and the exhibit's subject matter, the intended role of the visitor may be more or less integrated in the exhibit. For example, an immersion exhibition reconstituting an African rain forest with a pathway may provide a setting and ambience in which visitors can immerse themselves, playing the role of themselves, i.e., that of a person walking along a rain forest path. A stronger degree of immersion may be observed in exhibitions which assign the visitor a specific character to play, for instance, that of an animal in its habitat. Finally, exhibitions that utilize virtual reality can allow visitors to act on the represented world, modifying it in real time. In sum, the degree of visitor integration in an immersion exhibition falls within the range from *setting and ambience* to *role play* and finally to *real-time modification of environment* (Belaën 2003; Mortensen 2010).

Visitor Reactions to Immersive Exhibitions

How well an immersive exhibition disseminates its meaning and message depends on how well the visitor recognizes and accepts the represented world and the role assigned to them. This is an undertaking which requires a certain suspension of reality, and not all museum visitors are willing and/or able to do this. Common visitor reactions to immersion exhibitions range from *resonance*, where visitors willingly surrender themselves to the immersion premise, to *distance*, where the visitor considers the staging of the content to be disproportionate to the content itself, and finally to *rejection*, where the visitor figuratively and sometimes literally fails to enter the immersive environment (Belaën 2003; Mortensen 2010).

Keywords

Indigenous; Minority; Teacher education

Main Text

Indigenous and minority science teacher preparation programs target specific cultural populations who are underrepresented in the mainstream science teacher population. There are a variety of approaches to indigenous and minority science teacher education: programs that target accessibility, those that focus on cross-cultural pedagogy, and programs that can be characterized as transformative.

Access-Oriented Science Teacher Education

Accessibility-focused science teacher education programs provide supports to prospective indigenous and minority education students. Access programs recognize that there is not an even playing field when trying to gain entry into and remain in post-secondary education programs and try to rectify the underrepresentation of indigenous and minority science teachers by providing a variety of supports. Examples of these programs are the University of Manitoba Access Program (targets minority and indigenous students for several degree programs including primary and secondary teacher education), the Aboriginal Teacher Education Programs at Queen's University, Kingston, University of Alberta, and the University of Saskatchewan. Financial support is often a part of access-oriented programs, but academic and social supports are viewed as important factors for success. Some examples of social supports in these programs are personal counseling to deal with home sickness and family issues, help with the transition to an urban center, assistance with locating day cares or other family resources, and help connecting to cultural resources in an urban setting (such as elders, peers, and cultural programming). Academic supports may also be a part of the access-oriented science teacher preparation programs. Academic supports could include tutoring, upgrading, and study skills development. In access-oriented programs, indigenous and minority students attend classes in the mainstream science teacher education program. In other words they are external to the actual education program and provide supports to students from the outside. The programs have been very successful in Canada in increasing the representation of indigenous and minority teachers in mainstream schools, but primarily at the primary level and rarely students graduate as science specialists.

Indigenous and Minority Science Teacher Education That Includes Culturally Relevant Approaches

There are some teacher education programs that are more culturally based. Usually these programs are separate from the mainstream but affiliated with a post-secondary institution. Some programs are community based which makes it easier to incorporate local knowledge and culture into all aspects of the teacher education program. Examples of these programs are the Bachelor of Teaching (Anangu Education) at the University of South Australia and the Northern Teacher Education Program (NORTEP) based out of the University of Saskatchewan. However, the process by which cultural knowledge and Western science are incorporated into teacher preparation varies. Some programs focus on incorporating cultural into instruction, others on developing teachers as border crossers to help students navigate their worldviews and the views of science, and still other programs embed indigenous language into science instruction.

Some examples of science teacher preparation programs that incorporate culture into instruction are the Rekindling Traditions project (http://www.usask.ca/education/ccstu/welcome.html) and Malama I Ka ʻAina (http://malama.hawaii.edu/Chinn). Both of these projects were for practicing science teachers. Rekindling Traditions was a project led by Glen Aikenhead, which sought to lead science teachers through a process in order to produce culturally relevant science units for use in science classrooms. Aikenhead used a border-crossing approach to science teacher education in this project. Aikenhead (2006) describes an effective culture-brokering teacher as one who “clearly identifies the border to be crossed, guides students back and forth across that border, and helps them negotiate cultural conflicts that may arise” (p. 235). Chinn’s project worked with science teachers to develop teaching approaches that emphasized the importance of place (Chinn 2007).

Transformative Science Teacher Education

Some educators have argued that cultural understandings are transmitted through language, and the only way to develop a transformative science program that incorporates indigenous understanding is if it is taught within the local language and culture. Pihama et al. (2002) developed a theoretical framework that positions Kura Kaupapa Māori as transformative praxis. Kaupapa MāoriTheory evolved out of transformative praxis in New Zealand education driven by the incorporation of Māori theoretical and methodological preferences and practices, i.e., being and acting Māori (Sexton 2011). McKinley (2005) has argued that “one of the main ways in which Indigenous knowledge systems can survive and thrive is through the establishment of programs taught through Indigenous languages so that a dialectal relationship between language and knowledge is established that continues to act as the wellspring” (p. 227). This fact emphasized a need for a cross-cultural approach to science teaching that includes language instruction and the transmission of indigenous knowledge in its language of origin. This has been the approach in Māori science education, a model with demonstrable successful outcomes. An example of this is Te Wānanga Takiura that offers a bachelor’s degree qualification in Kura Kaupapa Māori teaching. Te Wānanga is a tertiary education program that embraces a Māori worldview, values, and aspirations.

Indigenous Knowledge

Mischack Gumbo
Department of Science and Technology Education, University of South Africa, Pretoria, South Africa

Keywords

Indigenous; Science; Science Education in the Non-West; Values

As indicated by the entry title, this piece of work is based on *indigenous knowledge (IK)*. In an attempt to explain or define it, some related concepts such as *indigenous* and *indigenous people* are explained. It is important to define these concepts separately before combining them. To make indigenous knowledge more explicit, an example in the form of a picture from a real life situation is provided.

There are various definitions of the concept *indigenous*. The term refers to plants, animals, or people that naturally belong to a particular place. One can further define it as native – not introduced directly or indirectly according to historical record or scientific analysis into a particular land or region or environment from the outside but indigenous or natural to a region or place. When applied to denote human beings, the term *indigenous* is associated with people originating or developing naturally in a particular land or region or environment. It is thus the term used to describe people who are the original inhabitants of a particular geographical area.

In keeping with the meaning of *indigenous* above, it can be deduced that *indigenous people* are the custodians of indigenous knowledge. However, it should be noted that the definition of indigenous people is not always clear. This definition is complicated by the fact that this term includes culture, identity, language, tradition, faith, and belief. In this case the term *indigenous people* refers to people naturally originating in a particular country/region/place (or aboriginal to a place), namely, natives or simply Blacks in the case of South Africa. Some people have been born in South Africa and/or their grand-grandparents were also born in this country. Unfortunately, no matter how patriotic and loyal they may be, they cannot be referred to as the indigenous people of South Africa, but they do qualify to be the citizens of South Africa. The principles of Ubuntu (caring, tolerance, respect, communal, etc.) by which indigenous Africans live allow them space to be part of the South African community. This also means that all Africans (Blacks) who found themselves in India cannot claim to be indigenous people of India even though some of them have been born in that country. This is due to the origin of their forefathers being (South) Africa from a diasporan perspective.

The term "indigenous people" is closely related to indigenous knowledge. Indigenous knowledge implies knowledge that *originates* and is exclusive to an area without borrowing from or being influenced by knowledge from outside it. The literature regarding indigenous knowledge systems does not lead to one single definition of the term but rather to a description thereof, which in itself must indicate the problem with understanding what the term really means. The concept is referred to in different forms that could include terms like indigenous knowledge, indigenous technical knowledge, local knowledge, folk knowledge, traditional knowledge, traditional environmental (or ecological) knowledge, people's science, and more.

Indigenous knowledge can be broadly defined as the knowledge that an indigenous (local) community accumulates over generations of living in a particular environment. This definition

Indigenous Knowledge, Fig. 1 Indigenous knowledge applied in the traditional medical practice

encompasses all forms of knowledge – technologies, know-how skills, practices, and beliefs – that enable the community to achieve stable livelihoods in their environment. Indigenous knowledge is the homegrown and local knowledge – knowledge that is unique to a given culture or society. It is the basis for local-level decision making in agriculture, health care, food preparation, education, natural-resource management, and a host of other activities, and it is more evident in rural communities which have not adopted more of the urban lifestyles typical of the western culture.

Indigenous knowledge is the information base for a society, which facilitates communication and decision making. Indigenous information systems are dynamic and are continually influenced by internal creativity and experimentation as well as by contact with external systems. It forms livelihoods of indigenous people who depend almost entirely on specific skills and knowledge essential for their survival. Accordingly, for the development process, as indicated above, indigenous knowledge is of particular relevance for the following sectors and strategies: *agriculture, animal husbandry, and ethnic veterinary medicine (refer to the picture below), use and management of natural resources, primary health care, preventive medicine and psychosocial care, saving and lending, community development, and poverty alleviation.*

Indigenous knowledge is relevant on three levels for the development process. Firstly, it is most important for the local community in which the bearers of such knowledge live and produce. Secondly, development agents (CBOs, NGOs, governments, donors, local leaders, and private sector initiatives) need to recognize, value, and appreciate it in their interaction with the local communities. Before incorporating it in their approaches, they need to understand it – and critically validate it against the usefulness for their intended objectives. Lastly, indigenous knowledge forms part of the global knowledge. In this context, it has a value and relevance in itself. Indigenous knowledge can be preserved, transferred, or adopted and adapted elsewhere.

Indigenous knowledge is not a system of knowledge that is in opposition to a general so-called western scientific knowledge system and should not be compared to such, but evaluated on its own merit. At the same time indigenous knowledge systems cannot be interpreted or evaluated from a Eurocentric view alone. They have to be seen and understood within their own cultural contexts. Indigenous knowledge systems are also not static and place bound; they are systems of local knowledge that warrant integration into the mainstream of knowledge.

Indigenous knowledge systems are a key element in the development of poor communities and provide “culture-fit” problem-solving strategies for a diversity of situations, for instance, in primary health care, preventive medicine, and veterinary medicine. Traditional herbs, such as displayed in Fig. 1 above, play an important role in formal and informal medical systems in South Africa.

Indigenous Knowledge Systems and the Nature of Science

Dawn Sutherland
Research Office, Canada Research Chair in Indigenous Science Education, The University of Winnipeg, Winnipeg, MB, Canada

Keywords

Cultural contexts; Knowledge; Science

Chalmers (1980) poses a fundamental question in the title of his book, *What Is This Thing Called Science?* Philosophers of science and science educators for decades have attempted to create one clear, all-encompassing definition of science. However, these two groups have rarely developed definitions on which they both agree. The complexity involved in establishing one agreed definition of science is in part due to the difference in the purpose of the definition. Philosophers look for a definition of science that will provide an accurate depiction of the process of science. This definition serves as a guideline to those in the pursuit of scientific inquiry, the scientist, and the production of new scientific knowledge. In other words, philosophers develop a functional definition of science.

On the other hand, science educators attempt to obtain a definition of science that will provide direction to those in the pursuit of learning already preestablished scientific knowledge. Thus, the definition of science is a pragmatic one, used to design curriculum, develop teaching strategies, and encourage the understanding of scientific knowledge. The motives of each discipline make the creation of one broadly adequate and acceptable definition of science virtually impossible.

In science education one definition of Western science, also referred to as Western modern science or Eurocentric science, is “the pursuit of knowledge and understanding of the natural and social world following a systematic methodology based on evidence” (British Science Council 2009). This definition seems to be one in which both science educators and philosophers of science agree. The definition of the nature of science varies from curricula and policy objective statements; however, in general it refers to the “. . .values and assumptions inherent to the development of scientific knowledge” (Lederman 1992, p. 331).

Many science educators describe the nature of science by identifying its various presuppositions or tenets. This process has led to an inventory of tenets which may include nature is knowable, science is contextual, science is predictable, scientific knowledge is dynamic, scientific knowledge is generalizable, science is linear, science subscribes to Cartesian dualism, science is reductionist, science is anthropocentric, and science can represent reality. Research programs in science education that focus on the nature of science have looked at the public's understanding of science, science teacher's understanding of science, and student's understanding of science using these tenets as a guide for evaluation.

In the new millennium, scientists have been urged by some international history and philosophy societies to learn from systems of indigenous knowledge. These indigenous traditions – which have also been labeled as local, traditional, or folk knowledge – developed as adaptations to their environments conditioned by their specific cultural contexts. The International Council for Science (ICSU) created a picture of indigenous knowledge that describes it as:

> A cumulative body of knowledge, know-how, practices and representations maintained and developed by peoples with extended histories of interaction with the natural environment. These sophisticated sets of understandings, interpretations and meanings are part and parcel of a cultural complex that encompasses language, naming and classification systems, resource use practices, ritual, spirituality and worldview. (2002, p. 3)

Many authors have tried to identify the fundamental attributes of indigenous knowledge. One such list created by Aikenhead and Michell (2011) includes the following attributes for indigenous knowledge: place-based, holistic, relational, dynamic, systematically empirical, based on cyclical time, rational, and spiritual. Research programs in science education that focus on indigenous knowledge and the nature of science tend to concentrate on the process of incorporating indigenous knowledge into science instruction and the processes of learning science in a cultural context.

Indigenous Medicinal Knowledge

Herbert Lwanga
LOG‘EL PROJECT, Kampala, Uganda

Indigenous medicinal knowledge (IMK) refers to the sum total of all knowledge and practices whether explicable or not, used in diagnosis, prevention, and elimination of physical, mental, and social imbalance and, relying exclusively on practical experience and observation, handed down from generation to generation whether verbally or in writing (WHO Traditional Indigenous Medical Programme 2008; see Soewu, Adekanola (2011)). IMK's diverse methods include physical, mental, and spiritual therapies, usually strongly influenced by the culture and beliefs dominant in a particular community.

Balasubramanian (1997) notes that IMK serves the health needs of the vast majority of people in developing countries where persistent poverty and marginalization limits access to Western medicine. IMK helps to translate natural resources into products and services of unique and organic value, improves nutritional levels by utilizing local food materials from the immediate environment, and improves health and income levels of indigenous communities for more sustainable livelihoods. Moreover, many herbal plants known to IMK have become essential raw materials for making pharmaceutical products; hence, there is an important link between IMK and the developed world (Fabricant, Farnsworth 2001).

IMK can be important in science education as a way for indigenous schools to link science with local knowledge and for students in the developing world to learn more about how the resources of the developing world contribute to scientific knowledge. IMK and science education jointly can help to translate natural resources into products and services of unique and organic value, improve nutritional levels by utilizing local food materials from the immediate environment, and upgrade the health and income levels of indigenous communities by accessing them to quality and affordable herbal medicines available in their respective localities – for community-wide, sustainable livelihoods (Nelson-Harrison et al. 2002).

The term Indigenous has come to identify those groups of people whose cultural, political, and ancestral genealogy and identity are connected to and have historical rights in particular territories. Many Indigenous people around the world have experienced colonization, attempted genocides, or formations of contemporary nation states that have bearing on their own sovereignty and self-determination. There are estimated more than 350 million Indigenous peoples across the earth. Indigenous peoples have, to varying degrees, maintained, won, or struggled for cultural and political distinction from mainstream culture and political system of nation states within the border of which many indigenous many communities are now enclosed. However, there are many Indigenous communities who do not have sovereign recognition by nation states. It is important to note that this does not mean these communities are not Indigenous; rather it is an indicator of the ongoing tensions and struggles over territory and cultural and political self-determination. Indigenous students are the children and adults with communal and genealogical ties to Indigenous communities – that is, students who themselves and/or their families are engaged in the communal and cultural life of Indigenous peoples. Many Indigenous peoples have rich knowledge systems, traditions, and traditional knowledge that are a vibrant part of community life. For many Indigenous peoples, their knowledge systems are intimately connected to their lands. Indigenous communities have been impacted by colonization in a myriad of ways, one of which is through generations of intermarriage, forced removal from homelands to new land bases, and a variety of assimilation and relocation policies that encouraged and demanded separation from tribal communities into urban locations. For some, these imposed separations were not permanent: many relocation survivors have created rich and vibrant contemporary Indigenous communities in ceded urban territories. However, these intertribal communities increase the complexity in understanding Indigenous children because many are mixed race and multi-tribal with diverse connections and participation in their cultural practices.

Indigenous Technology

Mischack Gumbo
Department of Science and Technology
Education, University of South Africa, Pretoria,
South Africa

Understanding "indigenous technology" begins with defining *indigenous*. The possible definitions are many. The term is used in reference to plants, animals, or people that naturally belong to a particular place (Hornby 1998, p. 606). It can be defined as "native," as in something not introduced directly or indirectly according to historical record or scientific analysis into a particular land or region or environment from the outside (Kim and Berry (1993, p. 2). *Indigenous* is associated with people originating or developing naturally in a particular land, region, or environment (Kim and Berry 1993, p. 2). *Indigenous* is a term used to describe people *who* are *the* original *inhabitants* of a particular geographical area (Pollock 1995, p. 21).

Indigenous people are the custodians of indigenous technology. The definition of indigenous people is not always clear (Psacharopoulos and Partrinos 1994, p. 21) as it is complicated by the fact that the term *indigenous people* includes culture, identity, language, tradition, faith, and belief (Gumbo 2001). However, indigenous people may be thought of as those people naturally originating in a particular country or region or natives. There may also be specific names such as Blacks in the case of South Africa. To be indigenous, people must be in their indigenous environment. Thus, for example, Black Africans even if born in India cannot claim to be indigenous people of India.

With respect to *technology*, technology refers to the totality of the means employed to provide objects necessary for human sustenance and comfort (Arnoldi, Geary and Hardin 1996, p. 31). It is the science of construction (Gillet 1973, p. 2). This definition can be extended to include the use of tools that are in turn the products of the same technology. Technology is the application of scientific and other organized knowledge to practical tasks by hierarchically ordered systems that involve people and machines (Naughton 1981, p. 8). Others define technology as the know-how and creative process that may use tools, resources, and systems to solve problems to enhance control over the natural and man-made environment in an endeavor to improve human conditions (Treagust and Mather 1990, p. 53). It is regarded as human knowledge applied to the solution of existing practical problems (Waks 1995, p. 2.2). Technology can therefore be defined as a disciplined process where human knowledge, skills, and resources are used to construct tools in order to find a solution to existing practical problems by investigating, designing, developing, and evaluating products, processes, and systems.

Taken together, *indigenous technology* refers to the technological knowledge, skills, and resources transmitted or handed down from the past indigenous people to the present ones to meet their needs and wants by means of investigating, designing, developing, and evaluating products, processes, and systems with an intention of solving the practical problems. Indigenous technology is used by the native inhabitants of a country or region and it constitutes an important part of its cultural heritage.

Characteristically, indigenous technologies:

- Are recognized as animate, imbued with the breath of life and they live in form and function.
- Emerge from the implicate order to reflect the art of skillful living. Indigenous technologies are pragmatic. It is responsive and responsible to the ecology in which it lives.
- Attract the learning spirit(s) and provide a learning ecology that supports the revitalization and transformation of awareness and knowledge.
- Are intended to enhance the ability to maintain and renew balance and harmony within a multidimensional environment.
- Are created within a sensory environment that builds on our sense of relationship, meaning, balance, feeling, memory, and place as well as sight, sound, smell, taste, and touch.
- Seeks to engage and evoke significant knowledge and experiences reflective of the indigenous world through meaningful interactions.
- Have the obligation to come into existence, to be used, and to transform within an ethical space that is responsible to life in all its forms.
- Have intrinsic value because we know their ancestry and what their place is in our world.

The following photos show examples of indigenous technology in South African. These technologies address such needs as shelter, food, defense, and clothing.

Factories; Manufacturing; Outside learning; Site visits

Industry visits are a valuable component in the educational landscape. These visits take various forms and can involve teachers and students from both elementary and high schools. Teachers are keen to participate in visits when the links to the curriculum are clear and explicit, but often find it difficult to make time to initiate links with industry or to see and appreciate the wide range of curriculum-relevant activities that a site visit can offer (Parvin and Stephenson 2004). Industry wishes to foster relationships with local schools, but can find it difficult to know what to offer, beyond sponsoring a football team or buying books and equipment for schools. Organizations that broker better relationships between schools and industry are important to build and sustain partnerships. Organizations in the UK include *CIEC Promoting Science* (www.ciec.org.uk) and *STEMNET* (www.stemnet.org.uk). As well as fostering relationships, these organizations create freely available materials demonstrating relationships between the science, technology, and mathematics curricula and their applications in the "real world." These materials include practical science experiments which are grounded in industrial storylines and which address important scientific concepts, skills, and knowledge. These activities can be carried out in the classroom, in after-school science clubs, to prepare for a visit and to develop the storyline further. An example of these activities can be found at www.scienceofhealthyskin.org.uk, which is aimed at elementary teachers for use with 9- to 11-year-old students. The resource encourages links with companies that produce active ingredients in sun creams, which use lanolin in cosmetic products, and in which foaming is an important criterion of product design.

To ensure effectiveness of industry visits, brokerage organizations train industry personnel and teachers so that they can work together. During training, industry personnel discover which areas of their site might have the greatest impact on students and highest relevance to the curriculum. For example, they learn how to engage students in practical activities or demonstrations in their site's laboratories and help show the vast scale and degree of automation of production, while ensuring that students meet a range of scientists and engineers engaged in design, production, management, and marketing. This allows students to appreciate the wide range of careers to which studying science can lead. Meeting the "real person" face-to-face in the industrial setting has a much higher impact on students than watching a video of that person at work. A particularly important aspect for girls is seeing women carrying out scientific and technical roles, thus providing positive role models to which they can aspire.

Effective site visits can have a long-lasting impact on students, who can be switched on to considering studying science beyond compulsory school age and potentially taking up a career in industry. Even if students do not consider such career paths, effective industry visits help them to develop a more balanced and authentic perspective of industry, beyond the commonly perceived images of chimneys, pipes, and pollution, as a 5-year study of students' ideas of industry has shown (Evans et al. 2004).

Information Processing and the Learning of Science

Richard White
Monash University, Clayton, VIC, Australia

In the second half of the twentieth century, cognitivism replaced behaviorism as the dominant paradigm in psychology. Where behaviorism avoided speculation about unobservable processes such as thinking and reflection and concepts such as understanding, mind, and will, cognitive psychology postulated models of mental processes that are involved in learning and problem solving. These models of information processing derived from digital computers, which became common at this time. The brain was pictured as a machine, like the computer, which accepted input via the senses, processed it into meaningful form, stored it, and was able to retrieve it on demand.

The classic model was of serial processing, as in the first Turing machines, where each incoming bit of information is dealt with by a central processing unit following a predetermined algorithm with the outcome placed in its turn in a memory slot, in fixed sequence. The model had shortcomings: serial processing is too slow to explain the brain's rapidity in managing complex performances; it is brittle, in that damage to any one step destroys the whole process, while the brain is robust, able to fill in gaps in input and to recognize and remedy minor errors; it is inflexible, following a rigid sequence of operations and so cannot cope with novel or messy input, something that the brain does quite well. In an attempt to reduce these shortcomings, parallel processing which handles multiple tasks simultaneously, a feature of later computers, became part of the model. Nevertheless, the model remains a model, of a machine, imperfectly matching the subtlety and complexity of the brain. As has been pointed out frequently, computers cope easily with tasks that the brain finds challenging, while the brain readily solves problems that defeat even the most powerful computers. Therefore, application of information processing to the subtleties and complexities of teaching any subject, and perhaps especially of science in its own complex depiction of the natural world, will not provide a comprehensive guide to classroom action. That does not make the model totally useless, however, just as the inabilities of the wave and particle models to explain all the phenomena of light do not make them useless in physics. There are aspects of the model that can inform teaching.

In its basic form, information processing depicts learning as a sequence of operations: selection, translation, storage, and retrieval White (1998).

Selection. As do all living organisms, humans react to stimuli coming from their surroundings. They are not, however, aware of every single stimulus. They attend to things that they judge important. While some of this judgment is instinctive, as in reaction to fast-moving objects near the head, much depends on previous learning. People observe stimuli that seem important to them at the time and ignore the rest. In this they differ from a computer, which accepts all of the input it receives. Thus, learning is not a linear process, but an interactive or recursive one.

Teachers manage students' selection by pointing out the features that matter of an object or event, such as the parts of a flower or a chemical reaction. Their success depends on whether the students accept the teacher's assertion that these features are worth attending to, and that acceptance in turn depends on a complex mix of the student's needs and purposes and on existence or absence of competing stimuli (such as behavior of other students). In other words, the students' motivations for learning, liking for science and for individual topics within it, and relation with the teacher affect what they attend to. So does their physical state: as teachers soon realize, tiredness or illness inhibit alertness and consequently selection.

Translation. According to the information processing model, learners translate observed stimuli into a meaningful form, initially held in a short-term memory buffer of limited capacity. In early childhood children acquire many skills of translation, rapidly increasing their capacity to make sense of their environment. Translation remains important in later learning, where students might need guidance to understand what they are seeing or are told. For instance, differentiating a landscape into features such as horsts, peneplains, and faults has to be learned. An important consequence is that the experienced and knowledgeable observer sees a smaller number of units than the tyro, who can be overwhelmed by the detail. If too much information comes in, the short-term buffer is overloaded, and much is lost. Teachers therefore need to teach students how to see, how to form the information into a smaller number of larger meaningful units. This needs care, for students might come to only ever see what the teacher directs them to see, and so might miss curious elements.

Information that has been processed into meaning can follow two paths. In one, it is erased by newer incoming stimuli and immediately forgotten. In the other, it remains in working memory until it is either processed further into long-term memory or is lost. Thus, people can recall events for some days, but unless the event is linked with existing knowledge for some reason, after a few days or even shorter the memory is lost.

Storage. Some of what is translated is stored as knowledge in long-term memory. Theorists have proposed various divisions of this knowledge, such as semantic versus episodic, propositional versus procedural, declarative versus non-declarative, words and images, propositions, algorithms, images, episodes, and strings. These divisions may be important in science education, since different forms of knowledge may be learned differently and therefore need to be taught in different ways; because individual learners may have idiosyncratic preferences and vary in the ease with which they acquire each form; and because different mixes of forms will result in different qualities of understanding.

Storage in long-term memory is a function of individual preference of the learner and of actions of the teacher: what the learner is interested in and perceives as meeting a need and what the teacher emphasizes as important or makes interesting. Storage can be as unorganized, unconnected elements, or as a highly interlinked network. Level of understanding is a consequence of extent of linking. Effective teaching is likely to involve making clear connections between individual pieces of knowledge within a topic and across topics. Thus, a student who perceives commonalities between gravitational, electric, and magnetic fields will have better understanding than one for whom these are unrelated topics.

Retrieval. Models of information processing do not prohibit reorganization of knowledge subsequent to its acquisition, through reflection that creates perception of new links, but essentially they present a static notion of knowledge: it is acquired and remains in long-term memory more or less in its original form, whereas human memory is more dynamic. Where in a computer what is retrieved from a memory cell is what is stored there, in humans retrieval involves reconstruction, in which factors such as context affect the recall. In one context, one might recall knowledge of motion as Aristotelian and in another as Galilean/Newtonian or a tomato as a fruit in a biology class but as a vegetable in the kitchen. The influence of context on reconstruction is largely responsible for the alternative conceptions that became the focus of much research in science education in the last third of the twentieth century. Students who learned a scientist's explanation for a phenomenon often maintained a non-science explanation as well, offering one explanation in one context and the other in another.

Metalearning. The notion of metalearning came later than models of information processing but fits readily with them. Metalearning refers to knowledge of processes of learning, awareness of their application, and ability and willingness to control them. Thus, metalearning can refer to conscious and deliberate selection, translation, storage, and retrieval (Brown 1987; Georghiades 2004).

While metalearning is fundamental to quality of learning in all subjects, it is particularly important in science education, which presents students with explanations of the complex natural world that may be at odds with beliefs that they have acquired through folk lore or through unguided experiences. Resolution of such differences is unlikely without conscious management of learning processes. Training students in metalearning is an advanced teaching skill. For accounts of practical programs, see Baird and Northfield (1992) and Adey and Shayer (1994).

Inquiry, Assessment of the Ability to

Wynne Harlen
Graduate School of Education, University of Bristol, Bristol, UK

Keywords

Formative; Inquiry skills; Reliability; Summative; Test; Validity

To inquire (also spelled enquire) is a term used in both daily life and in education, meaning to investigate or seek information to answer questions. In education, the ability to inquire is relevant in many subject domains, such as history, geography, the arts, as well as science, mathematics, technology, and engineering, when questions are raised, and the skills of generating, collecting, and using data are used in developing understanding. In science, understanding of the natural and made world is developed through using skills such as raising questions, collecting data, reasoning and reviewing evidence in the light of what is already known, drawing conclusions, and communicating results. Although an inquiry is generally initiated by a question, in education the value of the activity is more than finding an answer; it contributes both to the understanding of the "big ideas" that apply beyond the specific event or phenomenon being studied and to the development of skills that enable further learning.

Science Inquiry Skills

Skills used in scientific investigation and inquiry are identified in slightly different ways in different curricula and standards statements. However, they have much in common and generally include the following:

- Asking questions
- Generating hypotheses or possible answers
- Making predictions
- Planning and carrying out investigations
- Analyzing and interpreting data
- Constructing explanations based on evidence
- Evaluating and communicating findings

The assessment of the ability to use these skills has to take account of three key points. First is that students have to be using, or given the opportunity to use, the skill in order for their ability to be assessed. Second is that any skill has to be used in relation to some subject matter: there can be no "content-free" skill. Questions and tasks have to be asked about something, observations are made about particular objects and events, and investigations are planned to answer questions about particular phenomena. There has to be some subject matter involved when skills are used and what this is makes a difference to whether skills are used. For example, a student may be able to plan an appropriate investigation about a situation where he/she has some knowledge of what are likely to be the variables to control, but fails to do this if the subject matter is unfamiliar. This has important consequences for assessment. The subject of a particular task or test item is just one of a potentially large number of alternative subjects. Practice bears out the possibility that a student's result would be different if an alternative subject had been chosen; thus there is a variation in the results associated with the choice – an unavoidable error – since no two tasks with different subject matter or contexts can be exactly equivalent. To emphasize the role of content knowledge, the National Research Council adopted the term "practices" in place of "skills" (NRC 2012, p. 30). However, given the acknowledgment that some knowledge of the content is always involved, it does not seem necessary to abandon the use of this familiar term.

A third key point follows from the general recognition that assessment should be aligned with the educational goals and student learning objectives to be achieved through the curriculum content and pedagogy. This alignment is essential for validity of the assessment. Following the conception of the validity of an assessment as the extent to which there is evidence supporting inferences drawn from the results (Messick 1989), the validity of an assessment of ability to inquire depends on evidence that, when being assessed, students are engaged in activity that involves the use of some or all of the inquiry skills. This would not be the case, for instance, if a student simply recalls the answer to a question rather than using skills to work it out. Furthermore, the processes being used by the students should reflect the view of learning underlying inquiry-based pedagogy. This view is that students are active agents in their learning, bringing their existing experience and ideas to bear in pursuing questions or addressing problems that engage their attention and thinking. By collecting information for themselves, they have the evidence of what works and what does not work in helping them to make sense of different aspects of the world around. In addition, there is emphasis on individuals making sense of experience with the help of others, indicating a sociocultural constructivist perspective on learning and underlining the value of collaboration, communication, dialogue, and argumentation.

Assessment Purposes

Assessment of students' learning involves generating, collecting, and interpreting evidence for some purpose. Three main purposes of assessment are commonly identified: assessment to assist learning (formative assessment), assessment of individual students' achievement (summative assessment), and assessment to evaluate programs (Pellegrino et al. 2001). The focus here is on the first two purposes, which have a direct impact on individual students.

Formative Assessment of the Ability to Inquire

The practice of formative assessment, through teachers and students collecting data about learning as it takes place and feeding back information to regulate teaching and learning, is clearly aligned with the goals and practices of inquiry-based learning. It also supports student agency in learning through promoting self-assessment and participation in decisions about next steps, helping students to take some responsibility for their learning at school and beyond. Thus formative assessment fosters inquiry-based learning through supporting students in gathering and interpreting evidence in a manner that develops their understanding.

Gathering and Interpreting Data

Formative assessment is essentially in the hands of teachers who gather evidence students' skills and understanding by:

- Using questions designed to elicit students' thinking and reasons for their actions
- Promoting classroom dialogue
- Reviewing students' notebooks

For this purpose, teachers' questions are best framed to show interest in the students' thinking ("What are your ideas about what's happening here?") and to encourage the use of inquiry skills ("How are you going to test that idea?" "What will you do with these results?"). Promoting collaboration and dialogue among students not only fosters shared thinking but provides opportunity for teachers to observe how students interact and to listen to what they are paying attention to and how they are using words. The contributions and thinking of individual students can be gleaned from review of their notebooks.

However, whether the assessment is formative depends on how the evidence is interpreted and used. In formative assessment, interpretation is in terms of progress toward the specific goals of the lesson or unit of work. Both teacher and students should be aware of these goals, which determine the kind of evidence required to judge students' progress. Through discussion with students, questioning that elicits their understanding of what they are doing and listening to how they explain what they are doing, the teacher decides about the relevant next steps, which may be to intervene or simply to move on. Assessment does not need to lead to action in order to be formative – an appropriate decision may be to take no action to change the ongoing activity.

Feedback to Students and into Teaching

The main use of evidence in formative assessment is to provide feedback, which is a two-way process: feedback from teacher to students and feedback from students into teaching. Feedback to students is the mechanism by which future learning opportunities are affected by previous learning and as such has the potential to be a powerful influence on learning. Feedback is most obviously given by teachers to students orally or in writing but also, perhaps unconsciously, by gesture, intonation, and indeed action, such as when assigning tasks to students. The focus and form of the feedback have to be carefully judged by the teacher. The focus of the feedback influences what students pay attention to, and the form it takes determines whether it can be used to advance learning. The work of Butler (1988) has been of considerable influence in distinguishing between judgmental and nonjudgmental feedback. Feedback that helps learning should be nonjudgmental, that is, it should:

- Focus on the task, not the person
- Encourage students to think about the work, not about how "good" they are
- Indicate what to do next and give ideas about how to do it

In contrast, feedback that is judgmental is expressed in terms of how well the student has done (this includes praise as well as criticism) rather than how well the work has been done, making a judgment that encourages students to label themselves and compare themselves with others.

In formative assessment, feedback into teaching, using information that teachers pick up from observing their students, is used to inform teachers' decisions about how to help students take their next steps in learning. This feedback enables teachers to adjust the challenges they provide for students to be neither too demanding, making success out of reach, nor too simple to be engaging. In this way, teaching is regulated so that the pace of moving toward the learning goals is adjusted to ensure the students' active participation.

Student Self-Assessment

An important source of feedback to the teacher comes from students' self-assessment and peer assessment, since the criteria students use in judging the success of their work reflect their understanding of what they are trying to do. Involving students in self-assessment and in making decisions about what their next steps should be and how to take them is a shared aim of formative assessment and of inquiry-based teaching. A prerequisite for being able to judge their work is that students understand what they are trying to do, not in terms of what is to be found, but in terms of the question to be addressed or problem to be solved. In addition, they need to have some notion of the standard they should be aiming for, that is, what is "good work" in a particular context. The criteria to be used by students in assessing their work can be conveyed implicitly through feedback from the teachers or developed more explicitly through brainstorming with students about, for instance: What makes a good plan for an investigation? What should be included in a good report of an inquiry? Understanding the goals of their work and the quality criteria to be applied supports the aim of increasing students' responsibility for their work and develops their recognition of what is involved in learning (metacognition).

In Summary

Key practices of using assessment formatively to develop students' ability to inquire are:

- Students being engaged in expressing and communicating their understandings and skills through classroom dialogue, initiated by questions framed to elicit students' thinking
- Feedback to students that provides advice on how to improve or move forward and avoids making comparisons with other students

- Teachers using information about ongoing learning to adjust teaching so that all students have opportunity to learn
- Students understanding the goals of their work and having a grasp of what is good quality work
- Students being involved in self-assessment so that they take part in identifying what they need to do to improve or move forward
- Dialogue between teacher and students that encourages reflection on their learning

Summative Assessment of Ability to Inquire

Summative assessment is not a continuous part of teaching and learning as is the case for formative assessment where skills and understanding are assessed during inquiry-based activities. Rather, it takes place at certain times when a summary of students' achievement is needed in order, for example, to report to parents, students' next teachers, and the students themselves; to select students for courses; to accredit their learning; or to monitor progress of individuals and groups of students as they pass through the school. Information for these purposes may be gathered in various ways, the most common falling into three main groups:

- Tests or special tasks given under controlled conditions or embedded in classroom activities
- Summarizing information gathered by teachers during their work with the students over a period of time
- Building a record over time, as in a portfolio created by teachers and/or their students

The choice of method will depend on the use to be made of the result and the demand that the particular use makes for reliability of the results. The reliability of an assessment refers to the extent to which the results can be said to be of acceptable consistency or accuracy for a particular use. Reliability is defined as, and, where possible, estimated quantitatively, by the extent to which the assessment, if repeated, would give the same result. In the case of formative assessment, judgments are made about action to take in a particular situation involving only the teacher and students, and the notion of making a repeatable judgment is not relevant. No judgment of grade or level is involved, so reliability in this formal sense is not an issue in formative assessment. However, when assessment results are used by others and may involve students being compared or selected, as in summative assessment, reliability becomes important.

It is important to realize that the extent to which the reliability of an assessment can be raised is limited by the interaction of reliability and validity and the effect that optimizing one has on the other. This is best illustrated in relation to items in a test. Attempts to ensure high reliability will inevitably favor the inclusion of items that can be consistently marked or marked by machine, limiting the range of outcomes that can be covered in the test and lowering its validity. Extending the range of what is assessed to the application of knowledge and skills requires the use of more open-response items where judgment is needed in marking, inevitably reducing the reliability. Thus there is a trade-off between reliability and validity which applies to all summative assessment whatever form it takes. It presents a particular problem in the assessment of skills such as involved in the ability to inquire.

Using Tests or Special Tasks for Assessing Ability to Inquire

The use of tests or special tasks is a time-honored approach to summative assessment. It is attractive because the tasks can be controlled and presented to all students in the same way, thus appearing to give the same opportunities for students to show what they can do. Tests and tasks can take different forms (e.g., written or performance) and can be presented in various ways from highly formal tests to special tasks embedded in normal work.

For ability to inquire to be validly assessed, the tasks or test items should require the use of inquiry skills. But, as noted earlier, skills are used in relation to some content, and so the task will be set in a context, requiring the skills to be used in relation to particular subject matter. Various steps can be taken to reduce the influence of knowledge of the subject matter. For instance, in Fig. 1 the subject is chosen as likely to be very familiar to the 11-year-old students concerned and thus does not constitute a barrier to engagement. In Fig. 2, all information needed about the subject for answering is given in an attempt to ensure that this knowledge is not a barrier.

Figure 1 is an item used in a survey of students aged 11 years. The subject matter is likely to be familiar to these students; thus the level of knowledge required is low, and the burden of the task is about conducting a fair test. The format for answering – and the requirement of the scoring rubric for the answer in each box to be correct – makes the chance of succeeding by guessing very low. But it also means that students have to read and understand the instructions for recording their answer; otherwise, there is a risk of failure for reasons other than not having the skill needed to the answer the question.

Figure 2 is an item written for the PISA surveys of 15-year-olds (OECD 2000). Students are asked to use the given information to support alternative conclusions about action that could be taken. The information is authentic and presents the sort of problem that students able to inquire should be able to engage with. The two parts to the task illustrate the uncertainty of interpreting scientific information in certain cases. In theory, all the information is provided, and the students are told how to interpret the chart. They do not need to know how carbon dioxide, methane, and particles and their effects on clouds cause heating and cooling. However, it is arguable that without any knowledge of these things, the question is likely to be meaningless, and they are unlikely to engage with the problem posed.

Figures 1 and 2 illustrate some of the features of written test items that endanger the validity of the test. The most obvious is the inevitable demand for reading and understanding the question and, depending on the answer format, for writing ability. In addition, the attempt to place the task in a context that can seem real to the student means that some sort of “story line” is presented as a context for the task. Students have to read and engage with the context in order to respond to the question. There is evidence that these features of the item do affect students’ measured attainment. The effect of the choice of a particular context can be reduced by using a range of contexts, balancing out the effect of any one. But since there is a limit to the length of a test, this would mean a larger number of shorter items, each assessing a small part of the ability to inquire. It raises the question of whether this is a valid way of assessing the ability to combine different skills in conducting a whole inquiry.

Some of the deficiencies of written tests – particularly the dependence on reading and writing – can be avoided by performance items, where students carry out a whole or part of an investigation with real objects and equipment. The question still has to be presented to the student who has to engage with it as if it were his or her own, and the situation is far from that of a normal classroom, since the students may be working alone (sometimes in pairs) with an administrator present to observe their actions. However, it does give an opportunity for student to explore, try out approaches, and start again if necessary. The main problem is one of generalizing from the very small number of extended investigations that it is feasible for any one student to undertake. Again it is the context that has a strong influence on the outcome. There is strong research evidence that students who perform well in one investigation will not necessarily do so in another testing the same skills but in a different context. Consequently, it is useful to consider alternatives to tests.

Summarizing Teacher-Based Assessment

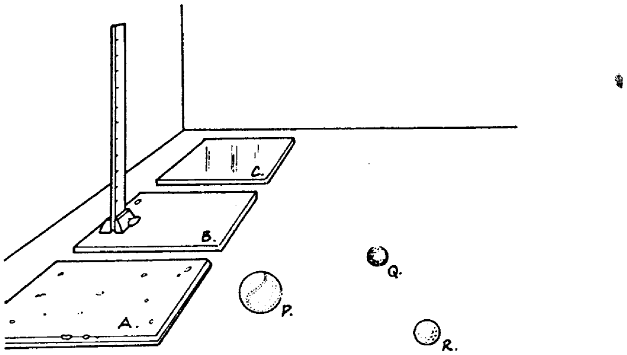
One of the main alternatives to tests draws on the fact that the experiences that students need in order to develop desired skills also provide opportunities for their progress to be assessed. The key factor is judgment by the teacher. Assessment by teachers can use evidence from regular activities supplemented, if necessary, by evidence from specially devised tasks introduced

Inquiry, Assessment of the Ability to, Fig. 1 From APU Report of Science at age 11, DES 1985

Emma and Anita were finding out if the surface on which a ball is bounced makes a difference to how high it bounces.

They found three different kinds of surface, which they called A, B and C.

They also had three different balls P, Q and R.



For a fair test what should they change in their trials and what should they keep the same?

Tick Change or Not change for each thing below:

	Change	Not change
The ball	☐	☐
The surface	☐	☐
The height it is dropped from	☐	☐

to provide opportunities for students to use the skills to be assessed. The limitation on the range of evidence that can be obtained through a test does not apply when assessment is teacher based.

There are other advantages that go beyond more valid assessment of understanding and inquiry skills, since a greater range of competences can be included. Observation during regular work enables information to be gathered about processes of inquiry rather than only about products.

Assessment by teachers is not just a matter of teachers using their individual judgments about what evidence to use and how to interpret it. Summative assessment by teachers must follow agreed procedures and be subject to quality control measures appropriate to the use of the results, that is, stricter control for higher-stakes use. Evidence of students' use of inquiry skills will be gathered by various means, as for formative assessment, and interpreted using broad criteria relating to skills development. Procedures for making judgments generally involve some to-ing and fro-ing between data and criteria to make an "on-balance" judgment as to which particular criteria are met. It is common for criteria to be identified at different "levels," so that the outcome of the assessment can be expressed in terms of the level at which a student is performing. Levels are produced by mapping the progress of students in a particular area of learning, using evidence from research

Read the following information and answer the questions which follow.

WHAT HUMAN ACTIVITIES CONTRIBUTE TO CLIMATE CHANGE?

The burning of coal, oil and natural gas, as well as deforestation and various agricultural and industrial practices, are altering the composition of the atmosphere and contributing to climate change. These human activities have led to increased concentrations of particles and greenhouse gases in the atmosphere. The relative importance of the main contributors to temperature change is shown in Figure 1.

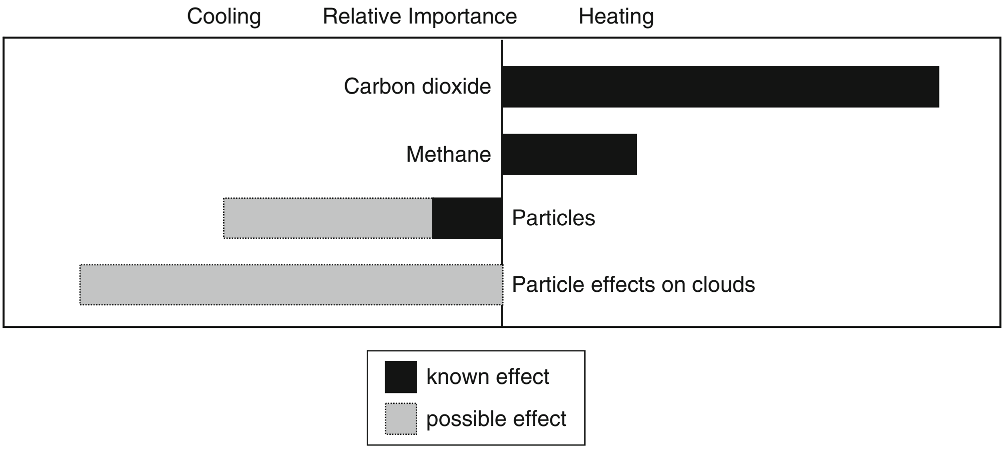


Figure 1: Relative importance of the main contributors to change in temperature of the atmosphere.
Source: adapted from http://www.gcrio.org/ipcc/qa/04.html

Bars extending to the right of the centre line indicate a heating effect. Bars extending to the left of the centre line indicate a cooling effect. The relative effect of 'Particles' and 'Particle effects on clouds' are quite uncertain: in each case the possible effect is somewhere in the range shown by the light grey bar.

Figure 1 shows that increased concentrations of carbon dioxide and methane have a heating effect. Increased concentrations of particles have a cooling effect in two ways, labelled 'Particles' and 'Particle effects on clouds'.

Item 1:

Use the information in Figure 1 to support the view that priority should be given to reducing the emission of carbon dioxide from the human activities mentioned.

Item 2:

Use the information in Figure 1 to support the view that the effects of human activity do not constitute a real problem.

Inquiry, Assessment of the Ability to, Fig. 2 PISA assessment of Science 2000 and from teachers' experience. Some care has to be taken in using levels, however, as there is a risk of students becoming labeled and indeed labeling themselves in terms of levels achieved (Harlen 2013).

The most commonly expressed criticism of assessment by teachers concerns the reliability of the results. It can indeed be the case that, when no steps are taken to assure quality, teachers' judgments are prone to a number of potential errors. However, there are various ways in which the reliability of teacher-based judgments can be brought to a level comparable with that of tests. These include group moderation and the use of exemplars. In group moderation, teachers meet to review samples of students' work. The purpose is not to verify decisions about particular students' work, rather to arrive at shared understandings of criteria and how they are applied, thus improving the reliability of future assessments. The provision of examples of students' work (which can be in the form of video recording of inquiry in action) shows how certain aspects relate to the criteria of assessment, clarifying the meaning of the criteria in operation. Good examples also indicate the opportunities that students need in order to show their achievement of skills.

Building a Record over Time

This approach to summative assessment creates a portfolio that is not a sample of all a student's work over a period of time, but reflects the best performance at the time of reporting. The evidence is accumulated gradually by retaining what is best at any time in a folder, or other form of portfolio (including computer files), and replacing pieces with better evidence as it is produced. The evidence can take a variety of forms from photographs, videos, artifacts, as well as writing and drawings. The approach enables students to have a role in their summative assessment by taking part in the selection of items in the folder or portfolio, a process for which they need some understanding of the broad goals and quality criteria by which their work will be judged. It is important that time is set aside at regular intervals specifically for students to review their work. This gives them time not only to decide what to put in the "best work portfolio" but also to consider what they can improve.

The final form of the portfolio is assessed at the time when a summative judgment is needed, either by the teacher or by external assessors, depending on the purpose and requirements of the assessment procedures. The process involves comparing evidence from the portfolio with the criteria to identify the "best fit."

In Summary

Some key features of summative assessment of ability to inquire are:

- Taking place at certain intervals when achievement has to be reported
- Requiring methods which are as reliable as possible without endangering validity
- Involving students using inquiry skills within a context, the nature of which is likely to affect students' engagement and performance
- Reporting achievement in terms of criteria describing the extent of use of inquiry skills
- Involving some quality assurance procedures commensurate with the use made of the results
- Where appropriate, involving students in the assessment and in this way contributing to their learning

Content, Context, and Practices

Inquiry as a teaching strategy operationalizes the teaching of scientific inquiry as content by providing a context for the teaching and learning of the practices of science. The need for contextualizing the content of science within the practices of science has a long history. In 1910, John Dewey argued that a conceptual, discipline-based form of scientific knowledge could not be learned in isolation from the "intelligent practice" of science. The publication of Joseph Schwab's *The teaching of science as enquiry* (1962) proposed that science teachers should provide opportunities for their students to engage in the practices of science as a strategy for the teaching and learning of science. The practices of science have recently been defined by the National Research Council [NRC] (2012) in the United States as:

1. Asking questions
2. Developing and using models
3. Planning and carrying out investigations
4. Analyzing and interpreting data
5. Using mathematics and computational thinking
6. Constructing explanations
7. Engaging in argument from evidence
8. Obtaining, evaluating, and communicating information

Engagement with the practices of science, it was argued, should be built around an increasing student sophistication in developing scientific questions: the gathering of evidence, the manipulation and analysis of that evidence, and the proposal and communication of scientifically justifiable explanations. Major impediments to the broad adoption of Schwab's ideas have been the resilience of an abstract curriculum that privileges concepts over context and the associated issue of teachers' cultural reproduction of a traditional view of science education.

Arising from these impediments is a preconception that equates the teaching of inquiry with a single teaching strategy: open-ended activities that are "hands-on" for students and "hands-off" for teachers. This preconception, in turn, justifies many teachers not teaching inquiry. The reasons that are given to support this decision (which is often made subconsciously) include the perceived difficulty of teaching from a constructivist perspective, the added time and energy required, and teachers' perceived need to meet the expectations of the curriculum. Other concerns include the physical limitations of the classroom, a belief that safety will be compromised, and the capacity of students to engage with the levels of analysis, argumentation, and evaluation described in documents such as the *National Science Education Standards* (NRC 1996). Support from colleagues, the costs of apparatus and consumables, placing material in the proper sequence, and the demand of preparing students for further study are also cited as concerns.

For teachers, to move beyond these reasons and embrace inquiry as a teaching strategy requires the development of an identity that allows for the questioning of contemporary science education. An important component of this transformation is to recognize that inquiry, as a teaching strategy, should simultaneously reflect the practices of science and the development of scientific knowledge about the natural world. The Science Teaching Standards of the *National Science Education Standards* (NRC 1996, pp. 27–54) provide a number of criteria through which teachers can begin to question and assess their abilities for, and understandings of, the teaching and learning of inquiry:

1. Teachers of science plan an inquiry-based science program for their students.
2. Teachers of science guide and facilitate learning.
3. Teachers of science engage in an ongoing assessment of their teaching and of student learning.
4. Teachers of science design and manage learning environments that provide students with the time, space, and resources needed for learning science.
5. Teachers of science develop communities of science learners that reflect the intellectual rigor of scientific inquiry and the attitudes and social values conducive to science learning.
6. Teachers of science actively participate in the ongoing planning and development of the school science program.

These standards provide teachers with a foundation from which to develop opportunities for using inquiry as a teaching strategy. To build on that foundation, teachers need to understand two other important aspects of the shift in their teaching practice. First, the practices of science can be considered as both learning outcomes and teaching strategies, as they provide both the means and ends of science teaching and learning. As learning outcomes, students should develop the abilities of inquiry through their work with the practices of science, concomitantly coming to an understanding of how scientific knowledge evolves. As teaching strategies, the practices of science open opportunities for learning both core disciplinary concepts (see NRC 2012, pp. 103–200) and the concepts that transcend the disciplinary boundaries, such as cause and effect, structure and function, and stability and change (see NRC 2012, pp. 83–102). Second, there is no evidence that any one teaching approach is more effective than any other in actively involving students in developing the knowledge, understandings, and scientific abilities that constitute inquiry. The selection of the appropriate strategy at the appropriate time is very much the realm of the professional science teacher, hence the importance attached to the collaborative and collegial learning of teachers as they seek to shift their practice. In selecting the appropriate strategy, teachers must be explicit in the learning outcomes that they are seeking, the scaffolding that will be needed if students are to achieve those outcomes, and the links between content and practices. Developing those links through inquiry opens opportunities for students to become proficient in science (Duschl et al. 2007), giving them the capacity to:

1. Know, use, and interpret scientific explanations of the natural world
2. Generate and evaluate scientific evidence and explanations
3. Understand the nature and development of scientific knowledge
4. Participate productively in scientific practices and discourse

Central to the use of inquiry as a teaching strategy is the active engagement of students in investigations in which students answer scientific questions through the practices of science. The use of the word “practices” is a reflection of the evolution of thinking around inquiry as a teaching strategy. Following the US publication of *Inquiry and the National Science Education Standards* (NRC 2000), the essential features of investigations were seen to be the extent to which a:

1. Learner engages in scientifically oriented questions.
2. Learner gives priority to evidence in responding to questions.
3. Learner formulates explanations from evidence.

4. Learner connects explanations to scientific knowledge.
5. Learner communicates and justifies explanations.

With the publication in the United States of *A Framework for K-12 Science Education* (NRC 2012), the emphasis was been broadened and deepened to incorporate the practices of science. If students are to develop proficiency in science, such a progression through investigations must link and reiterate the practices of science to both the appropriate core disciplinary concepts and the concepts that transcend the disciplinary boundaries. Investigations are a foundation on which students can "learn about experiments, data and evidence, social discourse, models and tools, and mathematics and for developing the ability to evaluate knowledge claims, conduct empirical investigations, and develop explanations" (Bybee 2011, p. 38). This emphasis recognizes that the abilities and understandings that students develop, and display, will demonstrate a progression over time. Students require substantial scaffolding in the practices of science if they are to become proficient, and a well-designed progression will guide students through a number of graduated steps. Important aspects of this guiding include giving meaning to the investigation in terms of other student learning and allocating adequate time for the investigation.

Within the literature, the graduated steps of inquiry are generally viewed as a continuum, with the level of complexity being influenced by factors such as the amount of information given to the student, the level of teacher guidance that is offered, and the sophistication of the students' abilities. The least complex level of inquiry is generally known as a confirmation (or verification) inquiry. Students are generally provided with the question and procedure, and the results are generally expected. This level has value in verifying concepts and training in the safe and correct use of apparatus. The next level of complexity, the structured inquiry, investigates a research question using a prescribed procedure. Confirmation and structured inquiries make up the majority of textbook investigations, but for students to become proficient in science, they must have opportunities to carry out investigations of greater complexity. Moving further along the inquiry continuum, the guided inquiry gives students the opportunity to develop their own investigation in response to a question. The most complex investigation, or open inquiry, requires students to develop their own topic-related research question and strategies for gathering, analyzing, and reporting their data. It is unreasonable and counterproductive to expect students to conduct complex investigations without having experienced some success in less complex investigations. Similarly, to limit students to less complex investigations is to stifle student interest and success. A well-designed progression to increasingly complex investigations is crucial for student learning and success.

There and Back Again: From Inquiry into Social Problems to Disciplinary Scientific Inquiry

Curriculum has many meanings. Here, it is broadly conceptualized as comprising the domains of, and rationales for, subject matter and intended learning outcomes, nature and organization of instruction and learner experiences, and interactions among students and teachers within the immediate settings of classroom and school, as well as broader societal contexts. The meanings of *inquiry*, particularly in the context of science education, also are numerous. These include scientific inquiry (how scientists conduct their practice), inquiry teaching (as means, pedagogy, or an instructional approach to facilitate science content learning), inquiry learning (as an active process of learning, which assumes that students construct understandings in ways similar to how scientists develop claims to scientific knowledge), and inquiry as content (as ends, or subject matter to be learned) (Abd-El-Khalick et al. 2004; Anderson 2007). Inquiry as content includes several outcomes related to developing the skills, procedural knowledge, and habits of mind requisite for *doing* scientific inquiry, as well as learning *about* scientific inquiry, that is, its underlying epistemological underpinnings. In the context of these broad definitions, this entry discusses inquiry as an organizing theme or strand in science curriculum and focuses on the historical treatment of inquiry as content within such curriculum. For discussions of inquiry teaching and inquiry learning, the reader is referred to the entries *Inquiry, as a teaching strategy* and *Inquiry, learning through*, respectively. This entry, it should be noted, mostly is focused on the context of science education in the USA. This country is used as a case study to illuminate some broad historical patterns and trends, patterns which tend to have similarity (if not always shared time frames) with the treatment of inquiry as a curriculum strand in other national contexts.

Deboer (2004) traced the introduction of science into US school curriculum to the middle of the nineteenth century alongside other mainstay subjects of school curriculum, such as mathematics and grammar. Prominent scientists of the time, such as Thomas Huxely, argued that observation and inductive reasoning were the distinctive features of scientific investigation that should characterize science learning, propel student intellectual development, and discipline student minds (as stipulated by the theory mental discipline, which was the contemporary, dominant theory of learning). This view, Deboer continued, compelled other prominent contemporary intellectuals to champion the structuring of science and laboratory instruction as a process of scientific investigation whereby students experience natural phenomena firsthand, "make their own investigations and draw their own inferences" (Herbert Spencer 1864 as cited in Deboer 2004, p. 23). In 1892, the Committee of Ten of the US National Education Association strongly endorsed the use of laboratories in secondary science education. The Committee emphasized the need to abandon the simple memorization of facts in favor of the personal development of students' reasoning skills and their abilities to inductively acquire scientific understandings.

By the turn of the twentieth century, social issues associated with urbanization, immigration, and other problems brought about by the Western industrial revolution of the previous century were in full swing. Coupled with the influence of John Dewey's pragmatism, education was now more focused on practical work, which was deemed necessary to solve social and economic problems. The latter focus also aligned with child-centered approaches championed by Dewey and his calls to engage students with investigating questions related to their experiences. As early as 1910, there were calls to include in science curriculum more useful applications to the real world. With the release in 1918 of the Cardinal Principles of Secondary Education by the US Department of the Interior, the applied nature of laboratory work in science education was bolstered with an emphasis on scientific reasoning and problem solving abilities needed to address socially significant issues. In 1932, the Thirty-First Yearbook of the US National Society for the Study of Education identified training in *the* scientific method and the application of this method to solving social issues and students' own problems to be among the major themes that should be present in the science curriculum.

By the 1950s, criticisms of the science curriculum's emphases on addressing student personal interest, practical applications, and societal problems were mounting. Concerns were directed at the lack of academic and disciplinary rigor, and training in scientific methods and processes. The Soviet Union launching of the Sputnik satellite in 1957 exacerbated these concerns – which now were directly linked with US national security, interests, and economic competitiveness – and precipitated unprecedented US federal funding for developing new science curricula, the now dubbed Alphabet Curricula or First Generation Projects. These curricula were academically rigorous, focused on disciplinary content knowledge and scientific processes, and aimed toward developing the next generation of practicing scientists. The term "inquiry" was now formalized as describing a major theme in the science curricula of the 1960s and 1970s. These curricula were particularly influenced by Joseph Schwab's writings, which stressed the need to address both the substantive and syntactical structures of science, the latter specifically referring to the application of cannons of evidence toward developing claims to scientific knowledge. Schwab believed that "scientific content and processes were intimately connected and inseparable . . . [and that] content should be taught in relation to the methods that generated that knowledge" (Deboer 2004, p. 28). Schwab did not argue that students should be able to conduct scientific inquiries themselves, but rather understand the nature of such inquiry. Thus, learning *about* scientific inquiry became part and parcel of science curricula. Science educators now were explicitly distinguishing between two meanings of inquiry in the context of science education, namely, learning about "inquiry as content," that is, "as it appears in the scientific enterprise," and "inquiry as pedagogic technique," that is, "using the method of scientific inquiry to learn some science" (Rutherford 1964, p. 80).

Somewhat parallel projects in England began about 5 years after the first of the US projects, and impacted in major ways on that country and the large number of former British colonies around the globe. These were collectively known as the "Nuffield Projects," now often termed the second-generation projects. They were much more strongly shaped by expert school science teachers. To a considerable extent, these projects focused much more on "inquiry as pedagogic technique" and, for some projects such as the Schools Council Integrated Science Project (SCISP), embedded this inquiry in "real" contexts and linked it closely with problem solving. These uses of and contexts for inquiry were early (1970s) forms of Science-Technology-Society curricula.

Difficulties for US students and science teachers associated with the academic rigor of the early Alphabet curricula, coupled with the debates of the 1980s regarding the effectiveness of the 1960s and 1970s inquiry-oriented curricula, shepherded in the USA a return to a focus on "inquiry" that enables students to address broader societal issues in an increasingly scientific and technologically laden world. These efforts first took the form of the Science-Technology-Society curricula of the 1980s and 1990s, a perspective also emphasized in the major Canadian report of the early 1980s *Science for Every Student*: *Educating Canadians for Tomorrow's World*. This turn or return came into full swing during the last decade of the twentieth century, which witnessed the release of several US reform documents that also had some impact internationally, most notably the 1989/1990 *Science for All Americans* and 1993 *Benchmarks for Science Literacy* (Benchmarks) by the US American Association for the Advancement of Science, and the 1996 *National Science Education Standards* (Standards) by the US National Research Council (NRC). Similar documents included the 1997 Canada's Council of Ministers of Education *Pan-Canadian Science Project* and the 1998 report, *Beyond 2000*: *Science Education for the Future*, in the UK.

These documents solidified the construct of scientific literacy as the major focus of school science education in the USA and in some other parts of the world. This focus chiefly aimed at preparing citizens able to make informed decisions regarding science-related personal and social issues and engage meaningfully in democratic societies that were becoming increasingly dependent on the enterprise of science. Interestingly, the *Benchmarks* included understandings about scientific inquiry as a subset of the more overarching construct of nature of science. These included an understanding of the role of evidence, logic, and imagination in scientific inquiry (lack of a universal scientific method), as well as the aims of generating verifiable predictions and explanations in which scientists' biases and idiosyncrasies are diminished. In comparison, the *Standards* included separate learning outcomes for students' understandings of nature of science, students' understandings about scientific inquiry, and their ability to do scientific inquiry. The latter included abilities related to questioning; designing and conducting investigations; formulating explanations, models, and predictions; and communicating and defending explanations. The *Standards* emphasized understandings about inquiry including that investigations and methods are guided by questions and that scientific explanations are developed from evidence and current scientific knowledge.

Scientific inquiry, in the sense of capturing what scientists do, has been a fixture in school science curricula over the past century and a half, that is, for what is essentially the history of school science education. Nonetheless, as Deboer (2004) concluded, there emerges – at least in the US context – a pattern related to the function and intended outcomes of inquiry as content in such curriculum. In the latter half of the nineteenth century, scientific inquiry was intended to develop in students what was deemed the pinnacle of scientific method of the time, that is, inductive reasoning. The first half of the twentieth century emphasized inquiry as means to address applied issues and to enable students to solve social problems beyond the realm of disciplinary science. This emphasis gave way in the curricula of the 1960s and 1970s to a renewed focus on scientific disciplines and inquiry as scientific method, with the aim of preparing future scientists. Next, the theme of scientific literacy in the reform efforts of the 1980s and 1990s revived the focus on inquiry as a crucial component for addressing, and making decisions about, science-related personal and social issues. These reforms delineated goals for learning to do scientific inquiry – now represented as a varied set of integrated abilities and skills as compared to a universal scientific method – and learning about scientific inquiry.

The next wave of reforms in the USA, which was initiated with the NRC's 2012, *A Framework for K-12 Science Education*: *Practices*, *Crosscutting Concepts*, *and Core Ideas* (Framework), fits nicely within the above pattern. The construct of scientific literacy and goal of enabling students to address broad social problems hardly receive any mention in the *Framework*. While the *Framework* highlights the role of science in informing citizens' decision making, the two major goals for K-12 science education are identified as "(1) educating all students in science and engineering and (2) providing the foundational knowledge for those who will become the scientists, engineers, technologists, and technicians of the future" (NRC 2012, p. 12). School science education would deepen students' "understanding of the core ideas of . . . [scientific] fields," and enable them "to engage in public discussions on science-related issues, to be critical consumers of scientific information related to their everyday lives, and to continue to learn about science throughout their lives" (NRC 2012, pp. 8–9). There clearly is a return to a disciplinary focus in science curriculum (albeit coupled, for the first time, with engineering) along with strong Schwabian undertones of intertwining the learning of core disciplinary ideas with scientific processes. Scientific inquiry persists under the label of scientific (and engineering) practices, which include engaging students with and learning about: asking questions, developing and using models, planning and conducting investigations, analyzing and interpreting data, using mathematical and computational reasoning, constructing explanations and arguments, and handling information (NRC 2012, p. 1).

Pendulum swings between emphasizing inquiry-related curricular outcomes that prepare students to *either* engage in disciplinary scientific inquiry *or* address broader social problems seem to derive from a one-dimensional approach. Such an approach to inquiry as a curriculum strand or inquiry as content will, in all likelihood, fail to capture or serve the complex and nuanced agenda of precollege science education required to address the needs of students, future citizens, and future scientists in the twenty-first century. Abd-El-Khalick (in Abd-El-Khalick et al. 2004) argued for a multidimensional heuristic that defines a space of inquiry-related outcomes, whereby subsets of these outcomes are brought to the forefront – and others pushed to the background – of curriculum, teaching, and learning along the horizontal and vertical dimensions of school science education. One dimension would include a set of target knowledge domains and understandings, including conceptual/disciplinary, epistemic, and social, to be learned with inquiry. A second dimension would include a range of inquiry-related abilities and skills, such as problem-posing; designing investigations; gathering and interpreting data; generating, testing, and refining models and explanations; and building arguments, negotiating assertions, and communicating ideas. A third dimension could comprise a range of foundational mathematical, linguistic, manipulative, and cognitive and metacognitive skills needed to meaningfully engage in inquiry at one level or another. A fourth dimension would comprise the spheres, including disciplinary, personal, social, and cultural with which any of the aforementioned outcomes could interface, as either a context for learning about or a domain for applying inquiry. When educators – ranging from curriculum theorists to science teachers – navigate this four-dimensional space, they would consider the elements on each dimension either as possible outcomes of, or as prerequisites for meaningful engagement in, inquiry-based science education. "The former would help conceive and place more emphasis on inquiry as means (inquiry as teaching approach), while the latter thinking would help gauge the level at which students could engage in inquiry and help emphasize inquiry as ends (inquiry as an instructional outcome)" (Abd-El-Khalick et al. 2004, p. 415).
