Rekindling Joy in Medicine Through Thoughtful Communication: A Practical Guide

Tara Sanft, MD[1] and Eric Winer, MD[1]

Joy in medicine, or the loss of it, is a popular topic of conversation, even more so since the pandemic. Burnout in oncology is common and diminishes the satisfaction of practicing medicine. One of the challenges clinicians face is the way in which modern clinical practice takes us away from what we find most meaningful in our work: time with patients. Strategies like being kind, expressing gratitude, and using effective communication skills can establish more connection with our colleagues and our patients, and, in turn, result in a more joyful work environment. Creating space for more moments of feeling deep interconnectedness with patients and colleagues can rekindle feelings of joy in oncology practice. This article reviews the concepts of joy in medicine, the term *sacred moments*, and outlines practical strategies and communication skills that are effective in enhancing the patient-provider relationship.

INTRODUCTION: REKINDLING JOY STOKES THE EMBERS OF BURNOUT

> "A good life happens when you stop and are grateful for the ordinary moments that so many of us just steamroll over to try to find those extraordinary moments."—Brené Brown

The practice of oncology is full of complexities. Scientific advancements in detection, treatment, and technologies mean that we can partner with patients to provide exceptionally detailed, personalized care. This article examines the human side of personalized care delivery, the tools we use every day to connect with, and care for our patients. Modern medical practice often challenges our connection with patients, and we need an all hands on deck approach to repairing the aspects of work that bring the most meaning to oncology providers. Here, we provide context for our definition of joy in medicine, outline challenges to maintaining a joyful workplace, and propose considerations for individuals wanting to create more moments of feeling connected to patients and colleagues (Fig 1).

The Merriam-Webster Dictionary defines joy as to experience great pleasure or delight.[1] References to joy in medicine can be traced back to the Hippocratic Oath which states "May I long experience the joy of healing those who seek my help." The concept of cultivating joy in medicine has gained attention in recent years with books titled Recapturing Joy in Medicine and Finding Joy in Medicine, a podcast titled Joy in Medicine, and organizational focus on strategies to enhance joy in medicine including the American Medical Association and the Institute for Healthcare Improvement.[2,3] It is notable that the topic of rekindling, recapturing, or enhancing joy in medicine has become popular over the decade. A simple PubMed search reveals 1,800 publications on this topic since the 1940s and that most (1,300) have been published in the past decade and 50% of those since 2020 (Fig 2). The focus on rekindling joy undeniably correlates with the increasing prevalence of burnout among medical professionals. If burnout literally means to extinguish a flame, rekindling joy is to focus on strategies that stoke the embers of motivation and professional fulfillment.

When considering joy in oncology, the words pleasure and delight may not easily come to mind because their essence conjures a sense of playfulness, and cancer care often feels more serious. New York Times writer and columnist David Brooks makes a distinction about joy stating: "Happiness involves a victory for self. Joy involves the transcendence of self. Happiness comes from accomplishments. True joy is the present that life gives you as you give away your gifts."[4] The gifts clinicians have to give to patients include the gift of healing. Healing happens through understanding what is ailing the patient and offering treatments to relieve suffering. Clinicians can also give the gift of bearing witness to suffering; therapeutic presence can sometimes be the most powerful gift we have to offer in the face of serious, life-threatening illness. This joy is often experienced most acutely in the room with the patient, during shared moments of deep connection.

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATION

- This practical guide reviews behaviors and skills that clinicians can adopt for partnering with patients during oncology visits and makes a case for applying them broadly to colleagues and teammates involved in clinical care.

A recent study on the concept of *sacred moments* provides a framework for describing the joy experienced in oncology care that arises through partnerships with patients. In the study, sacred moments were defined as brief periods of time in which people experience a deep interconnectedness that may possess spiritual qualities and emotions.[5] In our interpretation, sacred moments are spiritual in the sense that there is awe and wonder at witnessing the strength of the human spirit. They have been described as times when the patient or provider (or both) experienced a transient sense of being deeply interconnected as if time had stood still. After experiencing a sacred moment, one might feel a sense of joy, peace, gratitude, and empathy.[5] These moments can promote feelings of deep meaning and a sense of honor in caring for patients. If the fulfillment one feels after these moments motivates and sustains the clinician's desire to continue caring for patients, one might think of such moments as the equivalent to putting a log on a fire, stoking embers that are at risk for extinguishing. These moments might offer an antidote to the sense of low professional accomplishment that clinicians often experience as part of burnout.

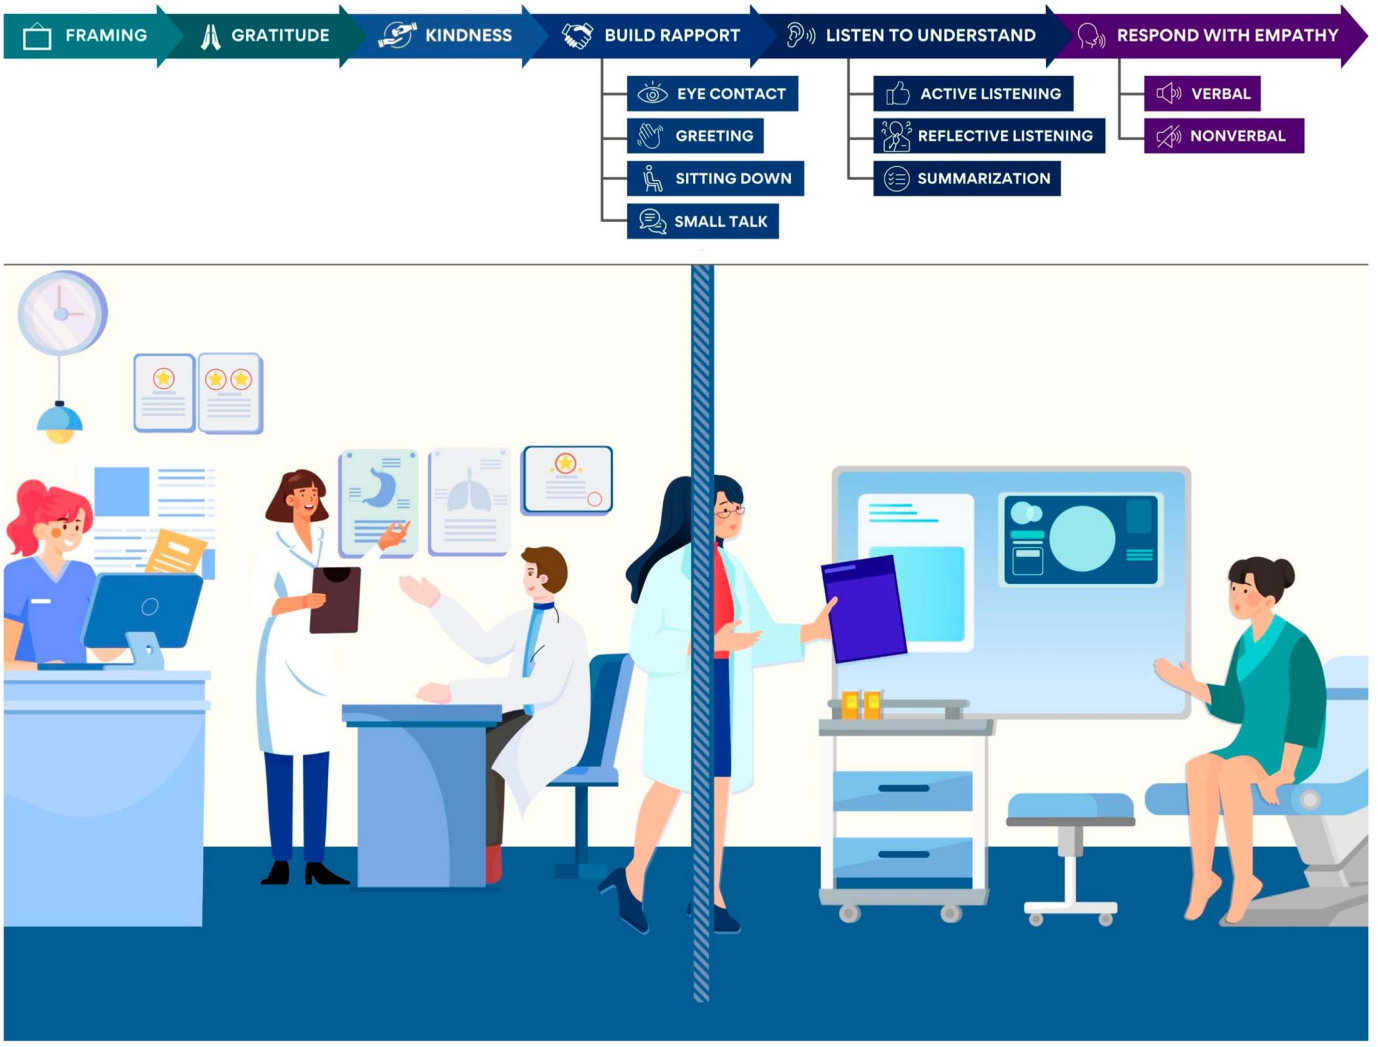

FIG 1. Strategies for creating conditions that allow for connection and thoughtful communication.

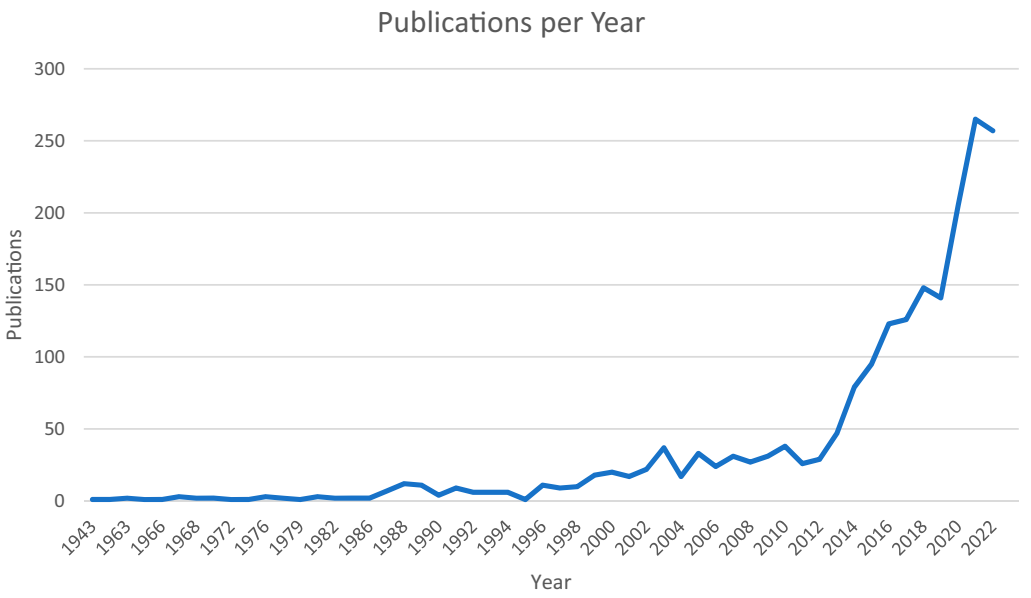

FIG 2. The number of PubMed publications per year matching the search term joy in medicine.

SACRED MOMENTS AS A SOURCE OF JOY

Sacred moments contain five elements: (1) an interconnectedness between patients and providers; (2) intense emotions and empathy; (3) a sense of awe and spirituality; (4) occurrence during conversations on the end-of-life or during moments in the clinical visit that seem relaxed and open; and (5) having profound meaning for the clinician and the patient.[5] Clinicians correlated these moments with a stronger therapeutic alliance and increased feelings of presence. Patients report that these moments occur when there was trust in the clinician and lead to an enhanced therapeutic relationship, greater satisfaction with that clinician, and better mental health outcomes.[6]

Enhancing communication skills such as listening and expressing empathy may increase the opportunity for sacred moments to arise, thereby leading to more fulfilling experiences, ultimately making the work more joyful. Structural and procedural barriers exist that exacerbate the challenge of making time for these moments. Despite these barriers, we will focus on solutions that are more readily within the control of the clinician and could be adopted while we wait for structural change.

Sample dialogue used throughout the text is derived from the author's (T.S.) experience and used to illustrate the concepts discussed in this study. An example of a sacred moment is recounted below.

> Physician: "I told a new mom she has metastatic breast cancer. I am amazed by how she handled herself. She maintained her composure, her optimism. She thanked me for letting her know, said she felt like this was what the results would show. I am reeling on the inside, full of thoughts about the future for her, and full of awe at her calm presence."

JOY IN MEDICINE IS THREATENED

Threats to joy in medicine come in many forms. Results of a Google search for loss of joy in medicine lists many articles discussing the problem of burnout in medicine. Burnout is an occupational syndrome of emotional exhaustion (EE), depersonalization (DP), and sense of low personal accomplishment (PA).[7] In a meta-analysis from 2019, pooled prevalence rates of oncologists showed that 32% had high EE; 24% had high DP; and 37% had low PA.[8] Similar findings have been reported among oncology fellows, physician's assistants, nurses, and pharmacists.[9-11] A study looking at themes of occupational and personal consequences of the pandemic on US oncologists found that COVID-19 exacerbated preexisting factors including external and internal factors contributing to burnout. External pressures include increased productivity expectations, high patient volumes, reimbursement issues, and administrative burdens. Internal pressures experienced by oncologists include the complexity of caring for patients with serious illness, addressing intricate treatment and psychosocial issues, a lack of balance between personal and professional demands, and lack of support from institutions to process grief and loss.[12]

The Stanford model of professional fulfillment characterizes three domains that, when optimized, best enhance professional fulfillment and, by proxy, mitigate burnout. The domains are thought to be of equal importance: (1) the efficiency of practice, (2) the culture of medicine, and (3) personal resilience. To address the threats to joy in medicine, health care systems and institutions must provide the scaffolding to ensure the practice environment is efficient and the workload demands are reasonable to allow all

clinicians to experience meaning in their interactions.[13] For instance, a study of 23 highly functional primary care practices found that effective and efficient models of care, such as shifting from physician-centric model of work distribution to a shared-care model that provides higher levels of clinical staff support, promote joy in the practice of medicine.[14]

The culture of medicine exacerbates the loss of joy by promoting endurance and exhaustion in the name of patient care. Working excessive hours, skipping meals or bathroom breaks, and missing major life events such as weddings and graduations are explained away as acceptable behavior because it is in service to the patients. With the pandemic came an onslaught of slogans stating health care workers are heroes, furthering the notion that clinicians are superhuman.[15] The concept can be exhilarating, yet it is partially based on fiction, and unfortunately, perpetuating this culture of exhaustion is not sustainable. The great resignation of health care workers across the nation is a testament to the fragility of the concept that health care workers are invincible. In 2021, 117,000 physicians resigned or retired, the largest group of some 334,000 health care workers to leave the profession.[16] This creates a quandary for the oncology workforce which is already strained by shortages. Oncology clinicians are human beings caring for other humans, challenged to handle the enormous expectations put on them to deliver cancer care. Institutional and systemic changes are needed to refine professional norms largely focused on self-sacrifice and a lack of vulnerability. Correcting systemic problems in the medical culture and refining ways of working are beyond the control of any one individual. Recent efforts such as ASCO's partnership with Vital Worklife and the Medical Society of Virginia to offer SafeHaven, a comprehensive offering of physician well-being resources, is an example of a novel investment in oncology workforce well-being at a national level.

The third domain of professional fulfillment is personal resilience. This may be somewhat of a misnomer as doctors score higher on resilience scales than other US workers.[17] Personal resilience refers to the individual *skills*, *behaviors*, *and attitudes* that contribute to physical, emotional, and professional well-being.[18] In a sense, this is what any one individual can modify or control on a consistent basis at work and at home. Therefore, addressing individual skills, behaviors, and attitudes such as learning and practicing effective communication skills could give clinicians more influence over the workplace. Actively adopting certain behaviors such as being kind, listening, and responding to emotions with empathy can create an environment that fosters collegiality and teamwork. This, in turn, can change the microculture of the clinical setting. When colleagues communicate clearly and treat one another with the utmost respect and generosity, the culture can change for the better and therefore enhance professional fulfillment.

CONSIDERATIONS: REKINDLING JOY BEFORE ENTERING THE ROOM

Joy and satisfaction in the workplace can be fostered by attitudes, behaviors, and communication skills practiced in the nonclinical spaces such as meetings, hallways, and workrooms. Anyone who has been on the receiving end of a spiteful comment will know how one difficult encounter can change the tone of the day. Similarly, a genuine, authentic compliment can induce feelings of happiness and make a day seem lighter and more fulfilled. In a recent *New England Journal of Medicine Catalyst* commentary "Finding Joy in Medicine: A Remedy for Challenging Times," the authors outline three practices to remedy burnout and provide a pathway to joy: framing, gratitude, and kindness.[19] These skills can be adopted by anyone on the oncology team and practiced in everyday settings not only between clinicians and patients. Culture is established through conversations and using framing, gratitude, and kindness can change culture by increasing the quality of relationships among colleagues. We will briefly review these practices below.

Framing can help overcome the tendency for humans to have a negativity bias. For example, a physician reviewing patient satisfaction scores may focus on a single negative comment rather than the positive comments. Framing helps overcome negativity bias by consciously reflecting on the situation and asking, "can I see this another way?" In this scenario, the question may be posed as "can I see the body of positive comments as a more accurate reflection of how patients feel about me?" Reflecting on this might help soften the reaction to negative input. Similarly, some physicians keep a feel-good file of thank you notes from patients and peers that they review periodically to help frame the positive impact they are having in the workplace.

Gratitude is the quality of being thankful. Gratitude includes being thankful for the things we often take for granted (eg, the security guard who always says good morning, the cleaning person who keeps the clinic space tidy, or the teammate who takes care of mundane tasks like peer-to-peer authorizations). Gratitude has health benefits including boosting mood, well-being, improving cardiovascular health, and increasing motivation to help others.[20] A study of 102 health care workers found those who kept a work-related gratitude diary had significantly lower depressive symptoms and perceived less stress compared with those who were assigned to writing in a work-related hassle diary or those assigned to not keeping a diary at all.[21] A recent study showed that expressions of gratitude buffered cardiovascular stress response among coworkers working on a stress-inducing task.[22] In workplace settings, expressing gratitude should be voluntary, allowed to be authentic, and built into recurring structures such as meetings and huddles.[19,20] Thanking staff for their hard

work and help at the end of a clinic is an easy way to express gratitude to teammates and allows for a few moments of goodwill before leaving the workplace.

Kindness is defined as doing something to help someone else. Many are called into oncology for the very purpose of helping someone else. The case of kindness in cancer care was made in a *Journal of Oncology Practice* article "Role of Kindness in Cancer Care," which outlines six types of kindness that can diffuse the negative impact a cancer diagnosis brings.[23]

Although lending kindness to patients facing a cancer diagnosis comes easily for many, less common is the recognition that kindness starts with oneself and when extended to all members of the team, reaps the most benefits. Recent data found that nearly one in four physicians suffers from frequent or intense feelings of imposter phenomenon (aka imposter syndrome), a psychological construct characterized by the persistent belief that one's success is undeserved rather than due to personal effort, skill, and ability. This leads to feelings of inadequacy and self-doubt despite objective proof of competence and achievement.[24] One skill to mitigate imposter phenomenon is self-compassion or the compassion individuals give to themselves in times of suffering. Although self-compassion has not been studied in oncology, it is gaining more attention for its use in the workplace.[25,26] Self-compassion is composed of three elements: self-kindness, a sense of common humanity, and mindfulness. Self-compassion can be taught and has been shown in randomized trials to improve outcomes in various populations.[27,28] In health care, there is preliminary evidence that suggests a mindfulness self-compassion intervention can reduce stress and improve compassion fatigue and resilience.[29,30] Self-compassion interventions could address the harsh negative reaction to one's perceived shortcomings that is common among those who may suffer periodically from imposter phenomenon.

CONSIDERATIONS: REKINDLING JOY WHILE IN THE ROOM

The tone of the visit is set by clinician's presence. Therapeutic presence is identified as a component of therapeutic effectiveness and requires eight attributes: being compassionate and empathic, respectful and nonjudgmental, genuine and authentic, trustworthy, fully present, valuing the intrinsic worth of the patient, being mindful of boundaries, and being emotionally resilient.[31,32] Presence can be established by having a mindful moment to prepare for entering the room and conveyed with nonverbal communication such as silence, eye contact, and avoiding distractions during the conversation.[33]

Essential communication skills in building the patient-provider partnership include creating rapport, allowing patients to share their story, listening to understand, and responding with empathy. Time in the room with patients is short.[34] Therefore, establishing rapport and a trusting relationship must happen very quickly in the course of the visit.

RAPPORT BUILDING

Oncology clinicians can build rapport in the first few minutes of the visit by making eye contact, in their greeting, by introducing themselves, and allowing the patient to introduce themselves and their loved ones. Sitting down is an important behavior in the clinic and in the hospital. Sitting at eye level with the patient lessens the hierarchy in the room and conveys to the patient that they have our full attention and that we have time for them. In the first few minutes of the encounter, it is critical to learn something about the patient's noncancer life (eg, where are they from, what kind of work do they do, what is their family situation). Small talk before big talk can help put a patient at ease. The Patient Dignity Question asks, "What do I need to know about you as a person to give you the best care possible?" and has been shown to help patients feel they are seen as whole persons and enhances clinician connectedness, respect, and empathy toward patients.[35] These few moments help to establish a bond, helping patients be known as a whole person rather than a person with a particular cancer or condition.

> Physician: "Tell me about yourself, what brings you joy in your life?"
>
> Patient: "Well, I like to go fishing and travel."
>
> Physician: "Please tell me more about that."
>
> Patient: "I really enjoy fishing with my sons. We used to go a lot when they were younger. Now we go once a year. That is an important weekend for me."

Rapport can be further built by giving the patient an opportunity to put on the table all the issues or concerns they are expecting to address during the visit. An example of this may be saying "I have reviewed your chart and know a lot about you. Before I start, I would like to know all the things you are hoping to cover today." This allows patients to present pressing questions and concerns at the beginning of the visit. Many of these concerns may be covered naturally during the visit and can help patients feel heard by allowing them to voice them up front.

> Physician: "It's so nice to meet you. I have reviewed your chart and spoke to your referring doctor and have a lot to cover. Before I do, what are all the things you are hoping to cover today?"
>
> Patient: "I don't know. I want to know if I will need to have my breast removed."
>
> Physician: "Ok, we will cover that, no problem. What else?"

Patient: "I want to know how long I will be out of work."

Physician: "We will cover that, too. What else?"

Patient: "I guess I really want to know if I'm going to die from this."

Physician: "That is an important question that we will certainly address. What else is on your mind?"

Patient: "That's it."

LISTENING TO UNDERSTAND

Listening facilitates understanding and listening without interruption promotes a therapeutic relationship.[36] Inviting and allowing patients to tell their stories without interruption can seem daunting to a busy physician or nurse. Studies show, however, that the time it takes for a patient to tell a story is not long. In one study, when doctors were instructed to listen without interruption, most patients talked for 2 minutes or less before taking a pause.[37] Unfortunately, other studies have demonstrated a decline in the time physicians allow patients to talk without interruption, with the most recent data published in 2019 showing an average time to interruption of 11 seconds.[38,39]

Listening skills can be broken down into two segments: active listening and reflective listening. Active listening includes the use of silence which can be bolstered by eye contact, head nods, and short verbal utterances that indicate listening such as hmm or go on. Reflective listening skills include echoing what the patient has said, requesting more information and summarizing in the clinician's own words. An example of an echo is if a patient says, "I've been struggling at home lately" and the clinician replies by repeating the word: struggling. This simple echo encourages the patient to say more about this. Echoing different words can emphasize curiosity about different parts of the phrase. The echo might be modified to state, struggling at *home*. Or perhaps there has been a change in condition recently, and the doctor or nurse wants to highlight this by echoing, struggling at home lately. These reflective statements demonstrate that the listener is paying attention and wants to know more.

Patient: "I'm just so grateful for my cancer."

Physician: "Grateful…"

Patient: "Well, before my cancer it was like I wanted to do something different, make changes, but after the cancer I realized I just needed to go for it. I've left my job and am volunteering at a museum and am so happy doing this."

Requesting is using phrases like "tell me more about…" to help draw out details of what the patient has already said. This open-ended statement allows the patient to determine what direction the story will take, may reveal what is on the patient's mind faster, and may help providers avoid assumptions. For instance, a patient might state, "I just want this to be over." Asking the patient to "tell me more about that" may allow the patient to disclose that they are worried about pain, worried about burdening a caregiver, or are thinking about something else entirely. Not assuming what this statement means and asking for the patient to say more about it can build a deeper relationship and avoid upsetting miscommunications.

Patient: "I wish I had planned more."

Physician: "Do you want to say more about that?"

Patient: "I wish I wrote a book "the girl's guide to metastatic breast cancer." I wish I had planned more for the end, but I didn't because it was too painful. I want to celebrate what I did do. I got to be a mom, got to discover the joy of being a mom and I feel like I've had some real success in my life which is that my son is a kind, lovable and caring human being, and he got to know me. When I look around my bedroom right now, I see all these mementos, special mom things like finger painted picture frames, things from baseball. I look at the photo of when I was first diagnosed. My son was 6 months old. We had portraits taken at JC Penny studio. We all sort of match as a family with what we are wearing. I remember being glad that I put those together. That was my first Mother's Day, and I thought it might be my last. That was 12 years ago. I don't know how I did it. I feel happy about that, I guess."

Summarizing is a very powerful tool that demonstrates to the patient that the listener has been paying attention and is trying to understand what is being said. Summarizing can be used by starting a sentence with "Let me see if I have this right…" or "Let me summarize what I've heard you say in my own words."

Physician: "So, if I'm hearing you correctly, you were doing fine until about three weeks ago when you noted this new pain in your abdomen. You tried different medications like tums and modified your diet but it's not getting better. And you're worried the cancer could be back because of the pain?"

Patient: "Exactly!"

RESPONDING WITH EMPATHY

Empathy as a communication skill has been shown to improve patient satisfaction, lowers anxiety and distress, improves self-efficacy, and improves clinical outcomes.[40] Recognizing and supporting emotion in encounters has been shown to improve the physician-patient relationship through establishing trust, improving patient satisfaction and compliance, and to save time.[40,41] In our careers, expressing empathy has often created sacred moments. Addressing emotional cues and providing verbal empathy can allow patients to feel seen and heard, and once that is

TABLE 1. Sample Phrases of Verbal Empathy Using the NURS Mnemonic

Description	Example
N, Name the emotion	"I think I can see how upsetting this is to you." "You seem sad as you are talking about this." "I heard you say you're frustrated."
U, Express acknowledgment that the emotional reaction is understood by the clinician	"Given what you've told me, I can see why you would feel this way."
R, Make a statement of respect for the patient's behaviors or actions, show appreciation for the patient, or acknowledge the difficulty of the patient's situation	"You seem to be handling this with grace." "Thank you for trusting me with this information." "You have a lot going on right now."
S, Supportive statements express how the clinician is able to align with the patient	"Let's see if we can make a plan together that feels right." "No matter what happens, I am here to support you."

established, the encounter can move on to discuss next steps and planning.

Empathy can be nonverbal and verbal. Nonverbal empathy includes body language such as leaning in to listen, making eye contact, or offering a touch on the shoulder or a tissue. Verbal empathy uses phrases to convey compassion. Verbal empathy can be more powerful than nonverbal empathy because when patients are experiencing strong emotions they may not recognize nonverbal cues but are able to hear words and therefore more easily receive and internalize empathy. Empathic statements can include Naming the emotion that is being expressed, expressing some level of Understanding about how the patient could feel that emotion, Respecting what the patient is going through, and lending Support in an authentic, relational way. A helpful mnemonic is NURS for four statements that give structure to lending verbal empathy.[42] Examples of empathic statements can be found in Table 1.

Verbal empathy is a powerful yet underutilized therapeutic tool. The frequency of empathic statements in oncology was studied by Pollak et al[43] who found, when given the opportunity, oncologists responded with verbal empathy only 22% of the time. Studies have shown physicians who expressed more empathy were evaluated more positively and had patients who reported higher levels of satisfaction and were more compliant with their doctor's advice.[44,45] Using empathic statements is a skill that can be taught and has demonstrated effectiveness in improving communication among oncologists with sustained improvements at 15 months.[46]

CONCLUSION: REKINDLING JOY BY LEARNING EFFECTIVE COMMUNICATION SKILLS

Partnering with patients through thoughtful communication is not only for clinicians who are naturally talented at communication or rate high in emotional intelligence. Training programs including courses offered by the Academy of Communication in Healthcare (ACH), Institute for Communication in Healthcare, and Vital Talk teach clinicians how to use communication skills in clinical encounters including those centering around serious news and end-of-life care. Teaching communication skills has been shown to improve patient satisfaction and improve physician burnout.[47,48]

Moments of feeling deeply connected have been described as profoundly meaningful for patients and clinicians alike. For clinicians, these moments serve as a reminder of why we chose oncology as a profession and supply fuel to the flames of burnout by making enhancing feelings of professional fulfillment. Partnering with patients through thoughtful communication can allow for more opportunity to experience these moments of deep interconnectedness, thus increasing feeling of joy in the practice of oncology.

overview

Patient Advocates and Researchers as Partners in Cancer Research: A Winning Combination

Laura D. Porter, MD[1]; Karyn A. Goodman, MD, MS[2]; Josh Mailman, MBA[3]; and Wendy S. Garrett, MD, PhD[4]

Inclusion of advocates as partners in research is now required by numerous international funding agencies. The role of advocates has expanded in recent years to include all areas of research, including basic cancer research, translational research, and clinical trial design and development. The involvement of advocates as partners in cancer research can be challenging for the advocate and for the researchers, but this collaboration is beneficial to all involved. Herein, we will define patient advocacy, explore advocate engagement, and share information on programs that train advocates and researchers to work together as partners.

Author affiliations and support information (if applicable) appear at the end of this article.

THE GROWTH OF PATIENT ADVOCACY

Patient engagement in research has grown significantly in the past 30 years,[1] primarily in the clinical research setting.[2] The roles of patient advocates in research vary from more limited involvement restricted to trial eligibility and feasibility to meet the requirements of funding agencies to engagement as patient partners at all levels of research. Some of the activities that advocates have engaged in are focus groups, grant reviews, steering committees, advisory committees, and clinical trial protocol review. These activities are being provided by several different stakeholders, including large private funding authorities, national organizations, government funded agencies, and pharmaceutical companies. Some of the national organizations in the United States include the National Cancer Institute Clinical Trials Network (NCTN) (which includes SWOG, the Alliance for Clinical Trials in Oncology, and ECOG-ACRIN Cancer Research Group and NRG Oncology), the Patient Centered Outcomes Research Institute (PCORI), the Department of Defense Peer Reviewed Cancer Research Program, the National Cancer Institute (NCI), the American Society of Clinical Oncology (ASCO),[3] and the US Food and Drug Administration (FDA). One example of the expanding roles of advocates is the NCI and the changes they have incorporated to enhance and expand the role of the advocates. Patient advocates have been engaged as partners with NCI cooperative groups since 2006, with changes in engagement and structure expanding in recent years.[4]

DEFINING A PATIENT ADVOCATE

Herein, we will define a patient advocate as a person with lived experience either as a patient with cancer/cancer survivor or an informal caregiver/carer of a person with cancer who is engaged in advancing something larger for themselves and their community, including increasing awareness, access to resources, and advancing research. This excludes paid professionals who are often referred to as patient advocates, because they are nurses or case managers who work to ensure that the patient is appropriately cared for in a system. There is little agreement on whether patient, partner, or patient partner is the most suitable term[5] to describe the engagement we are looking at. Another term that is used is that of a research advocate, which indicates that the patient advocate is involved with groups that influence the direction of the research.[6] This term is not being used universally in the literature, so we will use the term patient advocate.

DIFFERENTIATING TERMS FOR ENGAGEMENT

Engagement, participation, and involvement are all terms that are often used interchangeably in the literature about patient advocacy. The different terminologies used may be confusing as there is little consensus in the literature on the use of terms such as involvement, engagement, and patient-oriented research, raising the question of which definition should be considered most appropriate.[5] Here, we will use the following definition of engagement and will consider it equivalent to the international terms discussed below: The active, meaningful, and collaborative interaction between patient advocates and researchers across all stages of the research process.[7]

In the United States, we use the above definition. In Canada, the word patient engagement indicates that patients are partners in the research.[8] In the Netherlands, they use participation.[9] In the United Kingdom,

PRACTICAL APPLICATIONS

- Define who qualifies as a patient advocate.
- Differentiate between engagement and other forms of patient involvement.
- Discuss the benefits and challenges of partnering with and engaging patients.
- Demonstrate programs that are successful with training and evaluating their advocacy program.
- Future directions require standardization of definitions, training, and evaluation.

they differentiate between involvement which they define as patients and public involved as coinvestigators in research being carried out with or by members of the public, rather than to, about, or for them. In the United Kingdom, engagement is the dissemination of research knowledge to the public, and participation is when people take part in a study (patients provide data).[10] Engagement is often described as researchers doing research with patients, rather than for or on them, through integration of patients into the role of study team member.[11]

We will refer only to engagement where patient advocates are working as partners in research endeavors. We believe that patient advocates should be engaged in projects from conception to dissemination of the results spanning the spectrum of bench research to clinical trials.[12] Patient advocates have participated in focus groups, interviews, and time-limited roles and passive endorsements for both pharmaceutical companies and funded and funding agencies. We do not consider this engagement. Rather, this is participation and includes patients as clinical trial participants. Questions arise about defining what meaningful engagement is and how to measure it.[13]

In this review, we will discuss the use of patient advocates at all levels of research. The engagement of patient advocates in preclinical or basic cancer research is relatively new, but it is happening. The Patient-Centered Outcomes Research Institute and Cancer Grand Challenges require the engagement of patient advocates for their research funding programs.[14] Advocates can contribute at all steps in the process, and they can help formulate the research questions and identify patient concerns early in development of a research plan.[1] For clinical trial proposals, advocates can evaluate if a procedure or inclusion and exclusion criteria would be acceptable to patients. This may enable trials to move forward that are more acceptable to patients, more likely to recruit well and more meaningful for patients and their communities.[15]

REASONS PATIENT ADVOCATES BECOME ENGAGED

There are many reasons that patients and their caregivers become involved in advocacy. One major reason is a desire to help so that others may have an improved quality of life. Some of these include the opportunity to include the patient voice in the research process and the intellectual challenge[16] to add a human face and a sense of urgency to the research, to ensure that the patient is the focus of the research.[6]

> "Our experiences are all different but as a collective, we can share what works for the patient community, adding our thoughts to make sure it's relatable and relevant. Representation is important, it gives the patient voice a seat at the table and has shown that it's just as important as science. We have a PhD in experience–that offers a valuable opportunity to share in and guide the work being done"—Candace Henley, Patient Advocate[17]

Knowledge is power, and many patients find learning more about research progress in their disease and what is currently being investigated helpful for themselves and their loved ones.

BENEFITS OF ENGAGING PATIENT ADVOCATES AS PARTNERS

It has been reported in several studies that patient advocate engagement provided valuable contributions to research feasibility, acceptability, rigor, and relevance.[14] Engaging patients in research can increase its quality, and as health care providers integrate it into care, the quality of care will increase.[12] Engagement enables mutual learning, and the building of new skills, knowledge, and skills by patients increased understanding of basic science research and the broadening of researchers' perspectives, including an understanding of what is important to patients.[10,18] Patient partners can play an important role in disseminating research finding, which improves communication with the public and strengthens the research through trust of the research community, thereby increasing the impact of the patient voice.[6,15]

Engaging advocates early in the research process facilitates the design of more patient-centric clinical trials.[2] Engagement offers a mutual learning opportunity. Patient advocates can deepen their understanding of current research about their disease, and investigators can share their research results and become more effective scientific communicators. In addition, by interacting with patient advocates, investigators can grow their understanding of the priorities of those affected by the disease and focus their research on areas relevant to patients' needs.[15]

> "Collaboration between scientists and advocates is integral to making sure patients are represented in research and that their voices are heard. Many scientists find that collaboration with advocates strengthens their proposals by clarifying their goals and impact on patients. The relationship between

> advocates and scientists is mutually beneficial—as the advocates enrich ongoing research initiatives, they learn more about the latest scientific developments of their disease and future possibilities. Ultimately, both groups learn more about the other and develop an ongoing relationship characterized by a mutual respect and empathy."[19]

Engagement also offers advocates the opportunity to build new skills, knowledge, interests, and perspectives on their disease and the research enterprise. Some view patient engagement as a means of ensuring that research is patient-centered, useful, and trustworthy, leading to greater use and uptake of research results by the patient and the broader health care community.[20] Engagement fosters important discussions not only on what is important to patients but can inform the research on the appropriate questions to ask, methodology, and future research questions.[21] Patient advocate engagement increases trainee recruitment and retention as trainees have a greater appreciation of the purpose and impact of their research.[22] Engaging advocates may also enable a more ethical process in all phases of research. Overall, engagement encourages a sense of partnership between the advocate and the researcher, thereby increasing trust of the research community and ultimately increasing the trust of the patient community.[15,19]

CHALLENGES OF ENGAGEMENT

Challenges of engaging patient advocates at all stages of cancer research include a perceived lack of scientific knowledge, which may be frustrating for both advocates and researchers. Engaging patient advocates who are not trained in research presents a risk that they may feel ill equipped and lack confidence or understanding to voice their perspectives or concerns.[23]

Lauzon-Schnittka et al noted that patient advocates engaged in clinical trial development contributed to trial design by influencing inclusion or exclusion criteria; the designs selected, such as noninferiority designs, numbers and types of arms, and mixed methods; and decisions about assignment of participants. The advocates in some cases wanted more people in the study or interventions, which can lead to broader inclusion criteria; selection of designs, such as delayed start; or use of different participant assignment techniques, such as unequal random assignment.[8]

Another concern is that the same patients are recruited for engagement because the researchers may be familiar with them and have worked with them before.[20] Connections are important, and there are patient advocates who say yes when asked to participate and they are heavily relied on, which may result in a lack of diversity and opportunities for others. It is suggested that the patient advocates be pulled from the population being studied, although this comes with challenges, including finding individuals willing to participate.[18] It has been suggested by Perlmutter et al that developing a pipeline of patient advocates is important and that advocates are currently recruited on an ad hoc rather than systematic basis.[6] It is a challenge to ensure diversity within collaborations so that the interests of the well-educated White middle classes in rich countries do not dominate.[24] Greater diversity is needed in terms of age, class, sex, geography, ethnicity/race, immigration status, indigeneity, sexuality, and religion.[18]

There needs to be care in engaging advocates for research to avoid a tokenistic approach and attention paid to representation.[25,26] It has also been noted that there is a lack of measurement of meaningful engagement.[18] Largent et al[20] suggested that diversity can be increased by engaging more patient advocates to capture a wider variety of perspectives and experiences, by identifying and addressing obstacles or barriers to engagement, and determine which patients are presently engaged and assess their representativeness.

TRAINING AND EVALUATION

Engagement ensures that projects are relevant and valuable to the end users. There is broad agreement that the engagement of patient advocates should be meaningful, impactful, and measurable. The challenge is how to make the engagement of patient advocates in research more methodical and consistent[7] and how patient advocates are being engaged in research and how should they be engaged.[20] Questions arise about defining what meaningful engagement is and how to measure it.[13] Patient advocate engagement will be reduced to mere tokenism if patients are not capable of meaningfully contributing to the research enterprise because of a lack of preparation and training.[20]

Patient advocates are not always provided with the relevant resources to effectively contribute to the discussions.[27] Fox et al[15] found that most published evidence of patient engagement comes from clinical research; therefore, the benefits of patient advocate engagement in basic or translational research are unclear, and the current standing of patient advocate engagement overall is unclear.

The PCORI has trained advocates using voluntary training workshops, structured training interventions, and self-initiated training interventions.[28] A Canadian model for engagement is The Office for Patient Engagement in Research Activities (OPERA) in Ottawa that recommends ongoing education and training for both researchers and the advocates.[26] Table 1 demonstrates the processes used by several organizations in training and evaluating the effectiveness of patient advocates in research.

Effectiveness of engagement needs to be assessed by stakeholders in a structured manner to encourage constructive feedback of success and challenges in engagement.[23] Those skeptical of engagement want evidence of

TABLE 1. Formalized Cancer Patient Advocate Training Programs

Organization	Training Components	Evaluating Impact
AACR Scientist↔ Survivor Program	Meeting with scientific mentors Support to participate in poster sessions and networking at annual meeting	None noted
ASCO	Advocacy tools and resources including ASCO in Action, ASCO ACT Network videos, and podcasts Breaking down science for specific cancers Networking at the annual meeting	Advocate feedback on tools No. of advocates and advocacy organizations attending meetings
BMJ	Support for abstract submission Online presentations Peer review exercises	Cross-sectional survey to understand concerns and suggestions to improve the training materials and processes
Fight CRC	In-person training at academic centers Online modules throughout CRC continuum	Survey to advocates understanding research knowledge, skills, and confidence Survey to experts who have worked with advocates to understand strengths of the program, perceived impact, gaps, and satisfaction
FORCE	Self-paced, online educational course Expert-led webinars	Requests feedback from researchers who used patient input on impact of having advocates involved in their study
FOCR (Progress for Patients)	Online training modules to provide tools for advocates to communicate with drug researchers, developers, and regulators	Provide evaluation numbers for advocates who complete training to clarify research goals and refine questions in research process
PCORI	Patient Advocacy Executive review form Designed to be implemented for other organizations conducting clinical trials	Pre- and post-training survey data evaluating knowledge, confidence, skills, and self-efficacy
Research Advocacy Network	On-site training Customized workshops and webinars via online learning resources	Conduct evaluation of the effectiveness of advocate activities in basic, translational and clinical research

the costs, benefits, and risks before they become further engaged. Calls for measuring patient advocate effectiveness also raise questions about the effect on what and for whom.[29,30] Ideally, assessments should measure whether expectations were met by both the researcher and the patient advocate.[1]

INVOLVEMENT IN NATIONAL CLINICAL TRIAL DEVELOPMENT

Including patient advocates in the development of clinical trials is critical to the success of studies in terms of both effective patient accrual and communication of clinical meaningful outcomes to patients. In the NCI Cooperative Group Clinical Trials Network, now called the NCTN, there is a long history of engaging patient advocates across the clinical trial lifecycle and of incorporating feedback from patient advocates in the development and approval of clinical trial concepts.

In 2001, the Institute of Medicine published Crossing the Quality Chasm: A New Health System for the 21st Century to define priorities for improving the quality of health care in the United States.[31] A crucial outcome was recognition of the need for an increased emphasis on patient-centered care. In 2006, the NCI was establishing their own process for evaluating and prioritizing clinical trial concepts to be developed through the National Cooperative Group System. As a result, the NCI instituted disease-specific scientific steering committees composed of clinicians, biostatisticians, translational researchers, and patient advocates.[32] NCI Task Forces (TFs) also provided an initial forum for multidisciplinary discussion of concepts by disease-site experts before eventual submission to and evaluation by steering committees. Both TFs and steering committees created a demand for more training and support for patient advocates. In 2008, the NCI patient advocate steering committee (PASC) was formed. The PASC allowed for more interaction among the advocates participating on the NCI steering committees and TFs and provided an opportunity for defining roles and responsibilities. The priorities for the patient advocates were to bridge the gaps that exist among researchers, patients, and cancer communities. In the

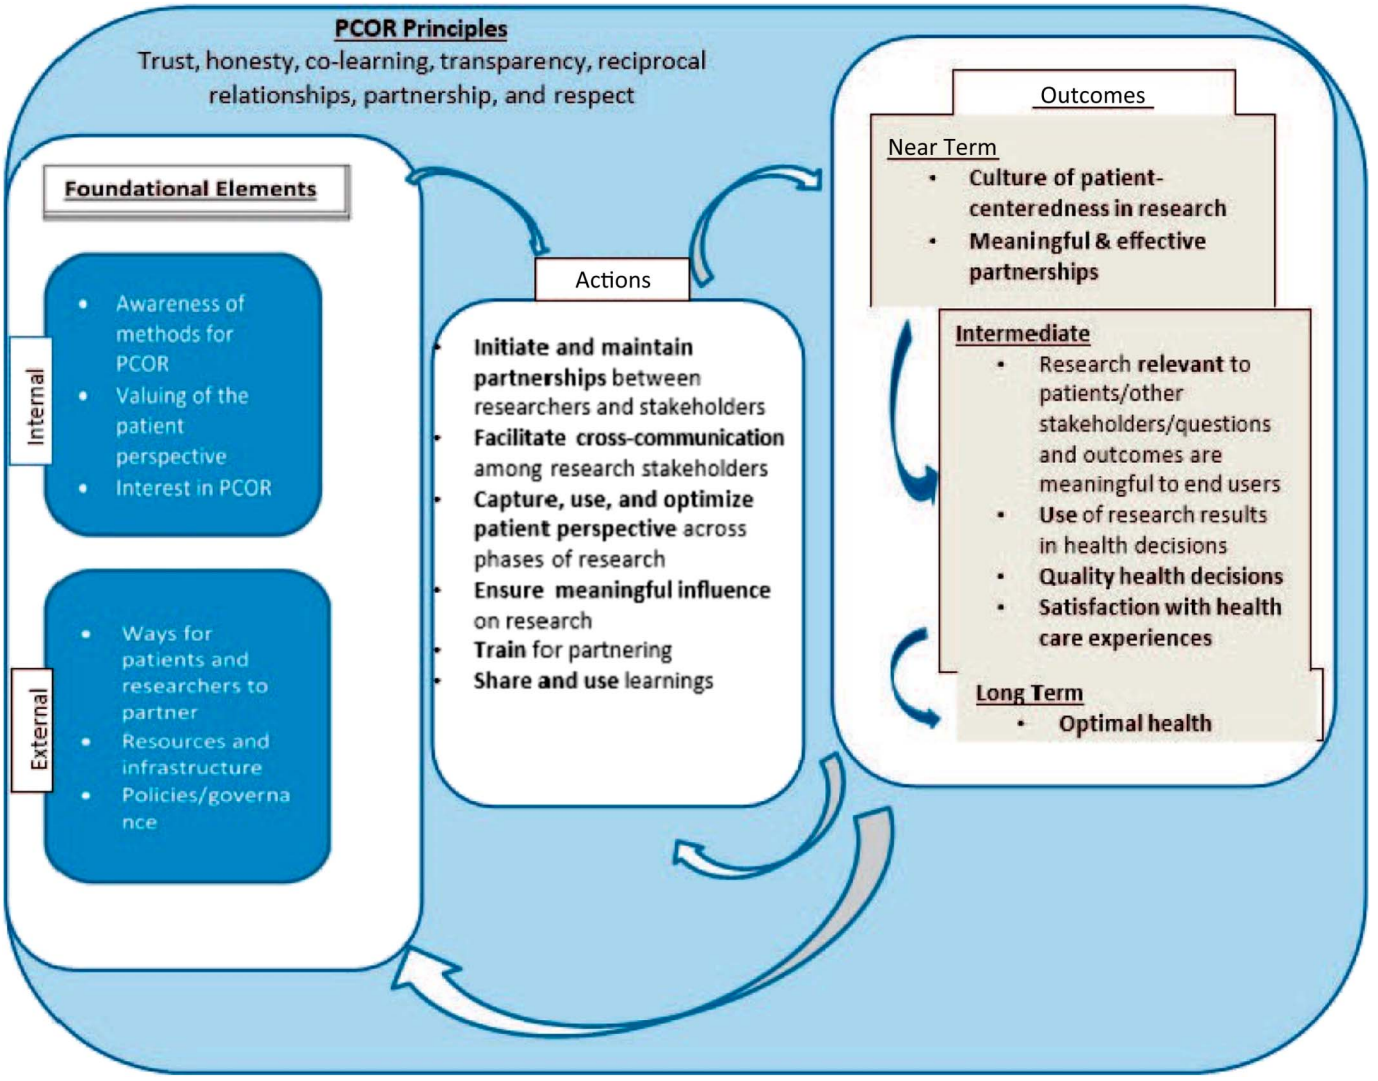

FIG 1. Conceptual model of PCOR. Reprinted from Frank et al[33] under the terms of the Creative Commons Attribution License (https://creativecommons.org/licenses/by/3.0/us/). PCOR, patient-centered outcomes research.

setting of the steering committees and TFs, patient advocates are more focused on giving constructive feedback on research design, appropriate eligibility criteria, feasibility issues, barriers to patient participation, and ensuring that research outcomes are patient focused. Patient advocates on the steering committees review each of the clinical trial concepts and provide written critiques and critical questions to make certain that the study is patient centric. Recently, PASC developed an updated patient advocate template for the written critiques that includes questions addressing six domains: (1) importance of the concept; (2) design or schema; (3) risk, benefits, and burden; (4) eligibility (inclusion and exclusion criteria, including important implications on diversity and representativeness of consenting patients); (5) accrual feasibility; and (6) additional patient-centric comments.[32] Patient advocates provide their feedback during the steering committee conference call closed sessions and are equal voting members on the steering committees. Study concepts can be disapproved on the basis of the feedback of patient advocates and concerns about whether studies are feasible or patient centric. In addition to patient advocate involvement on NCI steering committees and TFs, NCTN groups which are responsible for the initial development of clinical trial concepts and conducting trials also work closely with patient advocates. Each NCTN group has numerous advocates working with disease-specific committees to provide advice on trial design and when the study is open, advocates disseminate information about the study, engage advocacy groups, and help publicize NCI trial findings. There is a true bidirectional

nature of engagement. Patient advocate engagement is multipartite and mutually beneficial for patients and clinical trialists.

PARTICIPATION IN EARLY-CAREER INVESTIGATOR TRAINING

Professional societies and national organizations engage patient advocates in educating early-career investigators. ASCO has patient representatives on the ASCO Cancer Research Committee and ASCO Expert Panels for guideline development. The American Association for Cancer Research (AACR) connects advocates with scientists at their Annual Meeting through the Scientist↔Survivor Program (SSP).[2] Both ASCO and AACR invite patient advocates to participate as faculty in their joint workshop, Methods in Clinical Cancer Research (MCCR) workshop, an important training opportunity for clinical oncology researchers. Patient advocates teach in the didactic sessions and participate in small group sessions where early-career investigators present their clinical trial proposals. The patient advocates provide guidance on how to make the studies more patient-centric. For example, advocates give feedback on the study design. Specifically, advocates provide insight into the impact of clinical trial participation for patients and their families, regarding the number and kinds of required procedures, such as biopsies, the logistics of treatment, barriers to patient participation, the side effects of treatment, and personal financial toxicity. This feedback can shape clinical trials and help junior investigators develop studies with higher patient participation and satisfaction. Having the opportunity to work directly with patient advocates early in their career is incredibly impactful for investigators. Such interaction cultivates an appreciation for the complexities of balancing what we want to learn in a study with the participation demands placed on the patient and their social network and emotional support system. The MCCR workshop empowers patient advocates to be partners throughout the research continuum by working with young clinical researchers in the initial development of their trials. The workshop also creates the opportunity for patient advocates to be a point of contact for studies, learn about their progress, and help disseminate the results. The bond forged between investigators and advocates can make clinical research both more meaningful and successful.

FUTURE DIRECTIONS

Patient advocates as partners with researchers in cancer research has been expanding, but challenges still exist. Some of the challenges can be alleviated if there is a universal definition of who is a patient advocate. The definition of engagement should be universal to eliminate tokenistic patient representation and clearly define what is considered engagement. Training advocates and researchers is necessary to eliminate the difficulties that each may feel working together. A reproducible standardized evaluation of the engagement will help with assessing the success or failure of this partnership. We have discussed successful initiatives for engagement and partnerships in cancer research. One example is from PCORI (Figure 1). PCORI has funded hundreds of projects that have patient advocates engaged in different ways from community forums, advisory panels, and coinvestigators on research. PCORI was created to fund comparative effectiveness research that compares the benefits and harms of clinical interventions in real-world settings, so engaging people who will receive those interventions is particularly salient.[33]

> "Effective patient engagement requires effort of both the researcher and the patient advocate; both must be committed to the process and communicate throughout the engagement. Patient engagement must not be about checking off a box on a form, with minimal contact after funding is secured. It is about making a difference to the way science is conducted, with urgency and value of the patient perspective and experience."[1]

The integration of patient advocates as partners has expanded in all areas of cancer research. The principles of reciprocal relationships, colearning, partnership, trust, transparency, and honesty[34] are necessary to ensure successful partnerships between patient advocates and researchers in all areas of cancer research.

Impact of Prior Authorization on Patient Access to Cancer Care

Dario Trapani, MD[1,2]; Lianne Kraemer, MSc[3]; Hope S. Rugo, MD[4,5]; and Nancy U. Lin, MD[6,7]

Prior authorization (PA) is a type of utilization review that health insurers apply to control service delivery, payments, and reimbursements of health interventions. The original stated intent of PA was to ensure high-quality standards in treatment delivery while encouraging evidence-based and cost-effective therapeutic choices. However, as currently implemented in clinical practice, PA has been shown to affect the health workforce, adding administrative burden to authorize needed health interventions for patients and often requiring time-consuming peer-to-peer reviews to challenge initial denials. PA is presently required for a wide range of interventions, including supportive care medicines and other essential cancer care interventions. Patients who are denied coverage are commonly forced to receive second-choice options, including less effective or less tolerable options, or are exposed to financial toxicity because of substantial out-of-pocket expenditures, affecting patient-centric outcomes. The development of tools informed by national clinical guidelines to identify standard-of-care interventions for patients with specific cancer diagnoses and the implementation of evidence-based clinical pathways as part of quality improvement efforts of cancer centers have improved patient outcomes and may serve to establish new payment models for health insurers, thereby also reducing administrative burden and delays. The definition of a set of essential interventions and guidelines- or pathways-driven decisions could facilitate reimbursement decisions and thus reduce the need for PAs. Structural changes in how PA is applied and implemented, including a redefinition of its real need, are needed to optimize patient-centric outcomes and support high-quality care of patients with cancer.

INTRODUCTION: PRIOR AUTHORIZATION IN HEALTH CARE

Utilization review is an established component of cost management in health care, broadly implemented to control service delivery, payments, and reimbursements.[1] Such services and treatments can include diagnostics, medications, and surgical procedures. When utilization review is required by health insurers before patients can receive services or treatments, it is called prior authorization (PA).[2,3] (Table 1) Stated goals of PA include screening for appropriateness and efficiency and reducing the overutilization of unnecessary services or medications, thereby reducing health care costs. Historically, one aim of PA has been to catalyze the uptake of generic drugs; when coupled with policies facilitating use of generic medications and biosimilars, utilization management may yield improved system sustainability by exerting downward price pressure on medications.[4] In an era of growing innovation, the rising costs of oncology care have been concerning for sustainability.[5] As a consequence, PA has been applied more broadly to a larger set of health interventions. Although such a process may be viewed as legitimately grounded in some respects, it places a significant burden on patients and health care providers, contributing to negative outcomes with further strains on the already-stressed health care workforce. Indeed, the PA process raises essential questions about the proper roles of insurers and health care providers in the care of oncology patients and everyday medical practice. This article focuses on the PA process in the United States, but the issues raised also illuminate some of the tradeoffs faced throughout the world in controlling health spending on the one hand and striving for optimal care of individuals facing cancer on the other hand.

PRIOR AUTHORIZATION IN CANCER CARE

Rationale for PA in Oncology: Improving Efficiency in Health Care Spending

The fast pace of innovation in oncology has not only brought improvements in patient outcomes but also increased costs and overuse of non–cost-effective therapies.[6] US health expenditure accounted for $4.3 trillion US dollars (USD) in 2021, that is, $12,914 USD per person, corresponding to 18.3% of gross domestic product.[7] Of such an expenditure, 5.33% is allocated to cancer care alone, that is, more than $200 USD billion annually ($16,346 USD pro capita). This is four times than those for patients treated for noncancer conditions.[8] Oncology drugs

PRACTICAL APPLICATIONS

- Prior authorization (PA) is a type of utilization review that health insurers use to make decisions on the coverage of health interventions for individual patients.
- PA has been originally introduced as a mechanism to rationalize health expenditures toward more affordable and evidence-based treatment choices, including to improve uptake of generics and biosimilars, reduce inappropriate use of off-label therapies, and reduce overuse of expensive medications outside of their intended use.
- PA is subject to insurers' review: Patients experiencing denials as the outcome of PA review may yield adverse health outcomes and financial toxicity, as receiving less effective therapy, therapy with higher risk for toxicity, and/or less optimal supportive care.
- PA is associated with adjunctive administrative burden for health care providers, including the need for peer-to-peer review, and leads to delays in access to care for patients.
- The harmonization of the PA process with national cancer treatment clinical guidelines could help rationalize and simplify the process and reduce costs and treatment delays.
- The establishment of a set of regularly updated, evidence-based essential interventions, the use of national guidelines to inform coverage decisions, a global rethinking of the proper scope of PA requirements, attention to administrative burden and costs, safeguards to protect against abuse of PA requirements, and better implementation science can reshape the PA process as it is applied now.

account for the largest spending of any specialty and exceed 15%-30% of the overall cancer budget.[9] PA has been touted as a way to encourage high-value and cost-efficient budget allocation in oncology.[10] When implemented in the context of treatment guidelines aligned with best practice, PA policies have the potential to increase the quality of cancer care.[1]

From the perspective of payers, the PA process gives health insurance companies a chance to review how necessary a medical treatment or medication may be.[11] Examples of medications that may require PA are those that have dangerous side effects, are harmful when combined with other drugs, are often misused or abused, or should be used only for certain health conditions.[12] Cost is an explicit factor to be considered, for example in the case of medical treatments that have lower cost but equally effective, alternatives available.[11] Step therapy is frequently also built into the PA process to prioritize more cost-effective options. When used judiciously, PA can minimize the use of overly toxic treatments and enhance adherence to established clinical guidelines. For instance, a retrospective analysis of more than 13,000 chemotherapy treatment requests (CTRs) submitted by oncologists for PA has been cited as an example of how a pathway-driven PA process may improve medical oncology quality.[13] In this study, 11.6% of requests were denied even after peer-to-peer review with a board-certified oncologist employed by the insurer: Denials concerned supportive care and antineoplastic agents in the same proportion. One third of denials were due to lack of compendia support, one quarter due to clinical criteria, and 22.8% for problems with dose/frequency. In 10.7% of cases, clinical tests did not support use. A difficulty in assessing this analysis is a lack of granular data on the clinical scenario, the source of guidelines/compendia used, and the outcomes of patients in whom CTRs were denied. Indeed, the implicit assumption in analyses of this type is that the health insurer's assessment is the gold standard for oncology care, which may not be the case always.

Rationale for PA in Oncology: Improving Quality of Cancer Care

Quality improvement can be achieved with the disengagement from low-value clinical interventions or overuse.[14,15] PA can serve as a firewall against the misuse of medical interventions and improve adherence to best practices. A key example is the use of granulocyte colony-stimulating factors (CSFs) in patients receiving chemotherapy. It is reported that up to 30%-50% of patients receiving high-risk regimens for febrile neutropenia are not put under the appropriate CSFs prophylaxis while 30%-40% are prophylaxed outside current indications.[16] In an attempt to rationalize the use of CSFs, a site-wide program initiative was implemented for patients with metastatic colorectal cancer receiving care at a multicenter oncology practice network.[17] The intervention included educational materials, appropriate nonuse recommendations, and PA requirements. The preimplementation versus postimplementation comparison showed that use of CSFs was significantly reduced from 13.5% to 4.5%, with no change in short-term mortality because of complications of neutropenia.[17] However, because of the multipronged intervention, it is unclear to what extent the PA component per se contributed to the reduction in CSF use or if implementation of consistent internal guidelines was instead the primary driver of the observed changes. Another study reported that inclusion of a CSF decision support tool as part of the PA process for women with breast cancer receiving chemotherapy resulted in higher alignment with clinical guidelines.[18] After implementation, a significant decrease in

TABLE 1. Overview of the Main Definitions and Procedures Used in Prior Authorizations by Health Insurances in the United States

Term	Definition
Utilization review	A process of evaluation of the care plan of a patient. It is intended to determine the medical necessity, taking into consideration the treatment standards for a certain health condition, the availability of alternative treatments, and the cost implications
Preauthorization (or prior authorization)	A type of utilization review that health insurances apply to control service delivery, payments, and reimbursements of health interventions
Denial	An adverse determination of a previous request for a health intervention through preauthorization
Peer-to-peer review	A process in which the requests for coverage for a health intervention are discussed between the ordering physician or advanced health provider and another physician employed by the health insurance. The intent of the peer review is to discuss the medical necessity and obtain an authorization or appeal of a request previously denied
Appeal	A request for a second review of the original coverage determination
Medicare Advantage Organizations	A private contractor that can give benefits for Medicare, including part D
Medicare Compendia	A set of authoritative sources for use in the determination of a medically accepted indication of health interventions used by Medicare as a reference to decide on coverage decisions. The National Comprehensive Cancer Network Drugs and Biologics Compendium is the source used by the Centers for Medicare & Medicaid Services to determine coverage for cancer interventions
Clinical pathways	Evidence-informed algorithms developed by multidisciplinary expert committees to define tasks and/or type and sequence of interventions that should encompass most of the clinical practices used in specific clinical scenarios

the proportion of patients with CSF use was observed in the intervention states (75%-69%) compared with no significant change in the nonintervention state (72%-71%), without an increase in the incidence of febrile neutropenia.

How Prior Authorization Is Conducted

PA is a multistep process. Common scenarios requiring almost automatic requirements for PA include advanced imaging, expensive medications (including supportive care treatments), indications where alternative, cheaper, and equally active treatments exist, drugs historically prescribed outside their on-label use, and drugs with cosmetic indications. Specific coverage determination is often not reached through initial submission of medical information to the insurer, resulting in denials. Insurers can communicate reasons for denials and provide the opportunity to request a peer-to-peer review (^Fig 1). The stated intention of peer-to-peer review is to provide an objective and transparent forum for the appealing health care provider, to critically review the evidence with their assigned peer, and to assess the appropriateness of the proposed intervention in relation to accepted standard of care. In some instances, the decision for denial can be appealed, resulting in a second review of the original coverage determination. Submissions for PA, the peer-to-peer reviews, and the appeals are time-intensive procedures. As such, PA and linked procedures are associated with extra administrative work for health providers, including physicians and advanced care providers. There have also been widespread complaints about the qualifications and expertise of assigned peer reviewers, leading to calls by the American Medical Association and other professional organizations to enforce standards for peer reviewers regarding specialty training and clinical experience.[19]

Potential Implications of PA Requirements on Patients' Access to Cancer Treatments

PA is a time-intensive procedure that can increase the workload of health providers and result in delayed access to treatments. A 2022 landmark survey of approximately 1,000 US physicians from the American Medical Association described physician-reported delays in the delivery of interventions requiring PA, with 82% of the respondents reporting they had experience of treatment abandonment as a result of a denial.[20] One third of responders claimed that the delays because of the PA had resulted in serious adverse events for patients, including hospitalization (25%) and life-threating events (19%). Two thirds of physicians reported that PA led to ineffective initial treatment owing to requirements for step therapy. In addition, 31% of respondents considered the criteria for PA rarely or never mirroring best clinical practice, perceiving most of the peer-to-peer review and appeals as avoidable if internal insurance guidelines were regularly reviewed by providers who are topic experts.[15,20] Seeking to understand the impact of PA requirements in oncology specifically, in 2022, ASCO conducted a survey[22] among ASCO members. Nearly all survey participants reported a patient who had experienced harm because of the PA process, including delays in treatment (96%) and diagnostic imaging (94%), being forced into second-choice therapy (93%), increased out-of-pocket costs (88%), denial of recommended therapy (87%), disease progression (80%), and even loss of life

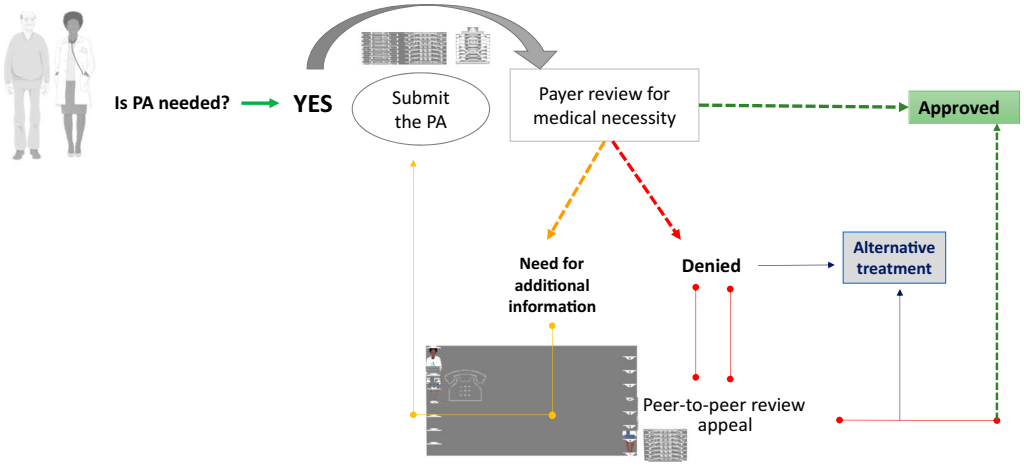

FIG 1. An overview of the current process of PA. PA, prior authorization.

(36%).[21] Ultimately, a potential detriment on overall survival was reported by 36% of the oncologists.[21]

Although very concerning, survey studies on the basis of provider self-report risk the potential for recall bias and have been criticized in this regard. There are relatively few studies in the oncology literature where access to detailed medical records was available to understand the nature of PA requests and denials. One such study conducted within a large US-based academic cancer center in Massachusetts from a cohort of patients with breast cancer reported that initial denials were received not only for antineoplastic agents but also for guideline-concordant use of supportive care medicines, such as CSFs and antiemetics, with extensive evidence supporting their use.[22] Delays could be as long as 14 days.[22] Notably, 13.6% of PA requests were for generic hormonal therapy used according to long-established standards of care. Overall, 97.5% PA requests were approved on the first request, suggesting that PA requirements added multiple layers of administrative complexity without any major impact on medication choice utilization. Another facility-based survey in the gynecology-oncology setting showed that PA was broadly requested for key interventions for cancer management such as imaging (54% of all PAs), supportive care medications (29%), and chemotherapy (17%).[23] Approvals occurred in 79%. Time to care delivery varied substantially, with a mean of 16 days and a broad range up to 98 days. As expected, patients whose requests were denied were forced into alternative options, with substantial changes in their previously recommended treatment plan.[23]

The often unpredictable variability in the decisions of insurers to cover certain procedures and denials can increase inequities in the delivery of cancer care. In addition, the additional workload and personnel requirements imposed by the PA process may deter providers from advocating for the best options for their patients. This is particularly of concern in less-resourced practice settings, which often serve the most vulnerable and historically underserved patients. Arguably, denial of PA is not a denial of treatment but of payment. Still, without insurance coverage, cancer treatments would be unaffordable to most patients. Indeed, it is estimated that 40%-50% of adults with a cancer history experience financial hardship.[24] When patients are denied high-value and important clinical procedures, they will often need to provide for their care with out-of-pocket expenditure, resulting in financial distress and risk of impoverishment.

Patients' perspectives. We explored the lived experience with PA from patients' perspectives and asked patients to share their stories, in conjunction with a long-standing patient advocate (L.K.), highlighting the implications on cancer care and capturing their emotions, when forced to change the treatment plan previously discussed with their providers (Table 2). Patients themselves experience vivid distress because of the intense efforts needed to advocate for their best care. The emotion reported is that of a fight against denials and of navigating many challenges to secure health insurer's approval. The experience of delays of life-saving treatment has been commonly reported, aggravated by the lack of transparency in the overall process of PA and the perception that who is making the decisions is not competent in the matter: deciding on the lives of people. Patients also underlined that not all patients are able to advocate for themselves through active efforts to have their treatments approved: Those who are too sick or those not experienced with insurance processes are left behind, leading to a chain of inequities, detrimental outcomes, and avoidable sorrow. "That's the last thing that I need as I fight for every minute of my life." "Patients deserve a medical system that works without patient intervention." "Insurance and ultimately cancer, won."

Potential Implications of PA Requirements on Patients' Access to Supportive and Palliative Care

At present, numerous supportive medicines require PA for coverage, even if broadly indicated in cancer management and frequently of low costs.[22,25,26] A notable trend in restricting

TABLE 2. Patients' Lived Experience on Pre-authorization

Patient Story	Narrative of Experience
Story 1	"While I've heard many different stories about how a prior authorization affects patients, I was living in blissful ignorance as to the mess that can ensue until a recent experience with getting a new **prior authorization for a** medication that I've been on for more than a year. This medication, **Capecitabine**, is an oral chemotherapy treatment for those of us with terminal cancer. Taking this medication is quite literally life or death for someone like me and the **psychological burden** of knowing that cancer could be growing out of control without medication can be extremely debilitating My private insurance company (through my husband's employer) requires that I use a specialty pharmacy that mails me my medication, for any medication taken long term. All of the pharmacy literature urges patients to use the website or application to refill medication. Dutifully, I went to the website to refill my prescription on 2/13 (a Monday) needing the meds the following Friday to start my next cycle. I get a call at 3:45 p.m. on Friday saying that a prior authorization was needed and so the medication can't be shipped and that the online system only checks for insurance paperwork needed at the time of mailing the medication Despite the fact that it was after the clinic closed at my doctor's office that Friday, I was able to get them to send in the paperwork to get the prior authorization via fax. The following week, **I began following up with everyone**. Took about a week for my doctor's office to discover that **they'd been using the wrong fax number**. Ironically, my insurance company kept sending back faxes saying that they needed more information, never mentioning it was the wrong number Once my doctor's office discovered that they'd been using the wrong fax number, my insurance company allowed one of the pharmacists to use the electronic prior authorization form and the information was received and processed within the time period allotted in my insurance contract. The pharmacy at my cancer center advanced me medication and my insurance company authorized the medication to be sent overnight and an extra dose ahead of the regular refill schedule, so I'd have medication on-hand The **burdens of living with a terminal cancer diagnosis** are many and varied. I already live in constant pain, have many side effects from the medication I'm on right now as well as the four other lines of treatment I've been on since 2017, take medication to manage depression and anxiety, have PTSD from all of the experiences thus far, see a variety of doctors and specialists and get regular bloodwork. **Being a forever patient is truly at least one full time job**. Adding on the trauma of knowing that I don't have the medication ie, quite literally keeping me alive and it can be just untenable. **"Patients deserve a medical system that works without patient intervention"**
Story 2	"My father passed away on March 28, 2022 after a long battle with Stage IV Oral Squamous Cell Carcinoma, which was overlooked by medical professionals and diagnosed in a very late stage. His form of cancer was very aggressive and progressed/further metastasized four times after initial diagnosis. I spent 3 years, from the time of diagnosis until his death, **waging a battle against cancer along with my Dad and unexpectedly, his own insurance company**. While my time should have been spent making memories in the final stages of my Dad's life, I spent that precious time advocating on behalf of my Dad. This cancer diagnosis felt like my own as it was trying to take something so precious. I advocated without hesitation, but at many points in time I thought about those who had no advocate. I saw them in the waiting room often. Knowing my father's experience, their **fate against cancer and equally against their insurance** was beyond worrisome While undergoing standard treatments, my Dad's cancer progressed again. In an effort to save his life, my Dad's oncologist switched gears and started a new regimen of zoledronic acid and pembrolizumab within just 6 days. We knew time was not on our side and while his oncologist set the expectation that he was unsure if/how my Dad's cancer would respond to this new treatment, we took the chance. Despite its aggressive nature, **2 doses of this new combination therapy stalled the progression of his cancer and visibly improved his quality of life** As infusions continued, each scan looked better than the last so I remained optimistic. While my Dad's cancer wasn't NED, we were inching closer to that milestone after each treatment. This continuation was necessary as stopping infusions could have caused it to come back with a vengeance. Based on his oncologist's medical expertise, and need for future treatment planning, he ordered a biopsy taken and sent it for genomic sequencing, analyzed through an FDA-approved test. I advocated on my Dad's behalf to get this test approved because his life absolutely depended on it. **After numerous denials, the nurse practitioner overseeing my Dad's care was scheduled for a peer-to-peer review** with insurance in order to get approval. The nurse practitioner called me immediately after the review concluded and quoted *"**physician admitted to him that he was not an oncologist and is unfamiliar with impact on genomic testing for cancer treatment** planning and therefore could not approve the test."* I was shocked. How is this a peer-to-peer review if the peer is not an oncology expert? Who decided that this physician (who lacked relevant experience and knowledge of genomic testing) was a suitable candidate to discuss the efficacy and medical necessity of the test? **My Dad's fate lay in the hands of someone who by his own admission didn't know the implications of the test**. My Dad's oncologist submitted a second request for the test to be approved and I called his insurance company many times questioning them as to why a physician insurance provider, not involved in his direct care, had greater oversight and influence over my Dad's health than my Dad's team of leading oncology experts. As we continued to contest the denial, scans showed that a new area was growing. While the rest of his body continued to respond favorably to his ongoing treatment, it was evident that his latest cancer development was resistant to the regiment. With no approval in sight, we ultimately gave up and opted for surgery on this new area in hopes that the cancer could be removed while still receiving pembrolizumab, as it continued to be effective in the rest of my Dad's body Following surgery, we marked 2 years on Keytruda. Then came yet another denial, this time for the very treatment keeping him alive. Insurance stated that the FDA and NCCN recommend a total treatment duration of 24 months for his diagnosis and my Dad had completed the recommended treatment cycle. Any future treatment was effectively denied. Despite a mountain of evidence supporting the efficacy in continued treatment **my Dad received 3 denials. The final letter was sent from an obstetrician-gynecologist**. Even pleas to the drug manufacturer were unsuccessful. I finally realized I could do no more **"Insurance and ultimately cancer, won"**

(Continued on following page)

TABLE 2. Patients' Lived Experience on Pre-authorization (Continued)

Patient Story	Narrative of Experience
Story 3	"I have had multiple experiences over my five years with metastatic colorectal cancer where pre-authorizations have either **limited my care or added a lot of extra effort and work** by my expert care team to provide me with their recommended care. One area where this has really become a challenge is in **scans**. I have disease in some organs that's only visible on CT scans and in other organs only visible on PET scans. Therefore, PET/CT is the only way to understand the full nature of my disease and at my center this combined scan is an option. However, my insurance will only approve one scan at a time. This includes **countless hours of my oncologist's team going through peer-to-peer reviews** and my going through my 'navigator' at the insurance company to try to resolve. Surprisingly, it is not always the less expensive scan, and it is **unclear** why sometimes when my team submitted for pre-authorization of a PET/CT the CT is approved and the PET is denied and other times the PET is approved, and the CT is denied. The insurance also does not require additional information from this chosen scan to justify the next scan. So, this preauthorization game does not at all relate to need or financial considerations, or any other logical rationale that I can tell, but rather that it is a policy, and therefore it is followed. What this has led to has been either needing to choose which portion of my disease we would like to see first or most often, and then filling in with the other scan on alternate dates or I have gotten one of the scans and as soon as it's completed, my team submits for the other scan, which then I get a week or two later. This two-step process not only can delay treatment decisions. It also adds **additional time toxicity** to my care of needing to go to the center multiple times to get the scan, scheduling, etc as well as more radiation exposure since the PET scan does include a low-resolution CT anyway. This also turns out to be more expensive for the insurance company as the scans are usually approved at different locations with different staff and adds additional common needs like bloodwork or accessing in my port that are therefore duplicated. While we've learned how to play this game over time, in the beginning **it was quite exhausting** to try to navigate and now **it's simply frustrating** that I as the patient and my team has to deal with all of this **extra complication for no reason**. And to think **all of this isn't actually to treat the cancer** but to understand what needs to be treated. The extra delays this has caused in terms of actually treating the cancer are quite **nerve wracking**. That's the last thing that I need as I fight for every minute of my life"

Abbreviations: FDA, the US Food and Drug Administration; NCCN, National Comprehensive Cancer Network; NED, no evidence of disease; PTSD, post-traumatic stress disorder.

the access to supportive care medicines has been reported for opioids, an essential treatment for neoplastic pain control.[27] In the period 2015-2021, the requirement for PA for two common formulations of long-acting opioids increased from no need for PA to 50% of Medicare prescription drug plans.[28] Additionally, many insurers reclassified four opioids of six available from lower tiers to tier 3 or specialty tier (ie, higher copayment requested) in Medicare part D coverage.[28] As a result, the out-of-pocket expenditure for optimal control of neoplastic pain increased up to four-fold. It is reported that such a restriction of the pain medications occurred in response to the opioid crisis in the United States; however, regulating cancer pain medications using the same tools as for opioids in the noncancer setting has had serious collateral consequences.[27,29] Denial of high-value drugs and supportive care management can increase the out-of-pocket expenditure and result in detriment for patients. Patients who are exposed to financial distress experience poorer quality of life and ultimately inferior survival outcomes.[30-32] Although evidence are limited on the impact of excluding supportive palliative care medicines from PA, we believe that a minimum set of essential interventions should be assured to all patients, with minimal administrative barriers.

Impact of PA Requirements on Health Care Providers and Health Systems

PA does not occur as an automated process but requires time and expertise from a highly skilled health workforce. It is reported that PA yields a substantial increase of the physicians' workload, corresponding to more than $68,000 USD time-equivalent per physician per year interacting with health plans, that is, $20 USD-$30 billion USD in the United States, annually.[33] Bingham et al created a time-driven activity-based model, estimating annual costs associated with obtaining PA for radiation treatment-related services[35] of $491,989 USD per institution.

Much of the dissatisfaction with the PA process is related to the time spent in supporting treatment decisions for patients, including peer-to-peer reviews and appeals. Physicians report frustration regarding the quality and flow of communications with insurers and the amount of documentation required.[35] Turnaround times for PA can widely vary. In the ASCO survey,[21] oncologists reported to have completed up to 50 PAs weekly, dedicating up to 40 hours every week. It is interesting to note that such an amount of time, 40-50 hours per week, corresponds to a full-time equivalent doctor's workload[36]: In substance, PA can double the average weekly workload. Bingham et al[34] estimated an overall time burden ranging from 92 to 95 minutes per PA event for radiation oncologists, when peer-to-peer discussion was required.

Half of the providers surveyed by ASCO had up to two staff in their practice dedicated to PA. Much of the bureaucratic hurdle was due to the burden of evidence requested to prove the clinical necessity of the interventions. The oncologist often perceived a lack of expertise of the authorization reviewers as a driver of denials and unsuccessful appeals and felt discouraged by the lack of transparency, especially on the criteria for coverage decisions.[21,35] Although some authorizations are smoothly managed and completed within 1 hour from the initial submission, escalation to peer-to-peer review occurs in a third of the

requests, and delays of ≥1 day occur in nearly a half of the cases.[21]

Oncology trainees are not spared: A survey circulated among medical physicians in training in the United States in 2019 showed that 70% of them were involved in some extent in the PA process.[35] The participation to this activity was associated with decreased enthusiasm for work and choice of the medical profession: Such a dissatisfaction was maximally reported by 83% of the medical oncology trainees.

In medical practice, dissatisfaction and challenges impeding the effective care delivery related to PA can result in clinician burnout and contribute to technology-induced and administrative burden-related distress.[37] Burnout is a substantial determinant of the workforce shortages, resulting in providers leaving oncology practice and changing their career paths.[38,39]

Taken together, the evidence suggests that while conceptualized to be a cost-containment and efficiency-improving procedure, PA is now a burden in terms of unfunded, adjunctive administrative labor. From a whole-health system perspective, the original intent appears to be ultimately corroded and possibly detrimental.

The Fundamental Question: Who Should Direct a Patient's Care and How Should Reimbursement Decisions Be Made?

One of the major problems exacerbated by the PA process is the fragmentation of patient-centered care. Rather than the locus of care centered on the patient, with shared decision making in concert with the oncology provider(s), many treatments and services must be precleared by insurers, each with their own policies and rules. Health insurers can formulate their own pathways for coverage decisions, although overarching regulations exist to govern their scope.[28] For example, the Medicare Advantage Organizations (MAOs) are private contractors that can give benefits for Medicare, including part D (drugs). In principle, MAOs should align with the initial criteria for service coverage set by Medicare. However, important divergences have been reported. In April 2022, the Office of Inspector General of the US Department of Health and Human Services issued a Report on the MAOs denials of procedures and medicines requested via PA.[40] The Inspector showed that MAOs had used decisional criteria beyond the Medicare coverage rules, putting adjunctive barriers to services that should not require extensive discussions. MAOs have requested adjunctive and unnecessary documentation to formulate their decisions to cover or not specific health interventions, restricting or delaying the access to cancer care while increasing the administrative burden for health providers.[40] The major determinants of inappropriate denials were errors during manual claims-processing reviews and system processing errors: 18% of all denials were about interventions meeting the Medicare rules for billing, which should have been covered.[40]

The PA system was ostensibly developed to optimize care delivery with a focus on noninferior, cost-effective options. However, the report of the Office of Inspector General portrays an alarming status quo: Insurance organizations have demanded unnecessary adjunctive workload for interventions of common practice and included in the basic services that Medicare has established on the basis of clinical relevance, impact, and cost-effectiveness. In short, given that insurance coverage is in many cases required for a patient to realistically access a treatment or service, insurers and MAOs are de facto governing the practice of medicine as it relates to individual patients. It can be debated if insurers are the most objective adjudicators because they have an inherent conflict of interest between optimizing revenues and supporting optimal patient care. In addition, there are controversies related to the choice of the adjudicators regarding their subject matter expertise, as well a relative lack of real-time oversight into internal reference guidelines adopted by insurers to make coverage determinations. Such variability in multiple critical decisional points generates more barriers and creates a mist of uncertainty, yielding frustration because of the arbitrary nature of some coverage requirements and the irreproducibility of final decisions. Finally, emerging reports of potential abuse including the use of automated algorithms to deny coverage of tests, medications, or treatments without true medical review only further erode trust between patients, health care providers, and insurers as to the true purpose of PA requirements.[41] The unpredictable or highly burdensome requirements for PA, in substance, can affect the clinical decision-making process and undermine the patient-doctor relationship.

BARRIERS, FACILITATORS, AND POTENTIAL SOLUTIONS

In the short term, health care providers can restructure systems to handle the current PA process more effectively, although it should be acknowledged that such efforts cost time and money. A pharmacy-based survey from 2022 reported that health benefits formulary management attitudes, differences in requirements between managed care organizations, and miscommunications seemed to drive many of the approval delays.[42] Additional determinants of delayed approvals have been reported in a recent, single-institution study with oral anticancer drugs.[43] A key factor that appeared to accelerate the time to approvals was the availability of a hospital-based specialty pharmacy. The proportion of patients who could eventually get treated within 7 days of prescription increased modestly from 47% versus 54% (adjusted odds ratio [aOR], 1.29; 95% CI, 1.00 to 1.68; $P = .05$) when the hospital-based specialty pharmacy was available. Although a positive study, it is important to note that despite the intervention, nearly half of adult oncology patients faced >1-week delays in medication approvals. Of note, a specialty pharmacy and dedicated

workforce to handle PA paperwork and other related services are not commonly available and not billable to insurers. As a result, although implementation of ad hoc services to manage PAs can be a short-term solution, a better long-term solution must be simplification of the process and reduction of the administrative burden. Reliance on specific services that only few centers can implement would yield to even more inequities in access to cancer care, with patients referred to smaller or less well-resourced centers left behind and systematically forced into second choices because of barriers imposed by the PA process. Solutions in this area should pursue simplification and efficiency first.

Specialty-Oriented, National Clinical Guidelines–Informed Tools Can Facilitate PA

A key driver of dissatisfaction is the burden for health providers to justify therapies and services broadly viewed as standard of care. A (sub)specialty-oriented, tool-based approach has the potential to support up-to-date, guideline-concordant care, while mitigating the problems associated with the frequent lack of disease specialists to review requests and reduce turnaround time to decisions.[35] Such an approach is concordant with the original intent of PA: to reduce the use of nonstandard interventions that can harm patients and assure efficiency in health expenditure. PA tools incorporating real-time decision support on the basis of the National Comprehensive Cancer Network Clinical (NCCN) Practice Guidelines in Oncology as the content for decision making have been piloted in one program of a large national payer.[44] The advantages of a structured tool-based approach for PA is in the data minimization to make the request and the transparent criteria for decision making, on the basis of national, most updated guidelines. The NCCN-based, pilot project for assisted PA reported a saving of $5.3 million USD for the state of Florida in 1 year, by aligning clinical decisions to best practices and requesting peer-to-peer review only in selected cases.[44] As with many policy prescriptions, the devil is in the details. Given the large number of insurance plans, there is the potential for such tool-based approaches to generate greater administrative burden if plans each use different decision tools and custom decision guidelines (^Fig 2).[45] As one oncologist has expressed, "If we're facing a situation where I have to use a different pathway based on whether my patient is a Blue Cross patient or an Aetna patient or Medicare Advantage patient, and each one of those has a different order set and different priority, that is going to create significant frustration and blowback from the oncology community."

Potential of Clinical Pathways to Facilitate PA

Clinical pathways are evidence-informed tools developed by multidisciplinary expert committees to define tasks and/or type and sequence of interventions that should encompass most of the clinical practice on the basis of a specific cancer type and stage.[46] It is well documented that adherence to best practices results in improved survival and quality of life for patients with cancer.[47] Alignment to common standards of treatment could improve efficiency and reduce discrepant decisions across decision makers. When clinical decisions are based on national treatment guidelines that are accepted by

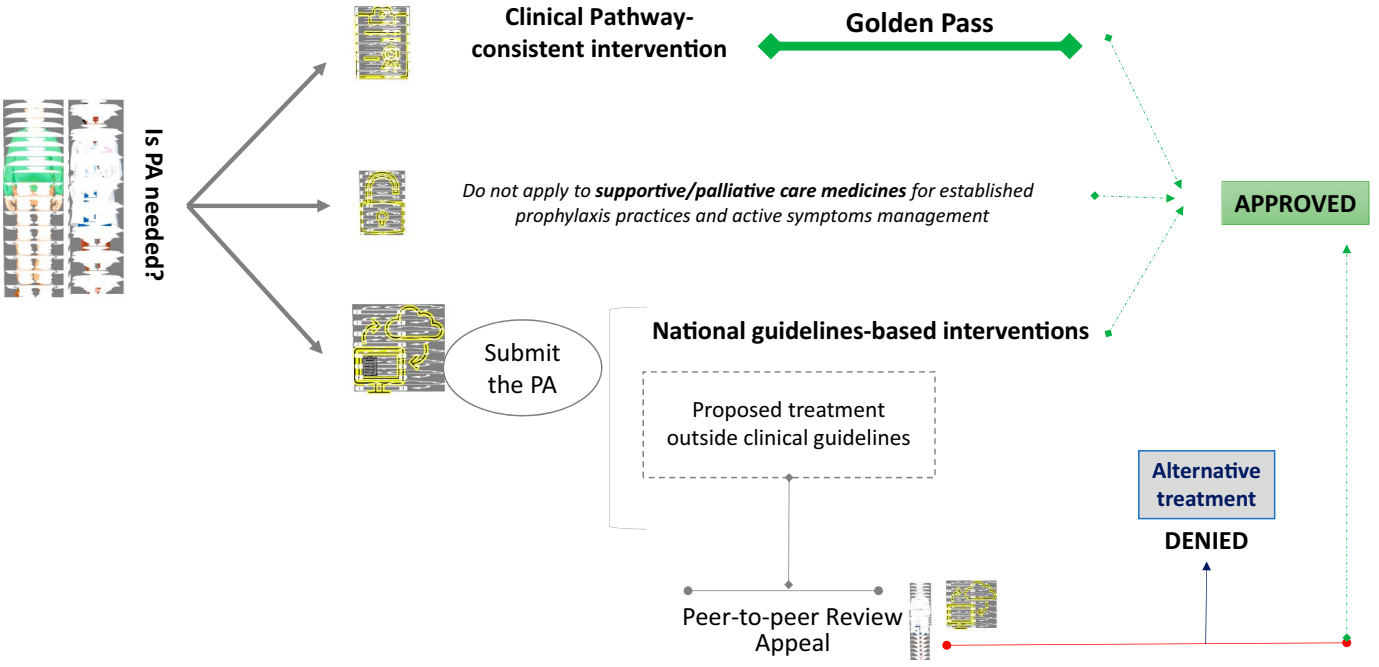

FIG 2. A proposed scheme for an evidence-informed next-generation PA process. PA, prior authorization.

Medicare as part of their compendia to inform reimbursement decisions, PA could be automatized and embedded in a transparent, web-based, consistent, and universal tool that should assist physicians in requesting cancer care interventions while assuring timely care delivery. In addition, with the widespread implementation of clinical pathways as quality enhancers at the institutional level, insurers should consider reducing the administrative burden when physicians can document that they navigated the pathways, instead of duplicating the efforts to align to institutional and then noninstitutional quality standards. Adherence-related metrics are broadly recognized as a key component of quality of care, with an acceptable threshold of ≥80% to state good quality.[48] This 80% threshold still provides space for patient-centered care and adjustment of the treatment plan according to patient preferences and comorbidities. Notably, the 80% threshold has been used by some health insurers, such as Blue Cross Blue Shield, to describe high pathways adherence.[49] Institutions with an adherence above such an established threshold of 80%, for example, may grant the benefit for a golden pass for facilitated preauthorization. A golden pass could bring benefits for high-quality institution to have their requests minimally scrutinized through preauthorization. Institutions may save workload and costs while investing in quality, and insurers would save costs.

Revisiting the Scope of PA

From multiple lines of evidence, it seems clear that tools supporting decision making on the basis of transparent criteria can enhance progress toward high-value care.[18] However, many groups have also demonstrated that implementation of internal clinical guidelines and pathways can deliver higher-quality care in the absence of coupled PA requirements.[50] In general, insurance-led PA efforts alone seem unlikely to deliver major benefits to patients, when not coupled with quality-oriented policy interventions. Accordingly, one could question if PA is truly needed in an era of rapid therapeutic advancements, institutional quality policies, and more attention toward sustainability.

The larger question at hand relates to the scope of PA, that is, what criteria should properly dictate where a particular treatment or service requires PA at all in the setting of oncologic care? Cost? Toxicity? Availability of generic or biosimilar substitutes? Evidence of overuse, misuse, or abuse? Just as importantly, what treatments or services should be *excluded* from PA requirements? Indeed, drastically restricting the scope of treatment or services subject to PA could go a long way in reducing negative impacts to patients, health care providers, and health care systems.

For supportive care medicines, we believe that a waiver of PA requirements should be granted because they are commonly requested when patients receive treatments with a moderate-to-high likelihood of adverse effects as prophylaxis or proactive treatments, making the timeliness a critical variable to minimize impact on quality of life. Where no misuse of supportive care medicines is well documented, insurers should not place barriers on their use. Supportive care drugs should be put under facilitated pathways for coverage without additional administrative requirements.

Experiences and Analogies From Other Countries' Experiences

Similarities in the PA process can be identified in countries outside the United States.[51] In Italy, a public fund covers antineoplastic treatments in the public setting. For some high-cost medicines, specific rules for prescription are in place to ensure the alignment with the on-label regulatory approvals. Although there is no formal PA process, providers must prove the appropriateness of their prescriptions for a set of drugs falling under a special monitoring scheme (commonly high-cost medicines) on the basis of an online registry.[52,53] These appropriateness registries enhance consistent prescription patterns while also help control the overall expenditure by informing value-based reimbursement models. Such an approach rhymes with the broader body of literature supporting quality improvement tools to enhance efficiency, especially if operationalized as consistent tools on the basis of consensus guidelines.

Policy Actions

ASCO has launched a campaign to urge the US Congress to pass PA reform.[54] ASCO's approach echoes the broad policy call to action of the American Medical Society on the basis of the need to define the appropriateness of PA, to deliver clinical validity and preserve continuity of care, enhance transparency in the process, and promote timely access to health service, including alternative billing strategies and exemptions for patients in need. In 2022, ASCO launched a campaign to endorse the passage of the Improving Seniors' Timely Access to Care Act to establish improved requirements and standards relating to PA processes under MAOs plans.[55] In September 2022, the US House of Representatives unanimously voiced the urgent need to facilitate access to health care, including cancer care, through efficient health policies aiming at reducing adverse impacts on patients deriving from unnecessary, non–evidence-based, and inappropriate bureaucratic procedures. The bill calls for an electronic authorization process. In addition, it calls the US Department of Health & Human Services to establish a process for real-time decisions for services that are part of the routine clinical practice. Such an item aims at facilitating clinical guidelines-driven or pathway-informed decisions. Approvals and denials are requested to be fully disclosed and reported to the Centers for Medicare & Medicaid Services to prompt review of the MAOs' decisions, encouraging these organizations to adopt evidence-based medical guidelines, developed, or adopted in consultation with physicians.

The Improving Seniors' Timely Access to Care Act has potential for broad impact on access to cancer care. Advocating to facilitate timely access to high-value cancer treatments is a policy and advocacy priority to ensure best care for all patients in need.

IMPLEMENTATION CHALLENGES AND FUTURE DIRECTIONS

The implementation phase of innovative and potentially transforming policies deserves strong efforts to turn commitment into impact. The implementation of the policy solutions outlined in the recently passed Access to Care Act and the ASCO agenda may present challenges at two levels.

First, there is a *structural* problem: The need to establish an online platform on the basis of common data standards, strong privacy data-sharing rules, and consistent web-based tools. It is critical to automatize a more efficient process: Health insurances manage PA and peer-to-peer review largely by phone and fax.[20] Yet, turning a fax-based procedure into an online form is not sufficient to streamline the process. Actions to tackle pragmatic issues, such as the need to manually input patient data to submit requests and lack of any linkage with the electronic medical records, can be instrumental. Moving online means thinking smart and approaching with innovative solutions, including prefilled fields and artificial intelligence support.

Then, there is an *ontology* question. Presently, PA appears closer to a chimera, with multiple layers of intentions and goals accumulated over the years that jeopardize the delivery of safest, effective, cost-effective health care. PA is still missing the opportunity to catalyze patient-relevant policy toward improved quality and sustainability. In the era of value-based health care, there is no excuse to restrict broad access to essential cancer care: Essential cancer interventions should be moved under facilitated reimbursement pathways,[56] as outlined in the *Cancer Moonshot* initiative[57] that aims at reducing cancer mortality through broadening equitable access to quality care. The challenge to cancer control, in substance, cannot disregard how patients access care.[58] In few words it means reducing bureaucracy, ending inefficiency, and delivering sustainable health impact. We would argue that in the current environment, there are insufficient barriers to imposing additional PA requirements under the assumption that PA policies save costs and reduce inappropriate care without negative consequences. By contrast, advocating to reduce PA requirements appears to require a higher burden of proof demonstrating evidence of harm and strong advocacy efforts.

Nevertheless, limitations of the evidence presented are acknowledged. The available data are mostly observational and derived from cross-sectional, survey-type studies. Better studies should be designed to capture and quantify the real impact of PA policies on patient outcomes and identify actionable barriers to result in renovated PA or alternative mechanisms to PA. Research approaches include the development of pragmatic clinical trials or ad hoc longitudinal policy case studies aiming at evaluating the impact of innovative PA and its alternatives on patient-centric outcomes.

In conclusion, the PA process for cancer management is a major barrier for the timely access to best care. The original role of PA to enhance efficiency, safeguard patients, and assure cost-savings appears nebulized in the complex world of its bureaucracy. In the short to medium term, a recent bill passed by the US House of Representatives has outlined specific policy goals to improve efficiency of the PA and to reduce nontransparent procedures. In the longer term, a fundamental reshaping of the PA process should be based on nationwide cancer control goals, as outlined by the *Cancer Moonshot* initiative, delivering equitable cancer care, through access to high-value essential cancer interventions while always keeping patients at the center.

Patient-Centered Care in the Management of Cancer During Pregnancy

Kimia Sorouri, MD, MPH[1,2]; Alison W. Loren, MD, MSCE[3]; Frédéric Amant, MD, PhD[4,5,6]; and Ann H. Partridge, MD, MPH[1,2]

The management of cancer during pregnancy requires a patient-centered, multidisciplinary approach to balance maternal and fetal well-being given the rarity of this clinical scenario and lack of substantial data. Involvement of oncology and nononcology medical specialists and ethical, legal, and psychosocial supports, as needed, is instrumental in navigating the complexities of care for this patient population. Critical periods of fetal development and physiological changes in pregnancy must be considered when planning diagnostic and therapeutic approaches during pregnancy. The complexity of symptom recognition and interventional approaches contributes to diagnostic delays of cancers during pregnancy. Ultrasound and whole-body diffusion-weighted magnetic resonance imaging are safe throughout pregnancy. Surgery can be safely performed throughout pregnancy, with the early second trimester preferred for intra-abdominal surgery. Chemotherapy can be safely administered after 12-14 weeks of gestation until 1-3 weeks before the anticipated delivery. Most targeted and immunotherapeutic agents are contraindicated during pregnancy because of limited data. Pelvic radiation during pregnancy is absolutely contraindicated, while if radiation to the upper body is needed, administration should only be considered early in pregnancy. To ensure that the total cumulative fetal exposure to ionizing radiation does not exceed 100 mGy, early inclusion of the radiology team in the care plan is required. Closer prenatal monitoring is recommended for maternal and fetal treatment-related toxicities. Delivery before 37 weeks of gestation should be avoided if possible, and vaginal delivery is preferred unless obstetrically indicated or specific clinical scenarios. Postpartum, breastfeeding should be discussed, and the neonate should receive blood work to assess for acute toxicities with follow-up arranged for long-term monitoring.

INTRODUCTION

A cancer diagnosis complicates approximately one in 1,000 pregnancies.[1-3] Delays in childbearing and growing rates of early-onset cancers have resulted in a rise in the incidence of cancer during pregnancy that is likely to continue for years to come.[1,4,5] Breast cancer, melanoma, hematologic malignancies, gynecologic cancers, and thyroid cancer are the most common types of cancers diagnosed during pregnancy in the United States.[1] The complexity of care and growing patient population support the need for greater evidence and guidance to inform the management of patients with cancer during pregnancy.

The authors of this study aim to use language inclusive of gender-diverse individuals. Terms such as women, patient, and individual are used as per the gender terminology from the evidence informing this document.

FRAMEWORK FOR PATIENT-CENTERED CARE

The diagnosis and treatment of cancer during pregnancy pose significant challenges as both maternal and fetal well-being must be considered. Optimizing maternal cancer outcome requires treatment that approximates standard diagnostic and therapeutic approaches that would be recommended for a nonpregnant patient. When treatment modifications are considered to avoid excess harm to the fetus or patient, including changes in timing or use of a particular treatment modality, it is critical to weigh potential risks to both the pregnant patient and the fetus while acknowledging the limitations of available evidence. This can pose medical and ethical challenges best addressed by a multidisciplinary care team with the most up-to-date knowledge of the cancer treatment options and fetal risks. When considering how to minimize fetal harm, understanding the patient's acceptance of risk to the fetus and options in this regard are critical. This discussion may be especially complicated by limited evidence regarding the risk of in utero exposure to newer drugs and modalities, as well as a paucity of the long-term outcomes data. Figure 1 outlines a framework to navigate these complexities.

Ethical and Legal Considerations

Treatment decisions for pregnant patients with cancer should center around patient preferences through

PRACTICAL APPLICATIONS

- Cancer care during pregnancy should approximate as closely as possible to the standard treatment for a nonpregnant patient with involvement of multidisciplinary supports, including both oncology and nononcology medical specialists and ethical, legal, and psychosocial supports, as needed.
- Ionizing radiation exposure to the fetus for diagnosis and radiotherapy, including use of radioactive agents, is to be limited to a cumulative dose of 100 mGy throughout the pregnancy.
- Risk of fetal harm with systematic therapy is greatest during the period of organogenesis; therefore, most chemotherapeutic agents can safely be administered after 12-14 weeks of gestation until 1-3 weeks before the anticipated delivery, although use of targeted therapy and immunotherapy during pregnancy is far more restricted.
- Surgery is ideally performed during the early second trimester, although surgery can be performed throughout the entirety of pregnancy when technically feasible with additional obstetric considerations.
- Closer prenatal monitoring is encouraged with routine biweekly fetal assessment during oncologic treatment with the goal of vaginal delivery, unless obstetrically indicated or particular clinical scenarios, after 37 weeks of gestation when possible.

shared decision making, individualized care plans, and guidance from multidisciplinary expert teams.[6] The complexity of caring for pregnant patients with cancer is exacerbated by the relative infrequency of cases and resulting limitations of both available literature and clinical experience. These limitations should be discussed in a transparent manner, adopting the ethical principles of treating rare diseases whereby limitations to traditional evidence-based medicine must be acknowledged and best available evidence in conjunction with clinical acumen must guide clinical decision making.[7]

A review of ethical principles relating to care of patients with cancer during pregnancy identifies patient autonomy as the primary guiding principle supporting shared decision making, centered on the patient's preferences, to facilitate informed decisions.[8] Balancing beneficence to the patient and the fetus is also a prominent theme. To uphold patient autonomy, recognition that fetal well-being may be dependent on maternal well-being is critical. However, patient wishes when balancing maternal and fetal well-being may position patient autonomy at odds with medical values, potentially jeopardizing the provider's duty of nonmaleficence and beneficence to the patient.[9] Thorough discussion is critical, including eliciting patient preferences in light of cancer prognosis and potential risks and benefits of treatment strategies for both patient and fetus. When treatment poses significant maternal and/or fetal risks, extensive multidisciplinary supports including psychosocial and ethical and legal counsel should be included throughout the decision-making process. The latter considerations have become increasingly complex in the United States since the 2022 Dobbs decision by the US Supreme Court overturning precedent set by *Roe v. Wade* (1973), resulting in decreased access to reproductive health care and potential prosecution of patients, their supporters, and clinicians for providing patient-centered reproductive care.[10]

Multidisciplinary Approach

Management of cancer during pregnancy requires a multidisciplinary team including oncology specialists (eg, medical oncologists, gynecological oncologists, surgical oncologists, hematologists, radiation oncologists, radiologists, and pathologists) and clinicians not routinely focused on cancer care, including maternal-fetal medicine specialists, neonatologists, pediatricians, obstetricians, anesthesiologists, clinical pharmacologists, ethical and legal advisors, and psychosocial providers (Fig 2). The Advisory Board on Cancer, Infertility and Pregnancy (ABCIP)[11] established in May 2021 offers an international online platform for physicians to request multidisciplinary consultations free of charge.[12] ABCIP operates under the International Network on Cancer, Infertility and Pregnancy and includes regional and national advisory boards in Belgium, The Netherlands, and Denmark with plans for expansion to Poland, Italy, and Spain-Ibero-America. An international board is available for physicians from regions without dedicated advisory boards. Recommendations from the respective advisory board are collated in a formal letter and returned within 4-7 days. Such international collaborative efforts, much like treatment of other rare diseases, may be instrumental in advancing cancer care during pregnancy.

Although multidisciplinary collaboration is recommended throughout the clinical decision-making process (Fig 1), team communication is particularly instrumental at particular junctures. During the diagnostic process, the pathologist should be informed of the patient's pregnancy because of the potential impact of the hyperestrogenic state on tissue morphology. We also encourage communication with the radiology team to provide an estimate of potential fetal radiation exposure and to identify potential modifications/shielding before imaging. Obstetrics, anesthesiology, and pain service teams should all confer to optimize perioperative management (eg, use of fetal monitoring, tocolytic agents, and postoperative pain management). Systemic treatment planning requires detailed discussion among oncology and obstetrics teams. Discussions with radiation oncologists and medical physicists to plan radiation therapy should be

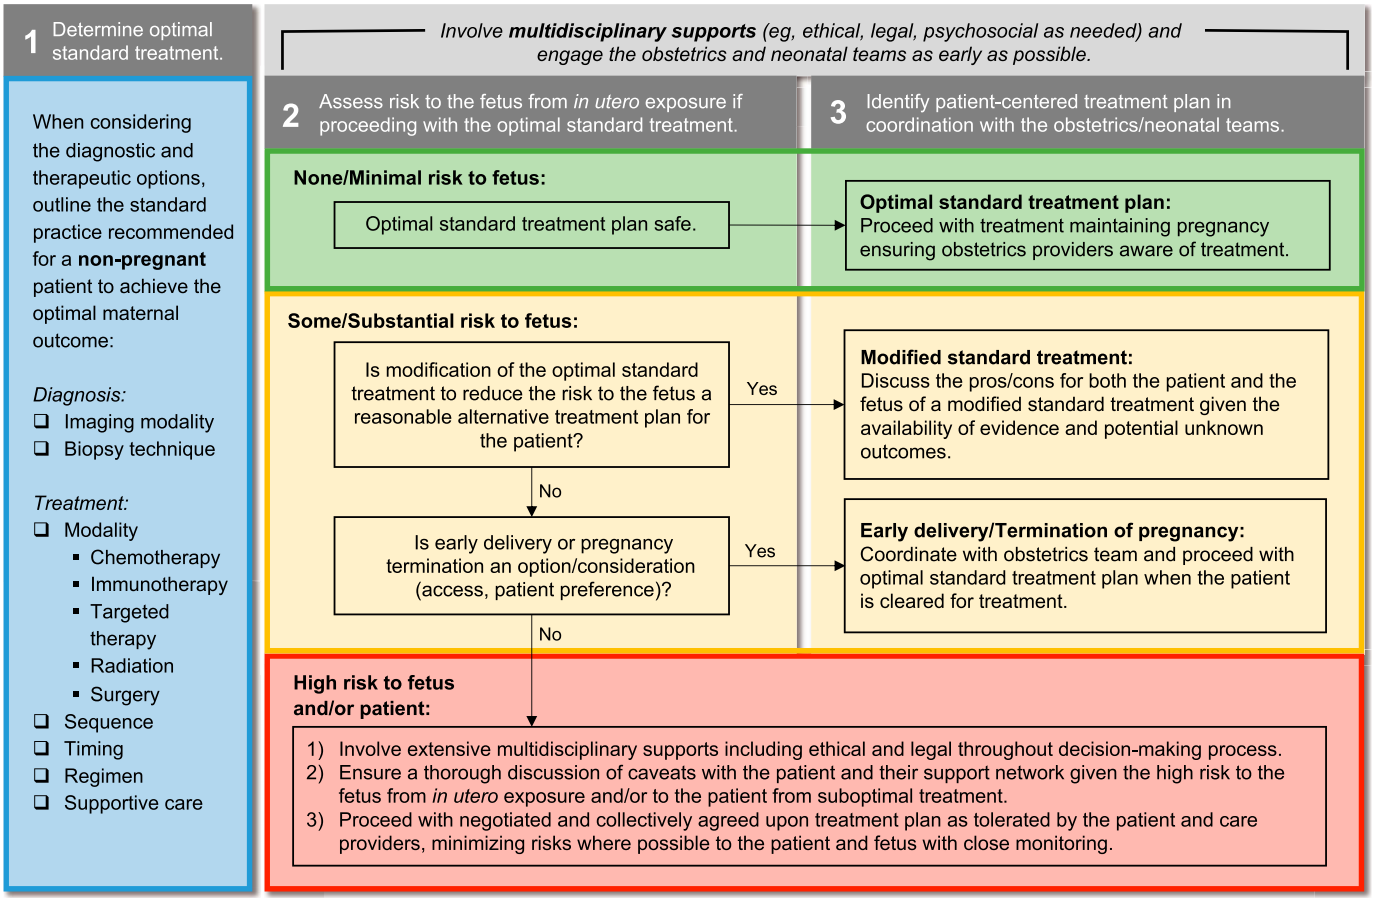

FIG 1. A multidisciplinary framework for management of cancer during pregnancy.

FIG 2. Multidisciplinary care team members to consider optimizing care of the pregnant patient with cancer.

initiated early to allow advance planning, particularly to optimize the timing of treatment and the potential need to develop shielding devices if radiation during pregnancy is considered. Psychosocial providers and resources are an integral component of care for this patient population given the substantial psychological burden of a young-onset cancer diagnosis, especially during pregnancy. Counseling is a critical opportunity to allow patients to openly discuss their concerns, potential outcomes, the impact on their loved ones, and planning for their futures. With the consent of the patient, loved ones and caregivers can be included in these discussions to ensure support from and for all parties.

A checklist of obstetric considerations for oncologists treating a pregnant patient with cancer is provided in Figure 3.

Fetal Development

Fetal risk from exposure to anticancer therapy is generally related to the gestational period. Therefore, structuring treatment decisions relative to the gestational timing of the pregnancy is optimal, and in contrast to historical practices,[14] preterm delivery is to be avoided whenever possible to prevent long-term neurodevelopmental effects and

Adapted from Amant et al.[13]

immediate consequences of prematurity, including hematologic, metabolic, and cardiorespiratory compromises.[15,16] The predominant phases of fetal development are the embryonic period, during which organogenesis primarily occurs, and the fetal period, a period of growth until delivery (Fig 4).[18] Drug exposure during the first trimester (until 12-14 weeks of gestation) confers the highest risk of miscarriage and fetal malformation.[19] Chemotherapy exposure during the fetal period is most likely to affect fetal growth, specifically an increased risk of small for gestational age fetus and intrauterine growth restriction (IUGR).[20] Nonpelvic radiation is possible in some settings in the first trimester and early second trimester, with maximization of the distance from the radiation field to the fetus and minimization of radiation exposure to the fetus.[21]

Physiological Changes in Pregnancy

The anatomic and physiologic changes in pregnancy substantially affect the pharmacokinetic (PK) properties of medications administered. Changes in PK properties occur for chemotherapeutic agents, analgesia, and antithrombotic medications.[22] Collectively, PK changes outlined in Table 1 may lead to decreased exposure to many drugs during pregnancy.[22-25] The majority of the cardiovascular and renal changes occur within the first trimester while gastrointestinal and hepatic changes fluctuate throughout pregnancy.[26] These changes have been demonstrated for docetaxel, paclitaxel, doxorubicin, epirubicin, and cisplatin.[27-30] However, the magnitude of underexposure for these drugs cannot be reliably estimated given the existing data and models. Longer-term data correlating current protocols with disease progression and survival are required to better understand whether modifications to medication doses administered during pregnancy are warranted.

The placenta also plays a key role in determining the impact of systemic therapy on the fetus and, therefore, the risk threshold for administering the drug. Transplacental transfer of compounds primarily occurs by passive diffusion with some contribution from active transporters and placental drug-metabolizing enzymes.[31] Compounds in the maternal circulation with a low molecular weight (<500 Da) that are lipid-soluble, non–protein-bound, and nonionized can easily cross the placental barrier to the fetus via passive transport.[31] There is also greater transplacental passage of drugs that are substrates for active transporters, such as P-glycoprotein, multidrug-resistant proteins, and breast cancer–resistant protein.[32] Cytochrome P450 enzymes and uridine diphosphate glucuronosyltransferases have been detected in the placenta with variable concentrations depending on the gestational age.[31] Although there are very limited data describing transplacental passage of chemotherapeutic agents in humans,[32] mouse and baboon models have confirmed placental transport of chemotherapeutic agents consistent with these principles.[33-35]

In balancing maternal and fetal beneficence, specific cancer types and situations arising early in pregnancy warrant thorough discussion of pregnancy termination, in consideration of the patient's personal preferences, logistical concerns, and any regional legislative restrictions. These include situations in which maternal health will be harmed by delaying/modifying therapy, particularly when such a compromise would also impair fetal health, such as any advanced malignancy where maternal life is imminently at risk, as well as aggressive lymphomas, AML, ALL, ovarian cancer with peritoneal spread, and cervical cancer that is of advanced stage or node-positive at diagnosis.

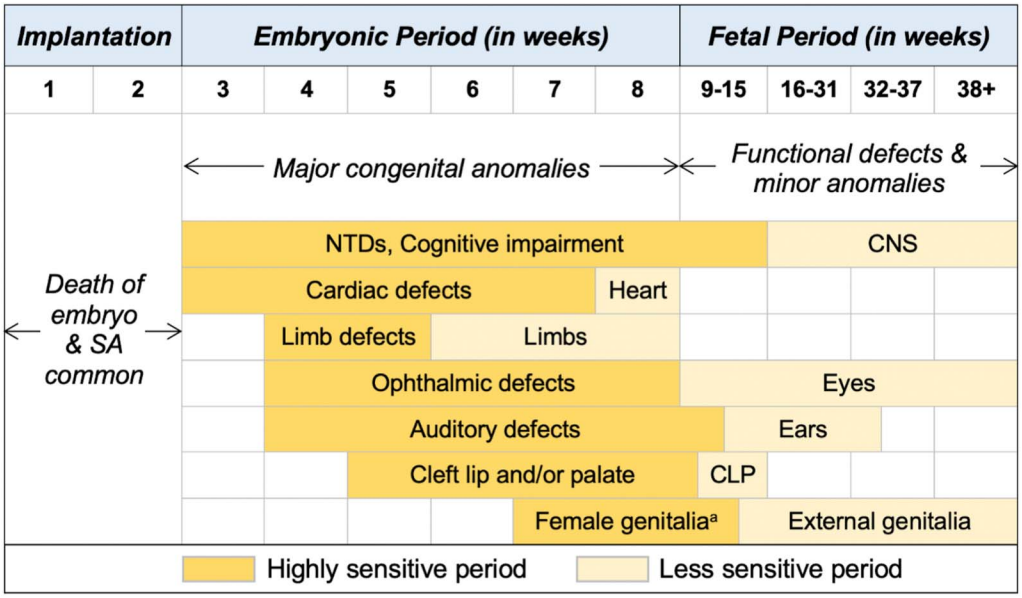

FIG 4. Critical periods in human fetal development. CLP, cleft lip and/or palate; NTD, neural tube defect; SA, spontaneous abortion. [a]Masculinization of female genitalia. Adapted from Moore et al.[17]

The recent Dobbs decision in the United States may have a detrimental effect on transparency when discussing treatment options, thus hindering a patient's ability to make an informed decision and diminishing their autonomy. Providers and patients may be reluctant or even unable to discuss options such as termination of pregnancy even when life-saving treatment cannot be delayed or where compromise in maternal survival because of a modified treatment plan is not acceptable to the patient. The need to obtain legal counsel may in some cases delay simply discussing this option, which could result in excess or unnecessary harm to the pregnant patient, the fetus, or both.

DIAGNOSTIC OPTIONS IN THE MANAGEMENT OF CANCER DURING PREGNANCY

During pregnancy, the patient's primary contact with health care providers are family physicians and obstetricians, the latter of whom are not as familiar with the presentation of nongynecologic cancers. Moreover, many cancer-related symptoms can mimic pregnancy symptoms (Table 2).[43] Collectively, these contribute to diagnostic delays of cancers during pregnancy, resulting in more advanced stage at diagnosis in some settings.[44,45]

TABLE 1. Summary of Physiological and Consequent PK Changes in Pregnancy

System	Gestational Changes	PK Impact
Cardiovascular	↑ Cardiac output ↑ Blood volume ↑ Total body water ↓ Serum albumin	↑ V_d of hydrophilic drugs ↓ C_{max} of hydrophilic drugs ↑ Free levels of protein-bound drugs
Renal	↑ Total body water ↑ Renal blood flow ↑ GFR	↑ Renal clearance
GI	↑ Delayed gastric emptying ↑ Gastric pH ↑ Small bowel transit time ↑ Nausea and vomiting	↓ C_{max} of orally administered drugs ↑ T_{max} of orally administered drugs ↓ Absorption of oral drugs
Hepatic	↑ Hepatic blood flow Altered enzyme activity	↑ Hepatic clearance Variable phase I metabolism

Abbreviations: C_{max}, maximum plasma concentration; GFR, glomerular filtration rate; PK, pharmacokinetic; T_{max}, time to maximum concentration; V_d, volume of distribution.

Imaging

The teratogenic effects of ionizing radiation restrict the imaging modalities considered safe during pregnancy. The total cumulative exposure to ionizing radiation during gestation must not exceed 100 mGy to limit deterministic effects, including fetal death, malformation, growth restriction, and long-term disability.[46,47] The former three occur primarily with exposure to ionizing radiation during organogenesis while the latter occurs during the fetal period.[46,47] The fetal radiation dose with whole-body (WB) positron emission tomography (PET) is approximately 10-50 mGy, and computed tomography (CT) varies from 0.01-0.66 mGy to 10-50 mGy for chest and pelvic imaging, respectively.[47] The stochastic effects, including long-term carcinogenesis and genetic defects, are dose-dependent such that there is no threshold.[47] Therefore, before staging, a multidisciplinary meeting with the radiologist and medical physicist is encouraged to ensure that only imaging required for decision making is pursued and to aim for single-step staging.[44,47,48]

Ultrasound and magnetic resonance imaging (MRI) are the only imaging options considered safe throughout all trimesters of pregnancy as they do not use ionizing radiation (Table 2). However, potential fetal risk from sustained temperature elevation still requires consideration, including restricting imaging to 30 minutes.[47,49,50] Fluorine-18-flurodeoxyglucose PET integrated with CT

TABLE 2. Cancer-Related Symptoms to be Aware of During Pregnancy

Cancer Type	Presenting Symptoms		Pregnancy Symptoms
Breast cancer[36]	Increased breast density and nodularity Skin changes Nipple discharge	≈	Hormonal and lactational changes in breast tissue
Hematologic malignancies[37,38]	Malaise	≈	Fatigue
	Shortness of breath	≈	Dyspnea of pregnancy
	Skin changes and pruritis	≈	Pruritus of pregnancy[a]
	Splenomegaly/hepatomegaly Abdominal or mediastinal mass	→	Obscured splenomegaly, hepatomegaly, or abdominal mass
	Cytopenia (anemia, thrombocytopenia)	≈	Dilutional anemia of pregnancy, gestational thrombocytopenia
Melanoma[39,40]	Change in existing nevus New and evolving lesion	→	Detection impeded by hyperpigmentation of pregnancy (ie, melasma/chloasma)
Cervical cancer[41,42]	Vaginal bleeding (particularly postcoital) Abnormal vaginal discharge	≈	Vaginal bleeding, cervical ectropion, and increased vaginal discharge

[a]Includes pruritic urticarial papules and plaques of pregnancy, cholestasis of pregnancy, prurigo gestationis, and pemphigoid gestationis.

(18FDG-PET/CT) is contraindicated during pregnancy because of the combined high ionizing radiation dose.[51] Therefore, WB diffusion-weighted MRI (WB-DWI-MRI) without contrast is the preferred imaging modality for cancer staging during pregnancy, if necessary.[21,52] If WB-DWI-MRI is unavailable for whole-body imaging, low-dose PET/CT can be considered after discussion with a medical physicist, or 18FDG-PET/CT can be performed with hydration and bladder catheterization.[48,53] Although there is increasing evidence supporting the use of WB-DWI-MRI for cancer staging,[52,54,55] and specifically for pulmonary lesions,[56] CT of the chest is still considered the standard imaging for suspected lung cancer or staging of cancers with high propensity for intrathoracic metastases.[57] The fetal effects of ionizing radiation are from direct exposure, with very minimal contribution from internal scatter.[58] Therefore, pelvic CT imaging is contraindicated throughout pregnancy, and abdominal shielding has no utility in reducing fetal exposure from nonpelvic imaging, although it may offer maternal reassurance.[51] MRI is preferred for abdominal and pelvic imaging.[44] When necessary, CT of the head, chest, and extremities can be performed.[47] Chest x-ray can also be considered.[47]

Contrast agents tend to have a low molecular weight and be hydrophilic, increasing transplacental passage to the fetus.[59] Gadolinium is contraindicated during pregnancy because of teratogenic risks.[60] If required, gadobenate dimeglumine and gadoterate meglumine are possible alternatives to gadolinium.[37,59] Iodinated contrast agents do not cause fetal malformations[59,61,62] but may cause neonatal hypothyroidism, so thyroid function testing should be pursued within the first week after delivery. For diagnosis of thyroid cancer, iodine-131 is contraindicated during pregnancy, and technetium-99m is the preferred radioisotope.[47] Pineapple juice has been used as a negative oral contrast agent with WB-DWI-MRI to visualize intra-abdominal lesions, most commonly for ovarian cancer.[53,63]

Biopsy

Pathologic diagnosis of some malignancies during pregnancy may be complicated by the hyperestrogenic state as this can influence tissue characteristics.[44] Consequently, a core needle or excisional biopsy to preserve tissue architecture is preferred to cytology from a fine-needle aspirate, although this may not always be feasible.[64] Moreover, because of changes in tissue, the pathologist must be informed of the pregnant state of the patient, particularly for melanoma, breast cancer, and cervical cancer. Regardless of gestational age, tissue and bone marrow biopsy should not be delayed.[21,37,53] Nonpelvic lymph node biopsies can be performed throughout pregnancy while pelvic lymph node dissection is limited to before 22 weeks of gestation (Fig 5).[53] For patients with breast cancer requiring sentinel lymph node mapping, radiation must be limited to a cumulative total of 5 mGy for the entire pregnancy.[47,65] Technetium-99m can be administered 2 hours before the surgical procedure, with <10% systemic circulation.[21] For fluorescence imaging, indocyanine green has minimal transplacental passage and appears safe in pregnancy,[66-68] while blue dyes are discouraged because of the risk of anaphylaxis.[69]

Cell-Free DNA

Noninvasive prenatal testing (NIPT) is a screening test for fetal aneuploidies that analyzes circulating cell-free DNA (cfDNA) in maternal plasma. The majority of the cfDNA is maternal, and a

small proportion is fetal in origin.[70] Occult maternal malignancies have been known to cause false-positive results for NIPT.[71] For an initial NIPT concerning for maternal cancer, repeat testing and comparison with maternal tissue is recommended.[72] If results remain positive, the patient should be referred to a multidisciplinary team to evaluate for an occult malignancy, initially with WB-DWI-MRI and blood work. If the repeat NIPT is negative, a third NIPT can be done postpartum, and the placenta can be tested for mosaicism.[72] Because of these ambiguities, NIPT is not reliable for a woman with a known cancer during pregnancy.[73] In recent years, there has been greater attention to using maternal cfDNA to diagnose asymptomatic malignancies.[74] The impact of such early detection of cancer on outcomes and management requires greater investigation.[75]

TREATMENT OPTIONS AND TIMING IN THE MANAGEMENT OF CANCER DURING PREGNANCY

Surgery

Surgery can be safely performed during all trimesters of pregnancy. Early second trimester is the preferred time for surgery, particularly for intra-abdominal surgery to balance technical difficulty of maneuvering around the gravid uterus and potential risk of miscarriage in the first trimester.[53] Surgical intervention during pregnancy has been associated with a higher likelihood of preterm delivery.[76] Therefore, it is important to discuss this risk with the patient and consider potential steps to mitigate fetal morbidity after viability, including administration of steroids for lung maturity (Fig 6). Locoregional anesthesia is preferred to general

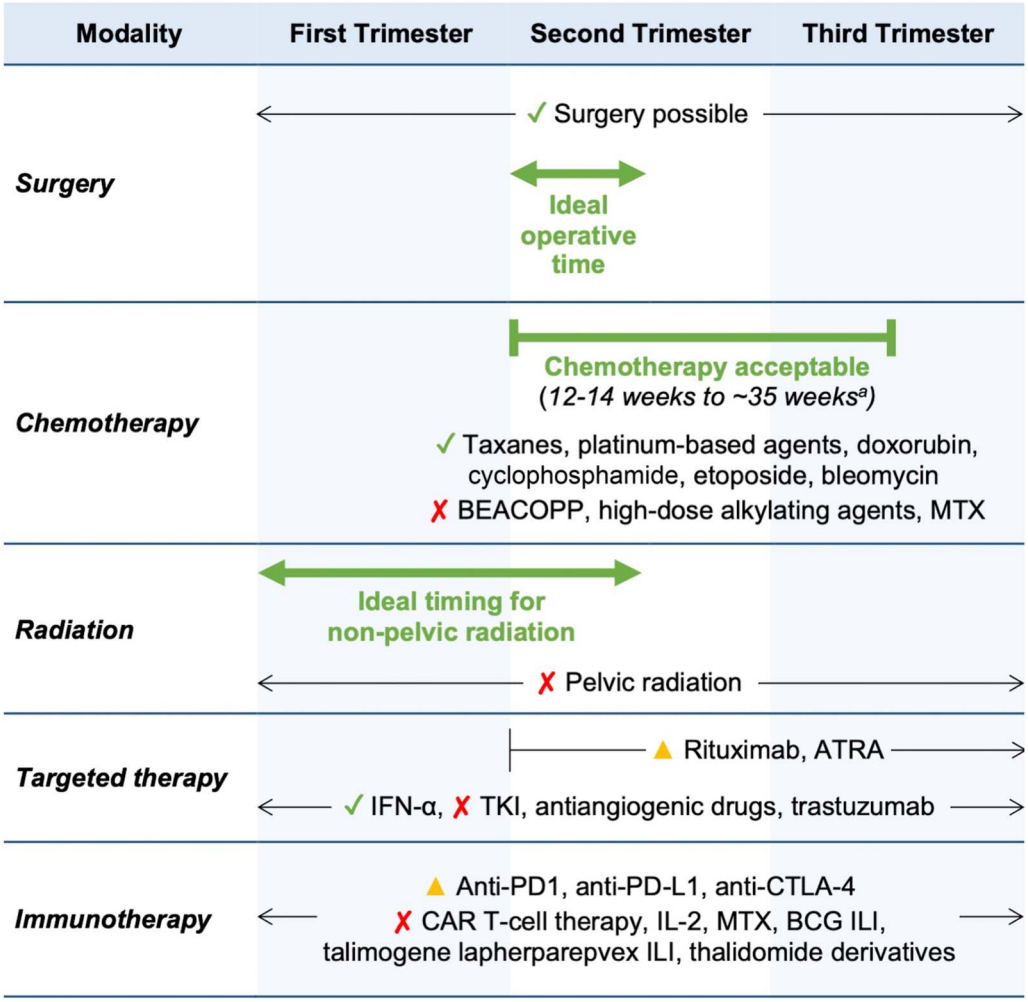

FIG 6. Therapeutic considerations. ATRA, all trans retinoic acid; BCG, bacille Calmette-Guerin; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone; CAR, chimeric antigen receptor; IFN-α, interferon-α; IL-2, interleukin-2; ILI, intralesional injection; MTX, methotrexate; TKI, tyrosine kinase inhibitor. [a]37 weeks of gestation acceptable for weekly chemotherapy regimen.

anesthesia whenever possible.[77] When considering a laparoscopic approach versus laparotomy, the following factors are to be considered: gestational age, experience of the surgeon, total anticipated procedure time (<90-120 minutes), and the feasibility of maintaining low intra-abdominal pressure (10-13 mmHg).[53] Intraoperative fetal heart rate (FHR) monitoring after viability should be discussed with the patient and the surgical, obstetrics, and neonatology teams to establish expectations of actions in case of intraoperative nonreassuring FHR. Postoperative fetal Doppler may also be preferred. Tocolytics may be considered for 48 hours postoperatively in the case of uterine manipulation during the surgery.[21,78] Given the limited analgesic options during pregnancy, consultation with the anesthesia team or any available specialized acute pain service is recommended for management of postoperative pain. The combination of surgery, immobility, malignancy, and pregnancy results in a highly prothrombotic state. Therefore, venous thromboembolism (VTE) prophylaxis with low molecular weight heparin (LMWH)[78] and an intermittent pneumatic compression device are critical considerations.

Chemotherapy

Generally, it is important to avoid delays in systemic cancer treatment when possible. Fortunately, the existing data and guidelines support the overall safety of many chemotherapeutic agents during pregnancy after 12-14 weeks of gestation and until the third trimester.[19,20,37,53,79-87] Most chemotherapeutic agents cross the placenta to the fetus in keeping with the drug properties previously outlined that facilitate transplacental passage. Consequently, exposure to chemotherapy is contraindicated before 12-14 weeks of

gestation to avoid the period of organogenesis when risk of fetal malformation and stillbirth is highest (Fig 6).[19,88] It is also recommended to avoid delivery at the hematologic nadir (ie, neutropenia and thrombocytopenia) from cytotoxic chemotherapy. Depending on the type and frequency of the regimen, chemotherapy is to be held 1-3 weeks before a high likelihood of spontaneous delivery (ie, 38-39 weeks of gestation) or a planned delivery, whichever is earliest.[89] Curative chemotherapy is not to be delayed to the postpartum period because of the negative impact on maternal prognosis. Fortunately, many conventional cytotoxic chemotherapy regimens for common cancers (ie, taxanes, platinum-based agents, doxorubicin, cyclophosphamide, etoposide, and bleomycin) are feasible with reasonable data for safety in pregnancy. Because of dose intensity, there are more limitations in treating hematologic malignancies,[32,37] and the following regimens and agents are contraindicated: BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone), high-dose alkylating agents (eg, busulfan, cyclophosphamide, and melphalan), and methotrexate, necessitating compromises in treatment if a pregnancy is to be maintained.[32,37] Standard dosing on the basis of actual weight of the pregnant patient at the time of drug administration is recommended.[21]

Radiation Therapy

As detailed previously, fetal exposure to radiation overall is to be limited to a cumulative dose of 100 mGy throughout the entire pregnancy (Fig 6).[90] Radiation doses within a range of 50 mGy to 100 mGy have potential deterministic effects while doses <50 mGy have no suspected fetal impact.[51,91] Therefore, consultation with a medical physicist is instrumental for both imaging and radiation therapy to accurately estimate fetal exposure.[51,92,93] Pelvic radiation is contraindicated throughout pregnancy. Limited data suggest that radiation to the upper body, if needed, can be done without clear harm to the fetus during the first and early part of the second trimester when the distance from the field to the fetus can be maximized.[91] When necessary, patient-specific abdominal shielding using bridge construction and/or tertiary shield walls is recommended instead of lead aprons.[94] This poses notable challenges in designing appropriate shielding because of the changing position and size of the fetus, often requiring replacement throughout the pregnancy.[64] This highlights the need for early and frequent consultation with the radiation oncologist and medical physicist in the care plan.

Targeted Therapy

There are very limited data to guide administration of targeted agents during pregnancy. Given the lack of evidence, considering the properties of the different agents that may affect transplacental passage can guide decisions when assessing risk to the fetus. Tyrosine kinase inhibitors (TKIs) are mostly small molecules that can theoretically cross the placenta, although high rates of transplacental transfer have not been demonstrated.[95,96] The use of imatinib is controversial; although there are case reports of pregnancies occurring in the setting of imatinib use after the first trimester without clear harm to the fetus,[88,97] extreme caution should be exercised. Fortunately, the necessity of this TKI during pregnancy should be very rare given that chronic myeloid leukemia (CML) can often be observed for some time and gastrointestinal stromal tumor can usually be initially treated surgically or observed. The evidence is even more limited for the use of other TKIs in the latter trimesters.[98] Therefore, TKIs are currently contraindicated during pregnancy (Fig 6).

The target for monoclonal antibodies is particularly relevant when considering fetal risk for use during pregnancy. Trastuzumab targets human epidermal growth factor receptor 2 (HER2) for breast and gastric cancer.[99,100] HER2 is involved in organogenesis and expressed in fetal kidneys.[101-103] Trastuzumab use in pregnancy has been associated with anhydramnios/oligohydramnios and is, therefore, contraindicated throughout pregnancy.[88,104] Rituximab targets B lymphocytes and is primarily used to treat non-Hodgkin lymphoma. Use of rituximab after the first trimester for cancer and noncancer indications has not been associated with fetal malformations,[105,106] although there have been reports of cytopenia in the neonate that resolves within days or months.[107-109] Given the benefits of treatment, rituximab can be used with caution in the second and third trimesters.[82,98,110]

Antiangiogenic drugs, such as TKIs and monoclonal antibodies that target vascular endothelial factor, have been consistently shown to be teratogenic in animal models with limited data in humans.[88,98] Therefore, antiangiogenic agents are currently contraindicated in pregnancy.

All-trans retinoic acid (ATRA), also known as tretinoin, is a form of vitamin A primarily used to treat acute promyelocytic leukemia (APL), a high-risk leukemia typically arising in young adults.[111] ATRA crosses the placenta and has been shown in animal studies to be highly teratogenic[88,112,113] and, therefore, should be avoided during the first trimester.[111] Case reports of ATRA use during the second and third trimesters are more reassuring and therefore can be used cautiously to treat APL in pregnancy.[88] Optimal treatment of APL has a >90% cure rate with modern therapy of ATRA and arsenic.[111] However, arsenic is absolutely contraindicated throughout all trimesters of pregnancy because of risk of fetal malformation and fetal death.[114] Therefore, treatment of APL in pregnancy is restricted to more traditional agents consisting of ATRA and anthracycline during pregnancy with arsenic administered postpartum.[115,116] There are currently insufficient data regarding potential compromise for maternal outcomes.[115]

Interferon-α (IFN-α) is a pleiotropic cytokine used to treat various conditions including melanoma and select hematologic cancers.[117] Because of high molecular weight, there is very limited placental transfer of IFN-α.[98,118] Case reports of IFN-α monotherapy reveal no evidence of fetal malformations, including use during the first trimester.[88,119] Therefore, IFN-α can be used throughout pregnancy, particularly as an additional treatment option for patients with CML and essential thrombocytosis.[37]

Immunotherapy

There are currently very little data available on the use of immunotherapeutic agents during pregnancy. The maternal immune system undergoes changes in pregnancy to allow for maternal tolerance of the semiallogenic fetus, primarily by regulatory T cells (Tregs).[120] Consequently, agents that target various aspects of the immune system pose concerns. Immune checkpoint inhibitors (ICIs) act on proteins on the surface of Tregs, including PD-1 and its ligand PD-L1 as well as cytotoxic T-cell lymphocyte-4.[121] These proteins are expressed at the maternal-fetal interface and have a role in maintaining maternal tolerance of the fetus.[122] Therefore, use of ICIs during pregnancy is discouraged (Fig 6). The few case reports available detailing in utero exposure to ICIs indicate risk of IUGR and/or placental insufficiency and at least one case of potential immune-mediated hypothyroidism in the neonate, but no evidence of malformations.[123,124] Therefore, ICIs can be considered with caution if necessary for maternal benefit. Immunomodulatory drugs that are derivatives of thalidomide (ie, lenalidomide and pomalidomide) and methotrexate have well-documented teratogenic effects and are strictly contraindicated.[88,125] Chimeric antigen receptor T-cell therapy is absolutely contraindicated during pregnancy while additional forms of immunotherapy, such as recombinant interleukin-2 and intralesional vaccines (bacille Calmette-Guerin and talimogene laherparepvec), are generally contraindicated.[123]

Supportive Treatment

Many commonly used supportive medications also must be modified during pregnancy (Table 3). Consultation with a clinical pharmacologist is highly recommended. Analgesia is primarily limited to acetaminophen and opioids, as nonsteroidal anti-inflammatory drugs in high doses are contraindicated during pregnancy because of risk of premature closure of the ductus arteriosus and oligohydramnios.[18] For antiemesis, metoclopramide is routinely used throughout pregnancy. Because of concerns for potential malformations with use in the first trimester, ondansetron is only recommended in the second and third trimesters.[126] Antenatal corticosteroids, particularly dexamethasone and betamethasone which readily cross the placenta in their active form, may increase the risk of long-term behavioral and neurocognitive disorders in early childhood,[127] although the benefits for lung maturity in preterm neonates may offset these risks.[128,129] Steroids with lower placental transfer (ie, methylprednisolone, prednisolone, and hydrocortisone) may generally be preferred for the prevention of chemotherapy-induced nausea and vomiting during pregnancy, although data for this approach are limited.[130-132] For patients requiring anticoagulation, such as patients with CML with platelets >1,000 × 10^9/L and high-risk patients with myeloproliferative neoplasms, LMWH is the only available option.[37] Aspirin (acetylsalicylic acid) at a low dose of 81 mg daily can be considered for low-risk patients with myeloproliferative neoplasms.[37] Recent data in both chronic neutropenia and cancer treatment settings have suggested no clear harm from the use of granulocyte colony-stimulating factor during pregnancy, including pegylated formulations.[80,133,134] Therefore, growth factor can be used when necessary with close monitoring for neutropenia and associated complications during pregnancy, particularly in the peripartum period.

Supportive strategies (eg, indwelling venous catheters during chemotherapy administration, and opioid administration)

TABLE 3. Supportive Treatment Options

Category	Available Agents
Analgesia	Paracetamol Morphine Sufentanil Lidocaine Ketamine Tramadol (short-term use)
Antacid	Omeprazole Pantoprazole
Anticoagulant	LMWH
Antiemetic	Metoclopramide Ondansetron Granisetron
Antihistamine	Clemastine fumarate Diphenhydramine
Antimicrobial	Antibiotics: macrolides, cephalosporins, PCN, MTZ Antiviral: acyclovir, valacyclovir, famciclovir Antifungal: amphotericin B
Hematologic support	Erythropoietin G-CSF ASA[a]
Steroid	Methylprednisolone Prednisolone Hydrocortisone

Abbreviations: ASA, acetylsalicylic acid; G-CSF, granulocyte-colony stimulating factor; LMWH, low molecular weight heparin; MTZ, metronidazole; PCN, penicillin.
[a]Low dose (81 mg).

pose additional risks in pregnancy (eg, thrombosis and infection) that warrant consideration and discussion with the patient. Additional interventions, such as bone marrow transplant, are absolutely contraindicated during pregnancy.

OBSTETRIC AND NEONATAL ISSUES IN MULTIDISCIPLINARY MANAGEMENT

Prenatal Care

The obstetrical management of patients diagnosed with cancer during pregnancy has shifted notably in recent decades such that chemotherapy is more frequently administered during pregnancy, allowing for improved maternal survival outcomes and decreasing need for iatrogenic premature deliveries.[81] Pregnancy dating with ultrasonography is recommended to ensure the most accurate timing in gestation and for baseline fetal assessment before initiating oncologic treatment, particularly systemic therapy.[21] Biweekly ultrasound should be pursued to monitor fetal growth and amniotic fluid volume, including uterine artery Doppler because of risk of placental insufficiency associated with certain cancer types and treatments when administered.[13,64,135] Doppler ultrasound is also useful in identifying fetal anemia associated with chemotherapy-induced myelosuppression.[136] In patients with cervical cancer who have undergone conization, cervical length assessment is also required.[53,137] Vaginal progesterone should be added if the cervical length is <25 mm, and cervical cerclage can be considered if there is no evidence of residual disease.[53,138] The patient and oncology team should be aware of potential chemotherapy-induced contractions associated with platinum and non–platinum-alkylating agents and urgently notify the obstetric team if they occur.[81]

Timing of Delivery

Because of the associated high short- and long-term morbidity,[15,139] premature delivery should be avoided when possible with the goal being term delivery at >37 weeks of gestation. However, particular clinical situations, such as unstable patients or those with acute leukemia, intracranial tumors, or cervical cancer not responding to chemotherapy, may necessitate early delivery.[37,140] Clinical and ethical conundrums may arise when the optimal treatment for the patient's cancer entails the use of a treatment with limited safety data and/or clear risk to the fetus before the pregnancy reaching term.

When considering the timing of delivery, it is also important to avoid the nadir of maternal and fetal myelosuppression associated with chemotherapy whenever possible.[141,142] Identifying and proactively managing both maternal and neonatal cytopenia from chemotherapy-induced myelosuppression is critical. Ensuring an adequate interval between the last chemotherapy dose and delivery is also particularly important for deliveries <38 weeks of gestation as preterm neonates have inadequate liver function to metabolize many chemotherapeutic agents, which may lead to toxicities and complications in the neonate.[143]

Mode of Delivery

For the mode of delivery, vaginal delivery is preferred unless obstetrically indicated or for specific clinical scenarios.[53] For example, patients with unresected cervical cancer are recommended to have a cesarean section (CS) to avoid seeding at the episiotomy site during vaginal delivery or obstruction of the birth canal. Large cervical cancers warrant a corporeal uterine incision.[144-146] Simple or radical hysterectomy and pelvic lymphadenectomy, if complete excision was not done during pregnancy, can be done concurrently at the time of the CS in these patients.[53] Additionally, patients with vulvar cancer should be recommended to deliver by lower segment CS because of concerns for vulvar wound dehiscence.[53] Patients with intracranial tumors may be recommended to have an early epidural with assisted second stage of delivery or CS under general anesthesia because of concern for elevated intracranial pressure (ICP) with Valsalva.[147,148] Patients with bone metastases may have similar recommendations because of risk of long bone fractures during labor.[64] Patients at higher risk of thrombocytopenia because of cancer type or treatment should receive blood work before delivery to allow for timely intervention, including platelet transfusions if necessary to meet platelet targets for vaginal delivery (>20 to 30 $\times$ 10^9/L), CS (>50 $\times$ 10^9/L) and an epidural (>80 $\times$ 10^9/L).[149,150]

Postpartum Considerations

The placenta should be evaluated histologically for metastases by an informed pathologist, particularly for patients with melanoma.[151] Placental metastases necessitate reconsideration of maternal staging and additional evaluation of the neonate. During the postpartum period, careful consideration of the safety and feasibility of breastfeeding requires multidisciplinary discussion. Previous breast treatment, short interval since last chemotherapy cycle (ie, <3 weeks), or need to resume systemic therapy after delivery will often impede the patient's ability to breastfeed.[88,152,153] However, individualization is possible since estimated levels of taxanes and anthracyclines in breast milk are very low 2-3 days after administration.[154] Appropriate counseling given the societal pressures of breastfeeding is critical to ensure the patient feels supported.[155,156] VTE prophylaxis consisting of LMWH and ICP devices should also be considered as appropriate during this period.

Pediatric Assessment

During the first days of life, the neonate should have a complete blood count, liver panel, and renal function assessment to rule out cytopenia and other toxicity from in utero

exposures, particularly if <3 weeks after last chemotherapy cycle.[53] In the rare instance of placental metastases, the neonate should be referred to a pediatric oncologist for further follow-up to rule out fetal metastases.[151]

Children exposed to platinum-based chemotherapy in utero should be evaluated for auditory dysfunction within the first year and again 5 years thereafter.[89,157] In case of anthracycline exposure, an echocardiogram is recommended within the first year and then every 3 years until early adulthood to assess for potential risk of delayed cardiotoxicity.[158] For long term, these children should be monitored for secondary malignancies and neurodevelopmental disorders. Although current evidence does not indicate a higher rate of cancer among children exposed to chemotherapy in utero, there is a theoretical risk because of patterns observed among childhood cancer survivors.[159] Existing literature demonstrates adequate neurological and psychological development of children exposed to chemotherapy in utero with follow-up to age 9 years.[79,160,161] Independent of specific treatment, Full Scale IQ scores have been shown to be negatively affected by preterm birth, maternal death, and maternal education level.[160] In a separate study, children followed up to age 6 years after maternal demise were noted to have lower verbal IQ and visuospatial long-term memory scores.[162] There is a theoretical impact on fertility in children with in utero exposure to gonadotoxic agents, although studies with longer follow-up are required. Currently, there is no indication that secondary sexual characteristics are altered in children exposed to cancer drugs in utero.[163]

CONCLUSION

Caring for patients diagnosed with cancer during pregnancy poses multiple complex medical, ethical, legal, and psychosocial challenges. The inherent difficulty of balancing maternal and fetal well-being is complicated by the increasing number and modalities of treatment options, rarity of this clinical scenario, and lack of substantial data to inform patients about short- and long-term risks for themselves and the progeny. Further research including contributions to national and international registries for maternal and pediatric outcomes from cancer in pregnancy is necessary to expand our knowledge, especially given the high-quality data from randomized clinical trials that are usually impossible in this setting. Ultimately, multidisciplinary care that is patient-centered at each step along the care pathway is paramount to optimize the well-being of the patient and potential progeny, especially in a complex social and medicolegal environment.

BREAST CANCER

Systemic Therapy in Older Patients With High-Risk Disease

Etienne G.C. Brain, MD, PhD[1]

overview

Adjuvant systemic treatments for older patients with breast cancer require constant dose or schedule adjustments of standards established for younger ones. This is mainly due to frailty that increases according to age (40%-50% of signals in all comers after age 70 years) and remains difficult to spot or diagnose accurately and therefore is often overlooked. Older patients are at higher risk to develop side effects whether under chemotherapy, optimized endocrine treatment, or targeted therapies. Pharmacokinetic reflects poorly functional reserves that reduce with aging and is therefore misleading. The demonstration of significant long-term benefits provided by adjuvant treatments is challenged by life expectancy, driven by multimorbidity status that increases with age, competing with cancer outcome. When geriatric assessment is incorporated into the multidisciplinary team, treatment decision process shows 30%-50% changes, de-escalating initial age-agnostic treatment choices in two of three cases. Finally, expectations from treatment vary over the years: In older ones, although not being exclusive, there is a general shift of preference for protecting functionality, cognitive functions, and independence, as summarized in quality of life that many systemic adjuvant treatment may jeopardize. These provocative considerations show importance to pay more attention to expectations expressed by older patients to limit gaps between what is thought by health care professionals as right, often on the basis of dose intensity models strongly engrained in oncology and that older patients may assess counterintuitively differently. The most achieved molecular testing to identify high-risk luminal tumors should be combined with determinant geriatric factors to bring relevant global information in the adjuvant setting for older patients.

GENERAL CONTEXT

Management of older patients with breast cancer raises many challenges. Representing the largest segment of the worldwide population, they should be the first target for treatment optimization. Ironically, specific data and guidance are missing from age 65 years, the official cutoff considered by regulators and developers to categorize older populations. New therapeutic strategies are still studied in younger adults, with fewer risks of development failure, ignoring two decades of debates that have stressed repeatedly the imperative need to change the rules of clinical research to match better with the epidemiological transition.[1-3] This emphasizes the artificial nature of many cancer guidelines established in a very controlled and selected younger population and then used improperly by direct extrapolation in older patients, taking poorly into account the competition of cancer with multimorbidity and frailty, all inflating in incidence with aging,[4,5] like through a distorting kaleidoscope. This also reinforces the value of all global efforts as those led by the Société Internationale d'OncoGériatrie (SIOG or the International Society of Geriatric Oncology) to publish updated summaries of the available evidence for the management of breast cancer in older patients,[6] setting recommendations according to the level of frailty.

In this context, the use of systemic treatments for localized breast cancer epitomizes one of the most relevant challenges faced by clinicians when treating older patients. These therapies are often associated with a narrow therapeutic ratio, as, for chemotherapy, the benefit of which may be undermined by a bad appraisal of frailty, potentially present in up to 40%-50% of all comers age 65-70 years and older, presenting with metastatic or early-stage breast cancer.[7,8] Most of these adjuvant treatments need a long follow-up to be able to observe an impact on disease relapse or survival, which may happen at a time point later than the estimated life expectancy of the individual. Discussion with a patient on such secondary prevention requires specific semantic skills and wording to make concrete and understandable the uncertainty of the benefit sought with adjuvant therapies as the difference between relative and absolute benefits easy to confuse for a lay audience. Finally, physicians and medical teams have to adapt to the changing perceptions of benefit and expectations with aging. Indeed, although this is not age-exclusive, younger patients often focus more on quantity of time because of social and family obligations. Older ones, marked by time flow and life experiences, are more in search for feeling safe, for maintaining control,

PRACTICAL APPLICATIONS

- Selecting appropriate systemic adjuvant treatment in older patients with breast cancer requires both assessing the risk of the disease and screening for frailty, with more in-depth geriatric assessment if screening is positive, to adjust regimens and schedules accordingly.
- Standards established in younger patients cannot be extrapolated easily to the treatment of older ones, especially regarding dose density, regimens with length exceeding 3 months, and the neoadjuvant approach opening to the postneoadjuvant rescue treatment strategy. Indeed, these three concepts fit in the dose intensity or dose-escalation concepts but may apply poorly to older ones.
- Although not age-exclusive, expectations from older patients differ from those expressed by younger ones. Older ones, marked by time flow and life experiences, are more in search for feeling safe, for maintaining control, independence, and cognitive functions, concepts that are very closely related to quality of life, to stay considered as a human being with a meaningful life.
- Older patients have been left behind from the development of the most achieved modern prognostic models using gene expression profiles for luminal breast cancer. As long as these age-agnostic molecular tests will not factor in essential information brought by geriatric assessment, especially competing risks for prognosis, their application to the most affected and growing population, patients who are 65 years and older, will remain very theoretical.

independence, and cognitive functions, concepts that are very closely related to quality of life, to stay considered as a human being with a meaningful life.[9,10] These essential individual aspects are best assessed through an extensive geriatric assessment evaluating the levels of frailty, intrinsic capacity, and resilience,[11] contributing to personalized medicine in older patients as much as the molecular portrait of any tumor sought in modern oncology to guide treatment.

DOSE INTENSITY AND FREQUENT NEED FOR ADJUSTMENT OF SYSTEMIC TREATMENTS

In older patients presenting with various tumors, including breast cancer, published data constantly show the frequent dose or schedule adjustments needed for cytotoxic agents, compared with official labels or standard schedules.[6,12,13] This is not limited to chemotherapy, and concerns optimized endocrine treatment[7,14] and targeted therapies.[15-17] This may seem in opposition to the historical concept of dose intensity described by Skipper,[18] overlapping with the maximum tolerated dose still broadly used for the development of new strategies, very anchored in the world of oncology where breast cancer has often served as an application model.[19,20]

For example, dose density is an important factor of success for adjuvant chemotherapy for early-stage breast cancer, irrespective of tumor phenotype, although the absolute effect is higher for endocrine-resistant disease than for luminal tumors. However, this may not easily apply to older people, given the increased risk of toxicity with such a schedule and the insufficient specific efficacy data, especially when translating into an almost provocative counterproductive effect after age 70 years according to subset analyses.[20]

This is also strongly and indirectly supported by the frequent (30%-40%) practical modification of the initial treatment plan created by the multidisciplinary team, as soon as some form of geriatric assessment is implemented into the treatment decision-making process, with then de-escalation occurring more often (two of three cases) than escalation.[21] Moreover, compared with standard schedules used in younger ones, this decrease in the intensity of systemic treatments in older ones, with a more frequent lower dose used up-front, apparently does not decrease treatment efficacy across different tumors, as shown in the Geriatric Assessment for Patients 70 years and older (GAP70+) cluster randomized study[22] or in other phase III trials.[23-25]

Data that are more recent and derived from the Hurria Older PatiEnts with Breast Cancer (HOPE) program tend to rebut this general consideration, especially for early-stage breast cancer, with inferior survival outcome when receiving relative dose intensity lower than 85% for adjuvant chemotherapy after age 65 years.[26] However, this may result merely from the well-known selection biases and lack of control found in prospective cohorts, missing the underlying creeping frailty that increases with age.

Another argument favoring a cautious approach of the concept of dose intensity in older ones is that pharmacokinetics poorly mirror functional reserves, failing to correlate with toxicity under similar physiological conditions. For instance, docetaxel pharmacokinetics show unaltered values in older patients with controlled renal and liver functions compared with younger ones while hematological toxicity is more frequent after age 65 years.[27] Indeed, pharmacokinetics cannot capture the decline of functional reserves, especially when they are collected along the first cycles of treatment, when the cumulative toxicity of chemotherapy on bone marrow has not yet reached its full impact, before being unveiled in later cycles. This may explain the crucial influence of the length of adjuvant chemotherapy for breast cancer on

the occurrence of serious side effects after age 65 years, holding the highest detrimental weight in the algorithm developed by the Cancer and Aging Research Group (CARG), CARG breast cancer (CARG-BC), with a 3-month threshold.[28]

Together with the retrospective works led on adjuvant trials for breast cancer run by the Cancer and Leukemia Group B (CALGB, now Alliance), these data should be a strong message of caution regarding the extrapolation of context of the benefits found in younger ones to older ones. They should remind all oncologists that, although chemotherapy may theoretically be active in older patients as in younger ones, it also brings more frequent and intense side effects.[29] If these occur, they may jeopardize all benefits sought with intervention, with no return to previous functional status and great cost on quality of life or even reaching rates of life-threatening events that would certainly be considered unacceptable in younger ones.

Practically, the more an adjuvant treatment may cause serious side effects, the more a significant and meaningful absolute benefit is necessary to envisage its use in older ones and the more a cautious adjustment of schedule, dose, and/or indication is needed on the basis of the level of frailty assessed. Algorithms, such as the Chemotherapy Risk Assessment Scale for High-age patients score[30] and the CARG general[31] or CARG-BC–specific[28] scores, may help estimate the risks of side effects of grade 3 and higher grade under chemotherapy. They may guide tailoring treatment intensity accordingly, as advocated by SIOG.[6] However, the reproducibility of these scores seems highly country-dependent, suggesting external factors,[32,33] so that they represent more a proof of concept of the role of factoring in the level of frailty in any treatment decision-making process for older ones than universal practical tools. They also highlight the challenges to implement in clinical practice frailty assessment and its two complementary concepts: intrinsic capacity and resilience.[11]

ADJUVANT SYSTEMIC TREATMENT AND HIGH-RISK DISEASE

Adjuvant systemic treatments for breast cancer vary greatly according to the tumor phenotype, which drives a large part of both the choice and the potential benefit of secondary prevention. From 0.5 to 1 cm tumor size, the two smaller categories, triple-negative breast cancer (TNBC, 10%) or tumors overexpressing the oncogene (HER2+; 10%), are generally considered at risk high enough, with most relapses occurring early (within 5 years) to sway the decision for adjuvant chemotherapy in older patients.[6,16,34] However, this general principle overlooks often the capital question of which chemotherapy should then be used in older ones.

Indeed, chemotherapy regimens most commonly used in younger adults, combining the two most important cytotoxic classes for breast cancer, anthracyclines and taxanes, have been poorly studied in older ones. The numbers of patients age 65 years and older enrolled in the clinical trials included in the successive meta-analysis conducted by the Early Breast Cancer Trialists' Collaborative Group from Oxford are limited and very illustrative of the issue. They reach at best 10% of populations studied, and this worsens sharply with older age (<2% after age 70 years),[35,36] questioning the universal properties, said not differing with age, of the proportional advantages on recurrences brought by combinations of anthracyclines and taxanes. The general conclusions, valid in younger ones, minimize the length of such chemotherapy regimens in older ones, especially sequential schedules that can spread over 6-8 months[35] when a 3-month threshold has been identified as a key factor for the occurrence of serious side effects in the adjuvant setting after age 65 years.[28] In addition, the concurrent addition of anthracyclines to taxanes (eg, doxorubicin + docetaxel or doxorubicin + docetaxel + cyclophosphamide regimens), that gives the clearest reductions in recurrence compared with sequential administration (eg, three cycles of epirubicin + cyclophosphamide, followed by three cycles of docetaxel every 3 weeks),[36] is also at very high risk of toxicity, including life-threatening ones,[37] to be recommended in older ones, even with systematic granulocyte colony-stimulating factor as primary prophylaxis for febrile neutropenia.

Although there are no specific prospective data demonstrating that one should not consider anthracyclines and taxanes combinations in older patients, there are none available and adequately powered supporting their use in this population, except in a few limited and poorly defined subgroups, not representative of the standard old population. On the other hand, requiring longer period of treatment to be delivered, regimens combining anthracyclines and taxanes increase significantly the risks of side effects and of the exhaustion of functional reserves, leading to decompensation of the underlying, frequent (about 50%), and unknown frailty. This should make oncologists think carefully before embarking their older patients on such treatment.

Actually, the largest amount of data in the literature for adjuvant chemotherapy in older ones refer to the regimens of shorter duration than those used in younger ones, as four cycles of either docetaxel or doxorubicin combined with cyclophosphamide (docetaxel + cyclophosphamide and doxorubicin + cyclophosphamide, respectively).[6,38] Paclitaxel given once per week for 12 weeks is also listed in the regimens available by extrapolation of its use for HER2+ disease[6,16,39] (Table 1). One should avoid modified or subjectively attractive regimens, such as oral chemotherapy with capecitabine or docetaxel once per week 3 weeks out of 4, as demonstrated by the CALGB 49907

(Alliance) and ELderly Docetaxel Adjuvant trials, respectively.[40,41]

For HER2+ disease, the rule to combine 1 year of trastuzumab with chemotherapy, sequentially if using anthracyclines, prevails. However, in older ones, shorter (6 months) trastuzumab schedules,[16,42] regimens limiting cardiac toxicity,[16,43] or chemotherapy-free strategy[44] might be warranted, especially in vulnerable patients.[6,16] A successful attempt conducted in the metastatic setting to use a chemotherapy backbone with side effects milder than taxanes[15] suggests that metronomic cyclophosphamide could be an alternative for earlier stages.[6,16] Finally, the limited absolute benefit provided by the adjuvant use of the second anti-HER2 antibody pertuzumab in addition to trastuzumab must be weighed against the increased risk of diarrhea, being suitable only for fit and high-risk individuals.[6,16]

For TNBC, poly chemotherapy backbones with platinum salts have never been adequately studied in older patients. Combining further such backbone given dose dense with pembrolizumab, the KEYNOTE-522 regimen[45] shows a challenging safety profile, especially in real-life series.[46] Never studied appropriately in older ones, it is hard to believe it would be compatible with a rate of 50% of frailty present in all comers after age 70 years.[7,8] This clearly indicates the continuation of age discrimination with modern strategies, such as immunotherapy, while abbreviated and more tolerable regimens could be developed but do not fit well the escalation model used for new strategies development.

Of note, when choosing a neoadjuvant strategy and observing residual disease at surgery, the postneoadjuvant concept has raised a lot of interest making almost standard the neoadjuvant approach for HER2+ tumors and TNBC with a tumor size of 15-20 mm. However, very few old individuals were enrolled in the CREATE-X and KATHERINE trials, using capecitabine or trastuzumab emtansine as rescue treatments.[47,48] It calls for a cautious application of this fully developed neoadjuvant approach (ie, including postneoadjuvant strategy) that should be reserved mostly for fit older ones because of the risk of side effects under chemotherapy increasing with age. Indeed, older patients may reach surgery in worse conditions, mitigating the beneficial effects of the neoadjuvant approach, especially if the breast cancer is already operable. Adding presurgery and potential extended postsurgery chemotherapy, neoadjuvant strategy also increases the total length of treatment of localized breast cancer and, in doing so, toxicity. This advocates strongly for not embracing the increasing use of such strategy in older ones as much as in younger ones, once the disease has been categorized as TNBC or HER2+.

The most important challenge is certainly the choice of adjuvant systemic treatment for the largest group of older patients with breast cancer, those with luminal disease (80%), because of the delay of occurrence of relapse colliding with life expectancy that is strongly associated with frailty. Multimorbidity status competes with breast cancer for prognosis so that the presence of one or more significant comorbidities makes the latter the first cause of death,[49] requiring thorough hierarchy in treatment choices.

In these patients, the benefit of chemotherapy added to endocrine treatment remains a conundrum, diluting with time[40] and not really solved by refined selections on the basis of gene expression profiles. Most programs that have investigated genomic tools have not considered the older population or only in very limited subcategories contrasting blatantly with their real proportion in the disease presentation. The iconic noninferiority trials, Trial Assigning Individualized Options for Treatment (TAILORx)[50] and Clinical Trial Rx for Positive Node, Endocrine Responsive Breast Cancer (RxPONDER),[51] have accrued hardly 10% of patients older than age 65 years while the trial Microarray In Node-negative (or 1-3 positive lymph node) Disease may Avoid ChemoTherapy (MINDACT) excluded those who are older than 70 years,[52] precluding any rational conclusion for the population most affected. In case of a high-risk recurrence score, adherence to chemotherapy may differ according to age. In TAILORx, of patients with a recurrence score above 25, only 5% were age 70 years and older. Some declined chemotherapy, and unfortunately, no follow-up will be available for valid interpretation.[53] Even the program Adjuvant Systemic Treatment for ER+ HER2– BC in women older than 70 years (ASTER 70s), the largest, inclusive, phase III superiority trial, presented at ASCO last year and conducted in nearly 2,000 women age specifically 70 years and older, failed to demonstrate a meaningful and significant benefit from chemotherapy added to endocrine treatment, when selecting patients at risk with the tumor genomic grade index.[8] These results holding true for any prespecified subgroup analysis including nodal (pN) status, they question the notion of treatment acceptability and the magnitude of potential benefit sought with such preventive treatments, such as chemotherapy or endocrine treatment. For instance, the literature on the minimum 3%-5% of absolute benefit supporting the use of adjuvant chemotherapy dates back to the early 2000s but included a very small number of patients older than 65 years,[54-56] questioning the reliability of such rates in the current epidemiological aging transition. The magnitude of benefit sought by older patients should be revisited, especially when the presence of dependants, an important factor influencing cares in older ones, was determinant for treatment choice in these works.[56]

So far, endocrine adjuvant treatment for 5 years should remain the mainstay of systemic adjuvant treatment in the older population with luminal breast cancer, irrespective of all other prognostic factors, with increasing interest for all new optimizing strategies as extended schedules and the use of inhibitors of cyclin D dependent kinases (CDK4/6i), especially

TABLE 1. Standards and Options for Adjuvant Systemic Treatment in Older Adults

Phenotype	Adjuvant Systemic Strategy
Triple-negative breast cancer	Chemotherapy is standard (from pT > 0.5 to 1 cm)
	Approved regimens
	Four TC once every 3 weeks + primary prophylaxis of neutropenia with G-CSF
	Four AC once every 3 weeks + primary prophylaxis of neutropenia with G-CSF
	Options
	Paclitaxel once per week × 12
	Neoadjuvant strategy (with or without postneoadjuvant capecitabine × six to eight cycles) in fit patients
	No supporting data
	Dose-dense regimens
	Chemotherapy regimens with sequential or concurrent use of anthracyclines and taxanes
	Poly chemotherapy regimens including platinum salts
	KEYNOTE-522 regimen (paclitaxel once per week × 12 + carboplatin, dose-dense AC, pembrolizumab)
HER2+ breast cancer	Chemotherapy is standard with 1-year trastuzumab (from pT > 0.5 to 1 cm), with endocrine treatment for 5 years if ER+ disease
	Approved chemotherapy regimens
	Four TC once every 3 weeks + primary prophylaxis of neutropenia with G-CSF + trastuzumab 1 year
	Paclitaxel once per week × 12 + trastuzumab 1 year
	Options
	Shorter duration (6 months) for trastuzumab
	Neoadjuvant strategy (with or without post neoadjuvant T-DM1 × 14 once every 3 weeks) in fit patients
	Trastuzumab without chemotherapy (especially if ER+ disease and frailty present)
	No supporting data
	Dose-dense regimens
	Chemotherapy regimens with sequential or concurrent use of anthracyclines and taxanes
Luminal breast cancer	Endocrine treatment alone for 5 years is standard
	Options
	Short (3-month) chemotherapy regimens once every 3 weeks (four TC, four AC + primary prophylaxis of neutropenia with G-CSF, or paclitaxel once per week × 12 in case of high-risk disease although poor evidence and guidance provided by gene expression profiles
	No supporting data
	Dose-dense chemotherapy
	Chemotherapy regimens with sequential or concurrent use of anthracyclines and taxanes

Abbreviations: AC, doxorubicin + cyclophosphamide; ER+, estrogen receptor–positive; G-CSF, granulocyte colony-stimulating factor; HER2+, HER2 3+ by immunohistochemistry and/or amplified by fluorescent in situ hybridization; pT, tumour size; TC, docetaxel + cyclophosphamide; T-DM1, trastuzumab emtansine.

as a substitute to chemotherapy (eg, EORTC 1745/EudraCT 2018-002553-30). Chemotherapy should stay in the list of options for high-risk situations, after geriatric assessment and an open discussion on the uncertainty and magnitude of absolute benefits, and side effects. Of note, this could also challenge the choice between a 3-month adjuvant chemotherapy with concentrated side effects and a 5-year adjuvant endocrine treatment with prolonged constraints. This would mirror the question of exclusive short adjuvant local radiotherapy (without endocrine treatment) versus exclusive

prolonged endocrine treatment (without radiotherapy), as investigated in the EUROPA trial, after breast conserving surgery for small and good prognosis tumors.[57]

FINAL CONSIDERATIONS

In clinical trials, there may be a large discrepancy of considerations on what matters the most between trialists and patients. When considering retrospectively the outcomes measured in a selection of published trials, patients and health professionals reached agreement on the primary end point in less than one third of the cases, questioning the relevance of the choice made by trialists to build the study design.[58] Furthermore, older patients may assess counterintuitively what health care professionals think as appropriate or justified. In the Age Gap Decision Tool cluster randomized program, the use of decision aids for supporting the choice of adjuvant chemotherapy or surgery had the reverse effect, almost halving the uptake of adjuvant chemotherapy or doubling the choices for primary endocrine treatment (*v* surgery).[59]

Given the high frequency of potential frailty in all comers with breast cancer after age 70 years (40% in ASTER 70s[8]), any modern optimized strategy for the adjuvant treatment of breast cancer should not solely rely on molecular prognosticators, regardless of promises. They should also factor in specific essential geriatric items, similar to what the PORTRET algorithm (from the prediction of outcome, risk of toxicity, and quality of life in older patients treated for breast cancer [the PORTRET] study) has shown feasible, mixing standard histopathological variables and others derived from the geriatric assessment, outperforming the English tool, Predict Breast Cancer.[60] Oncologists must learn reconciling the best information obtained from the tumor biology and from the patient in joined models to improve the discriminant power of these innovative tools adjusted to the growing and most affected aging population to reach the best medical decision and bring significant changes in attitudes.

Early-Stage Triple-Negative Breast Cancer Journey: Beginning, End, and Everything in Between

Hyo Sook Han, MD[1]; Praveen Vikas, MD[2]; Ricardo L.B. Costa, MD, MSc[1]; Nusrat Jahan[3]; Ammanuel Taye, MD[3]; and Erica M. Stringer-Reasor, MD[3]

Overview

Triple-negative breast cancer (TNBC) is a very heterogeneous and aggressive breast cancer subtype with a high risk of mortality, even if diagnosed early. The mainstay of early-stage breast cancer includes systemic chemotherapy and surgery, with or without radiation therapy. More recently, immunotherapy is approved to treat TNBC, but managing immune-rated adverse events while balancing efficacy is a challenge. The purpose of this review is to highlight the current treatment recommendations for early-stage TNBC and the management of immunotherapy toxicities.

INTRODUCTION

Triple-negative breast cancer (TNBC) accounts for approximately 10%-15% of breast cancer diagnoses and is defined by the absence of expression of the estrogen receptor, progesterone receptor, and human epidermal growth factor receptor 2 (HER2).[1] The prevalence of TNBC is higher in *BRCA 1* mutation carriers, young women (50 years and younger), and African American women.[2-4] TNBC, including early-stage TNBC, remains the most challenging breast cancer subtype to treat given limited targeted therapies, resulting in relatively higher rates of relapse and greater risk of mortality.[5] The goal of upfront use of systemic therapy in nonmetastatic TNBC is to reduce the risk of distant recurrence and death. This review will highlight current practices in both the neoadjuvant and adjuvant settings to treat TNBC.

THE ROLE OF NEOADJUVANT THERAPY

Previously, preoperative and postoperative chemotherapies were established as equivalent in efficacy per the National Surgical Adjuvant Breast and Bowel Project Protocols (NSABP) B-18 and B-27.[6] Historically, the primary advantage of neoadjuvant chemotherapy (NAC) was the improvement of surgical outcomes by downstaging cancer in the breast and axillary lymph nodes. However, there is now a near-unanimous consensus for NAC as the preferred approach to treat stage II or III TNBC per the ASCO and St Gallen International Consensus Guidelines.[7,8] A complete pathologic response means to have no invasive residual disease in the breast or the lymph nodes after completing neoadjuvant therapy (ypT0 ypN0 or ypT0/is ypN0). The achievement of a pathologic complete response (pCR) after NAC is recognized as a marker for systemic therapy sensitivity. In addition, pCR is associated with improved long-term outcomes in TNBCs, both event-free survival (EFS) and overall survival (OS; EFS: hazard ratio [HR], 0.24; 95% CI, 0.18 to 0.33; OS: HR, 0.16; 95% CI, 0.11 to 0.25).[9-11] More recently, the degree of response has been evaluated and is called the residual cancer burden (RCB). RCB scores of RCB-0 (pCR) and RCB-1 (minimum residual disease) denote more favorable outcomes. RCB scores of RCB-2 and RCB-3 (extensive residual disease) are unfavorable scores, indicating a higher risk of recurrence.[12,13] Therefore, identifying and administrating effective preoperative chemotherapy may help improve TNBC outcomes as patients who do not achieve a pCR after neoadjuvant therapy might have the opportunity to receive additional adjuvant therapies to reduce the risk of recurrence.

NAC REGIMENS: WHERE DO WE STAND?

Intensity and Frequency of Chemotherapy Influence Response

Anthracycline- and taxane-based therapies remain the most active chemotherapeutic agents to treat TNBCs. The intensity and frequency of these regimens also influence responses. For example, every 2-week or dose-dense doxorubicin 60 mg/m^2 IV and cyclophosphamide 600 mg/m^2 IV reduced the risk of recurrence and death compared with conventional every 3-week dosing of doxorubicin 60 mg/m^2 and cyclophosphamide 600 mg/m^2 (AC).[14] In addition, the ECOG 1199 study demonstrated that once weekly paclitaxel 80 mg/m^2 improved disease-free survival (DFS; HR, 0.69; $P = .001$) and OS (HR, 0.69; $P = .019$) compared with

PRACTICAL APPLICATIONS

- Triple-negative breast cancer (TNBC) remains the most challenging breast cancer subtype to treat because of its aggressive phenotype and limited treatment options.
- Neoadjuvant chemotherapy is the preferred approach to treat stage II or III TNBC.
- The addition of pembrolizumab to taxane-platinum–based chemotherapy followed by an anthracycline significantly increased pathologic complete response (pCR) rates and improved event-free survival in early-stage high-risk TNBC.
- Administering effective preoperative chemotherapy may help to improve TNBC outcomes as patients who do not achieve a pCR after neoadjuvant therapy might have the opportunity to tailor adjuvant therapies to reduce the risk of recurrence.
- Severe immune-related adverse events are rare but can be life-threatening. Recognizing and managing the side effects early may prevent death.

once every 3-weeks paclitaxel 175 mg/m^2 administration.[15] The current standard of care includes weekly paclitaxel or dose-dense paclitaxel as both have manageable side effect profiles and similar DFS and OS.

The Function of Platinum-Based Therapies in NAC

The addition of a platinum-based chemotherapy, such as carboplatin, to NAC regimens for TNBC has been studied in several randomized trials. Adding carboplatin to the paclitaxel- and anthracycline-based regimen increased the pCR rates in patients with TNBC.[16-18] GeparSixto was a randomized phase II study evaluating neoadjuvant carboplatin in patients with stage II or III TNBC and HER2-positive breast cancer. All participants received 18 weeks of chemotherapy with paclitaxel 80 mg/m^2 IV once weekly and non-pegylated liposomal doxorubicin 20 mg/m^2 IV once weekly. Patients with TNBC received simultaneous bevacizumab 15 mg/kg IV once every 3 weeks. Patients were randomly assigned to carboplatin AUC 1.5-2 mg/mL per min intravenously weekly (n = 296) versus no carboplatin (n = 299). The pCR rate was 53.2% with carboplatin versus 36.9% without carboplatin (P = .005) in patients with TNBC.[18] Notably, patients in GeparSixto who received carboplatin in addition to paclitaxel and nonpegylated liposomal doxorubicin had a significantly better 3-year DFS (HR, 0.56; 95% CI, 0.34 to 0.93; P = .024) and distant disease-free survival (DDFS; HR, 0.50; 95% CI, 0.29 to 0.86; P = .013).[19] Similarly, the BrighTNess trial, a phase III randomized study, evaluated the addition of the poly (ADP-ribose) polymerase (PARP) inhibitor veliparib (50 mg orally, twice daily) plus carboplatin AUC 6mg/mL/min IV once every 3 weeks for four cycles and paclitaxel 80 mg/m^2 intravenously once weekly for 12 doses (n = 316) versus carboplatin AUC 6mg/mL/min once every 3 weeks and paclitaxel 80 mg/m^2 once per week alone (n = 160) versus paclitaxel 80 mg/m^2 once weekly alone (n = 158) followed by AC every 2-3 weeks for four cycles for neoadjuvant treatment in stage II and III TNBC.[16] At the median follow-up of 4.5 years, the HR for the EFS was 0.63 (95% CI, 0.43 to 0.92; P = .02) for carboplatin plus veliparib with paclitaxel versus paclitaxel but 1.12 (95% CI, 0.72 to 1.72; P = .62) for carboplatin plus veliparib with paclitaxel versus carboplatin with paclitaxel.[20] The pCR rate increased in the carboplatin, paclitaxel, and veliparib group compared with the paclitaxel-alone group (168 [53%] of 316 patients *v* 49 [31%] of 158, P = .0001). There was no difference in the pCR rates between the two platinum therapy arms, demonstrating that the carboplatin improved the pCR and that veliparib did not contribute to the survival benefit. By contrast, the phase II CALGB40603 (Alliance) trial evaluated neoadjuvant carboplatin AUC 6 IV once every 3 weeks or bevacizumab 10 mg/kg once every 2 weeks added to once per week paclitaxel 80 mg/m^2 for 12 weeks followed by ddAC for four doses in patients with high-risk early-stage breast cancer.[17,21] One third of the patients were genomically identified as basal-like subtypes. This subtype had higher pCR rates when bevacizumab or carboplatin (54% *v* 41%, P = .0029; 60% *v* 44%, P = .0018) was added to standard NAC. In CALGB40603, pCR was associated with improved long-term outcomes when compared with minimum residual disease. However, CALGB40603 was not powered to assess the impact of carboplatin or bevacizumab on EFS or OS.[21] In both the GeparSixto and BrighTNess trials, patients without germline *BRCA1* and *BRCA2* mutations benefited more from the addition of carboplatin and those with germline *BRCA1* and *2* mutations showed superior response rates in both groups without much additive benefit from carboplatin.[16,22] In addition, the I-SPY Network reported increased pCR rates in the NAC investigational arm of veliparib 50 mg table by mouth twice a day plus carboplatin AUC 6 IV on weeks 1, 4, 7, and 10 followed by AC for four cycles compared with the control of paclitaxel 80 mg/m^2 IV once weekly followed by AC for four cycles in early stage HER2– breast cancers measuring at least 2.5 cm undergoing NAC of 51% versus 26% but increased toxicities in the investigational arm.[23] The most pivotal single-center, randomized phase III study conducted on the use of carboplatin was at Tata Memorial Hospital in Mumbai, India. Approximately 720 patients diagnosed with early-stage TNBC were evaluated. Patients were stratified by menopausal status. In the study, the addition of platinum-

based therapy with carboplatin AUC 2 once weekly and paclitaxel 100 mg/m^2 once per week for 8 weeks followed by four cycles of AC neoadjuvantly increased the pCR by 18.5% ($P < .001$), improved the EFS by 12.5% ($P = .004$), and had a higher OS rate of 11.2% ($P = .003$) in younger premenopausal women (50 years and younger).[24] There was no statistically significant improvement in pCR, EFS, or OS in women older than 50 years. The exact rationale for the significant interaction between age/menopausal status and carboplatin administration remains unclear. To date, to our knowledge, this is the only phase III study powered for EFS and OS that used platinum-based therapies in the NAC setting to treat TNBC. In summary, these studies demonstrated that the addition of carboplatin in NAC increased pCR rates in high-risk early-stage TNBCs and should be considered the standard of care in stage II or III high-risk early-stage TNBC (Fig 1). These data are encouraging for patients who may not be eligible for immune checkpoint inhibitors (ICPis) or have limited access to checkpoint inhibitors as platinum-based regimens in the NAC setting have demonstrated robust responses and improved survival. In general, weekly carboplatin administration may aid in adherence and minimize toxicities when compared with every 3-week carboplatin regimens. However, carboplatin does add additional side effects when combined with other chemotherapies such as myelosuppression, peripheral neuropathy, nausea, fatigue, alopecia, mucositis, nephrotoxicity, ototoxicity, infusion reactions, and electrolyte imbalance; therefore, personalizing therapy to account for comorbidities and functional status is important.

Chemoimmunotherapy Is the Standard of Care in Stage II and III TNBC

A new standard of care for high-risk early-stage TNBC was established with the US Food and Drug Administration (FDA) approval of pembrolizumab along with chemotherapy for high-risk early-stage TNBC in 2021.[25] Initially, the open-label, adaptively randomized, phase II I-SPY2 trial demonstrated that adding pembrolizumab to taxane-based chemotherapy followed by four cycles of AC significantly improved the pCR rate in TNBC (60% in the chemoimmunotherapy [CIT] arm *v* 22% in the chemotherapy arm, respectively).[26] In the phase III randomized KEYNOTE-522 trial, patients with previously untreated clinical or radiologic stage II or III (T1c N1-2 or T2-4 N1-3) TNBCs were randomly assigned 2:1 to receive neoadjuvant chemotherapy (NAC) with pembrolizumab versus placebo along with paclitaxel and carboplatin followed by anthracycline-based chemotherapy. After surgery, the patients received adjuvant pembrolizumab or placebo for up to nine cycles. Adjuvant capecitabine was not allowed. The addition of pembrolizumab to chemotherapy was associated with a significantly higher rates of pCR (64.8% in the CIT arm versus 51.2% in the chemotherapy-only arm).[27] In a subsequent interim analysis, CIT was associated with a significant improvement in EFS. The estimated EFS at 36 months was 84.5% in the CIT arm versus 76.8% in the chemotherapy-only arm (HR for an event or death was 0.63; 95% CI, 0.48 to 0.82; $P < .001$).[28] Interestingly, patients who achieved pCR in both arms had improved 3-year EFS rates at 94.4% with pembrolizumab and 92.5% with placebo (1.9% gain; HR, 0.73; 95% CI, 0.39 to 1.36). Conversely, the 3-year EFS rates for non-pCR patients were dismal in both arms, which were 67.4% with pembrolizumab and 56.8% with placebo (10.6% improvement; HR, 0.70; 95% CI, 0.52 to 0.95). Furthermore, the addition of pembrolizumab to chemotherapy shifted more tumors to lower RCB scores of 0 or 1, conferring a better prognosis. Tumors with RCB scores of 2 or III had worse outcomes in both groups, which may be an even more specific prognostic indicator than pCR versus non-pCR.[29] The RCB scoring system continues to be analyzed in clinical trials but is not used currently in clinical practices.

Although pembrolizumab is the only approved checkpoint inhibitor for the treatment of early-stage TNBC, several other checkpoint inhibitors, such as durvalumab,[30] cemiplimab,[31] and atezolizumab,[32] have been studied in combination with anthracycline-based NAC and showed similar promising results. In the phase III IMpassion031 study, the addition of atezolizumab 840 mg IV once every 2 weeks to nab-paclitaxel 125 mg/m^2 once per week for 12 weeks followed by ddAC for 8 weeks increased pCR rates to 58% in the CIT arm versus 41% in the chemotherapy-alone arm (rate difference 17%, 95% CI, 6 to 27, one-sided $P = .0044$).[32] In both the KEYNOTE 522 and IMpassion031 trials, both PD-L1–positive and PD-L1–negative patients had improvements in the pCR with the addition of checkpoint inhibitors to chemotherapy. The EFS data from Impassion031 are pending.[32] Despite a nonsignificant increase in the pCR rate in the phase II GeparNuevo trial, the addition of durvalumab to NAC was associated with a significant improvement in the 3-year invasive disease-free survival (iDFS), DDFS, and OS.[30] One critical factor among the studies is that the KEYNOTE-522 trial used carboplatin as part of the regimen, whereas IMpassion031 and GeparNuevo did not, which raised the question of whether carboplatins can be spared in some patients. In addition, pembrolizumab was also used postoperatively in KEYNOTE-522 but not in GeparNeuvo or the I-SPY network arms. These differences may contribute to the outcomes observed among the trials.

De-Escalation of Anthracycline-Based Therapies

Recently, there have been attempts to evaluate the nonanthracycline-based CIT regimens.

The NeoTRIP trial combined atezolizumab, carboplatin, and nab-paclitaxel and did not observe an improvement in the pCR rate in the CIT arm compared with the chemotherapy-only arm. EFS data are pending.[33] However, the single-arm,

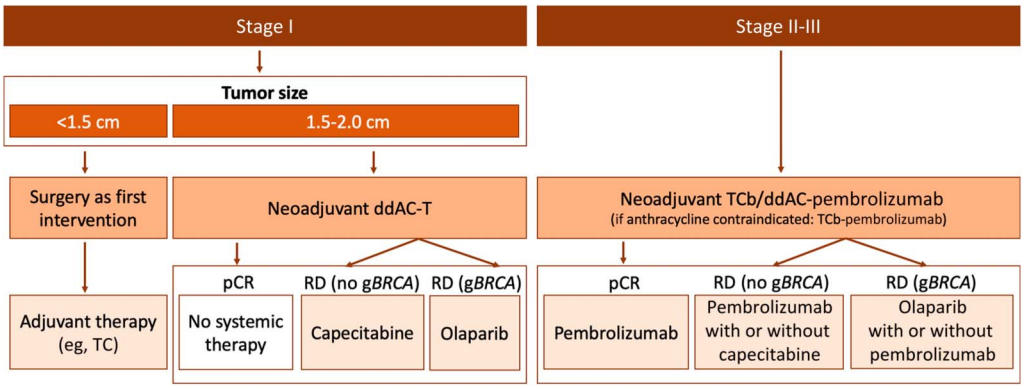

FIG 1. Treatment algorithm for early-stage triple-negative breast cancer. ddAC-T, dose-dense doxorubicin and cyclophosphamide followed by paclitaxel; g*BRCA*, germline *BRCA* mutation; pCR, pathologic complete response; RD, residual disease; TC, docetaxel and cyclophosphamide; TCb, paclitaxel and carboplatin.

multicenter, phase II NeoPACT study used a non-anthracycline-based CIT regimen including carboplatin AUC 6 IV, docetaxel 75 mg/m^2 IV, and pembrolizumab 200 mg IV in combination once every 21 days for six cycles. In this study, Sharma et. al[34] reported a pCR rate of 60% and a 2-year EFS of 88%, comparable to KEYNOTE-522. Although in an earlier stage of development, the combination of cemiplimab (a checkpoint inhibitor) with or without REGN 3767 (a lymphocyte-activation gene-3 inhibitor) along with paclitaxel followed by AC achieved a pCR rate of 53% in cemiplimab alone and 67% in cemiplimab/REGN 3767 compared with 29% in the standard AC-T chemotherapy-alone control arm without the use of adjuvant checkpoint inhibitors in the I-SPY network. In addition, RCB classes of 0 or 1 increased in the immune therapy arms compared with the nonimmune therapy control arm.[31,35] Neoadjuvant CIT is the standard of care for stage II or III TNBC. As the treatment paradigm for NAC continues to evolve for these early-stage high-risk TNBCs, escalation and de-escalation models will be important to tailor treatments for each individual. For the patients with stage I TNBC (T1a and T1b), taxane-based chemotherapy regimens, such as docetaxel and cyclophosphamide, remain the standard of care as those patients were not included in KEYNOTE 522 (Fig 1) and these small tumors often have a better prognosis.[36]

TAILORING POSTNEOADJUVANT THERAPY IN TNBC

NAC is indeed a standard option for most patients with early-stage TNBC as it allows for tailoring of adjuvant treatment under the premise that patients with residual breast cancer are at higher risk of cancer recurrence.[9] Historically, standard-of-care therapy without pCR was limited to observation until recent trials demonstrated a clinical benefit of adding adjuvant therapy in these cases. Initially, the benefit of this treatment approach was epitomized by the results of the CREATE-X trial as adjuvant treatment with capecitabine (1,250 mg/m^2 PO twice a day days 1-14, 6-8 cycles) improved OS of patients with TNBC and residual invasive disease after NAC when compared with observation (HR, 0.52; 95% CI, 0.39 to 0.90).[37] The ECOG-ACRIN EA1131 phase III trial attempted to challenge the role of adjuvant capecitabine against treatment with platinum agents (cisplatin or carboplatin) administered intravenously once every 3 weeks for four cycles.[38] The underlying hypothesis for this trial was that patients with residual basal-like TNBC (PAM50) could have improved iDFS when treated with platinums. The study was prematurely discontinued after an interim analysis observed that platinum agents were unlikely to show noninferiority or superiority to the standard capecitabine. The 3-year iDFS with basal subtype TNBC was 42% (95% CI, 30 to 53) versus 49% (95% CI, 39 to 59) with a HR of 1.06 for patients treated with platinum versus capecitabine, respectively. The overall substantially poor outcomes in this trial were likely a reflection of the underlying aggressive nature of basal-like TNBCs and higher-risk patients enrolled (at least 1 cm residual disease). For patient diagnosed with early-stage TNBC with residual disease, adjuvant capecitabine is highly recommended.

The Use of PARP Inhibitors in Early-Stage TNBC

PARP inhibitors such as talazoparib (ClinicalTrials.gov identifier: NCT03499353),[39] olaparib (GeparOla/ClinicalTrials.gov identifier: NCT02789332),[40] and veliparib (ClinicalTrials.gov identifier: NCT02032277; PMID: 29501363)[16] have been studied in the neoadjuvant setting.[39,41] Although these agents demonstrated activity in the neoadjuvant setting, none of these agents are currently used in phase III studies. Recently, the OlympiA trial further consolidated the benefit of tailored adjuvant therapy with the PARP inhibitor olaparib 300 mg twice a day for 1 year in patients with high-risk HER2-negative breast cancer and germline *BRCA 1* or *2* mutations.[42] Approximately 50% of patients received neoadjuvant therapy. Patients who did not achieve a pCR were eligible. Most tumors were classified as TNBC (82%). After a median follow-up of 2.5 years, the 3-year DDFS was 87.5% in the olaparib group and 80.4% in the placebo group (7.1% difference: 95% CI, 3.0 to 11.1). The HR for distant disease or death was 0.57 (99.5% CI, 0.39 to 0.83; $P < .001$).[43] On a second interim analysis for OS, olaparib significantly

improved outcomes compared with the placebo group (HR, 0.68; 98.5% CI, 0.47 to 0.97; $P = .009$).[43] In March 2022, olaparib was approved by the FDA for the adjuvant treatment of germline *BRCA 1* or 2 mutation carriers with high-risk HER2-negative BC who have been treated with neoadjuvant and/or adjuvant chemotherapy.

Careful review of the results from KEYNOTE-522 can shed light on the question regarding the tailoring of treatment with pembrolizumab in the adjuvant setting among nonresponders and responders to neoadjuvant CIT. In the KEYNOTE-522, EFS benefit in the pembrolizumab arm was also demonstrated for non-pCR patients, suggesting that a possible delayed activation of the adaptive immune system might improve clinical outcomes irrespective of pCR.[28] Similar findings were also noted in the phase II GeparNuevo trial, which combined durvalumab and chemotherapy only in the neoadjuvant setting and showed improvement in outcomes despite lack of significant improvement in pCR.[30] It should be emphasized that the magnitude of the treatment effect on continuation of adjuvant immune therapy on long-term clinical outcomes remains to be determined. Therefore, the risk-benefit ratio of adjuvant treatment with pembrolizumab should be carefully considered among pCR patients who experienced high-grade toxicities to NAC. On the basis of the available data, however, adjuvant pembrolizumab for pCR patients is advised (Fig 1).

The Alliance, an NCI cooperative group, has planned the OptimICE-pCR trial to evaluate the question whether the adjuvant ICPi can be safely omitted for patients with pCR. In addition, there are several recently completed trials evaluating the use of adjuvant immune therapy including SWOG S1418/BR006 (ClinicalTrials.gov identifier: NCT02954874) and OXEL (ClinicalTrials.gov identifier: NCT03487666). SWOG1418/BR006 is a phase III study to evaluate pembrolizumab as adjuvant therapy for TNBC with $\geq$1 cm of residual invasive cancer or positive lymph nodes (ypN1mi, ypN1-3) after NAC. Patients were randomly assigned to observation with standard of care compared with pembrolizumab IV every 3 weeks for 52 weeks. Adjuvant chemotherapy up to 24 weeks was allowed, and concurrent radiation to the affected breast or chest wall/regional lymph nodes was permitted. The OXEL study is a phase II open-label, randomized study evaluating nivolumab 360 mg IV once every 3 weeks $\times$ six cycles compared with capecitabine 1,250 mg/m^2 twice a day D1-D14 every 3 weeks $\times$ six cycles compared with nivolumab 360 mg IV every 3 weeks $\times$ six cycles and capecitabine 1,250 mg/m^2 twice a day D1-D14 every 3 weeks $\times$ six cycles combination in patients with TNBC with residual disease of 1.0 cm and/or node-positive disease after neoadjuvant therapy. The above studies will clarify the utility of adjuvant immune therapy in the absence of checkpoint inhibitors in the NAC setting. The next steps in the evolution of early-stage high-risk TNBC treatment paradigms are discussed in future directions.

IDENTIFICATION AND MANAGEMENT OF IMMUNE-RELATED ADVERSE EVENTS

ICPis, such as pembrolizumab, have been the most exciting development in the treatment of early- and advanced-stage TNBC. ICPi overall has a manageable safety profile. Most immune-related adverse events (irAEs) are mild and require close monitoring with continuation of ICPi therapy. However, the addition of pembrolizumab in the treatment of TNBC can lead to occasional serious and life-threatening irAEs, affecting various organ systems in the body.[44-46] Severe irAEs require early detection, prompt management, and discontinuation of ICPi. irAEs can be recognized and managed according to specific organ system–based toxicity. These toxicities range from cutaneous, GI, pulmonary, neurologic, nephrotoxic, endocrinopathies, hepatotoxic, cardiovascular, musculoskeletal, and hematologic toxicities.[44,47,48] The severity of these events is classified using the Common Terminology Criteria for Adverse Events (CTCAE) system developed by the National Cancer Institute (NCI). The common immune-related events are listed in this review. The exact mechanisms of these irAEs are not fully understood, but it is hypothesized that irAEs may be caused by autoimmunity and the enhancement of T-cell activation, resulting in the release of proinflammatory cytokines and infiltration of healthy tissue. Therefore, provider-patient education is warranted to detect and treat these adverse events early.

Endocrinopathies

Studies using ICPis in TNBC have reported on the incidence of endocrinopathies. The most reported endocrinopathy is thyroid dysfunction.[44] However, more serious endocrine irAEs include hypophysitis, immune-mediated diabetes mellitus, and adrenal insufficiency (AI). Identifying endocrinopathies can be challenging as patients often present with vague symptoms such as fatigue, headache, anxiety, tremor, and weight changes, which can also be attributed to chemotherapy agents concurrently administered. Identifying primary versus secondary endocrine dysfunction is often warranted to provide the most appropriate management.

Thyroid Dysregulation

The exact mechanism of thyroid dysregulation remains unclear; however, it is believed to be related to autoimmune thyroid destruction. In addition, patients with underlying untreated subclinical hyperthyroidism are at increased risk of developing thyroid-related irAEs. Clinical symptoms usually occur 3-6 weeks after the initiation of therapy and often start with a brief period of hyperthyroid and/or euthyroid state followed by longer-lasting hypothyroidism.[44,45]

When evaluating the thyroid axis, it is recommended to obtain thyroid-stimulating hormone (TSH) and free thyroxine serum levels to help identify primary versus secondary hypothyroidism. Patients with thyroid dysregulation often require permanent hormone replacement.

AI

AI is a rare irAE with only a 2% incidence. AI can result in acute life-threatening medical emergencies. Attentiveness to early warning signs/symptoms is necessary to avoid high mortality.,[44] Such adverse events have been reported as early as after a single dose of ICPi. In certain circumstances, hospitalization may be needed to correct electrolyte imbalance (hyponatremia, hyperkalemia), hypoglycemia, and shock. Steroid replacement and a prompt consult with an endocrinologist are advised.

CHECKPOINT INHIBITOR–ASSOCIATED DIABETES MELLITUS

Checkpoint inhibitor–associated diabetes mellitus is a relatively rare entity presenting as a new-onset hyperglycemia. It is associated with symptoms of polyuria, polydipsia, fatigue, and confusion. There is also the risk of life-threatening diabetic ketoacidosis that can result in coma or death.[48] Given the acuity and severity of these adverse events, hospitalization is often necessary.

IMMUNE-RELATED HYPOPHYSITIS

Hypophysitis can result in multiple hormonal imbalances, such as decreased levels of TSH, luteinizing hormone, follicle-stimulating hormone, and adrenocorticotropic hormone. Patients often present with fatigue, weakness, dizziness, nausea, headache, and visual impairment in the setting of pituitary enlargement.[44,45] In severe cases, hypophysitis can lead to loss of vision, decreased consciousness, and even coma. If suspected, a hormone assessment with laboratory test and an magnetic resonance imaging (MRI) of the brain are recommended for a diagnostic workup.

CUTANEOUS irAEs

Cutaneious toxicities range from a mild rash to an inflammatory dermatitis such as erythema multiforme. Rarely, patients can develop severe cutaneous adverse reactions that include Stevens-Johnson Syndrome or toxic epidermal necrolysis. Rash typically appears within the first 4 weeks of initiation of ICPi and is often the earliest observed irAEs.[45,46] It can be diffused or localized and can present in various forms (ie, maculopapular rash, pruritus, vitiligo, and psoriasis). The incidence of any-grade rash has been reported to be approximately 21% in CIT with a severe skin rash limited to only about 4% of patients. Management of this irAE includes topical steroids, systemic steroids, and a dermatology consultation.[45]

GI irAEs

GI irAEs are associated with ICPis including colitis, gastritis, and hepatitis.

Colitis

Colitis can present with diarrhea, abdominal cramps, and rectal bleeding, as well as fever and weight loss. Symptoms often occur within 6 weeks of the initiation of an ICPi when combined with chemotherapy. Mild cases can be managed with antidiarrheal, diet modification, and hydration. Moderate to severe cases may warrant endoscopy evaluation and treatment with corticosteroids and/or immune suppressants such as infliximab. In severe cases, bowel histology may mimic inflammatory bowel disease and warrant prompt hospitalization to avoid severe dehydration and sepsis.[48,49]

Gastritis

Gastritis may present with nausea, vomiting, epigastric pain, and dysphagia. Symptoms are often grade 1, can also present with diarrhea, and can be concurrently diagnosed with colitis. Supportive care practices are recommended. Endoscopy along with immunosuppressants may be warranted in severe cases.[48,49]

Hepatitis

Hepatitis is one of the most reported irAEs and mainly manifests as an increase in ALT and/or AST, with or without hyperbilirubinemia. Patients may be asymptomatic or present with loss of appetite, nausea, vomiting, or jaundice. Guidelines recommend extensive assessment of liver chemistries and screening for viral hepatitis as well as autoimmune liver damage. In addition, serial monitoring of liver function is necessary for early identification. ICPi-related hepatic toxicity often takes longer to resolve compared with other irAEs. Because of this, temporary or permanent suspension of ICPis may be required and treatment with high-dose steroids to alleviate the symptoms is often warranted. Of note, infliximab is contraindicated for the treatment of ICPi-related hepatitis because of an increased risk of hepatotoxic effects with infliximab therapy itself, and hence, mycophenolate mofetil or tacrolimus is used, if the patient is refractory to steroids.[48,50]

Musculoskeletal irAEs

Musculoskeletal irAEs can occur any time after the initiation of treatment of immune therapy. Presenting symptoms are fatigue, joint swelling, arthralgia, and myalgia.[48,51] Severe symptoms are associated with poor outcomes because of the negative effects on daily activity and quality of life. Most rheumatic irAEs respond to treatment with steroids; however, treatment with biologics may be needed in resistant cases.

Steroids are the agents used the most in the management of immune-related adverse events. There is growing concern

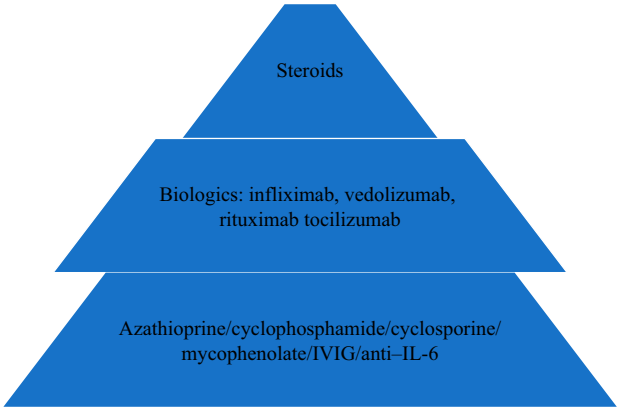

FIG 2. Treatment pyramid. Therapy options for moderate to severe immune-related adverse events in patients treated with immune checkpoint inhibitors (top to bottom). Moderate grade events can be managed with steroid. Severe events may warrant biologics, immune therapy, or combination therapy to mitigate symptoms. IL-6, interleukin-6; IVIG, intravenous immunoglobulin.

about acute and long-term toxicities resulting from dose and duration of steroid usage. Early recognition of steroid-related complications is important, and prophylactic agents to prevent opportunistic infections may be needed in select circumstances. GI prophylaxis with a daily antacid may be needed to reduce the risk of gastrointestinal discomfort while using steroids. Additionally, calcium and vitamin D replacement along with weight-earing exercise are encouraged to limit steroid-induced osteopenia while on prolonged steroids. When prescribing steroids, clinicians should take into consideration factors such as advanced age, immune status, and preexisting conditions like diabetes as these may increase the risk of steroid-induced complications.

ASCO has published updated guidelines on the management of immune-related adverse events in patients treated with ICPi therapy. Schneider et al[48] published detailed guidelines for the diagnosis and management of iRAEs by organ system. Some generalized recommendations on managing irAE along with certain commonly used agents are described here (Fig 2 and Table 1).

TABLE 1. General Recommendations on Immune-Related Adverse Events Management Arising From ICPi

Patients and caregivers should be educated about potential immune-related adverse events before initiating an ICPi
Any new symptom or laboratory/imaging abnormality should be carefully assessed for its association with an ICPi
ICPi therapy can generally be continued with close monitoring for most of the grade 1 toxicities. However, certain neurologic, hematologic, endocrinopathies, and cardiac toxicities will need special attention. A consultation with subspecialist is advised
ICPi therapy should be withheld for most grade 2 toxicities until the toxicity resolves or improves to a grade I toxicity
Corticosteroids at an initial dose of 0.5-1 mg/kg/d of prednisone or equivalent may be considered for grade II toxicities
Grade III toxicities necessitate interruption of ICPis, and high-dose corticosteroids (prednisone 1-2 mg/kg/d or equivalent) should be initiated. Corticosteroid taper should be gradual and administered over the course of 4-6 weeks
If the toxicity does not improve within 48-72 hours, use of other immunosuppressive agents like infliximab should be considered for certain toxicities
Grade IV toxicities often necessitate indefinite discontinuation, except for endocrinopathies that can be controlled with hormone replacement
A rechallenge of ICPis may be considered if a toxicity reverts to a grade 1 or resolves. Significant caution and close monitoring are required

NOTE. The total steroid dose can be administered once a day or split into a twice daily dose to adjust for tolerability.
Abbreviation: ICPi, immune checkpoint inhibitor.

FUTURE DIRECTIONS

There are many exciting developments in the use of NAC to treat TNBC. For example, antibody-drug conjugates (ADCs) are currently approved for second-line metastatic TNBC.[52,53] Multiple trials are ongoing to establish the efficacy of ADC with or without immune therapy in the neoadjuvant setting, such as sacituzumab govitecan (NeoSTAR, ClinicalTrials.gov identifier: NCT04230109)[54] and datopotamab deruxtecan (with or without durvalumab; I-SPY2, ClinicalTrials.gov identifier: NCT01042379).[55] Other exciting areas are the neoadjuvant use of cancer vaccines (ClinicalTrials.gov identifier: NCT04144023)[56] and oncolytic viral therapy (ClinicalTrials.gov identifier: NCT02779855) to target TNBCs.[57]

Using Biomarkers to Optimize Treatment in Early-Stage TNBC

A significant deficiency in NAC is the lack of adaptability and optimization of the treatment on the basis of response to therapy before surgery. Optimal modalities to predict early neoadjuvant therapy response are yet to be established. Multifeature MRI or diffusion coefficient in diffusion-weighted MRI to predict the pCR rate is currently under evaluation.[58,59] In addition, circulating tumor DNA (ctDNA) and circulating tumor cells (CTCs) are frequently incorporated in the current early-stage TNBC management in ongoing trials. Preliminary data suggest that detection of ctDNA and/or CTCs in patients with early-stage breast cancer after NAC is independently associated with a higher risk of disease recurrence.[60-62] Furthermore, the I-SPY 2 trial indicated that patients with TNBC are more likely to have positive ctDNA than other breast cancer subtypes before starting NAC (TNBC 86%, HER2+ 84%, hormone receptor–positive/HER2– 84%, $P < .01$).[60] In the realm of personalized adjuvant treatment, analysis of tumor tissue and/or tumor microenvironment of

residual or newly diagnosed tumor might eventually guide adjuvant treatment recommendations. Efforts are ongoing and are not ready for prime time. Schneider et al[63] reported results of a phase II trial (N = 193) of tumor tissue gene-directed therapies for the treatment of patients with residual TNBC. The estimated 2-year DFS for patients randomly assigned to the tumor-genomic matched approach was only 56.6% (95% CI, 0.45 to 0.70) compared with 62.4% (95% CI, 0.52 to 0.75) for patients randomly assigned to physician's choice (majority received capecitabine). Notwithstanding their potential predictive value, tumor analyses were limited by temporal and even spatial intratumor heterogeneity of breast tumors.[64] Liquid biopsies, including CTC and cell-free tumor DNA assessments, have long been studied as potential biomarkers of clinical utility for early-stage TNBC, but thus far, their value is largely prognostic.[65-69] These assays have been challenged by the need for both robust analytical and clinical validation before being declared as clinically useful in tailoring adjuvant treatments for patients with TNBC after neoadjuvant therapy. Currently, there are limited data available to guide the optimal therapy in postneoadjuvant therapy among the available standard-of-care options. The above biomarkers are to be further assessed by ongoing clinical trials.

Henceforth, tailoring of adjuvant treatments (optimization or intensification) for patients with residual TNBC will likely be equally guided by personalized approaches and new therapeutic strategies such as ADCs. The OptimICE-RD (ASCENT-05) is a large ongoing phase III study of 1,514 patients with residual TNBC (ClinicalTrials.gov identifier: NCT05633654), which will assess safety and efficacy of the addition of sacituzumab govitecan or capecitabine to pembrolizumab. In addition, TROPION-Breast-03, a study of Dato-DXd with or without durvalumab versus investigator's choice in patients with stage I-III TNBC without a pCR (ClinicalTrials.gov identifier: NCT05629585), will also evaluate the utility of adjuvant ADCs in high-risk TNBC. These trials will address an important area of an unmet need, the intensification of adjuvant treatment in patients with high-risk TNBC with newer targeted agents such as sacituzumab govitecan versus established agents such as capecitabine. There are ongoing efforts to evaluate combination immune therapies, targeted therapies, and vaccine trials for patients with TNBC with residual disease who are at highest risk of relapse (Table 2).

Conclusion

Despite current advances, TNBC remains the breast cancer subtype with the worse outcomes compared with estrogen receptor–positive and HER2-positive breast cancers, largely attributed to limited treatment options. Anthracycline- and taxane-based chemotherapy regimens remain the standard of care for high-risk TNBC, with the addition of ICPis for stage II and III TNBC. The careful management of immune-related adverse events is critical to avoiding severe life-threatening events. Several clinical questions around ICPi usage in TNBC remain unanswered, including the optimal pembrolizumab partner, continuation after pCR, and sequencing with capecitabine and PARP inhibitors. Finally, the continuous investigation of novel biomarkers and best-paired neoadjuvant and adjuvant therapies to optimize outcomes in high-risk tumors is needed.

Not Too Little, Not Too Much: Optimizing More Versus Less Locoregional Treatment for Older Patients With Breast Cancer

Jennifer Tseng, MD[1]; Jose G. Bazan, MD, MS[2]; Christina A. Minami, MD, MS[3]; and Mara A. Schonberg, MD, MPH[4]

Overview

Although undertreatment of older women with aggressive breast cancers has been a concern for years, there is increasing recognition that some older women are overtreated, receiving therapies unlikely to improve survival or reduce morbidity. De-escalation of surgery may include breast-conserving surgery over mastectomy for appropriate candidates and omitting or reducing extent of axillary surgery. Appropriate patients to de-escalate surgery are those with early-stage breast cancer, favorable tumor characteristics, are clinically node-negative, and who may have other major health issues. De-escalation of radiation includes reducing treatment course length through hypofractionation and ultrahypofractionation regimens, reducing treatment volumes through partial breast irradiation, omission of radiation for select patients, and reducing radiation dose to normal tissues. Shared decision making, which aims to facilitate patients making decisions concordant with their values, can guide health care providers and patients through complicated decisions optimizing breast cancer care.

Over 77,000 women age 70 years or older in the United States are diagnosed with breast cancer annually. As the population ages, this figure will rise.[1] Women age 70 years or older account for 31% of diagnosed breast cancers, and given widespread mammography use in older women, the majority are diagnosed with stage I, estrogen receptor–positive (ER+)/human epidermal growth factor receptor 2–negative (HER2–) tumors.[2] Although undertreatment of older women with aggressive breast cancers has been a concern for years, there is increasing recognition that some older women with stage I, ER+, HER2– breast cancers are overtreated, receiving therapies unlikely to improve survival or reduce morbidity.

Studies have found that omitting radiation therapy after breast-conserving surgery and/or omitting axillary surgery in women age 70 years or older with stage I, ER+/HER2– breast cancer does not affect their survival when taking endocrine therapy.[3–6] While radiation therapy after lumpectomy may reduce local recurrence, the absolute risk reduction is <10% and takes years to achieve.[3,5] Thus, women age 70 years or older with stage I, ER+/HER2– face decisions regarding de-escalation or omission of parts of their locoregional therapy. More than 70% of women age 70 years or older with breast cancer undergo axillary surgery and receive radiation therapy.[7–11] Is this appropriate treatment or overtreatment? In thinking about patients who are best suited for de-escalation of axillary surgery or radiation therapy, this management pathway assumes compliance with endocrine therapy. Unfortunately, studies have demonstrated close to one-third of patients will have early discontinuation of endocrine therapy.[12–14] For older patients who are of higher risk for early endocrine therapy cessation, radiation gains importance in decreasing risk of locoregional recurrence.

As breast cancer care makes advances, individualized therapy should consider unique patient preferences, risk factors, and overall goals of care. These take precedence over uniform, generalized recommendations. There can be significant physician and patient discomfort with deviating from traditional treatment paradigms and when recommending de-escalation of locoregional care for the older patient with breast cancer. What is considered de-escalation? When is it appropriate? And how do we think about de-escalation of locoregional breast cancer care in the context of ongoing clinical trials and advances in therapies and technologies? The ensuing discussion will initially review de-escalation of surgery and radiation therapy and afterward provide an overview of the importance of shared decision making (SDM) in the care of older patients with breast cancer (Table 1).

SURGERY

De-escalation of surgery for patients with breast cancer refers to reducing the extent or invasiveness of surgical procedures while maintaining optimal clinical outcomes. The goal of de-escalation is to minimize the

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Consider de-escalation of surgery for those patients with early-stage breast cancer, favorable tumor characteristics, are clinically node-negative, and who may have other major health issues.
- De-escalation of surgery entails decreasing the extent of surgery including offering breast conservation therapy over mastectomy for appropriate candidates, incorporating oncoplastic surgery techniques to increase patient eligibility for lumpectomy, and omitting or reducing extent of axillary surgery.
- De-escalation of radiation includes reducing treatment course length through hypofractionation and ultrahypofractionation regimens, reducing treatment volumes through partial breast irradiation, omission of radiation, and reducing radiation dose to normal tissues.
- Shared decision making, which aims to facilitate patients making decisions concordant with their values, can guide health care providers and patients through complicated decisions optimizing breast cancer care.

impact of surgery on a patient's physical and emotional well-being, without compromising the effectiveness of treatment.

De-escalation of surgery may be appropriate for patients who meet the following criteria:

1. Early-stage breast cancer: Patients with small, localized tumors are typically good candidates for breast-conserving surgery over mastectomy.
2. Favorable tumor characteristics: Patients whose tumors are hormone receptor–positive and HER2– may be good candidates for de-escalation of surgery. These tumors tend to be less aggressive and have a lower risk of recurrence, which may allow for less-invasive surgical procedures.
3. Clinically node-negative: Patients whose cancer has not spread to regional lymph nodes may be candidates for de-escalation of axillary surgery.
4. Other health issues: Patients who have other health issues may be more susceptible to complications from surgery, and de-escalation may be appropriate to reduce the risk of surgical complications and to balance the risks and benefits of breast cancer care.

Surgery for breast cancer may be de-escalated for the older patient in thinking about the appropriate extent of surgery in the breast and axilla. First, this can include removal of less breast tissue. The survival rates for patients with breast cancer who undergo lumpectomy versus mastectomy depend on the stage and aggressiveness of the cancer as well as the individual patient's overall health and other medical conditions. There is no significant difference in long-term survival rates between patients who undergo lumpectomy and those who undergo mastectomy for early-stage breast cancer. Lumpectomy with radiation therapy has been shown to be just as effective as mastectomy for treating early-stage breast cancer while allowing for breast preservation. Long-term follow-up of NSABP-06 found no significant difference in overall survival (OS) among women who underwent mastectomy and those who underwent lumpectomy with or without postoperative breast irradiation.[15] Additionally, for locally recurrent breast cancer after previous breast-conserving surgery, standard treatment historically has been mastectomy. However, there may be a role for repeat breast lumpectomy with radiation as studied in Radiation Therapy Oncology Group (RTOG) 1014 for select patients.[16] Furthermore, the Cancer and Leukemia Group B (CALGB) 9343 and PRIME II trials have demonstrated that patients who have early, low grade ER+ cancers can do well with surgery alone without adjuvant radiation.[3,4]

An older patient may also be able to consider oncoplastic reconstructive surgery after breast lumpectomy instead of mastectomy with postmastectomy reconstruction to de-escalate the extent of surgery in certain circumstances. Oncoplastic surgery involves combining breast cancer surgery with plastic surgery techniques to reshape and reconstruct the breast tissue, which can improve cosmetic outcomes while maintaining optimal clinical outcomes and allowing a greater proportion of patients to have breast conservation. Oncoplastic surgery may be used to achieve a more natural-looking breast shape after breast-conserving surgery. For example, in cases where a significant amount of breast tissue needs to be removed, oncoplastic techniques

TABLE 1. Recommendations for Clinical Practice in Locoregional Treatment of Older Patients With Breast Cancer

De-escalation of surgery	Offer breast conservation therapy over mastectomy for appropriate candidates Incorporate oncoplastic surgery techniques to increase patient eligibility for lumpectomy Omit or reduce extent of axillary surgery Consider whether appropriate to repeat breast conserving therapy for local recurrence
De-escalation of radiation	Reduce treatment course length with hypofractionation and ultrahypofractionation regimens Reduce treatment volumes through partial breast irradiation Consider appropriate patients for omission of radiation Reduce radiation dose to normal tissues
Shared decision making	Facilitates patients making decisions concordant with their values Guides health care providers and patients through complicated decisions

can be used to reshape the remaining tissue to maintain symmetry and contour. Oncoplastic surgery can minimize scarring and reduce the risk of complications in older patients with other medical conditions that may affect wound healing or increase the risk of infection. It can be a valuable option for older patients with breast cancer who desire both cancer removal and a good cosmetic outcome without necessitating a mastectomy. The specific techniques used depend on the patient's individual circumstances, including the size and location of the tumor, the amount of breast tissue to be removed, and the patient's overall health and preferences.

In addition to thinking about de-escalating the extent of surgery in the breast, de-escalation of surgery in the axilla is similarly important. In older patients with breast cancer, the omission of axillary surgery may be considered as a treatment option, particularly for those with early-stage disease and low risk of lymph node involvement. This is because axillary surgery, either in the form of sentinel lymph node biopsy (SLNB) or axillary lymph node dissection, can be associated with certain risks and complications, including lymphedema, numbness, and shoulder dysfunction. Several studies from Europe and North America have demonstrated no difference in breast cancer–specific mortality between undergoing axillary surgery versus no axillary surgery.[17–20] Furthermore, the International Breast Cancer Study Group trial 10-93 found that quality of life was significantly better in the group that avoided axillary surgery, and disease-free survival (DFS) and OS were similar for patients in the two arms of the trial.[6] The Society of Surgical Oncology's Choosing Wisely campaign now recommends that surgeons do not to routinely use sentinel lymph node surgery in women older than 70 years who have hormone receptor–positive breast cancer given this does not increase the risk of locoregional recurrence and has no adverse impact on mortality.[21,22]

De-escalation of surgery for breast cancer may be appropriate for certain patients with low-risk disease, where reducing the extent or invasiveness of surgical procedures can still maintain optimal clinical outcomes. However, the decision to de-escalate surgery should be made on a case-by-case basis, factoring in stage and grade of the tumor, the patient's age and overall health, and the presence of any comorbidities. The decision to de-escalate surgery is recommended to be made in consultation with a multidisciplinary team of breast cancer experts, including surgeons, medical oncologists, and radiation oncologists, who can help determine the optimal treatment plan for each patient on the basis of their individual circumstances.

RADIATION

Radiation therapy remains an integral component of breast conservation therapy for the majority of patients with early-stage invasive breast cancer.[23–26] In addition, regional nodal irradiation (RNI) improves cancer control outcomes for patients with axillary lymph node–positive or high-risk node-negative breast cancer.[27–29] However, our improved understanding of breast cancer biologic subtypes coupled with advances in diagnostic and therapeutic modalities has led to the recognition that there are likely subsets of patients who derive little benefit from adjuvant radiation therapy. De-escalation strategies include the following:

Reducing Radiation Treatment Course Length

Hypofractionation (HF) courses of whole breast irradiation (WBI) are now the standard of care. The data support HF courses for many patients undergoing RNI and postmastectomy radiation therapy (PMRT) as well. This reduces the treatment burden from 5 to 6.5 weeks down to 3 weeks or even less with ultrahypofractionation. HF refers to increasing the daily fraction size of radiation while simultaneously reducing the total number of fractions delivered and the total radiation dose delivered. Hypofractionated regimens are attractive in situations in which the radiosensitivity of the tumor cells is similar to the radiosensitivity of the surrounding normal tissues such that a higher dose per fraction can be delivered to obtain tumor control but a lower total dose delivered to reduce normal tissue toxicity.[30] The seminal UK START A and START B trials as well as the Canadian HF trial established that HF regimens result in similar cancer control outcomes with the same or reduced acute and late toxicities compared with conventionally fractionated radiation regimen.[31–36] The United Kingdom moved on with testing results of an ultrahypofractionated WBI regimen of 26 or 27 Gy in five once daily fractions (5.2 or 5.4 Gy/fraction) compared with HF WBI of 40 Gy in 15 fractions in the FAST-Forward trial in a group of women with fairly low-risk breast cancer (median age 60 years; 81% HR+/HER2–; median tumor size, 1.6 cm; 81% pN0; <25% received chemotherapy).[37] The United Kingdom has led to large studies investigating ultrahypofractionation, in which radiation is delivered to the whole breast in a total of five fractions. The UK FAST study randomly assigned women with early-stage breast cancer (pT1-2 pN0) to conventionally fractionated WBI (50 Gy/25 F) or to one of two experimental arms of either 30 Gy/5 F given once per week or 28.5 Gy/5 F given once per week such that all regimens were delivered over a total of 5 weeks (no tumor bed boost in any arm). The 10-year risk of ipsilateral breast events were similarly low across all groups (0.7% 50 Gy/25 F *v* 1.4% 30 Gy/5 F *v* 1.7% 28.5 Gy/5 F), but there were significantly worse normal tissue effects (eg, photographic changes in the breast, induration, edema) for 30 *v* 50 Gy but not for 28.5 *v* 50 Gy. Therefore, for patients with significant comorbidities or socioeconomic factors that preclude daily treatment, the 28.5 Gy in five fractions once per week is an acceptable alternative to conventionally fractionated WBI.[37]

The 26 Gy in five fraction regimen was much more tolerable, although there were still significantly higher rates of certain side effects, such as breast swelling, when compared with 40 Gy in 15 fractions. In addition, for patients requiring a tumor bed boost, this was delivered sequentially with an additional five to eight fractions, thereby increasing the course from 1 week to 2-2.5 weeks. Recent data from the Radiation Therapy Oncology Group 1005 study demonstrated that HF WBI of 40 Gy in 15 fractions with a concomitant boost to the tumor bed to a dose of 48 Gy in 15 fractions resulted in equivalent local control with similar acute toxicity, late toxicity, and cosmesis compared with WBI delivered with a sequential boost.[38] Thus, the RTOG 1005 regimen, which is delivered in 3 weeks, is an excellent option for high-risk patients requiring tumor bed boost.

HF regimens have also been used to deliver RNI and PMRT. In the START A and START B clinical trials, 8.3% and 14.6% of patients received hypofractionated PMRT.[31,32] In addition, Wang et al[39] performed a randomized noninferiority trial of HF PMRT (43.5 Gy in 15 fractions) compared with PMRT delivered as 50 Gy in 25 fractions in 810 patients with T3-4 and/or N2-N3 breast cancer and found noninferior local-regional control with HF PMRT. A recent meta-analysis of 25 trials involving almost 4,000 patients comparing efficacy and toxicity of hypofractionated versus conventionally fractionated PMRT showed no differences in local-regional recurrence, DFS, OS, or in any early or late toxicities between the groups.[40] The results of two recently completed randomized studies specifically comparing HF PMRT with conventionally fractionated PMRT in the reconstruction setting are highly anticipated.

Reducing Radiation Treatment Volumes

Partial breast irradiation. Most in-breast tumor occurrences are located within 1 cm of the original tumor bed.[41,42] This has led to numerous clinical trials comparing partial breast irradiation (PBI), which targets the tumor bed region with a margin of 1-2 cm, with WBI. All forms of PBI use HF, although some regimens are delivered twice per day with moderately large fractions (3.4-3.85 Gy $\times$ 10 fractions), while some are delivered daily with standard HF (2.67 Gy $\times$ 15 fractions) and others are given every other day with large fraction sizes (6 Gy per fraction $\times$ five fractions). Intraoperative radiation therapy delivers a single large dose (20-21 Gy) to the tumor bed with either low-dose photons or high-energy electrons.

The key APBI studies are summarized in Table 2. PBI should be considered as an alternative to WBI in the appropriate patient population, specifically patients who are 50 years or older with stage I, lymph node-negative (pT1 pN0), ER+/HER2– breast cancers. Across all techniques and fractionation schedules, it seems as though 10-year in-breast tumor recurrences are 2% or less when PBI (or WBI) is used in this patient population. Although there are no randomized studies that compare one PBI technique with another, it does seem that once daily PBI (30 Gy in five fractions given every other day or 40 Gy in 15 fractions given daily) is associated with low rates of acute and late toxicities and extremely high rates of favorable cosmesis.

Omission of Radiation Therapy

Biomarker-guided omission of radiation in hormone-sensitive breast cancer. While data support omission of radiation therapy in patients with ER+/HER2– breast cancer treated with lumpectomy and adjuvant endocrine therapy on the basis of age through the CALGB 9343 and PRIME II studies, recent focus has shifted to the use of genomic and immunohistochemistry-based biomarkers to help make these decisions with numerous ongoing prospective trials.[3,4] The recently reported LUMINA study was a single-arm prospective study that evaluated omission of radiation therapy in women age 55 years or older with grade 1-2 tumors that were $\leq$2 cm in size, surgical margins $\geq$1 mm, lymph node-negative, and had a low proliferative index (Ki67 $\leq$ 13.25%) and found that the 5-year risk of local-regional recurrence in the 727 patients enrolled was extremely low at 2.3%.[44]

Omission of radiation in HER2-positive breast cancer. Much of the de-escalation of radiation therapy has been focused on patients with ER+/HER2– disease. HER2+ breast cancers represent approximately 10%-15% of all breast cancers, and systemic therapy studies have demonstrated that patients with small node-negative tumors (pT1N0) have exceedingly low rates of local-regional and distant recurrences with de-escalation of systemic therapy.[45,46] For example, in the APT trial, patients who received lumpectomy with radiation therapy had <1% rate of in-breast recurrences.[47] This observation has led to a phase III randomized trial of postlumpectomy radiation versus omission of radiation in patients with pT1N0 HER2+ breast cancer treated with lumpectomy + axillary surgery and adjuvant chemotherapy with HER2-targeted therapy.

Reducing Radiation Dose to Normal Tissues

The entire field has shifted from a 2D anatomic landmark-based approach to design radiation fields toward 3D computed tomography (CT)–based radiation planning with improved delivery techniques such as 3DCRT using multileaf collimators to design fields,[48–50] prone breast radiation therapy,[51–56] inverse planned intensity–modulated radiation therapy, and volumetric modulated arc radiotherapy (RT), all of which have resulted in reduced treatment toxicities.[57,58] Respiratory gating with use of deep inspiration breath hold (DIBH) and improved image guidance during treatment delivery including real-time on-board

TABLE 2. Key Studies of De-Escalation Using HF and Ultrahypofractionation for Whole Breast Irradiation

Trial	Study Duration	N	Follow-Up (years)	XRT Dose	LR (%)
Whelan (OCOG)[16]	1993-1996	1,234	12	CF: 50 Gy/25 F	6.7
				HF: 42.56 Gy/16 F	6.2
START-A[12]	1999-2002	2,236	9.3	CF: 50 Gy/25 F/5 w	6.7
				HF: 41.6 Gy/13 F/5 w	5.6
				HF: 39 Gy/13 F/5 w	8.1
START-B[11]	1999-2001	2,215	10	CF: 50 Gy/25 F	5.2
				HF: 40 Gy/15 F	3.8

				UHF: 26 Gy/5 F	1.4

Abbreviations: CF, conventional fractionation; HF, hypofractionation; LR, local recurrence; N, number of patients; OCOG, Ontario Clinical Oncology Group; XRT, radiation.

imaging with cone beam CT capabilities further aid the field of radiation oncology to improve targeting and reduce radiation to normal tissue during treatment delivery.[43,59,60]

In Figure 1, a patient with a medially located lumpectomy cavity in the left breast underwent simulation in both the prone position and the supine position with use of DIBH because of concerns that the location of the lumpectomy cavity may result in a higher dose to the heart in the prone position. However, in this case in which contours for the target volumes (breast and lumpectomy cavity) and OARs were in place, the prone radiation plan resulted in lower mean heart dose (0.9 *v* 1.5 Gy) and substantially lower

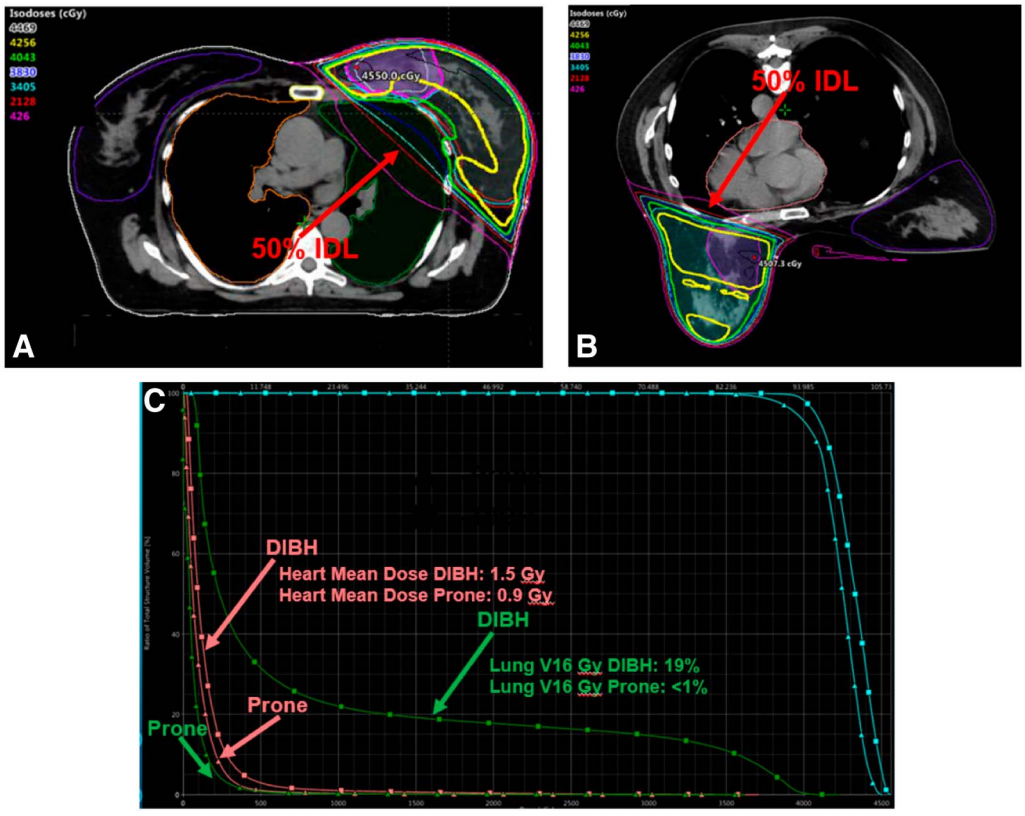

FIG 1. Individualizing radiation treatment technique. (A) This panel demonstrates radiation in the supine position with DIBH. (B) Same patient in the prone position. The 50% IDL is highlighted in the red arrow while the yellow and green curves represent the 100% and 95% IDL, respectively. (C) This panel demonstrates the dose-volume histogram. Curves with squares represent the DIBH radiation plan, and the curves with triangles are the prone radiation plan. DIBH, deep inspiration breath hold; IDL, isodose line.

volume of lung receiving ≥16 Gy (<1% prone *v* 19% DIBH) without compromising target volume coverage. This is an example of how RT approaches can be individualized to the patient and how modern radiation techniques and planning approaches can enable us to adequately cover our targets and reduce dose to normal tissues.

SDM

SDM, which aims to facilitate patients making decisions concordant with their values, can help to guide health care providers and patients through complicated decisions. It requires patients and providers to work together to select tests and treatments, with each party bringing different expertise to the decision-making process. Patients are responsible for sharing preferences while providers are responsible for informing patients of their treatment options and integrating relevant evidence-based information into the conversation.[61] SDM is particularly useful in the setting of multiple treatment options, when there is uncertainty regarding the evidence supporting a treatment or its outcomes, when there are both advantages and disadvantages that patients must weigh and when the decision is high impact as is the case for breast cancer treatment decision making for older women.[61] However, existing research demonstrates gaps in effective SDM with these women. Older women with breast cancer often report unmet informational needs, feel ill-prepared to communicate their preferences to their physicians, and feel uncomfortable asking their surgeons questions.[61] Furthermore, older women report being less likely to be given treatment choices, to engage in treatment decisions, and/or to be satisfied with treatment outcomes than younger women.[62] Many also have low knowledge of breast cancer survival and recurrence rates.[63] Yet, older women are increasingly interested in taking more active roles in treatment decisions, reporting that they would value educational materials to better understand their treatment options and to know what questions to ask.[64]

Decision aids (DAs) are educational tools that provide detailed, current information to guide patients through a deliberative process. Rather than replacing patient-physician interaction, they are intended to supplement the conversation.[65] They have been found to perform better than usual care with respect to improving patients' knowledge about risk perception and treatment outcomes, incorporating patients' preferences and values, and encouraging users to take a more active role in decision making without increasing anxiety. DAs also improve patient satisfaction with the decision-making process, possibly improving patient quality of life.[65]

A 2016 systematic review identified 23 individual breast cancer treatment DAs.[66] For this chapter, a literature review was performed for patient DAs for women with invasive breast cancer. Studies included were published since 2010 and included women age 65 years or older in the testing of the DA. Table 3 presents the 18 DAs identified. Six of the DAs focused on women age older than 65 years, two of which discussed RT and were only studied in Canadian women who had already chosen to undergo RT.[74,78] These DAs need to be tested among women facing this treatment decision. Another DA focused on SDM around cessation of surveillance mammography among women age 75 or older and encouraged older women to consider their tumor characteristics and life expectancy when deciding when to cease surveillance mammography.[80] Another study aimed to provide older women with information on their prognosis with and without breast cancer and with and without comorbidities.[73] Wyld et al[79] developed the Age Gap Decision Tool. This tool was developed for women age 70-99 years in the United Kingdom diagnosed with primary operable invasive breast cancer (T1-3, N0-1, M0). It considered a woman's age, tumor size, grade, ER and HER2 status, comorbidities and frailty to provide information on a woman's 2-year and 5-year OS, chance of breast cancer death, and chance of death from other causes if she is treated with (1) surgery plus endocrine therapy versus primary endocrine therapy and (2) surgery plus chemotherapy versus surgery alone. In a large cluster, RCT that included 1,339 women seen at 46 different breast units, use of the tool was associated with women having increased knowledge about treatments, more SDM, and with more women receiving primary endocrine therapy and fewer receiving chemotherapy (Table 2).[79]

Since there is a complex interplay between treatments that older women should consider when deciding on treatment, Schonberg et al[85] developed and pilot-tested a comprehensive DA for women age 70 or older with stage I, ER+/HER2– breast cancer. This DA was designed with low literacy principles, iteratively revised, and is on the preferred medium (paper) of older women. The DA encompasses surgical decisions (breast surgery and axillary surgery), the decision to proceed with RT, and endocrine therapy options. It also incorporates competing health issues into the decision process. In addition to the standard components of DAs, such as describing the health condition and the positive and negative features of treatment choices, the DA also includes a question prompt list since question prompt lists have been shown to increase patient knowledge, self-efficacy, identification of treatment preferences, and participation in decision making, especially among patients with cancer.[86] In a pilot pretest/post-test trial of 33 women, the DA improved women's knowledge of their treatment options and 97% would recommend it; the DA is available in the appendix of the article.[72]

Although DAs have been repeatedly shown to increase patient knowledge and reduce decisional conflict, successful integration requires engaging physicians in the process.

TABLE 3. Patient DAs for Older Women With Invasive Breast Cancer: Studies That Included Women Age Older Than 65 Years in Testing and Were Published Since 2010[a]

Reference	Participants	Decision	Methods	Results
Ager et al[67]	23 Australian women with history of stage I or II breast cancer; mean age, 58.6 (range, 43-67 years)	Contralateral prophylactic mastectomy	In-person interviews	The DA was found to be acceptable
Durand et al[68] (images of the DA in the article)	16 surgeons, 616 US women with stage I-IIIA breast cancer; mean age, 59.7 (±12.5 years)	Mastectomy *v* BCS	Three-arm RCT (Option Grid Text, Picture Option Grid [pictures + text], and usual care) with surgeon-level random assignment	Patients in Picture Option Grid arm had higher knowledge, improved decision process, lower decision regret, and more SDM compared with usual care. Patients in Option Grid text arm had higher decision process, better coordination of care, and more SDM compared with usual care arm
Freedman et al[80] (DA in the appendix)	21 US breast cancer survivors; median age, 78 (range, 75-92 years); 21 oncologists	Surveillance mammography	Observational cohort study of patients and survey of oncologists	Nearly all patients and clinicians would recommend the guide to others. Both previsit and postvisit patients reported strong intentions for surveillance mammography
Harwood et al[69] (images of the DA in the article)	Part 1: 28 Australian women with history of stage I/II breast cancer; mean age, 55 (range, 32-76 years) Part 2: Eight Australian women newly diagnosed with stage I/II breast cancer; mean age, 55 (range, 34-75 years)	Mastectomy *v* BCS; axillary dissection *v* sentinel node biopsy	Part 1: Qualitative Part 2: Observational cohort study	Part 1: Positive feedback on the DA Part 2: Too small but possible reduction in decisional conflict and possibly improved decisional satisfaction, knowledge, and choice
Hawley et al[70] (iCanDecide)	537 US women with stage I/II breast cancer; mean age 57 (±11 years; range, 21-84)	Locoregional and systemic treatment decision making	RCT: iCanDecide interactive and tailored website *v* iCanDecide static website[6]	Tailored DA associated with high-quality decisions and greater knowledge compared with nontailored DA. No differences in values-concordant treatment decisions by arm
Ke et al[82] (screenshots of the DA in the appendix)	15 Singaporean women with breast cancer who completed primary treatment (age range, 46-67 years); eight health care professionals	Breast cancer survivorship	Mixed methods	All patients found the final DA easy to navigate with sufficient interactivity
Lam et al[71]	276 Cantonese-speaking or Mandarin-speaking Chinese women in Hong Kong with stage 0-III breast cancer; mean age DA arm, 56.8 ± 10.8 years (mean age of controls, 54.6 ± 10.1 years)	BCS and RT, mastectomy, mastectomy and reconstruction	RCT:DA (take-home booklet) *v* standard information booklet (control condition)	Receipt of DA led to significantly lower decisional conflict scores, lower decision regret, and lower depression scores
Minami et al[72] (DA available in the appendix)	33 US women age 70 or older, with stage I, ER+, HER2– breast cancer; mean age, 74.7 ± 3.8 years	Mastectomy *v* BCS; lymph node surgery, RT, endocrine therapy	Pretest-post-test trial	Nearly all participants strongly agreed that the DA was helpful and that it prepared them for treatment decision making. Knowledge significantly improved after receiving the DA
Mühlbauer et al[73] (SPUPEO DA; images of DA in the article)	Part 1: 20 German women with history of early-stage ER+, HER2– breast cancer; mean age, 60 (range, 32-77 years) Part 2: 86 German women with history of early-stage ER+, HER2– breast cancer; mean age, 51 (range, 27-76 years)	Displayed age-based noncancer prognosis stratified by history of breast cancer and also by comorbidity for women 65-84 years	Part 1: focus groups Part 2: online survey	The DA was found to be helpful, informative, and interesting

TABLE 3. Patient DAs for Older Women With Invasive Breast Cancer: Studies That Included Women Age Older Than 65 Years in Testing and Were Published Since 2010[a] (Continued)

Reference	Participants	Decision	Methods	Results
Neve et al[74] (images of the DA in the appendix)	40 Canadian women undergoing or had undergone whole breast RT with stage I/II ER+, HER2–, breast cancer; median age 72 (range, 65-86 years)	Adjuvant RT including WBRT, APBI, and omission of RT	Pretest-post-test trial	Decisional conflict decreased after using the DA, and nearly all stated the DA was useful for future patients
Raphael et al[83]. (BRASA DA)	Dutch women with T0-T3, N0, or N1 breast cancer facing a choice about RT; control group mean age 60.4 (±11.3 years), intervention group mean age, 62.8 (±12.6 years)	RT (boost/no boost, chest was RT, low-risk breast cancer)	Preintervention and postintervention trial	Knowledge increased with receipt of the DA, and fewer chose additional RT. There was no change in decisional conflict with DA
Savelberg et al[81] (images of the DA in the appendix)	84 Dutch women with stage I/II breast cancer; mean age, 61.1 (±9.9 years)	Surgical treatment	Observational cohort study	SDM was high as measured by CollaboRATE; 67% of patients used the DA at home
Sivell et al[75] (Bresdex)	62 women from the United Kingdom with stage I/II breast cancer; mean age, 53.3 (range, 29-80 years)	Designed to support surgical decision making	Observational cohort study	After receiving the DA, readiness to make a decision increased. There was no significant improvement in knowledge
Ter Stege et al[84] (borstreconstructie keuzehulp)	17 Dutch women with a history of making a decision about breast reconstruction (mean age, 51.3 [range 31-77 years]) and 40 health care professionals	Breast reconstruction after mastectomy	Semistructured qualitative interview with patients, survey of health care professionals	The DA was perceived to be informative, helpful, and easy to use
Tucholka et al[76]	227 US women with stage 0-III breast cancer; median age, 59 (range, 27-80 years)	Considering breast surgery	RCT: standard cancer websites (breastcancer.org) *v* health dialog DA	Receipt of the DA was associated with higher knowledge; both arms found the interventions helpful
Vodermaier et al[77]	111 German women with stage I-III ER+ breast cancer; mean age, 55.2 (±11.0 years)	Surgical and systemic treatment	RCT: a 20-minute decision board intervention plus an information brochure *v* usual care	Receipt of the DA was associated with less decisional conflict; no effect on anxiety, depressive symptoms, or quality of life
Wong et al[78] (images of the DA in the article)	Part 1: 16 Canadian women with stage I, ER+/PR+ breast cancer completed WBRT; median age, 77 (range, 71-84 years) Part 2: 36 Canadian women with stage I, ER+/PR+ breast cancer receiving WBRT; median age, 75 (range, 66-95 years)	Adjuvant radiation therapy	Part 1: qualitative Part 2: pretest-post-test study	All women thought the DA was helpful and informative. Patients experienced less decisional conflict and were more knowledgeable after using the DA
Wyld et al[79] (Age Gap Decision Tool)	1,339 UK women with T1-3, N0-1, M0, breast cancer; mean age, 78 (±6 years; range, 70-99)	Surgery plus ET *v* PET; surgery *v* surgery plus chemotherapy	Cluster RCT of two DAs (surgery and ET *v* PET; chemotherapy *v* no chemotherapy) *v* usual care; 46 breast units were randomly assigned	Use of DAs increased knowledge, facilitated SDM, and increased use of PET and decreased use of chemotherapy; no effect on global quality of life

Abbreviations: APBI, accelerated partial breast irradiation; BCS, breast-conserving surgery; DA, decision aid; ER+, estrogen receptor–positive; ET, endocrine therapy; HER2–, human epidermal growth factor receptor 2–negative; PET, primary endocrine therapy; PR+, progesterone receptor–positive; RCT, randomized controlled trial; RT, radiotherapy; SDM, shared decision making; WBRT, whole breast radiotherapy.

[a]If the age range of patients in the study was not reported, studies were included where the mean age plus the standard deviation was 65 years or older.

Qualitative studies have found that trust in one's surgeon is a key factor influencing older women's breast cancer treatment decisions,[63] but surgeons may overestimate older women's recurrence risk and the benefits of radiation therapy after breast-conserving surgery,[87] that surgeons may lack familiarity with recommendations to omit SLNB and the data supporting this recommendation, and that surgeons may lack the skills to engage older women in SDM.[88] Physicians in general tend to underestimate patient desire to participate in treatment decisions, especially for older adults, and are often incorrect when they attempt to infer patient treatment preferences.[89,90]

There thus remains much work to be done on SDM improvement with older patients with breast cancer. Physicians need training in SDM and DA use overall, but specific to this population is the need for tactful integration of patient health and life expectancy into treatment conversations. The relative risks and benefits of treatment (or omission of treatment), and the concepts of overtreatment and undertreatment in this patient population, require broaching the topic of remaining life expectancy.[91] Since the benefits of breast cancer treatments (ie, reduction of breast cancer morbidity and/or mortality) may take years to achieve, it is necessary to estimate if an older women is likely to live long enough on the basis of her overall health to have a chance of benefitting. The ePrognosis website provides risk calculators to help clinicians estimate older adults' mortality within the next 14 years (eg, the Lee-Schonberg index). Patients with a >50% risk of mortality during a specific time (eg, 10 years) are estimated to have a life expectancy less than that time since life expectancy is the median survival of a population.

Using the Lee-Schonberg index as a brief method for geriatric assessment, Mott et al[92] developed and pilot-tested a strategy for oncologists for de-escalating radiation therapy after breast-conserving surgery and for omitting SLNB. Their strategy considers whether a patient is a minimizer (tends to prefer a wait and see approach) versus a maximizer (tends to prefer taking action), estimates patients' health and overall prognosis using the Lee-Schonberg index, and provides tailored scripts for clinicians to explain why radiation therapy after breast-conserving surgery and SLNB may not be beneficial. The 22 oncologists (15 surgeons/eight radiation oncologists) who tested this strategy found it useful, particularly the assessment of patients' 10-year prognosis; however, some were concerned with patients seeing their overall prognosis while others felt it helped foster communication. Evidence-based strategies for oncologists to incorporate discussion of patient overall health and life expectancy in treatment decisions are much needed.

SDM around breast cancer treatment may also be challenging because these decisions often involve the preferences and values of patient family members in addition to those of patients themselves. An analysis of physician notes of patients older than 80 years diagnosed with breast cancer found that 71% had a family member present during consultation and that treatment decision making often occurred collaboratively between older women, their families, and physicians.[93] Clinicians may want to assess patient preferences for family involvement in decision making, welcome and involve family involvement when appropriate, and recognize that family involvement in the decision-making process may start before the initial visit and continue afterward.[94]

This discussion of SDM has focused on treatment decisions faced by older women with low-risk breast cancers; however, older women with more aggressive breast cancers also face many breast cancer treatment decisions (eg, chemotherapy, immunotherapy), and the approach to SDM should be similar. High-quality SDM for breast cancer treatment decisions in older women must consider the lag time to benefit from each treatment, whether the patient has adequate remaining life expectancy to have a chance of benefiting from the treatment, how the patients value the potential benefits and risks of each treatment, and the patient's preferences. The lag time to benefit is the time between when a treatment is given and the time to when improvement in breast cancer survival would be expected based on data from clinical trials.[95] If the patient's life expectancy because of their other health conditions is shorter than the lag time to benefit from the treatment, the patient will be very unlikely to benefit from the treatment. A formal geriatric assessment may also help inform oncologists and older women of their likelihood of benefiting from treatment and may inform SDM.[96]

The complexity of treatment options set by the current breast cancer literature requires physicians to be skilled in SDM communication. To engage older women in SDM, Mulley and Sepucha recommend a multistep approach that includes (1) inviting a patient to participate; (2) presenting the treatment options; (3) the benefits and harms of each treatment, (4) eliciting patient priorities, concerns, or decisional needs; (5) facilitating deliberation with involvement of trusted others; and (6) then implementing the shared decision.[97] The Agency for Healthcare Research and Quality has published example language for clinicians to use for these conversations.[98] For example, to invite patients to participate, a clinician may say "I want to go over all the options so we can find a path that works for you" and to elicit patients' values and preferences, a clinician may say "As you think about your options, what's important to you?" To facilitate deliberation, a clinician may ask older women to describe their understanding of their treatment options and to encourage these patients to take time to consider their options and to consult trusted family or friends.

While preferred decisional roles can run the gamut from passive to active in older patients with breast cancer,[99] nearly all older women regardless of their preferred decision-making role want treatment decisions to incorporate their values and preferences. Therefore, physicians need the skills to facilitate high-quality decisions. As the oncologic community continues to work toward tailored individualized breast cancer care, effective, feasible, sustainable interventions aimed at improving SDM in older adults are much needed.

BREAST CANCER

Managing a Long and Winding Road: Estrogen Receptor–Positive Breast Cancer

Michael Gnant, MD[1]; Nicholas C. Turner, MD, PhD[2]; and Cristina Hernando, MD[3]

overview

We review key topics in the management of estrogen receptor (ER)–positive human epidermal growth factor receptor 2–negative breast cancer. The single biggest challenge in management of this disease is late relapse, and we review new methods for identifying which patients are at risk of late relapse and potential therapeutic approaches in clinical trials. CDK4/6 inhibitors have become a standard treatment option for high-risk patients in both the adjuvant setting and the first-line metastatic setting, and we review data on optimal treatment after progression on CDK4/6 inhibitors. Targeting the estrogen receptor remains the single most effective way of targeting the cancer, and we review the developments in new oral selective ER degraders that are becoming a standard of care in cancers with ESR1 mutations and potential future directions.

INTRODUCTION

In this section, we review key current topics in the management of estrogen receptor–positive breast cancer. We review therapeutic options that may reduce the risk of late relapse, how to optimally use CDK4/6 inhibitors in the clinic, and how the new class of oral selective estrogen receptor downregulators (SERDs) is entering clinical practice with elacestrant for patients with advanced *ESR1*-mutant breast cancer.

LATE RECURRENCES IN ESTROGEN RECEPTOR–POSITIVE BREAST CANCER: WHAT ELSE CAN WE DO?

The most prevalent form of breast cancer is characterized by hormone receptor–positive tumor cells[1]; in modern terminology, we call it luminal breast cancer.[2] Approximately two of three patients are affected with this subtype that is characterized by relatively limited, but long-term, risk of recurrence.[3] More than half of all disease recurrences occur after 5 years of the initial diagnosis, and a life time trade-off of these late relapses for the rather limited early recurrence risk exists.[4,5] Currently, all disease recurrences that occur after 5 years are called late; however, most clinical trial databases end at 10 years, and with the exception of the Oxford group, very few firm data exist for truly long-term results, for example, 20 or 30 years after diagnosis.[6,7]

Interestingly, prognostic factors affecting long-term risk are tumor size and nodal status, which are classical prognosticators for breast cancer.[8] Despite all research efforts, it is still not exactly understood how late relapse works in terms of biology, particularly how the disease survives for prolonged periods including those of effective adjuvant anticancer treatment. The most likely concept is that breast cancer cells can undergo epithelial-mesenchymal transition,[9] escape from the primary tumor into the circulation,[10] even before diagnosis, and that some of these cells can undergo mesenchymal-epithelial transition again, and gain the ability to home in the bone marrow, most likely in the endosteal niche.[11] In that niche, subtle changes of the microenvironment equilibrium between stimulating and calming factors are probably decisive for the fate of these cells, resulting in either quiescence and dormancy or senescence and apoptosis.[12] However, a completely unresolved mystery is how these cells remember that they originally came from a large or node-positive tumor, given that these classical risk factors appear to remain risk factors for late relapse, that is, awakening of the dormant cells.

Since we have effective adjuvant therapies that reduce the risk of relapse for luminal breast cancer, the idea of extending treatment durations is in fact intriguing. Since the risk of recurrence persists for longer than 5 years, why not increase treatment durations accordingly? Since the risk of disease recurrence persists for a long term in luminal breast cancer, extending the risk-reducing adjuvant antihormonal therapies for 10 years or longer in theory makes sense.

Unfortunately, this compelling idea has its limitations: Cumulation of side effects (potentially outweighing any benefit) and loss of therapeutic efficacy are limiting this concept in clinical practice. Apparently, breast cancer (seemingly including its dormant stem cells) develops resistance mechanisms over time, and none of our contemporary endocrine therapies, as efficacious as they are, comes without sometimes substantial tolerability issues. The former can be overcome by changing drugs for intervention[13]; in an attempt to

PRACTICAL APPLICATIONS

- Adjuvant CDK4/6 inhibition, with abemaciclib, substantially reduces the risk of relapse and is a standard of care for patients with high-risk disease.
- Elacestrant is a new treatment option for patients with advanced breast cancer and *ESR1* mutations in circulating tumor DNA.
- Oral selective estrogen receptor degraders are in multiple clinical trials with the potential to become a future mainstay of endocrine therapy.
- Late relapse remains a key challenge of treating estrogen receptor–positive breast cancer, with more than half of relapses occurring 5 or more years since diagnosis.

address different targets, the latter is challenging to overcome in clinical practice.

Oral selective estrogen receptor modulators (SERMs), such as tamoxifen and aromatase inhibitors (AIs), are the mainstay of adjuvant endocrine therapy (ET), and both classes of drugs have been studied extensively with respect to extending treatment durations. The ATLAS and aTTom trials provided signals that 10 years of tamoxifen decreased the risk of recurrence but did not affect overall mortality unequivocally, and the extension resulted in an increase in endometrial cancer and pulmonary embolism.[14,15] In postmenopausal women, adding AIs after 5 years of tamoxifen yielded significant improvements in three large clinical trials,[16-18] but the situation is less clear if AIs are already used in the first quinquennium of adjuvant therapy—the respective extension trials showed controversial results (trial results summarized in Table 1).[20,22,24,26] In summary, for the majority of patients with luminal early breast cancer, 7 years of adjuvant endocrine treatment appears to yield the optimal benefit/harm relation.[25]

Another concept of reducing the risk of long-term disease recurrence is adding additional drugs. Interestingly, bone-targeted therapies, such as adjuvant bisphosphonates, have been shown to reduce recurrences and breast cancer mortality,[27] only in the postmenopausal setting.[28] In addition to favorably have an impact on bone health impairments,[29-31] which are among the important side effects of endocrine therapies, antiresorptive therapies can apparently parch the bone microenvironment,[32,33] and this may disadvantage the reactivation of dormants, eventually reducing overt bone metastases or distant disease relapse after secondary spread to other organs.[34] Recently, it was shown that even relatively short-term adjuvant treatment with the anti-RANK ligand antibody denosumab reduces breast cancer recurrence many years after stopping the therapy.[35]

Other classes of drugs that can be added to standard endocrine therapies are CDK4/6 inhibitors. In addition, these inhibitors of cyclin-dependent kinases 4 and 6 have been practice changing in metastatic breast cancer (mBC) and are currently considered the standard of care in combination with ET for the first- or second-line treatments of advanced hormone receptor–positive breast cancer.[36-44] However, for early breast cancer, the addition of CDK4/6i has yielded mixed results. Although two large adjuvant studies of adjuvant palbociclib were negative,[45,46] the addition of abemaciclib to standard ET increased disease-free survival of high-risk patients significantly.[47,48] Whether this benefit will also have an impact on late recurrences remains to be seen, but abemaciclib is also used in the currently recruiting ADAPTlate trial (ClinicalTrials.gov identifier: NCT04565054) to address this question. Results of the adjuvant ribociclib study (NATALEE; ClinicalTrials.gov identifier: NCT03701334) will be presented at the ASCO 2023 meeting.

Another evolution of luminal breast cancer treatment has been the development of agents addressing alternate growth pathways of hormone receptor–positive tumor cells. The inhibition of mTOR, PI3CA, and AKT has been demonstrated to be effective at least in the subgroups of patients with mBC[49-52]; however, whether these drugs can be used in the adjuvant setting remains unanswered, partly because of the nontrivial side effect profile. Some of the new oral SERDs have also demonstrated the activity in the advanced setting and are rapidly moved to the early breast cancer field in large clinical trials, for example, giredestrant (lidERA Breast Cancer, ClinicalTrials.gov identifier: NCT04961996), imlunestrant (EMBER-4, ClinicalTrials.gov identifier: NCT05514054), elacestrant, and camizestrant (CAMBRIA-1, CAMBRIA-2). Since these agents appear to be particularly effective in patients with ESR-1 mutations that are associated with resistance toward standard endocrine therapy[53] or even be able to prevent them, they appear to be promising candidates for future treatment standards.[54]

The main challenge in addressing late breast cancer relapses is the identification of who is actually at risk. None of the aforementioned interventions will likely be without side effects, and even putting the financial toxicity issue for society aside, it is highly unlikely that all relapse-free patients, for example, at 10 years of follow-up, will undergo an additional therapeutic intervention to tackle their residual risk, which is probably around 1% per year at that stage. Thus, identification of patients at risk is crucial.

So far, multigenomic tests have been developed to assess risk, mainly to assist in the clinical decision making

TABLE 1. Trials of Extended Adjuvant Endocrine Treatment

Trial	Endocrine Therapy Before Random Assignment	Randomized Treatment	No. Premenopausal/ Postmenopausal	Follow-Up, Months	Outcomes		Toxicity
					DFS	OS	
aTTom[15]	Tam 5 years	Nil Tam 5 years	6,953 pre/post	108	RR = 0.75 4% absolute at 7 years	0.86 ns 2% absolute at 7 years	More endometrial cancer and PE with longer TAM; less ischemic cardial events
ATLAS[14]	Tam 5 years	Nil Tam 5 years	6,846 pre/post	Approximately 120	RR = 0.75 3.7% absolute at 7 years	RR = 0.71 ns 2.8% absolute at 7 years	More endometrial cancer and PE with longer TAM; less ischemic cardial events
MA-17[19]	Tam 5 years	Placebo AI 5 years	5,187 post	80[a]	HR 0.58 4.9% absolute at 7 years	HR = 0.82 ns HR (N+ = 0.61)	More hormone-related side effects with AI
ABCSG-6a[17]	Tam 5 years[b]	Nil AI 3 years	856 post	62.3	HR = 0.53, $P = .03$ 3.4% absolute at 10 years	HR = 0.89 ns	More hot flushes, asthenia, somnolence
NSABP B-33[18]	Tam 5 years	Placebo AI 5 years	1,598 post stage II-III	30[a]	RR = 0.68 ns 2% absolute at 4 years	Not reported	More arthralgia, fatigue, bone pain, fractures (ns)
NSABP B-42[20]	AI 5 years Tam->AI 5 years	Placebo AI 5 years	3,923 post stage I-IIIA	82.2	HR = 0.85 ns 3.3% absolute at 7 years	HR = 1.15 ns	More arterial thrombembolic events after 2.5 years with AI; HR 1.85 (1.18 to 2.88)
MA-17R[21]	Tam->AI 5+ years	Placebo AI 5 years	1,918 post stage I-III	75.6	HR = 0.66 4% absolute	HR = 0.97 ns	More bone related toxic effects with longer AI
DATA[22]	Tam 2-3 years	AI 3 years AI 6 years	1,860 post stage I-III	49.2	HR = 0.79 ns 0.8% absolute at 5 years	HR = 0.91 ns	More osteopenia/osteoporosis and arthralgia with longer AI
GIM-4[23]	Tam 2-3 years	AI 2-3 years AI 5 years	2,056 post stage I-III	140.4	HR = 0.79 5% absolute at 12 years	HR = 0.77 4% absolute at 12 years	More osteoporosis arthralgia/ myalgia and cardio vascular events with longer AI (1% v <1%); Fractures reported similar
IDEAL[24]	5 years (AI 29%, Tam 12%, Tam-> AI 59%)	AI 2-3 years AI 5 years	1,824 post stage I-III	79.2	HR = 0.92 ns Second primaries HR = 0.39	HR = 1.04 ns	Reported similar
ABCSG-16[25]	5 years (AI 7%, Tam 51%, Tam-> AI 42%)	AI 2 years AI 5 years	3,484 post stage I-III	118	HR = 0.99 ns	HR = 1.02 ns	Significantly more bone fractures with longer AI

[b]Half of the patients had received Tam/aminoglutethimide combination for the first 2 years (within trial ABCSG-6).

whether patients with early luminal breast cancer should also receive adjuvant chemotherapy.[55] Several of these tests have also been applied for the late recurrence setting[56-59]; however, for the majority, this constituted merely an extrapolation of a test developed on data sets of the first 5 years to the extended setting. Only Breast Cancer Index has demonstrated some utility in predicting the benefit of extended treatment durations.[60-62]

More recently, technology has evolved to detect circulating tumor DNA in the blood of patients with cancer. In addition to early detection and treatment effect monitoring, this may be the future of identifying patients with early breast cancer who are clinically cured but biologically on the verge of disease recurrence; promising early results have been reported.[63-65] However, many questions remain unanswered at this point of time.[66,67] In addition to issues of technology, frequency of testing, and affordability, most

effective interventions must be defined—not least because of ethical and patients communication aspects. Once we tell a patient that she might be at increased risk to experience disease recurrence soon, we should also have something to offer to her—ideally a clinical trial with some type of intervention. The results of such translational-clinical research projects will have to be awaited, for example, from the TREAT trial (ClinicalTrials.gov identifier: NCT05512364).

The dream of the future is that we could change our target. Although we become reasonably effective in targeting proliferating tumor cells, we are still close to clueless on how to identify, measure, and address the issue of dormancy and quiescence.[68-71] Only when we decipher their mysteries, we will effectively be able to identify, prevent, and treat late disease recurrence. This future time point will mark the beginning of an era in which we might humbly start talking about cure of this disease.

USING CDK4/6 INHIBITORS IN EARLY-STAGE AND ADVANCED HORMONE RECEPTOR–POSITIVE BREAST CANCER

Advanced Breast Cancer

The addition of CDK4/6 inhibition to the first-line ET of patients with advanced breast cancer (ABC) is the standard for the vast majority of patients with advanced estrogen receptor (ER)–positive human epidermal growth factor receptor 2 (HER2)–negative breast cancer. Given the good tolerability of CDK4/6 inhibitors, advancing age and minor comorbidities should not be a reason to give ET alone, although patients with significant comorbidities or poor performance status may occasionally not be appropriate. All three clinical CDK4/6 inhibitors (abemaciclib, palbociclib, and ribociclib) have the same effect on progression-free survival (PFS) and are all recommended by the guidelines in combination with an AI or fulvestrant in patients who relapse on adjuvant AI.[72,73] Although ribociclib improved overall survival in combination with AI,[39] with abemaciclib numerically improving survival, palbociclib did not appear to improve OS in the PALOMA-2 trial.[74] Overall survival was an underpowered secondary end point, and there was substantial cross-over to receive CDK4/6 inhibitor after progression, and a negative finding for PALOMA-2 is a distinct possibility. Potentially, there is a genuine difference between palbociclib and ribociclib/abemaciclib that is somehow not captured in the PFS readout. Indeed, palbociclib is a relatively less selective inhibitor of CDK4,[75] compared with CDK6, with CDK6 inhibition thought to possibly limit the activity because of CDK6 inhibition in the bone marrow resulting in toxicity. Abemaciclib also weakly inhibits CDK2,[76] which may enhance abemaciclib activity.

Selection of which inhibitor to use in clinical practice is a matter of physician choice, with the use of palbociclib plus AI since the PALOMA-2 OS readout. Abemaciclib has a higher incidence of diarrhea, fatigue, and thromboembolism.[77] Both ribociclib and palbociclib have a higher incidence of bone marrow suppression and neutropenia. Ribociclib has a higher incidence of nausea and liver function test abnormalities (compared with palbociclib in cross-trial comparison) and rarely QTc prolongation.[78] General clinical advice is to consider switching between CDK4/6 inhibitors if the patient develops side effects characteristic of one inhibitor and not the other.[72]

Biomarker Selection of Patients for Advanced CDK4/6 Therapy

Given the efficacy of CDK4/6 inhibitors and relatively good tolerance, a high level of evidence for a biomarker would be necessary to omit therapy. Rarely, biomarker subsets have relatively advanced evidence of true resistance to therapy, especially in cancers with *RB1* loss mutations/deletions[79] (approximately 2% of treatment-naive breast cancer) and cancers with a basal-like gene expression profile[80] (approximately 2% of treatment-naive breast cancer). However, establishing both biomarkers robustly is challenging in the clinic, for example, identifying cancers with homozygous *RB1* loss (would be resistant) instead of heterozygous loss (not resistant), and the guidelines do not recommend testing for these defects. Rare *FAT1* mutations may also signify true resistance, but with the same challenge of identifying true homozygous loss.[81]

Multiple markers of lower benefit from CDK4/6 inhibitors have been identified, including *BRCA2* germline mutations,[82] high *CCNE1* expression,[83] gene expression signatures of high E2F signaling,[83] and high interferon signaling.[84] None of these are generally considered clinically useful, as the activity of CDK4/6 inhibitors is lower but still present in the resistant groups. Postmarketing surveillance has demonstrated a low approximately 1%-2% rate of pneumonitis on all three CDK4/6 inhibitors,[85] and physicians should be alert to this possibility in patients with respiratory symptoms.

Therapy After Progression on CDK4/6 Inhibitor

A substantial evidence base is developing on treatments after progression on CDK4/6 inhibition. After progressing on AI plus CDK4/6 inhibitor, it is clear that single-agent ET is substantially less efficacious than after progression on AI. For example, in the CAPITELLO-291 study, the median PFS on fulvestrant alone was 2.6 months (95% CI, 2.0 to 3.5) with previous CDK4/6 inhibitor treatment and was 7.2 months (95% CI, 4.8 to 7.9) without previous CDK4/6 inhibitor treatment.[86] Single-agent ET must be used cautiously in patients post-CDK4/6 inhibition and largely reserved for patients with low-volume nonvisceral disease, strong ER expression, and long response to previous ET, as well as substantially older or patients with substantial comorbidities. The exception may be those with *ESR1* mutations in liquid biopsies at progression,[53] as discussed in the next section.

Substantial evidence suggests that PI3 kinase inhibition with alpelisib in patients with *PIK3CA* mutations[87] is active post-CDK4/6 inhibition, and AKT inhibition with capivasertib (not licensed at the time of writing) in patients with AKT1 pathway variants (*PIK3CA*/*AKT1*/*PTEN* mutations) is also active post-CDK4/6 inhibition. Generally, such combination therapy should be considered instead of single-agent ET post-CDK4/6 inhibition. There are little data on the activity of mTOR inhibition post-CDK4/6 inhibitor, but there is no scientific rational to expect lower activity of everolimus, and the use of everolimus in *PIK3CA* or *AKT* pathway wild-type patients is generally considered.

Limited data suggest that continuation of CDK4/6 inhibition and changing of ET partner are beneficial. The phase II MAINTAIN trial randomly assigned patients who had progressed on ET plus CDK4/6 inhibitor to exemestane or fulvestrant with or without ribociclib,[88] with improvement in PFS (HR, 0.56; 95% CI, 0.37 to 0.83; $P = .004$). However, the phase II PACE study did not observe a benefit for continuing palbociclib in a similar random assignment (HR, 1.11; $P = .62$).[89] Few patients in MAINTAIN had previous ribociclib, whereas 90.9% of patients in PACE had previous palbociclib, possibly providing an explanation for the difference between studies. As both studies are phase II studies, there remains no high-quality evidence to support continuing CDK4/6 inhibition after progression in clinical practice; although if this is done, a switch in CDK4/6 appears advisable. Abemaciclib in phase II trials also appears to have single-agent efficacy after progression on a different CDK4/6 inhibitor.[90] There is also evidence that switching ET backbone on molecular, but not clinical progression, may be beneficial. In the PADA-1 trial, patients on AI plus palbociclib who develop detectable *ESR1* (ER) mutations in circulating tumor DNA liquid biopsies before clinical progression had improved PFS when AI was switched to fulvestrant (HR, 0.61, $P = 0.0040$),[91] and this is being investigated further in the SERENA-6 trial (ClinicalTrials.gov identifier: NCT04964934).

Adjuvant CDK4/6 Inhibition

Two years of adjuvant abemaciclib, in addition to AI with or without ovarian suppression, has become the standard therapy for high-risk patients with ER-positive and HER2-negative breast cancer. The initial results of the MONARCH-E trial showed benefit from adjuvant abemaciclib (HR, 0.75), although the report was after only a median follow-up of 15.5 months, with very few patients having completed a full 2 years of follow-up.[92] A recent update, after 42 months, demonstrated a further strengthening of benefit with an invasive DFS at 4 years of 85.5% in the abemaciclib arm versus 78.6% (HR, 0.653; 95% CI, 0.567 to 0.753; $P < .0001$).[48] There was clear evidence of carryover benefit with piecemeal analysis in 1-2 years of follow-up where HR = 0.674 and in 3+ years (after completing abemaciclib) where HR = 0.602.

Follow-up at this time is immature, but the clear evidence for hangover benefit beyond stopping adjuvant abemaciclib and 6.9% absolute benefit at 4 years of follow-up clearly suggests that abemaciclib should be offered to all high-risk patients within the criteria of the trial (four or more positive lymph nodes or one to three lymph nodes with one of the following additional features: tumor >5 cm, grade 3 tumor, and Ki67 >20%). Translational research on the MONARCH-E trial is eagerly awaited, and so far it is clear that high proliferation cancers (Ki67 > 20%) and lower proliferation cancers (Ki67 ≤20%) derive the same relative benefit,[48] although cancers with high Ki67 derive greater absolute benefit because of the association with a higher risk of relapse.[48]

The adjuvant setting appears to draw a clear difference between palbociclib and abemaciclib. In marked contrast to MONARCH-E, there was no benefit from 2 years of adjuvant palbociclib in PALLAS (HR, 0.96; 95% CI, 0.81 to 1.14; $P = .65$).[45] Although perhaps differences in trial design (lower-risk patients in PALLAS) and compliance (42% of patients discontinued palbociclib before the planned 2 years) might explain some difference; by far, the most plausible difference is between the two drugs in this adjuvant setting. In the metastatic setting, abemaciclib has a higher single-agent response rate in heavily pretreated endocrine-resistant disease than palbociclib and ribociclib. Early relapses in the adjuvant setting are dominated by cancers with high proliferation, which are relatively insensitive to ET, potentially matching more single-agent data in the metastatic setting. Abemaciclib weakly inhibits CDK2,[76] which possibly explains the higher level of activity in endocrine-resistant cancers and might possibly provide a mechanistic understanding of the different activity seen in the adjuvant setting.

There are no data yet on the treatment of patients who relapse after adjuvant abemaciclib. In the absence of evidence, it would seem reasonable in clinical practice to offer CDK4/6 inhibition again in the metastatic setting for those with at least a gap of 24 months since completing abemaciclib, and this may extend less certainly to include those with at least a gap to 12 months. It is unlikely that patients who relapse on adjuvant abemaciclib, or within a year of stopping, could derive significant benefit from further CDK4/6 inhibition at the time of relapse.

SERDs in Breast Cancer: Where Do We Stand?

The majority of breast cancers express ER α, which has been widely and successfully prosecuted as a drug target, although various classes of endocrine therapies approved for the treatment of ER+ breast cancer exist (Fig 1).[93]

AIs, such as anastrozole, letrozole, and exemestane, block the conversion of androgens to estrogen, decreasing levels of circulating estradiol (E2) and therefore reducing the activation of ER. SERMs (ie, tamoxifen) exert their action by binding to intracellular ERs and competing with estrogen. SERDs, such as fulvestrant and others, will inhibit the transcription of ER-regulated genes by hampering the open chromatin conformation of the ER when binding to the receptor, destabilizing it, and causing impaired mobility, which will result in the downregulation and degradation of the receptor protein.[94]

Intramuscular administration of fulvestrant limits its dosing, prompting the development of orally administered alternatives. Furthermore, ET resistance is a significant limitation of luminal breast cancer treatments, as approximately 15%-30% of patients will present de novo resistance mechanisms and 30%-40% will acquire resistance during ET.[95,96]

One of the most recognized and studied molecular mechanisms of therapeutic resistance is the appearance of ESR1 mutations, leading to ligand-independent activity and promoting tumor growth plus resistance to ET. Prevalence of such mutations depends on the duration of ET and can be detected in 20%-40% of patients previously receiving AI for mBC. Mutation rates have been observed to be much lower in the case of recurrent breast cancer and <1% in ET-naive patients, hence suggesting the acquisition of ESR1 mutations during AI treatment in the metastatic setting.[97,98]

ESR1 mutations can be detected via noninvasive detection of circulating tumor DNA (ctDNA) in the patient's plasma. Clinical trials (such as the SoFEA trial) have already demonstrated significantly better PFS with the use of SERDs (fulvestrant) than with AIs (exemestane). Furthermore, currently evaluated strategies implementing the use of ctDNA to determine ESR1 mutations may result in the establishment of a new predictive biomarker with implications in decision making for ET selection (ie, PADA-1 trial).[91,99]

Another established ET resistance mechanism is the growth promoting PI3K-AKT-mTOR and RAS/RAF/MEK/ERK pathways, through which ER-mediated transcription without estradiol binding can be reactivated, driving ER signaling-independent resistance. In addition, mutations in the cyclin-dependent kinase 4/6 (CDK4/6) cyclin D1 axis will frequently appear in ER+ BC inducing inactivation of retinoblastoma protein and resulting in tumor progression through cell cycle.[13,102]

Current Data With SERDs

First-line treatment of patients with ER+ mBC has pivoted to the use of CDK4/6 inhibitors in combination with ET; however, some patients will develop resistance to this approach, frequently because of ESR1 mutations. Currently, novel oral SERDs are being explored in this setting. Novel SERDs are associated with a higher bioavailability in comparison with fulvestrant, leading to greater efficacy.[103] Furthermore, oral administration results in a more convenient approach, as opposed to intramuscular for fulvestrant. Recently, data from phase II and III clinical trials have been communicated, highlighting differences for some of the new oral SERDs in development.

The first oral SERD to demonstrate significant survival improvement over standard-of-care treatment was elacestrant in the open-label, international, phase III EMERALD trial. In this study, patients with ER+/HER2– ABC were randomly assigned to receive oral elacestrant or standard-of-care ET (fulvestrant, anastrozole, letrozole, or exemestane), with two primary end points: PFS in all population and PFS in patients harboring ESR1 mutation.

Of the 478 patients randomly assigned, 228 had ESR1-mutated tumors. Elacestrant significantly improved median PFS in comparison with SOC (HR, 0.70; $P = .002$). The PFS rates in all patients at 6 months and 12 months were 34.3% and 22.3%, respectively, with elacestrant, compared with 20.4% and 9.4%, with SOC (HR, 0.70; $P = .0018$). For patients with *ESR1* mutations, PFS rates at 6 months and 12 months were 40.8% and 26.8%, respectively, with elacestrant, compared with 19.1% and 8.2% at 6 months and 12 months, respectively, with SOC (HR, 0.55; $P = .0005$).[53] Most adverse events (AEs) were mild, and no grade 4 treatment-related AEs (TRAEs) were reported. The most common AEs observed with elacestrant were nausea (35.0%), fatigue (19.0%), and decreased appetite (14.8%); grade 3 and 4 AEs were reported in 27.0% of patients in the elacestrant arm versus 20.5% in the SOC arm.[53] On the basis of these data, US Food and Drug Administration granted approval to elacestrant for postmenopausal women with ER+, HER2-negative, ESR1-mutated ABC or mBC with disease progression following at least one line of ET. Determination of ESR1 mutations is required through liquid biopsy, which is an approved companion diagnostic tool.[53] In addition, longer duration of benefit on previous endocrine and CDK4/6 inhibitor benefit was associated with more pronounced elacestrant benefit.

Giredestrant is another oral SERD that has been investigated compared with ET (fulvestrant or an AI) in patients with HR-positive and HER2-negative ABC, progressing after one or two lines of previous systemic therapy. The primary end point (investigator-assessed PFS) was not met. There was a numerical improvement of PFS with giredestrant compared with ET (5.6 months *v* 5.4 months; HR, 0.81; $P = .1757$). Higher clinical benefit and objective response rates were reported with giredestrant. PFS benefit was reported to be more pronounced in patients with ESR1 mutations (HR, 0.60; $P = .0610$).[104]

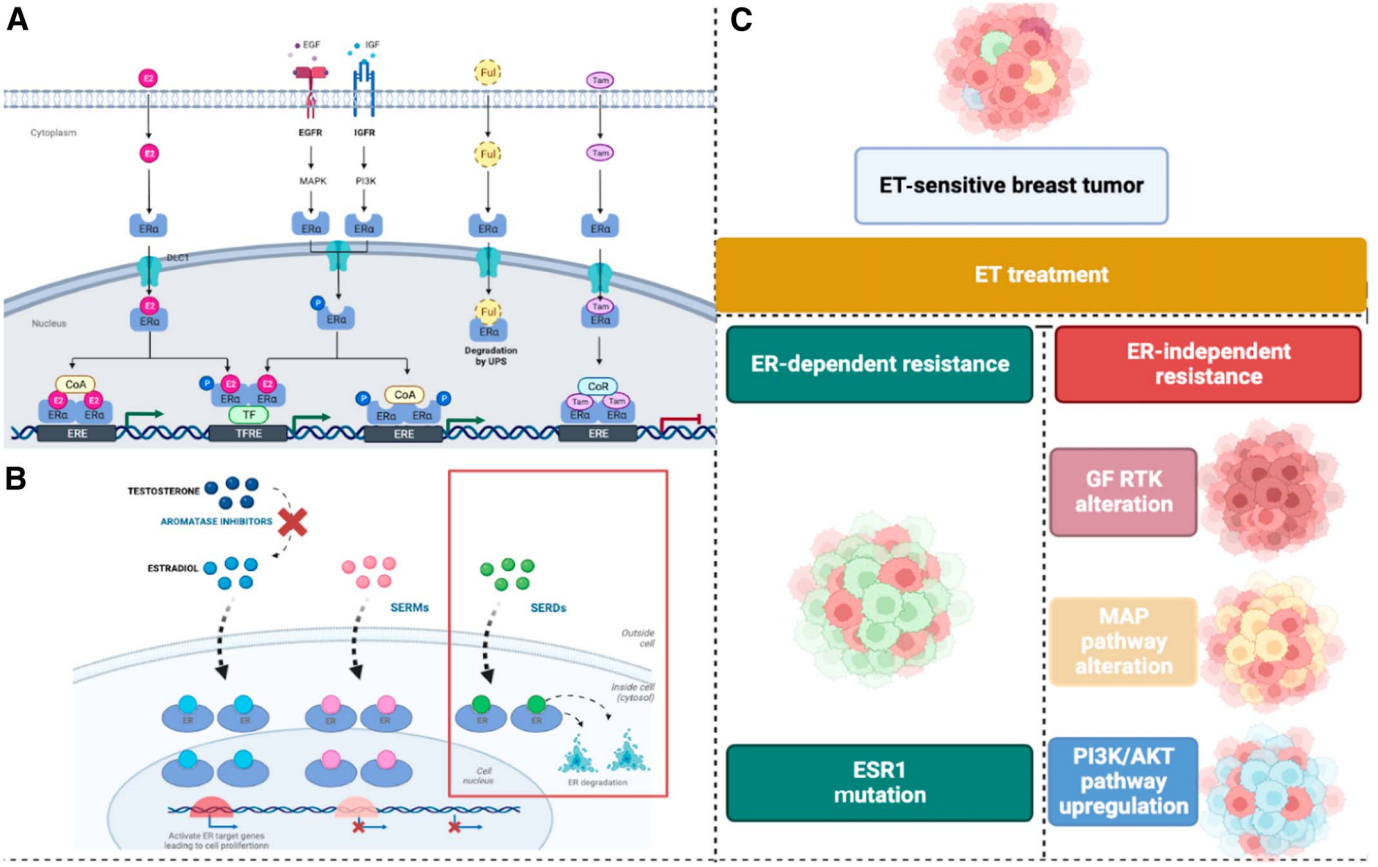

FIG 1. (A) Molecular pathways involved in ER functionality and the evolving mechanisms of resistance to ET. (B) Endocrine therapies and their mechanisms of action: AIs, SERMs, and SERDs. AIs block estrogen production through inhibition of androgen conversion to estrogens. SERMs inhibit the formation of the estrogen-ER complex. SERDs reduce the ability of translocation to the nucleus, thus inhibiting the transcription of ER-regulated genes and inducing the degradation of the ER-SERD complex consequently from impaired mobility. (C) ET resistance mechanisms upon ER dependence: ESR1 mutations will appear consequently after treatment with ET and mediate resistance through constitutive ER activity. ER-independent resistance is mediated via various mechanisms, such as mutations or amplifications of growth factor-driven RTKs (HER2, EGFR, and FGFR), alterations in MAPK pathway components (ie, KRAS, BRAF, MAP2K1, and NF1), and upregulation in the PI3K/AKT pathway. AI, aromatase inhibitor; AKT, protein kinase B; CDK, cyclin-dependent kinase; CoA, coactivator; CoR, coactivator receptor; E2, estradiol; EGFR, epidermal growth factor receptor; ER, estrogen receptor; ERE, estrogen response element; ERK, extracellular signal-regulated kinase; ESR1-mut, ESR1-mutant; ESR1-wt, ESR1 wild-type; ET, endocrine therapy; FGFR, fibroblast growth factor receptor; Ful, fulvestrant; GF RTK, growth factor-driven receptor tyrosine kinase; HER2, human epidermal growth factor receptor 2; IGF, insulin growth factor; MAPK, mitogen-activated protein kinase; MEK, meiotic chromosome-axis-associated kinase; mTOR, mammalian target of rapamycin; p, phosphate; PI3K, phosphoinositide 3-kinase; Rb, retinoblastoma; SERD, selective estrogen receptor degrader; SERM, selective estrogen receptor modulator; Tam, tamoxifen; TF, transcription factors; UPS, ubiquitin-proteasome system. Adapted from Lloyd et al[100] and Wang and Tang.[101]

A further oral SERD that demonstrated promising antitumor activity in initial phase I/II studies was amcenestrant. In the phase II AMEERA-3 trial, amcenestrant was compared with ET of physicians' choice in postmenopausal patients with HR-positive and HER2-negative ABC who had received ≤2 previous lines of ET and ≤1 previous chemotherapy or ≤1 targeted therapy for advanced disease. The study did not meet its primary end point, with the median PFS of 3.6 versus 3.7 months (HR, 1.051), and the development of amcenestrant was discontinued.[105]

Camizestrant is also a new oral SERD explored in the SERENA-2 trial: a phase II study in which 240 previously treated patients with HR-positive and HER2-negative ABC were randomly assigned to receive oral camizestrant at 75 or 150 mg once daily or fulvestrant with approximately one third of the patients having ESR1 mutations. Camizestrant demonstrated a statistically significant benefit in the median PFS at 75 mg and 150 mg, compared with fulvestrant (7.2, 7.7, and 3.7 months and adjusted HR, 0.58 and 0.67, respectively). In patients with ESR1 mutations, the median PFS with camizestrant 75 mg was 6.3 months and

9.2 months with camizestrant 150 mg while the PFS with fulvestrant was reported at 2.2 months (HR, 0.33 and 0.55, respectively). Regarding safety, grade 3 or above TRAEs occurred in 1.4% of patients receiving camizestrant 75 mg, 2.7% receiving camizestrant 150 mg, and 1.4% in those treated with fulvestrant.[106]

Tolerance of oral SERDs has generally been acceptable, with the most class-related frequent side effects being grade 1-2 nausea and fatigue. Arthralgia and hot flushes, common with AIs, have also been seen with some SERDs. For elacestrant, gastrointestinal toxicity has been reported as nausea, dyspepsia, and vomiting, although capsule formulation had a higher prevalence compared with tablets. Other toxicities of special interest are bradycardia, reported with camizestrant and giredestrant, and visual disturbance, only with camizestrant.[107,108]

Oral SERDs have demonstrated promising results in patients with ESR1 mutations. However, some tumors may lose sensitivity to ET by the activation of other pathways such as membrane receptors (HER2, EGFR, and FGFR), upregulation of oncogenic transduction (MAPK and PI3K/AKT), and dysregulation of the cell cycle through the cyclin D1/CDK4/6 pathway, hence the rationale for combinations with other targeted drugs.

Currently, oral SERDs are being studied in combination with CDK4/6 blockade in treatment-naive ABC where ESR1 mutations are less frequent (SERENA-4, ClinicalTrials.gov identifier: NCT04711252; persevERA, ClinicalTrials.gov identifier: NCT04546009). Other examples of combinations with targeted therapies are the EMBER clinical trial evaluating imlunestrant combined with alpelisib (ClinicalTrials.gov identifier: NCT04188548); the AKT inhibitor capivasertib is being combined with camizestrant in the SERENA-1 trial (ClinicalTrials.gov identifier: NCT03616587); camizestrant and imlunestrant are also being explored in combination with the mTOR inhibitor, everolimus, which acts as a downstream of the PI3K/AKT pathway.

Finally, these new ER-targeting agents are being evaluated in the window of opportunity (WoO) and neoadjuvant studies, allowing for in vivo activity evaluation, biomarker and pharmacodynamics change assessment, and prediction of their activity in the adjuvant setting.[109,110] ELIPSE (with elacestrant, ClinicalTrials.gov identifier: NCT04797728) SERENA-3 (camizestrant, ClinicalTrials.gov identifier: NCT04588298), and CooPERA (giredestrant, ClinicalTrials.gov identifier: NCT04436744) are some of the examples of WoO studies evaluating novel SERDs. Data from the CooPERA study have already demonstrated superior Ki67 reduction with 2 weeks of single-agent giredestrant versus anastrozole and have guided the development of studies in the adjuvant setting, such as the lidERA trial (ClinicalTrials.gov identifier: NCT04961996).

Liquid biopsy in the adjuvant and metastatic setting is an opportunity for the longitudinal collection of ctDNA, with early detecting of the emergence of ESR1 mutations, and guiding the design of studies where switching the treatment is prompted by the discovery of these mutations (SERENA-6, ClinicalTrials.gov identifier: NCT04964934).

FUTURE CONSIDERATIONS

We are witnessing the arrival of an improved drug class, resulting in an encouraging therapeutic strategy for patients with tumors expressing ESR1 mutations in the metastatic stage, as well as the dawn of the liquid biopsy era. Significant progress can be achieved by developing methods to identify patients whose tumors continue to have ER signaling in the metastatic stage, with greater precision than just identifying ESR1 mutations. This will enable the identification of individuals who are most likely to benefit from new therapies, a crucial step forward.

On the other hand, resistance to treatment may require several driver events to occur synergistically. In pretreated mBC, tumor heterogeneity suggests that genomic and nongenomic resistance drivers may emerge simultaneously during therapy. Therefore, further research is critical to understand the impact of these drivers on drug sensitivity.

The potential for next-generation SERDs to revolutionize the treatment of ER+ breast cancer is significant. As we continue to gather more clinical trial data, assessing the effectiveness and tolerability of these agents as ET backbones in monotherapy and in combinations will be essential to understand their impact on outcomes and identify where they fit into standard practice.

BREAST CANCER

Advances in the Management of Menopausal Symptoms, Fertility Preservation, and Bone Health for Women With Breast Cancer on Endocrine Therapy

Matteo Lambertini, MD, PhD[1,2]; Luca Arecco, MD[1,2]; Terri Lynn Woodard, MD[3,4]; Audrey Messelt, MD[4]; and Kristin E. Rojas, MD, FACS, FACOG[5,6]

overview

In patients with hormone receptor–positive early-stage breast cancer, adjuvant endocrine treatment administered for up to 5-10 years after diagnosis significantly reduces the risk of recurrence and death. However, this benefit comes with the cost of short- and long-term side effects that may negatively affect patients' quality of life (QoL) and treatment adherence. Among them, the prolonged estrogen suppression associated with the use of adjuvant endocrine therapy in both premenopausal and postmenopausal women can induce life-altering menopausal symptoms, including sexual dysfunction. Moreover, a decrease in bone mineral density and an increased risk of fractures should be carefully considered and prevented whenever indicated. For young women diagnosed with hormone receptor–positive breast cancer with unfulfilled childbearing plans, several challenges should be addressed to manage their fertility and pregnancy-related concerns. Proper counseling and proactive management of these issues are critical components of survivorship and should be pursued from diagnosis through the breast cancer care continuum. This study aims to provide an updated overview of the available approaches for improving the QoL of patients with breast cancer receiving estrogen deprivation therapy, focusing on advances in the management of menopausal symptoms, including sexual dysfunction, fertility preservation, and bone health.

INTRODUCTION

Hormone receptor–positive disease is the most common breast cancer subtype, and endocrine therapy is the mainstay of treatment. In early-stage breast cancer, adjuvant tamoxifen or an aromatase inhibitor (AI), in addition to ovarian function suppression (OFS) in premenopausal women, are associated with a significant reduction in the risk of recurrence and death.[1-3] However, this benefit comes with the cost of potentially distressing short- and long-term side effects that negatively affect patients' quality of life (QoL) and decrease treatment adherence.[4]

The acute toxicity of (neo)adjuvant chemotherapy is often reversible and generally lasts for a limited treatment period. By contrast, adjuvant endocrine therapy is administered for up to 10 years, during which side effects may be constant and, if untreated, irreversible.[5] While the expected benefits of endocrine therapy in reducing disease recurrence are well known, its undesirable side effects are underestimated and only sometimes optimally managed.[6] Nowadays, treating the physical and psychological effects of cancer and its therapy are considered critical components of survivorship care,[7] and not addressing these concerns can adversely affect treatment adherence. Proactive management of the symptoms and associated burden of endocrine therapy is a complex balance of tolerability, treatment adherence, and QoL.[4]

This study aims to review the available approaches for improving the QoL of patients with breast cancer who are receiving endocrine therapy, focusing on advances in the management of menopausal symptoms, including sexual dysfunction, fertility preservation (FP), and bone health.

HOT FLASHES AND GENITOURINARY SYNDROME OF MENOPAUSE

While antiestrogen therapy effectively reduces breast cancer risk in both the preventive and adjuvant settings, prolonged estrogen suppression below the normal postmenopausal range and estrogen receptor modulation can induce life-altering menopausal symptoms, such as hot flashes, vaginal dryness, and painful sex. Overlooking life-altering disruptions in sexual health and overall well-being influences treatment adherence and negates our efforts to improve oncologic outcomes.[4]

Vasomotor Symptoms

One of the hallmarks of estrogen suppression is the onset of hot flashes caused by a disruption in the

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Addressing the physical and psychological effects of cancer and its treatment are critical components of survivorship care. For patients receiving adjuvant endocrine therapy, proper counseling and proactive management of treatment sequelae and their associated burden will improve patients' quality of life and optimize treatment adherence.
- Vasomotor symptoms are reported in more than 80% of women on antiestrogen therapy and are typically more severe in younger patients. Aside from behavioral modifications, clonidine, gabapentin, attenuated doses of antidepressants (serotonin reuptake inhibitors and serotonin-norepinephrine reuptake inhibitors), and oxybutynin effectively decrease hot flash frequency and severity. However, treatment should take into account patient comorbidities and side effect profiles.
- Genitourinary syndrome of menopause can manifest as not only vaginal dryness but also increased infections, painful sex, and recurrent bladder infections. Treatment should include a discussion on reducing contact with potential irritants, regular use of a nonhormonal moisturizer, and an appropriate lubricant for sexual activity. Some patients may also benefit from vaginal dilators and pelvic floor physical therapy. Patients with severe disruptions in the genitourinary examination or nonresponsive to nonhormonal therapies should be offered low-dose vaginal estrogen or dehydroepiandrosterone after discussing the potential risks and benefits of treatment.
- Young women with breast cancer are at risk for infertility after receiving gonadotoxic chemotherapy. While endocrine therapy is not directly gonadotoxic, the time during which it is administered results in additional age-related declines in fertility. Options for fertility preservation should be discussed and offered before treatment to maximize opportunities for conception. It is reasonable for appropriately selected women to take a break from endocrine therapy after 18-30 months to try to conceive.
- Estrogen deprivation is a significant cause of reduced bone mineralization and increased risk of fractures. Hence, in patients with breast cancer receiving adjuvant endocrine therapy, proper attention to and monitoring of bone health is required. Whenever indicated, several strategies exist for preventing bone demineralization and reducing the risk of fractures in this setting.

hypothalamic perception of core body temperature. Hot flashes are common in women on endocrine therapy and are reported in 80% of women on tamoxifen and 93% with the addition of ovarian suppression. Hot flashes are typically more severe in younger patients and can negatively affect QoL.[4]

Aside from behavioral modifications such as exercise, avoiding triggers, and dressing in layers, randomized trials have shown cognitive behavioral therapy to be effective.[8] Data are mixed regarding the effectiveness of acupuncture.[9] Clonidine is a centrally acting alpha agonist that showed a 37% reduction in hot flashes but may lead to sleep disruption, dry mouth, and constipation.[10] Gabapentin is only effective at the 900 mg/d dose (300mg three times/day), which can induce significant sedation if not carefully tapered up.[11] Serotonin reuptake inhibitors (fluoxetine and paroxetine)[12,13] and serotonin-norepinephrine reuptake inhibitors (venlafaxine)[14] resulted in a more than 50% reduction in hot flashes, but side effects and concern for interaction with tamoxifen have limited their use.[15] Of note, sexual dysfunction symptoms, such as hypoactive desire and orgasm dysfunction, are prevalent in up to 80% of individuals taking antidepressants.[16] Oxybutynin (2.5 mg or 5 mg twice a day) was shown to significantly reduce hot flashes and improve QoL measures in a recent placebo-controlled trial and seems to be relatively well-tolerated. Side effects of oxybutynin during the 6-week course of the trial resembled those of other anticholinergics and include dry mouth, abdominal pain, and difficulty urinating.[17]

Genitourinary Syndrome of Menopause: Dryness and Atrophic Changes

The constellation of gynecologic sequelae ranging from dryness to recurrent urinary tract infections is termed genitourinary syndrome of menopause (GSM). Patient-reported dryness, itching, stinging, burning, and dysuria should alert the provider to the presence of atrophic changes to the mucosa of the vulva and the vagina. These hypoestrogenic effects may prompt women to apply a variety of over-the-counter topical therapies, including feminine washes, alcohol-based wipes, supermarket moisturizers, and other products with artificial fragrances. Patients should be counseled on the difference between moisturizers (to be used at regular intervals for treating GSM) and lubricants (PRN application), and encouraged to select their own lubricant while paying attention to potential offending ingredients. Silicone-based lubricants are preferred due to duration of action and less sticky, although water-based lubricants should be used with silicone non-compatible condoms or silicone devices.

The first step in mitigating the irritation and burning associated with GSM is minimizing exposure to potential irritants.

Patients should avoid potential offenders and start a vaginal moisturization regimen with a simple emollient such as single-ingredient organic coconut oil, which also has natural antimicrobial and antifungal properties[18]; however, it should not be used with condoms. A nonhormonal vaginal moisturizer with hyaluronic acid can be added once the burning symptoms abate, and these are available in creams, gels, and suppositories.[19] Vaginal moisturizers are intended to be used at least several times per week on a long-term basis. Patients should be counseled regarding the difference with lubricants, which have only short-term effectiveness for immediate sexual activity. Finally, patients should be encouraged to read labels and avoid products with artificial fragrances, parabens, petroleum, propylene glycol, and glycerin.[20]

Consistent use of a hyaluronic acid vaginal moisturizer can significantly improve symptoms of dryness, irritation, and painful sex.[19] However, prolonged estrogen deprivation can induce more dramatic changes in vaginal architecture, resulting in vaginal shortening, stenosis, and even a complete inability to participate in sexual activity. For these patients, adding low-dose vaginal hormones (either estradiol or dehydroepiandrosterone [DHEA]) can improve elasticity and promote collagen remodeling, especially if used with a vaginal dilator.[21]

The most effective treatment of GSM is vaginal estrogen, which promotes lactobacillus recolonization, increases vaginal blood flow, heightens sexual response, and improves mucosal thickness and elasticity.[21] However, previous pharmacokinetics studies of large (25 mcg given nightly for two weeks, then twice weekly) doses of vaginal estradiol applied to untreated atrophic mucosa found increased estradiol levels in the blood.[22] While usually short-lived, this potential for systemic absorption limits provider comfort with its use in women with a history of breast cancer. Notably, this absorption is less likely to occur with lower doses of commercially available vaginal estradiol tablets (4 mcg and 10 mcg nightly 1-2 times per week), along with the low-dose estrogen vaginal ring (2 mg estradiol delivering 7.5 mcg per 24 hours for 3 months).[23] Application to less atrophic mucosa after a period of nonhormonal moisturizer use may also further decrease the risk of absorption.

Overall, observational data have not suggested an increased risk of breast cancer recurrence with the use of vaginal estrogen.[24] However, a recent retrospective study of Danish patients treated for breast cancer between 1997 and 2004 suggested an association with breast cancer recurrence in a subset analysis limited to those on AIs.[25] Notably, treatment of this cohort predated the use of human epidermal growth factor receptor 2–targeted agents, when recurrence rates were higher, and potential confounders of recurrence, such as physical inactivity and body mass index, were not accounted for. Finally, the timing of recurrence was not defined, which is relevant since early recurrences are more likely to be attributed to residual disease than vaginal estrogen use.[26] Therefore, these data should be considered in the context of balancing an increased risk of recurrence due to noncompliance with endocrine therapy with a possible slight increase in recurrence risk with vaginal estrogen therapy (Fig 1).

For patients with external dyspareunia (pain with insertion), vaginal androgens are an additional adjunct that share some functions of vaginal estrogen but may better address persistent pain. The only US Food and Drug Administration (FDA)–approved androgen for vaginal use is an intravaginal tablet of 6.5 mg prasterone nightly or synthetic DHEA. DHEA is converted to either testosterone or dihydrotestosterone in the vulva and vagina and works similarly to vaginal estradiol while also targeting androgen-specific vulvovaginal receptors for pain. The active forms of testosterone are inactivated by glucuronidation before being eliminated through the circulation.[27] Prasterone's functioning through intracrinology may constitute a more palatable version of vaginal hormones for cancer care providers and patients with cancer. While the testosterone derivatives may be converted to estrogens by aromatase, a double-blind Alliance trial found that women on AIs experienced GSM symptom improvement without significantly increasing circulating estradiol.[28] In summary, vaginal DHEA or vaginal estrogen may be recommended to appropriately counseled patients who do not respond to nonhormonal therapies according to a 2018 American Society of Clinical Oncology Guideline Summary.[29]

Compounded vaginal testosterone is effective for the treatment of GSM. One study found that women treated with a very low dose (300 mcg nightly) for four weeks had serum estradiol levels that remained below the menopausal range cutoff (20 pg/mL).[30] However, there is not currently an FDA-approved version of vaginal testosterone. As with all compounded therapies, patients should be counseled that purity and efficacy are not monitored, and there is no government dosing regulation. The medical indication should be documented, and patients should be provided the financial disclosures of prescribers, pharmacists, and pharmacies. Furthermore, compounding pharmacists should provide written warnings of potential adverse effects, clearly stating that the preparation is not government-approved.[21,31]

GSM: Vaginal Stenosis and Levator Spasm

Untreated GSM may progress to vaginal shortening and narrowing, known as vaginal stenosis (VS). First described in women undergoing pelvic radiation, it has also been reported in women receiving estrogen-suppressing therapies and may manifest as the sensation of hitting a wall when intercourse is attempted. For example, in a South Florida sexual health after cancer program, approximately half of the women on

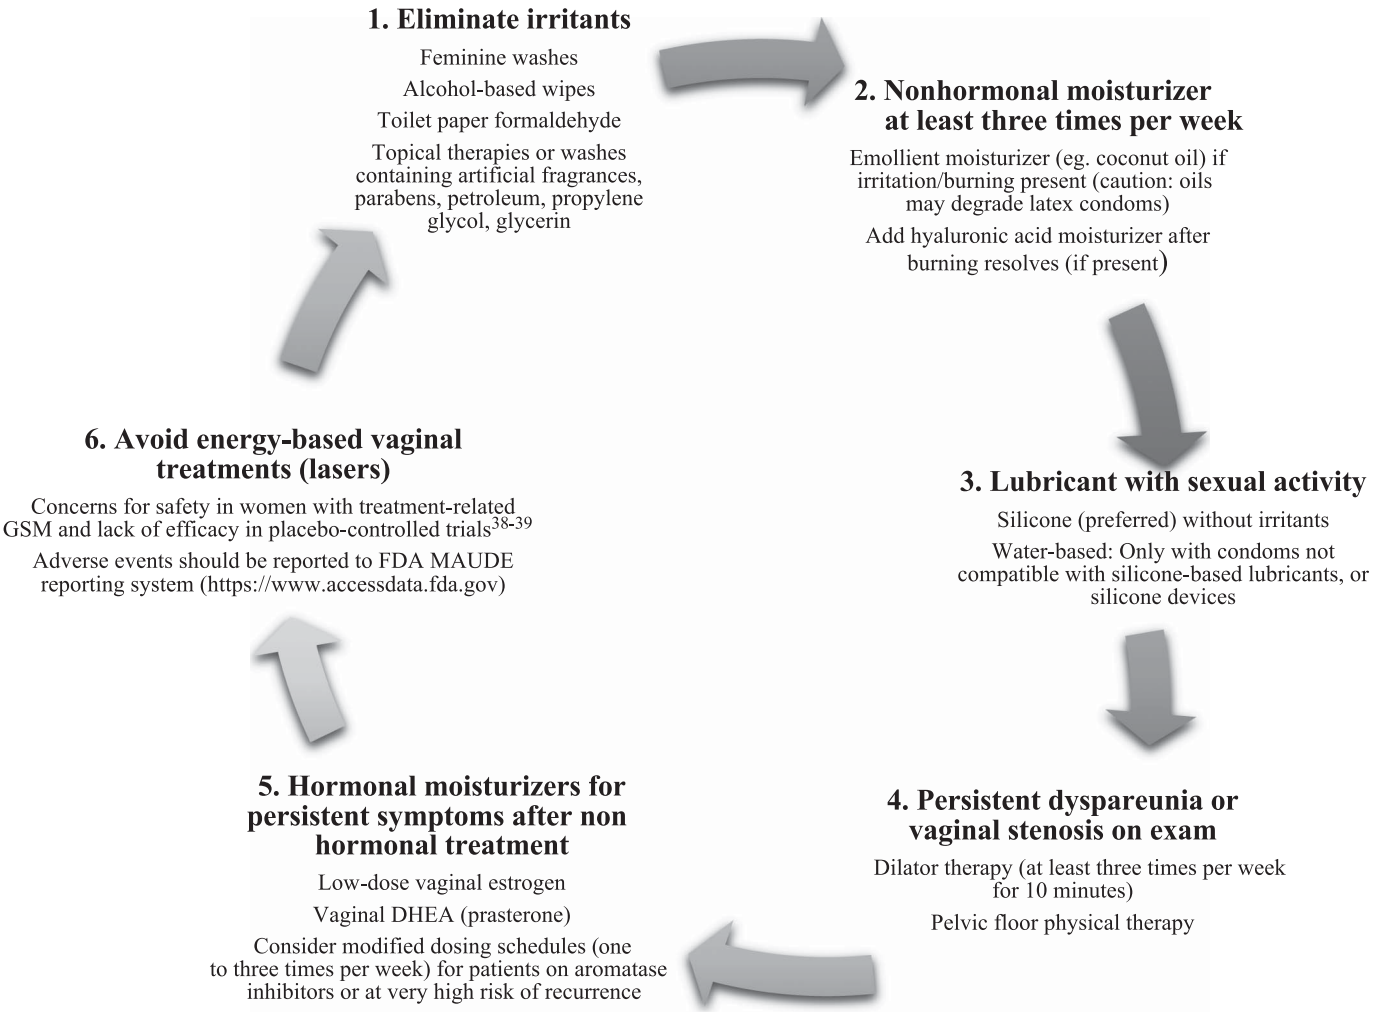

FIG 1. GSM treatment algorithm. FDA, US Food and Drug Administration; GSM, genitourinary syndrome of menopause.

antiestrogen therapy presenting for treatment of sexual dysfunction were found to have VS, making penetrative intercourse extremely painful and/or impossible.[32]

Patients who have experienced episodes of painful sexual activity may develop anticipatory anxiety, leading to pelvic floor muscle spasm during intimacy. For these patients, along with those found to have stenotic changes on examination, treating the atrophic mucosa with an appropriate moisturizer combined with dilator therapy improves elasticity and provides biofeedback during pelvic floor relaxation exercises. The effectiveness of consistent vaginal dilator use (three times per week for 10 minutes per session) has been reported in several studies.[33-35] However, patient adherence to a vaginal dilator regimen is low, with only half continuing use at 6 months.[36] Pelvic health physical therapists can be a critical resource for patients with pelvic floor muscle spasm or VS on pelvic examination. These specially trained physical therapists can work one-on-one with patients to develop a specialized treatment plan, including therapeutic exercise, manual therapy, dilator work, and biofeedback. Future initiatives should focus on improving provider and patient comfort with recommending and using dilators.[37]

Caution: Vaginal Lasers

Inadequate screening and treatment of women's sexual health disorders have fostered an environment where patients seek alternative therapies for treating GSM, some of which include the term vaginal rejuvenation. Intravaginal treatment with energy-based devices such as CO_2 and radioablative lasers is being marketed specifically to patients with breast cancer, but the lack of quality research demonstrating benefit and an ongoing concern for patient harm should dissuade clinicians from directing patients toward these therapies.

These procedures (currently not covered by insurance) were not shown to be effective in two sham-controlled

prospective trials. Eighty-five patients with GSM were randomly assigned to two treatments with a CO_2 laser or a sham laser therapy (where the device was inserted but not completely activated). There was no significant difference between the laser and the sham group with regard to patient-reported symptoms, vaginal health indices, QoL scores, or histologic comparisons.[38] A 2023 double-blind, sham-controlled trial of women on AIs randomly assigned to 5 monthly sessions of laser or sham laser therapy found similar results.[39] Furthermore, patients with cancer treatment-related severe GSM may be susceptible to abnormal healing after treatment with these devices designed to induce microscopic injury followed by collagen formation. Most of the commercially available devices were not FDA-approved to be used in the vagina but instead cleared for use through a fast-tracking program of the FDA known as 510(k), where manufacturers may register their devices without the FDA explicitly examining whether the devices are safe or even effective. In 2018, the FDA issued an advisory warning to consumers about bad actors promoting the unapproved, deceptive devices and described how numerous cases of vaginal burns, scarring, and chronic pain had been reported.[40] At least seven manufacturers were warned to cease advertising their products for an unapproved use. Patients who have experienced adverse events are encouraged to submit their experience to the FDA's Manufacturer and User Facility Device Experience (MAUDE) online database (https://www.accessdata.fda.gov).

FERTILITY PRESERVATION

Breast cancer is the most common malignancy diagnosed in women, and approximately 10% of new cases are diagnosed in women of reproductive age.[41] Unfortunately, many will not have realized or completed their family building plans at diagnosis. With survival rates reaching 90%, FP and family building are paramount.[42] Many women with cancer express their desire to have children, and the interruption or inability to do so causes significant distress. Existing guidelines recommend fertility counseling and FP referral for all individuals at risk for cancer-related infertility; however, overall utilization remains low.[43-45]

Treatment of breast cancer introduces several unique challenges regarding FP. The use of gonadotoxic chemotherapy can result in premature ovarian insufficiency, and the risk of negative reproductive impact increases with age. Alkylating agents are known to be highly gonadotoxic, but many other agents also carry some degree of risk; for newer agents, such as targeted therapies and immunotherapies, the reproductive risk is mostly unexplored.[46] Additionally, for women with hormone receptor–positive disease, the need for endocrine therapy for 5-10 years results in a reproductive hiatus, leading to an age-related decline in fertility.

Many women strongly desire and prefer having biological children, which emphasizes the need to discuss FP measures before initiating cancer treatment. Fortunately, several viable FP options exist for women diagnosed with breast cancer. The standard of care for FP before cancer treatment is assisted reproductive technologies (ART)—embryo cryopreservation and oocyte cryopreservation.[47] Both involve stimulation of the ovaries with injectable gonadotropins to recruit multiple follicles containing oocytes followed by oocyte retrieval (most commonly performed transvaginally). This process takes approximately two weeks and requires multiple visits for monitoring. Recent advances in ART have made FP more feasible for women with a new breast cancer diagnosis, including random start protocols, consecutive ovarian stimulation cycles (when feasible from an oncology perspective), and estrogen-lowering adjunctive agents.

While ovarian stimulation cycles are traditionally started based on menstrual cycle timing, random start protocols allow for the initiation of stimulation at any point during the menstrual cycle. This is of particular benefit in women for whom delaying gonadotoxic treatment for more than two weeks is not possible. Fortunately, outcomes of random start protocols are comparable with traditionally timed protocols, with the greatest difference being slightly longer periods of stimulation and higher doses of gonadotropins used.[48] While pursuing FP may slightly delay the initiation of cancer treatment in women with early-stage breast cancer, there is no difference in invasive disease-free survival (74 *v* 67%) or overall survival (84 *v* 81%) at 5 years.[49]

Consecutive ovarian stimulation cycles (ie, repeated stimulation of the ovaries over successive cycles) are safe and effective for FP in selected patients with breast cancer who may have lower ovarian reserve and oocyte yields by increasing the total number of oocytes retrieved without negatively affecting cancer treatment outcomes.[50]

One safety concern when performing ART for women with estrogen-sensitive breast cancer is the potential effect of the supraphysiologic estradiol levels reached during ovarian stimulation on tumor progression. Administration of AIs (letrozole) or selective estrogen receptor modulators (tamoxifen) in addition to stimulatory gonadotropins allows multifollicular development without a significant increase in estradiol levels. Use of these adjunctive agents during ovarian stimulation has resulted in comparable oocyte yield without increasing the risk of recurrence or compromising overall survival.[51,52]

There are additional benefits to using ART in women with hereditary breast cancer syndromes. Having embryos from ART allows for preimplantation genetic testing for monogenomic/single-gene defects (PGT-M) where cells sampled from fertilized embryos are tested for genetic mutations.[53]

This allows for the selection of embryos that do not carry mutations known to increase the risk of cancer. There is also evidence that *BRCA* carriers are at increased risk for diminished ovarian reserve (DOR), a loss of ovarian function that places them at increased risk of infertility even in the absence of gonadotoxic cancer treatment, although the association of *BRCA* pathogenic variants and DOR remains controversial.[54] The use of ART allows women with DOR to maximize their reproductive potential in a way they would not be able to with attempts at spontaneous conception. Finally, women with germline *BRCA* pathogenic variants are recommended to undergo risk-reducing bilateral salpingo oophorectomy between age 35 and 40 years for *BRCA1* carriers and between age 40 and 45 years for *BRCA2* carriers or after childbearing is complete; if they have cryopreserved eggs or embryos, they still have the opportunity to conceive without delaying surgery.[55]

There are women for whom ART is not an appropriate option, most commonly because of limited time or medical concerns. These women have alternative FP options that may be considered. Ovarian tissue cryopreservation (OTC; ie, the surgical removal of an ovary or ovarian tissue fragments typically completed via laparoscopy with cryopreservation of ovarian cortex and eventual reimplantation of this tissue) may be appropriate for women younger than 35 years who do not have time or do not wish to undergo ovarian stimulation. While OTC is no longer considered experimental and has resulted in approximately 200 births worldwide,[56] it is much less widely practiced than oocyte and/or embryo cryopreservation and should only be performed by providers with experience in this technique.[57-59]

Ovarian suppression is another option for minimizing the impact of chemotherapeutic agents on ovarian function and potentially also on fertility. Gonadotropin-releasing hormone (GnRH) agonists are used to decrease the release of gonadotropins from the pituitary gland, decreasing follicular development in the ovary. This causes the ovaries to become quiescent during gonadotoxic treatment and seems to reduce the risk of chemotherapy-induced premature ovarian insufficiency and to improve the rates of pregnancy after treatment completion.[60,61] While the use of GnRH agonists reduces the likelihood/risk of developing chemotherapy-induced premature ovarian failure in premenopausal women with breast cancer, for patients interested in FP, it should not be substituted for other methods of FP. The menstrual suppression that results from the use of GnRH agonists is an additional benefit, which reduces concerns regarding menstrual bleeding and anemia in the setting of chemotherapy-related bone marrow suppression. Patients who receive ovarian suppression with GnRH agonists during chemotherapy should be counseled on the high likelihood of the acute onset of side effects associated with hypoestrogenemia, including hot flashes, night sweats, changes in mood, insomnia, fatigue, diminished sexual interest, vaginal dryness, dyspareunia, and bone pain.

In patients who have completed cancer treatment resulting in infertility, several options exist for family building, including use of donor oocytes, donor embryos, or traditional adoption. However, these options do require investment of significant time, energy, and money and are not always widely available.

Historically, women with a history of breast cancer were advised not to become pregnant, but recent data have changed the paradigm for pregnancy after breast cancer. Available data show that in women who completed proper treatment and follow-up for breast cancer, pregnancy does not worsen oncologic outcomes,[62,63] even with a history of hormone receptor–positive disease[64,65] or in *BRCA* carriers.[66] Despite these outcome data, women with a history of breast cancer understandably express fear of recurrence in the context of stopping endocrine therapy for childbearing.[67] Fortunately, recent data from a large international trial (POSITIVE trial) showed that interrupting endocrine therapy after 18-30 months did not worsen short-term oncologic outcomes in women with a history of mostly stage I or II breast cancer. While the majority of women resumed endocrine therapy after conception attempts, 24% had not, raising concerns about compliance and longer-term safety.[68]

While breast cancer remains both common and likely to affect fertility in its survivors, significant advances in both cancer treatment and fertility treatment have made it more possible than ever for breast cancer survivors to build their families in various ways. Despite these advances, many significant barriers still exist. For example, there is inadequate psychological and decision support for women making choices about FP and the pursuit of pregnancy after cancer treatment. Finally, financial access to FP remains a formidable obstacle, with single cycles costing on average $8,000 US dollars (USD) for oocyte cryopreservation and $10,000 USD for embryo cryopreservation in the United States, plus the cost of medications, any desired genetic testing, long-term storage, and eventual embryo transfer. Currently, only 13 US states mandate insurance coverage of FP, making it a financial impossibility for many[69] (Fig 2). Only by addressing each of these barriers through research and policy can we ensure holistic, comprehensive care for all young women diagnosed with breast cancer.

BONE HEALTH

In women, the rate of bone loss increases with age, and estrogen deficiency is its primary cause.[70] Estrogen deprivation due to endocrine therapy in premenopausal and postmenopausal women with breast cancer accelerates

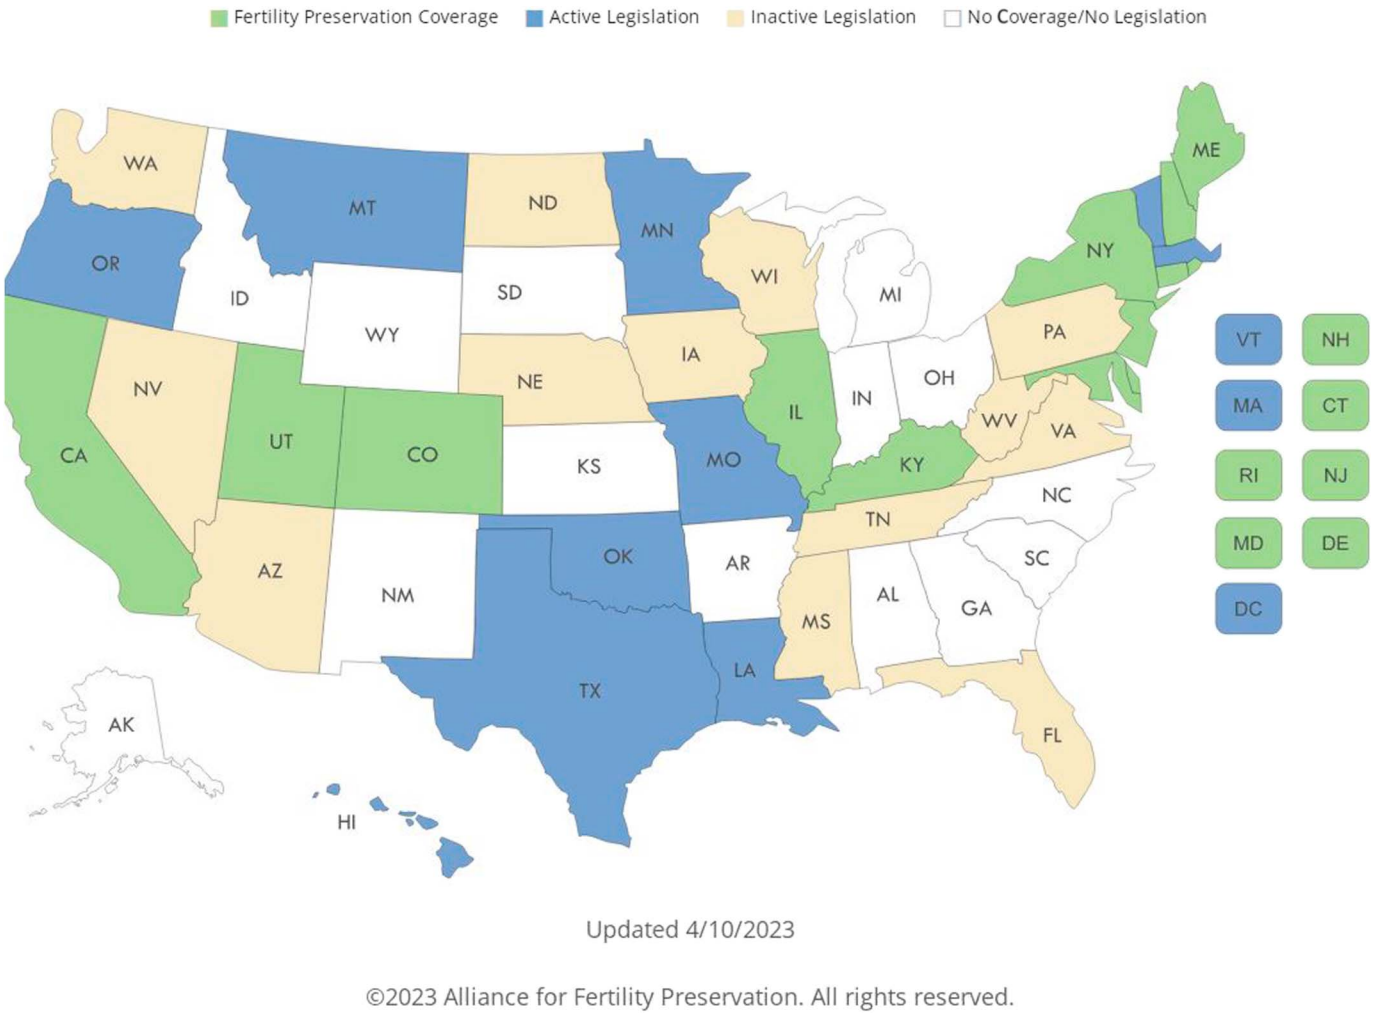

FIG 2. States covering fertility preservation for patients with cancer. Figure used with permission from the Alliance for Fertility Preservation https://www.allianceforfertilitypreservation.org/state-legislation/.

bone turnover, leading to decreased bone mineral density (BMD) and an increased risk of fractures.[71]

In premenopausal women, each available adjuvant endocrine treatment option (tamoxifen *v* tamoxifen plus OFS *v* AI plus OFS) increases bone loss.[72-74] While AI plus OFS results in the greatest decline in bone health (with an annual BMD loss of up to 11%), tamoxifen before menopause is associated with a decrease in BMD (up to 2% per year).[70] The effect of these therapies continues even after treatment discontinuation, leading to an increased proportion of patients with osteopenia and osteoporosis.

The influence of bone loss on fracture risk in women on estrogen suppression is understudied. The Austrian Breast and Colorectal Cancer Study Group Trial 12 (ABCSG-12) reported similar fracture rates in patients receiving OFS plus either AIs or TAM.[73] However, the results of the Tamoxifen and Exemestane Trial (TEXT) and the Suppression of Ovarian Function Trial (SOFT) studies showed a higher number of fractures during adjuvant endocrine therapy with OFS plus AIs (7.7%) as compared with OFS plus tamoxifen (6.0%) or tamoxifen alone (5.3%).[75]

In postmenopausal women, AIs are associated with greater bone turnover, bone loss, and fracture risk compared with tamoxifen.[70] Two large metanalyses reported a 47% (odds ratio [OR], 1.47; 95% CI, 1.34 to 1.61)[76] and 35% (relative risk, 1.35; 95% CI, 1.21 to 1.51)[77] higher risk of fractures with AI than tamoxifen. Extended use of AIs beyond 5 years further increases the risk of fractures. In a recent meta-analysis, extended AIs were associated with a 34% (OR, 1.34; 95% CI, 1.16 to 1.55) higher risk of fractures compared with placebo or no treatment.[78]

Considering the major impact of adjuvant endocrine therapy on bone health, all patients should be clearly informed about the risk of bone loss and fractures before treatment initiation.[79] Optimal management of bone health in this setting

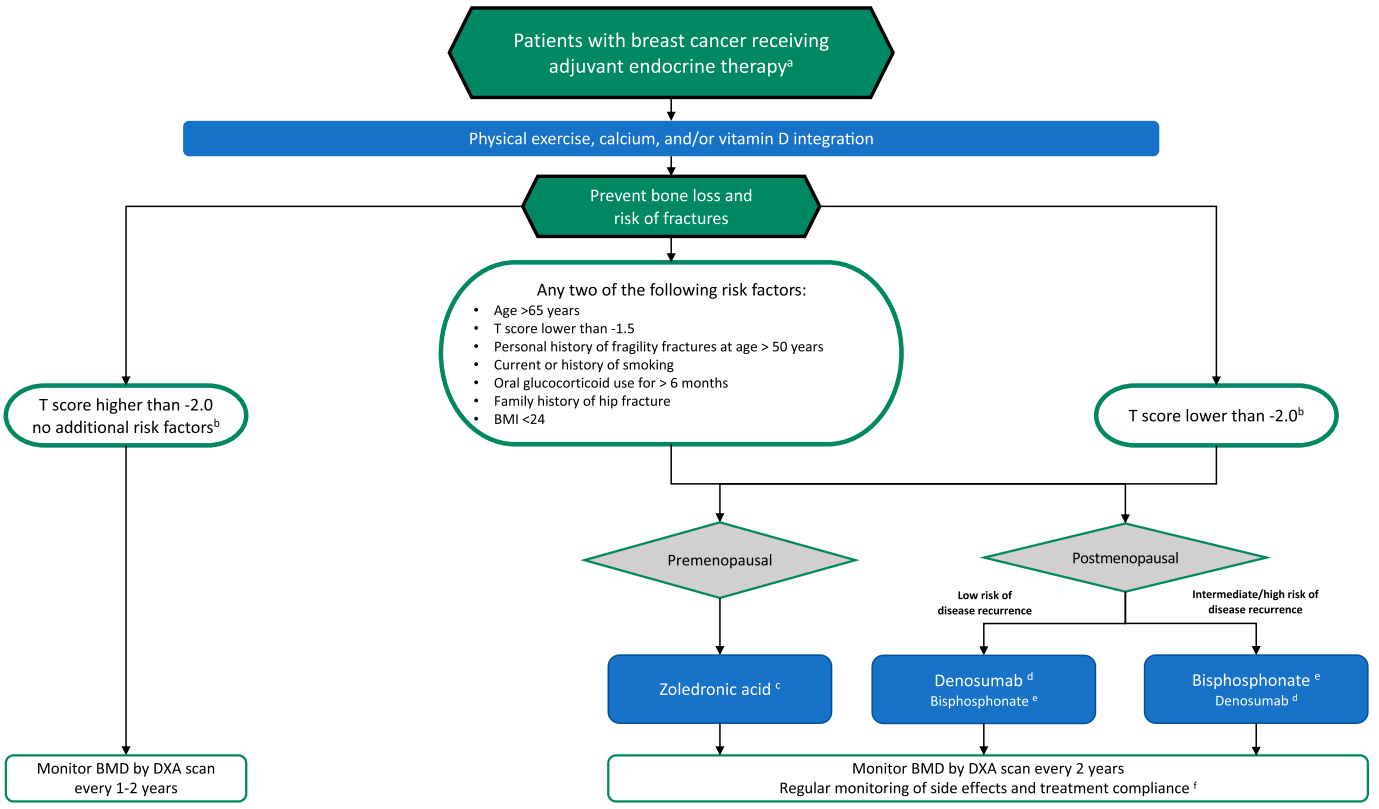

FIG 3. Algorithm for managing bone health in women receiving adjuvant endocrine therapy for breast cancer. [a]Include AIs, ovarian suppression therapy/oophorectomy (±tamoxifen or AIs), as well as tamoxifen alone in premenopausal patients. [b]Bone health can be measured by DXA, monitoring change in a patient's BMD with the T score that categorizes patients on the basis of standard deviations from the mean BMD of a healthy, young adult women. Generally, a 10% loss in BMD can be equated with one standard deviation drop in T score and can increase fracture risk by 2.6 times. The lowest T score from the spine and the hip should be used. [c]Preferred schedule of zoledronic acid: 4 mg intravenous every 6 months. [d]Preferred schedule of denosumab: 60 mg subcutaneously every 6 months (a bisphosphonate should be used on completion of denosumab therapy to prevent rebound osteoporosis). [e]Intravenous zoledronic acid every 6 months, weekly oral alendronate or risedronate, or daily oral ibandronate for the duration of endocrine treatment/for up to 5 years. [f]Regular dental care and attention to oral health are advisable to prevent possible osteonecrosis of the jaw. AI, aromatase inhibitor; BMD, bone mineral density; DXA, dual X-ray absorptiometry. Adapted from Coleman et al.[79]

includes a proper assessment of other risk factors for osteoporosis and the patient's BMD with a dual x-ray absorptiometry scan[80-82] at baseline and during adjuvant endocrine therapy (Fig 3).

Prevention and Management of Bone Loss

Limited evidence is available to counsel patients with breast cancer on the impact of calcium, vitamin D, and exercise to improve bone health. Nevertheless, a calcium-enriched diet, moderate resistance, weight-bearing exercise, and vitamin D uptake are recommended in all patients receiving treatments that may adversely affect bone health, such as adjuvant endocrine therapy.[79]

Bone-targeted agents (BTAs), such as bisphosphonates and denosumab, represent the most tested and widely applied pharmacological strategy to counteract bone loss in clinical practice. These agents inhibit bone resorption through a different mechanism of action. Osteoclasts ingest bisphosphonates through endocytosis during bone resorption, which leads to cell death through a cytotoxic effect for non–nitrogen-containing compounds (eg, clodronate) or a direct apoptotic effect for nitrogen-containing agents (eg, zoledronic acid, ibandronate, and pamidronate). Denosumab is a monoclonal antibody binding receptor activator of nuclear factor kappa B ligand (RANKL) that inhibits the binding of RANK with subsequent suppression of bone resorption.[79]

In premenopausal women receiving OFS plus AI versus tamoxifen with or without OFS, intravenous zoledronic acid (4 mg once every 3-6 months) is the only BTA effective in preventing BMD loss across several randomized trials (Table 1).[73,83,85] Moreover, its use seems to be associated with a reduction in the risk of fractures.[85] To our knowledge, to date, no randomized trials have investigated the use of oral bisphosphonates or denosumab in premenopausal women receiving adjuvant endocrine therapy.

TABLE 1. Largest (>1,000 patients) Randomized Trials on the Impact of Bone Antiresorptive Agents in Preventing Bone Loss and Fractures in Women With Early-Stage Breast Cancer (modified and updated from Waqas et al[70])

Study	Population, N	Intervention, n	Drug, Dose, Duration, and Route of Administration	Follow-Up	Mean BMD/T Score Change From Baseline	Fracture Data
Gnant et al[73] 2008 (ABSCG-12)	Stage I-II BC Adjuvant OFS + AI: 201 Adjuvant OFS + TAM: 203 Premenopausal: 100% Median age: 45 years N: 1,803 (N: 404 bone substudy)	Zoledronic acid (n = 205) *v* Controls (n = 199)	Zoledronic acid 4 mg, q6M for 3 years I.V.	60 months	LS: +4% *v* –6.3% TH: +3.9% *v* –4.1%	NR

Abbreviations: AI, aromatase inhibitors; BC, breast cancer; BMD, bone mass density; FN, femoral neck; HR, hazard ratio; I.V., intravenous; LS, lumbar spine; NR, not reported; OFS, ovarian function suppression; q3M, every 3 months; q6M, every 6 months; q4W, every 4 weeks; S.C., subcutaneous; TAM, tamoxifen; TH, total hip; Zol, zoledronic acid.

[a]Nuzzo et al[83] analysis included <1,000 patients, but it was performed in the context of the HOBOE trial with >1,000 patients.

In postmenopausal patients receiving AIs, several randomized trials demonstrated a benefit of both bisphosphonates (intravenous or oral formulations) and denosumab in preventing bone loss, while more limited evidence exists on their effect in reducing the risk of fractures (Table 1).[84,86,95] Dose schedules for patients on estrogen suppression are similar to those used for the management of osteoporosis in postmenopausal women.[88] Irrespective of age and BMD at baseline, denosumab (60 mg once every 6 months with adequate calcium and vitamin D supplementation) has the strongest evidence supporting its use in postmenopausal women receiving AIs, with a near 50% reduced risk of fractures both for patients with baseline T scores of –1 or higher (n = 1,872; HR, 0.44; 95% CI, 0.31 to 0.64) and for those with a T score of less than –1 (n = 1,548; HR, 0.57; 95% CI, 0.40 to 0.82).[86]

Anticancer Effect of BTAs

The rationale behind investigating BTAs as anticancer therapy relies on the established role that the bone microenvironment plays in the development of metastases.[89] In premenopausal women, the use of bisphosphonates as anticancer agent is controversial. There are currently no randomized trial data supporting the use of denosumab in this population (Table 2).[90-93] Both the ABCSG-12 and HOBOE trials reported a benefit with the addition of zoledronic acid to OFS as adjuvant endocrine therapy.[91,93] On the contrary, premenopausal women in the AZURE trial did not benefit from the addition of zoledronic acid to endocrine therapy.[92] In the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analysis, among the 4,616 women younger than 45 years, no benefit of bisphosphonates on bone recurrences was observed (RR, 1.00; 95% CI, 0.79 to 1.26).[94]

In postmenopausal women, many randomized trials sought to determine the potential anticancer effect of adjuvant oral or intravenous bisphosphonates (Table 2).[84,90,92,95-97] As shown by the EBCTCG meta-analysis, the use of bisphosphonates significantly reduced the risk of bone recurrences (RR, 0.83; 95% CI, 0.73 to 0.94) and breast cancer–specific mortality (RR, 0.91; 95% CI, 0.83 to 0.99).[94] Among the different bisphosphonates, a similar benefit was observed for clodronate (n = 5,053), zoledronic acid (n = 9,290), and ibandronate (n = 3,072), whereas there was no apparent effect in the smaller oral pamidronate group (n = 953). The beneficial effect of bisphosphonates was observed in all breast cancer subtypes.[94] The SWOG S0307 trial did not find a difference in disease outcomes between three different bisphosphonates given for 3 years: oral ibandronate (50 mg daily), oral clodronate (1,600 mg daily), or intravenous zoledronic acid (given monthly for 6 months and then every 3 months).[97] Hence, these are the preferred regimens to be considered for this purpose.[98]

Controversial data exist for the anticancer effect of denosumab (Table 2); while the ABCSG-18 trial showed a potential beneficial effect mostly in terms of DFS,[86,95] the D-CARE study that included patients with high-risk early-stage breast cancer did not show any effect.[96]

Bone Health: Practical Applications and Future Perspectives

In patients receiving endocrine therapy, proper management of bone health is a critical component of survivorship care.[99] Both prevention of treatment-induced bone loss and reduction in the risk of recurrence should be considered when counseling patients (Fig 2). The available types and dosing schedules of BTAs, as well as their toxicity profiles, including renal safety and risk of osteonecrosis of the jaw, should be discussed. However, osteonecrosis of the jaw is a rare event when using oral bisphosphonates or denosumab to prevent bone loss with 3- and 6-month schedules compared with more intensive treatments in patients with bone metastases.[100] In the main trials, the rates of osteonecrosis of the jaw ranged from <1% with clodronate, ibandronate, or 6-monthly zoledronic acid[91,97,101] to approximately 2%-5% with more intensive zoledronic acid or denosumab schedules.[96,102] For these reasons, an oral examination and preventive dentistry evaluation are recommended before starting therapy with BTA, and invasive dental procedures should be avoided during treatments.[79] Excretion of bisphosphonates occurs via the kidney, and both oral and intravenous formulations have warnings or contraindications regarding their use in patients with CrCl <30 mL/min (risedronate, ibandronate) or CrCl <35 mL/min (alendronate and zoledronic acid), mainly because of lack of data in patients enrolled in clinical trials with decreased renal function. However, when administered in accordance with the product characteristics (particularly regarding dose adjustments in patients with reduced renal function), bisphosphonates have not demonstrated additional renal toxicity, even in older patients.[103,104]

Notably, rebound osteolysis has been observed after the discontinuation of denosumab.[105] Although its pathophysiology remains uncertain, dormant osteoclast precursors may accumulate in the bone during treatment with denosumab and rapidly reactivate on drug discontinuation.[105] To date, there is no clear guidance on how to reduce the risk of rebound effect; small case series suggested that administration of zoledronic acid as two doses (6 and 12 months after the last denosumab injection) may help prevent the rebound effect and increased risk of fractures.[106]

Future research in the field should better address the impact of other potential breast cancer–related risk factors, including the bone safety profiles of newer targeted agents combined with endocrine therapy. Refined risk stratification

TABLE 2. Largest (>1,000 patients) Randomized Trials Studying Impact of Bone Antiresorptive Agents on Survival Outcomes in Women With Early-Stage Breast Cancer (modified and updated from Waqas et al[70])

Study	Population, N	Intervention, n	Drug, Dose, Duration, and Route of Administration	Follow-Up	Survival Data

Abbreviations: AI, aromatase inhibitors; BC, breast cancer; BMFS, bone metastases-free survival; Clo, clodronate; DFS, disease-free survival; DRFS, distant relapse-free survival; ET, endocrine therapy; HR, hazard ratio; I.V., intravenous; Iba, ibadronate; N.R., not reported; OFS, ovarian function suppression; OS, overall survival; P.O., per os; q3M, every 3 months; q6M, every 6 months; q4W, every 4 weeks; S.C., subcutaneous; TAM, tamoxifene; Zol, zoledronic acid.

[a]Perrone et al[93] presented at the 2022 Annual Conference of the Italian Association of Medical Oncology (AIOM).

would better inform clinical practice guidelines. In this regard, bone turnover biomarkers and new imaging techniques (such as high-resolution peripheral quantitative computed tomography) should be evaluated further.[107]

Anabolic bone drugs are not approved for use in this setting because of concerns of possible stimulation of cancer development and increased risk of recurrence.[99] Hence, at present, bisphosphonates and denosumab are the only BTAs used in clinical practice for patients receiving adjuvant endocrine therapy. Nevertheless, additional data are needed to better assess the role of BTAs in fracture prevention. Beyond their effect in patients undergoing endocrine therapy (as well as their role in the advanced setting in the presence of bone metastases), ongoing research is assessing the potential prophylactic effect of RANK/RANKL inhibition with denosumab in healthy carriers with a germline pathogenic variant in *BRCA* genes (ClinicalTrials.gov identifier: NCT04711109).

CONCLUSION

Patients with hormone receptor–positive early-stage breast cancer who report severe side effects from endocrine therapy are five times more likely to stop their prescribed medication, and 70% of them prematurely stop the treatment before 5 years.[108,109] Better addressing these QoL concerns, including menopausal symptoms, sexual dysfunction, FP, and bone health maintenance, can improve treatment compliance and therefore oncologic outcomes.

Improving Quality of Life During Chemotherapy: Cannabinoids, Cryotherapy, and Scalp Cooling

Alissa Michel, MD[1]; Richard T. Lee, MD[2]; Elahe Salehi, DNP, ANPBC[3]; and Melissa K. Accordino, MD, MS[1,4]

overview

There have been significant advances in the treatment of cancer in the past decade. However, patients continue to suffer from significant side effects of antineoplastic agents that greatly affect their quality of life (QOL), including chemotherapy-induced nausea and vomiting (CINV), chemotherapy-induced peripheral neuropathy (CIPN), and chemotherapy-induced alopecia (CIA). This review aims to provide an updated overview of emerging strategies for the management and prevention of these immediate and long-lasting side effects. The use of integrative medicine including cannabis continues to evolve in the realm of CINV and cancer-related anorexia. Although no pharmaceutical agent has been approved for the prevention of CIPN, cryotherapy, compression therapy and, more recently, cryocompression therapy have shown benefit in small trials, but there are concerns with tolerability especially related to cryotherapy. More data are necessary to determine an effective and tolerable option to prevent CIPN in large, randomized studies. Scalp cooling (SC), which has a similar mechanism to cryotherapy and compression therapy for CIPN prevention, has proven to be an effective and tolerable approach in randomized studies and has significantly limited CIA, an entity that definitively affects the QOL of patients living with cancer. Taken together, cannabis, cryotherapy, compression and cryocompression therapy, and SC all strive to improve the QOL of patients living with cancer by minimizing the side effects of chemotherapeutic agents.

INTRODUCTION

Because of advances in early detection and novel therapies, patients with cancer are now living longer.[1] Unfortunately, most antineoplastic therapies have a substantial risk of both short-term and long-term adverse effects that could significantly diminish cancer survivors' quality of life (QOL). Many patients who receive chemotherapy experience a multitude of side effects, including but not limited to nausea, anorexia, pain, neuropathy, fatigue, alopecia, and sexual dysfunction. These side effects can persist even after completion of chemotherapy. This review provides an introduction to the prevention and treatment of several immediate side effects of chemotherapy such as chemotherapy-induced nausea and vomiting (CINV) and chemotherapy-induced alopecia (CIA) and discusses emerging strategies to prevent and treat chemotherapy-induced peripheral neuropathy (CIPN), which is often a long-lasting side effect of taxane-based chemotherapy.

INTEGRATIVE, COMPLEMENTARY, AND ALTERNATIVE MEDICINE

The National Center for Complementary and Integrative Health has defined integrative, complementary, and alternative medicine (ICAM) as "a group of diverse medical and health care systems, practices, and products that are not presently considered to be part of conventional medicine."[2] The most recent Center for Disease Control study in the 2012 National Health Interview Survey found that one third of adults had used a form of ICAM during the past 12 months.[3] Among patients with cancer, the prevalence is even higher with almost half using a form of ICAM.[4] Herbs and supplements are the most common type of ICAM used by patients, and one, in particular, has grown in popularity—cannabis.

Historical Interest in Cannabis for Symptom Management

During the past few decades, there has been a growing interest in the use of phytocannabinoids, derived from the cannabis plant, to help with medical conditions. Two phytocannabinoids, in particular, have been studied extensively: tetrahydrocannabinol (THC) and cannabidiol (CBD). These agents were first derived from the cannabis plant (*Cannabis sativa* and *Cannabis indica*), and anthropologists have found evidence of their use over 2,000 years ago.[5,6] The medicinal use of cannabis grew in the 1800s and was even listed in the US Pharmacopoeia in 1850.[7] In the early 1900s, Mexican immigrants escaping the Mexican Revolution brought recreational cannabis to the United States. However, because of the growing stigma associated with its use, the Marijuana Tax Act was passed in 1937, making the cannabis plant illegal to grow.

PRACTICAL APPLICATIONS

- Chemotherapy-induced nausea and vomiting (CINV), peripheral neuropathy (PN), and alopecia significantly affect a patient's quality of life while undergoing treatment for cancer.
- Almost half of patients living with cancer report using some form of integrative, complementary, and alternative medicine.
- Cannabis use is implicated in improving CINV and cancer-related anorexia and might play a role in treating chemotherapy-induced PN.
- Cryotherapy, compression therapy, and cryocompression therapy may improve rates of PN in patients receiving chemotherapy via restricted blood flow to susceptible nerves.
- Scalp cooling offers an effective means of preventing chemotherapy-induced alopecia with minimal side effects and high rates of tolerability.

In the 1960s, there were a public resurgence in interest in recreational cannabis and, along with it, a growing interest in its use for medical conditions. However, in 1971, the United States classified cannabis as a schedule I drug within the Controlled Substances Act, indicating that cannabis had a high potential for abuse and no accepted medical indication. By the 1980s, among a paucity of medications for CINV, THC was found to have benefits for treating CINV and HIV/AIDS-induced anorexia, leading to Food and Drug Administration (FDA) approval of two synthetic forms of THC—dronabinol and nabilone. After FDA approval, in 1996, California became the first state to pass legislation making medical cannabis legal, and since then, 37 states and the District of Columbia have passed laws to legalize medical cannabis.[8] In December 2019, the US Congress passed legislation that removed hemp-derived CBD as a schedule I drug, permitting as it contains <0.3% THC. This change in legislation was based on the fact that CBD is not associated with cognitive and psychomimetic side effects and is considered safe with a low risk for abuse potential.[9] After this change in legislation, many states passed laws classifying hemp-derived CBD and THC as dietary supplements, which has led to further confusion regarding cannabis regulation in the United States.

The National Survey on Drug Use and Health indicates a growing use of cannabis by adult Americans from 10.4% in 2002 to 13.3% in 2015.[10] The Behavioral Risk Factor Surveillance System survey from 2016 and 2017 indicated current cannabis use of approximately 8% overall and, among individuals with cancer (nonskin cancer), rates ranging from 4.4% for those 55 years and older up to 23.7% in those age 18-23 years.[11] The National Health and Nutrition Examination Survey reported that 40.3% of patients with cancer had used cannabis in the past and that use of cannabis had increased from 9.3% to 12.3% from 2005 to 2014.[12] In states with legalized medical cannabis, use remains higher among patients with cancer as indicated by a study from Washington State, which found that 21% of patients surveyed had used cannabis in the past month.[13] This rate is similar to a 2018 cross-sectional analysis conducted in a community oncology office in Michigan, which found approximately one in five patients with cancer who were receiving chemotherapy used cannabis in the past 30 days.[14] Interestingly, the incidence was similar across those with early- versus advanced-stage cancer, but patients reporting cannabis use reported more pain, nausea, appetite issues, and anxiety on an electronic self-reported questionnaire than those who were not using cannabis.[14]

Mechanism of Action: Cannabis

While the rates of cannabis use in patients with cancer diagnoses continue to grow, research is growing about the potential benefits of cannabis although this has been limited because of the schedule I designation by the Drug Enforcement Administration. It is well established that THC and CBD work through the endocannabinoid system, with THC having a high affinity for cannabinoid receptors (CB1 and CB2). These G-protein–coupled receptors lead to decreased activation of neurotransmitters at the synapse in a retrograde signaling mechanism. CB1 receptors are found throughout the nervous system, whereas CB2 receptors are found primarily on immune cells. Although CBD has a lower affinity for the cannabinoid receptors, it appears to modulate signaling of anandamide, an endocannabinoid molecule, by increasing anandamide uptake or by decreasing its degradation, which then leads to increased activation of the endocannabinoid system. In addition, CBD appears to activate 5-HT1A and transient receptor potential subfamily V member receptors. It is thought that activation of 5-HT1A receptors in the dorsal raphe nucleus, which leads to release of 5-HT in terminal forebrain areas, may explain the antinausea effects of cannabis.[15] Growing data indicate that cannabis might have anti-inflammatory effects, which may relate to the presence of CB2 receptors on immune cells.[16,17] The variety of mechanisms through which THC and CBD exert their effects may explain the resultant different effects that THC and CBD have on different symptoms such as pain. Although the landscape has changed with regard to the use of legalized cannabis, the evidence for both the short- and long-term effects of cannabis and efficacy for specific indications has begun to emerge.

Cannabis for CINV and Anorexia

CINV has a significant impact on a patient's QOL while on treatment.[18] A review by the National Academies of Science, Engineering, and Medicine in 2017 concluded that, "there is conclusive or substantial evidence that cannabis or cannabinoids are effective" for chronic pain, CINV, and multiple sclerosis-related spasticity.[19] In a review by May and Glode,[20] the authors focused on the use of dronabinol, an orally active cannabis-based medication, which contains a synthetic version of THC. Although corticosteroids, serotonin receptor antagonists, and neurokinin receptor antagonists are well-known and effective antiemetics, dronabinol was approved by the FDA in 1985 for the treatment of CINV in patients who had failed conventional antiemetic treatments. One of the early studies from 1980 randomly assigned 55 patients to THC, prochlorperazine, or placebo and found that THC completely resolved nausea in 40 patients versus only eight with prochlorperazine and five with placebo.[21] Since that time, several clinical trials have been conducted.

One such randomized control study by Meiri et al[22] in 2007 included 64 patients receiving moderately to highly emetogenic chemotherapy who were randomly assigned to receive dronabinol, ondansetron, combination therapy, or placebo after initial prechemotherapy antiemetics on day 1. The trial found that the absence of nausea was similar between active treatment groups with 71% of patients free of nausea in the dronabinol group, 64% in the ondansetron group, and 53% in the combination group versus 15% in the placebo group ($P < .05$).[22] Nausea intensity and vomiting/retching rates were lowest in the dronabinol group.[22]

A systematic review by Tramèr et al[23] evaluated 1,366 patients within 30 randomized clinical trials who were treated with three different cannabis-based medications: oral nabilone, oral dronabinol, and intramuscular levonantradol. The review found cannabis-based medications to be more effective antiemetics than prochlorperazine, metoclopramide, chlorpromazine, thiethylperazine, haloperidol, domperidone, or alizapride with a number needed to treat of six for complete control of nausea and a number needed to treat of eight for complete control of vomiting.[23] Notably, there were higher rates of beneficial side effects including sedation or drowsiness and euphoria as well as higher rates of harmful side effects including dizziness, dysphoria, depression, and hallucinations. Of note, this review was published in 2000 with articles from 1975 to 1996; thus, the comparison arms were either placebo or older CINV treatments.

More recent data assessing cannabis's role in CINV include a phase II clinical trial that compared the combination of THC:CBD and more modern antiemetic regimens. The trial demonstrated an improvement in complete response from 14% to 25% with the addition of THC:CBD to standard antiemetics.[24] Although nearly one third of patients experienced cannabis-related side effects, most commonly sedation, dizziness, and disorientation, 83% of participants still preferred cannabis to placebo.[24] A review by Allan et al[25] identified seven randomized controlled trials assessing the role of medical cannabis in CINV, found a number needed to treat of three, and concluded reasonable evidence for improvement in nausea and vomiting symptoms.

Although clinically both dronabinol and nabilone are recommended for CINV resistant to standard treatments by ASCO and National Comprehensive Cancer Network (NCCN), more randomized controlled trials incorporating modern antiemetic regimens are needed.[26,27]

Similar to CINV, cancer-related anorexia remains a prevalent and distressing symptom for patients living with cancer. In a systematic review by Razmovski-Naumovski et al,[28] five studies of medicinal cannabis interventions (dronabinol, nabilone, and cannabis extract) compared with either placebo (n = 4) or megestrol acetate (n = 1) were analyzed. The efficacy of dronabinol was demonstrated in one of five trials with patients experiencing improvement and enhancement in chemosensory perception and other secondary outcomes such as taste of food and premeal appetite compared with placebo.[29]

Cannabis for Pain

Initial preliminary clinical research has indicated the potential benefits of THC and CBD for pain. Most studies analyzing the use of cannabis in pain have looked at nabiximols and found a benefit for chronic pain. Notably, nabiximols, an oral spray containing THC and CBD, has been approved in Europe and Canada for the treatment of nausea and vomiting as well as spasticity and pain. A systematic review and meta-analysis by Whiting et al,[30] which looked at randomized clinical trials of cannabis use for numerous indications including CINV and chronic pain, found moderate-quality evidence for the use of cannabis for the treatment of chronic pain and spasticity, with a 41% increase in reporting a 30% or greater improvement in pain among reviewed studies. One randomized, placebo-controlled study evaluated the effect of oromucosal Sativex (THC:CBD) on neuropathic pain of different etiologies. The trial reported a 22% reduction in the primary outcome of pain intensity scores after a 5-week treatment period.[31]

Only one study thus far has evaluated the use of phytocannabinoids for CIPN.[32] In this crossover study, 16 patients were provided nabiximols (THC 2.7 mg:CBD 2.5 mg) spray or placebo and instructed to start with one spray and then increase by one to two sprays per day until they reached a dose that helped their pain without exceeding 12 sprays per

day over approximately 4 weeks and, after a 2-week washout period, switched arms. Although the primary outcome was not met in this small study, five patients did have a >2-point reduction in pain with a number needed to treat of five. A review by the Cochrane Library sought to assess the efficacy, tolerability, and safety of cannabis-based medicines for chronic neuropathic pain, including CIPN. The review found that although cannabis-based medicines may improve pain relief when compared with placebo, the quality of the data was rated very low to moderate, and there was moderate-quality evidence that more people dropped out because of adverse events with cannabis-based medicines compared with placebo. Overall, the review noted that there was no high-quality evidence to suggest value of cannabis-based medicine in the treatment of chronic neuropathic pain.[33] The evidence was limited by short study duration and relatively small sample sizes. In another systematic review by Nugent et al,[34] investigators found low-strength evidence for cannabis in the relief of neuropathic pain across 27 chronic pain trials. These reviews stand in stark contrast to the findings of systemic reviews of Boychuk et al[35] and Lynch et al,[36] which found cannabis-based medicines to be effective and well-tolerated in chronic neuropathic pain, although notably both excluded malignancy-associated neuropathic pain. More recently, an Israeli team of investigators conducted a retrospective analysis looking at the effect of cannabis on oxaliplatin-induced peripheral neuropathy (PN) in 768 patients treated with oxaliplatin and 5-fluorouracil–based combinations for gastrointestinal malignancies.[37] Waissengrin et al[37] found a significant difference in grade 2-3 CIPN in cannabis-exposed patients versus controls (15.3% *v* 27.9%, respectively; $P < .001$). Interestingly, the authors further suggested a protective effect of cannabis given higher rates of neuropathy-spared patients among those treated with cannabis first compared with those treated with oxaliplatin first (75% *v* 46.2%; $P < .001$).[37] Importantly, although cannabis continues to be explored as an option for prevention of CIPN, duloxetine remains the only agent that has appropriate evidence to support its use in the treatment of patients with established and painful CIPN.[38]

Although the evidence is still lacking with respect to the use of cannabis-based medicines, all reviews have articulated the need for high-quality clinical studies to adequately answer this question, and this conclusion was echoed at the recent NCI-sponsored symposium on cannabis.[39]

PREVENTION OF CHEMOTHERAPY-INDUCED PERIPHERAL NEUROPATHY

CIPN is a severe dose-limiting toxicity of many commonly used chemotherapy agents, including taxanes, platinum-based drugs, and vinca alkaloids, and newer more targeted drugs such as antibody-drug conjugates, including ado-trastuzumab emtansine. PN is a common side effect with the incidence of about 30%-40% in patients treated with any neurotoxic chemotherapy and up to 73% in those treated with taxanes specifically. CIPN can present with a wide range of symptoms and severity and can substantially affect QOL.[40,41]

CIPN is caused by neurotoxic effects on neurons, with sensory symptoms tending to be greater than motor or autonomic symptoms.[41] Damage to the dorsal root ganglion neurons and their axons leads to features such as acral pain and paresthesias as well as dysesthesia, allodynia, and hyperalgesia.[42] In general, CIPN occurs in a dose-dependent manner with symptoms typically beginning during the first 2 months of treatment, progressing while chemotherapy continues and then stabilizing after treatment is completed. There are drug-specific features such as the acute neurotoxicity of oxaliplatin, which includes cold sensitivity and muscle cramping and normally peaks within 2-3 days after each dose.[38] On the other end of the spectrum lays the phenomenon referred to as coasting whereby the neuropathy associated with cisplatin treatment worsens after discontinuation of the drug.[41] In addition, paclitaxel causes a pain syndrome, classically in a truncal/hip distribution, that occurs in the days following each dose, and while previously described as arthralgias or myalgias, newer data suggest that these symptoms are instead a manifestation of acute neuropathy.[38,43,44] Although symptoms vary greatly, CIPN has a profound impact on QOL and can limit patients' daily functioning and motor activities with symptoms persisting for years after treatment.[45,46] Importantly, CIPN can affect cancer outcomes given the need to dose reduce or even hold certain chemotherapeutic agents, which may ultimately result in inferior survival.

For many years, investigators have sought out approaches to prevent CIPN without much success. At present, mitigation of CIPN primarily focuses on dose modification to prevent worsening CIPN once symptoms become apparent. ASCO has recently updated their guidelines for the prevention of CIPN and reconfirmed that no agents are recommended for the prevention of CIPN.[38] Similarly, the European Society for Medical Oncology (ESMO) has established guidelines which confirm that no pharmacologic agent exists to prevent CIPN.[42]

Although no pharmacologic agent has yet been established for the prevention of CIPN, the ASCO and ESMO CIPN guidelines note several nonpharmacological interventions, including compression therapy, cryotherapy, and exercise for the prevention of CIPN.[38,42] However, given that current data originate from small studies, no recommendation can be made on the utility of such interventions in clinical practice

although there is emerging interest in these approaches, which we aim to review here and summarize in Table 1.

Cryotherapy for Prevention of CIPN

Some studies have suggested that cryotherapy may reduce the occurrence of CIPN, especially in those patients receiving taxane-based chemotherapy. The hypothesized rationale for the neuroprotective effect of limb hypothermia in CIPN invokes cold-induced vasoconstriction, which leads to reduced exposure of peripheral nerves to the neurotoxic chemotherapeutic agent. The first suggestion of efficacy for this method came from a retrospective exploratory analysis conducted by Eckhoff et al[47] of 1,725 Danish patients with breast cancer (BC). Although 34% of patients included in the study reported PN during treatment, the odds ratio (OR) of PN was significantly reduced in those patients who wore frozen gloves or socks during treatment. The study found that 40% of the patients, who received cryotherapy with the intention of decreasing onycholysis, had a 44% reduction in subsequent neuropathy, compared with patients who had not received the cryotherapy ($P < .0001$).[47] In a prospective, self-controlled trial by Hanai et al,[48] 36 patients with BC, receiving treatment with once-weekly paclitaxel, wore frozen gloves on the dominant hand for 90 minutes during treatment. The incidence of objective CIPN, measured by the monofilament test, and subjective CIPN at a cumulative dose of 960 mg/m^2 of paclitaxel was significantly lower on the intervention side than on the control side (hand: tactile sensitivity = 27.8% *v* 80.6%, OR = 20.00, 95% CI = 3.20 to 828.96, $P < .001$; foot: tactile sensitivity = 25.0% *v* 63.9%, OR = infinite, 95% CI = 3.32 to infinite, $P < .001$).[48] Importantly, no patient dropped out because of cold intolerance.

In a larger study by Beijers et al,[49] 180 patients were randomly assigned to either wear frozen gloves on both hands or not wear frozen gloves. Patients were treated with oxaliplatin, docetaxel, or paclitaxel for mostly colorectal cancer or BC. Notably, 31 patients (34%) discontinued the intervention of frozen gloves because of discomfort. Intention-to-treat analyses showed no important differences in reported CIPN on the basis of the European Organization for the Research and Treatment of Cancer Quality of Life (EORTC QLQ) CIPN20 subscale. Although there was no difference reported on the CIPN20 scores, which may be attributed to the fact that lower extremities were not treated with cryotherapy, researchers found a clinically relevant decrease in tingling in fingers/hands and less trouble in opening a jar or bottle because of loss of strength in those who adhered to frozen glove treatment than in those in the control group.[49]

Although there are several trials of cryotherapy, which are encouraging, these studies are retrospective, underpowered, and uncontrolled or used an unblinded self-control (ie, opposite limbs) group and thereby subject to placebo effects.[47,48,56,57] In addition, although the feasibility of cryotherapy is there, many studies exhibit poor compliance or discontinuation because of discomfort.[58] The effectiveness of ice/gel packs and frozen gloves may furthermore be limited because of steep cooling gradients, nonuniform cooling, and the inability to adjust the temperature in the case of intolerance.

Cryotherapy Using a Continuous-Flow Cooling Device (without or with cyclic compression for prevention of CIPN)

Given that many patients are unable to tolerate cryotherapy using frozen gloves/socks, continuous-flow cooling devices offer easier implementation and better tolerance. These devices provide a constant low temperature over the duration of treatment, with the rationale being that continuous flow cooling has been shown to be superior to crushed iced for musculoskeletal injuries or postoperative pain.[59,60] In an internally controlled pilot study by Sundar et al,[50] 20 patients with BC underwent cryotherapy via continuous-flow limb hypothermia of one limb for a duration of 3 hours while receiving paclitaxel. The noncooled side served as the control. The study found that there was a mild improvement in nerve conduction studies (NCSs) at 6 months in the cooled limb compared with the contralateral untreated limb. Importantly, in comparison with frozen gloves, the treatment was well tolerated without dropout. The authors found a significant correlation between the amount of skin cooling and motor nerve amplitude preservation at 6 months ($P < .0005$) using NCSs for measurement.[55]

Compression Therapy for CIPN Prevention

Interestingly, compression therapy may also offer an effective means of preventing CIPN via similar mechanisms of restricted blood flow to susceptible nerves. In a self-controlled study by Tsuyuki et al,[51] patients with BC receiving nab-paclitaxel wore two surgical gloves, one size too small, on their dominant hand and no gloves on their nondominant, control hand. The study found that compression gloves resulted in lower rates of sensory and motor peripheral neuropathies in the protected hands versus control hands (sensory neuropathy 21.4% *v* 76.1%; motor neuropathy 26.2% *v* 57.1%) using the common terminology criteria for adverse events (CTCAE) and Patient Neurotoxicity Questionnaire.[56] Given the subjective nature of reporting neuropathy, a subsequent double-blind, phase II trial assessed the effectiveness of the same procedure, surgical glove compression for the prevention of paclitaxel-induced PN, by having patients don two gloves, both one size too small, on the one hand (intervention side) versus two normal sized gloves on the other hand (control side).[61] Forty-nine patients were evaluated, and there was no significant difference in sensory or motor neuropathy between the study and control sides.[61]

TABLE 1. Trials for Prevention of Chemotherapy-Induced Peripheral Neuropathy[1]

Intervention	Control	Authors	Trial Design	No.	Chemotherapy Agent	End Point and Results	Tolerance of Intervention
Cryotherapy—FG or socks worn for decreasing onycholysis	None	Eckhoff et al[47]	Retrospective exploratory analysis, controlled	1,725	Docetaxel	CIPN incidence; OR, 0.56; 95% CI, 0.38 to 0.81	NA
Cryotherapy—FG on the dominant hand	Nondominant hand without gloves	Hanai et al[48]	Prospective, nonrandomized, self-controlled	36	Paclitaxel	CIPN incidence; hand: 27.8% *v* 80.6%, $P < .001$; foot: 25.0% *v* 63.9%, $P < .001$	No discontinuations because of cold intolerance
Cryotherapy—FG	No FG	Beijers et al[49]	Randomized, controlled	180	Oxaliplatin, docetaxel, or paclitaxel	EORTC QLQ-CIPN20 subscales; no difference in subscales, reduced tingling in fingers/hands (β, –10.20; 95% CI, –3.94 to –3.14; $P = .005$), and less trouble in opening a jar or bottle because of loss of strength in hands (β, –6.97; 95% CI, –13.53 to –0.40; $P = .04$) in the FG group compared with the control group	31 (34%) patients discontinued frozen gloves, mainly because of discomfort
Cryotherapy—continuous-flow cooling device	None	Sundar et al[50]	Prospective nonrandomized pilot study	20	Paclitaxel	SNAP amplitude change; –19.9% *v* –25.8% ($P = .16$); there was correlation between the degree of skin cooling and motor amplitude preservation ($P < .0005$)	No discontinuations because of cold intolerance; one patient required one intracycle thermoregulator temperature increase of 1°C toward the end of a hypothermia session
Compression therapy—two SGs one size too small on the dominant hand	Nondominant hand	Tsuyuki et al[51]	Prospective, nonrandomized, self-controlled	43	Nab-paclitaxel	Rates of CTCAE grade 2 or higher sensory and motor peripheral neuropathies were significantly lower for SG-protected hands than for control hands; sensory neuropathy 21.4% *v* 76.1%; motor neuropathy 26.2% *v* 57.1%	No discontinuations because of intolerance

TABLE 1. Trials for Prevention of Chemotherapy-Induced Peripheral Neuropathy[1] (Continued)

Intervention	Control	Authors	Trial Design	No.	Chemotherapy Agent	End Point and Results	Tolerance of Intervention
Cryotherapy—FG and socks *v* compression therapy compression garments to upper and lower extremities 15-30 mmHg	Loose gloves and socks	Accordino et al[52]	Randomized, controlled phase IIb, adaptive sequential design	63	Nab-paclitaxel, paclitaxel, or docetaxel	Change in FACT-NTX; success, defined as a <5-point decrease from baseline in the FACT-NTX at 12 weeks, occurred in 64.7% of patients treated with compression and 41.1% of patients treated with cryotherapy and placebo	Adherence to study garments (worn ≥80% of infusions) occurred in 72.7.% of patients treated with compression, compared with 35.0% of patients treated with cryotherapy
Cryotherapy—FG *v*, compression therapy—two gloves one size too small of the dominant hand	Non-dominant hand	Michel et al[53]	Randomized, controlled	122	Nab-paclitaxel	Rates of CTCAE grade 2 or higher sensory neuropathy; cooling: 25% *v* 46%; *P* = .0008; compression: 23% *v* 39%; *P* = .0016 with similar efficacy (no significant difference was found: *P* = .7303)	NA
Cryocompression therapy	Continuous-flow cooling and controls with no hypothermia	Bandla et al[54]	Prospective nonrandomized, controlled	13	Paclitaxel or docetaxel	NCS motor amplitude change; NCS_{3m} cryocompression *v* NCS_{3m} control: ankle stimulation: 8.1% ± 21.4%, *P* = .004; below fibula head stimulation: 12.7% ± 25.6%, *P* = .0008; above fibula head stimulation: 9.4% ± 24.3%, *P* = .002	One patient required an intracycle temperature increase
Exercise	Chemotherapy without exercise	Kleckner et al[55]	Randomized, controlled	355	Taxane-, platinum-, or vinca alkaloid–based chemotherapy	CIPN symptom scale (0-10); hot/coldness in hands/feet (–0.46 units; *P* = .045) and numbness and tingling (–0.42 units; *P* = .061)	NA

Abbreviations: CIPN, chemotherapy-induced peripheral neuropathy; CTCAE, Common Terminology Criteria for Adverse Events; EORTC QLQ-CIPN20, European Organization for Research and Treatment of Cancer Quality of Life Questionnaire-CIPN twenty-item scale; FACT-NTX, Functional Assessment of Cancer Therapy Neurotoxicity; FG, frozen glove; NA, not available; NCS, nerve conduction study; OR, odds ratio; SG, surgical glove; SNAP, sensory nerve action potential.

In a recently completed randomized, phase IIB adaptive sequential selection trial that compared cryotherapy (frozen gloves/socks), compression therapy (compression garments 20-30 mmHg on upper and lower extremities), and placebo (loose gloves/socks), compression therapy had the highest probability of success in a future randomized phase III trial. There were 64 patients randomly assigned in triplets (n = 20 cryotherapy, n = 22 compression, n = 22 placebo), and the stopping criterion was met after the 17th triplet (n = 51) had been evaluated for the primary end point. Success, defined as a <5-point decrease from baseline in the Functional Assessment of Cancer Therapy Neurotoxicity at 12 weeks, occurred in 64.7% of patients treated with compression and 41.1% of patients treated with cryotherapy and placebo. Adherence to study garments (worn ≥80% of infusions) occurred in 82.4% of patients treated with compression, compared with 29.4% of patients treated with cryotherapy. In this pilot study, compression was the most effective and tolerable intervention, whereas cryotherapy was not successful likely related to poor tolerability, suggesting the need for future studies.[52]

Recently, at ESMO 2022, the POLAR trial by Michel et al[53] randomly assigned 122 patients with BC to either cooling via frozen glove or compression via two surgical gloves, one-size smaller than tight-fitting size, of the dominant hand while receiving taxane-based therapy. No intervention was performed on the other hand. Cooling and compression were both highly effective in prevention of grade ≥2 CIPN using the CTCAE (cooling: 25% *v* 46%, *P* = .0008; compression: 23% *v* 39%, *P* = .0016) and showed similar efficacy.[59]

Cryocompression Therapy for CIPN Prevention

More recently, cryocompression therapy has been investigated as a tolerable approach with the goal of enhancing the depth of cooling by adding dynamic pressure to cooling to improve efficacy. The nonpainful sensory input of dynamic pressure is thought to inhibit pain sensation via the gate control theory of pain. Sundar et al[50] who had previously researched continuous-flow cooling devices in a pilot study conducted a proof-of-concept study using cryocompression limb wraps on all four limbs in 13 patients receiving taxane chemotherapy.[62] Cryocompression was administered at 16°C with a cyclic pressure of 5-15 mmHg. In comparison with retrospective data collected by the same group, the study found that cryocompression achieved significantly greater skin temperature reductions compared with continuous-flow cooling and control ($P < .0001$) while also illustrating an improvement in NCS compared with the controls who showed significant deterioration at 3 months.[62] The authors postulated that the ability to achieve lower temperatures led to improved efficacy in mitigating neurotoxicity.

SWOG 2205 (ICE COMPRESS) is a recently launched randomized phase III, cooperative group trial to evaluate the aforementioned modalities with 1:1:1 random assignment of patients scheduled to receive taxane-based therapy to either limb cryocompression continuous compression or low cyclic compression, all using a novel Paxman limb cooling compression system. The study aims to enroll almost 800 patients and hopes to elucidate the most effective and tolerable CIPN prevention strategy.[63]

Exercise for CIPN Prevention

In addition to cryotherapy and compression therapy, exercise has been studied as a mechanism for preventing CIPN and is postulated to prevent and treat CIPN through changes in inflammation and sensory pathways in the brain.[64,65] In a randomized study of 355 patients, 79% with BC, patients were randomly assigned to either chemotherapy alone or chemotherapy plus Exercise for Cancer Patients (EXCAP), a 6-week, moderate-intensity, at-home walking, and resistance exercise program.[55] The trial showed that exercise significantly reduced CIPN symptoms, on a scale of 0-10, of hot/coldness in hands/feet (–0.46 units; *P* = .045) and did not significantly reduce numbness and tingling (–0.42 units; *P* = .061) compared with the control group.[55]

While at this time, approved pharmacologic agents are lacking for the prevention of CIPN, researchers continue to explore nonpharmacologic interventions including cryotherapy, cryocompression therapy, and exercise-based programs. More randomized controlled studies are needed with larger patient populations given that these options remain as promising, yet understudied solutions.

PREVENTING HAIR LOSS: SCALP COOLING FOR ALL?

Chemotherapeutic agents used for cancer treatment introduce many adverse effects, with hair loss being one of the most devastating toxicities. Alopecia can greatly reduce QOL and negatively affect body image for patients with BC, many of whom consider hair loss to be the most traumatic aspect of chemotherapy treatment.[66,67] This fear can negatively affect outcomes with BC treatment as up to 8% of patients with BC decline chemotherapy to avoid hair loss.[68] In many cases, a head scarf or a wig can be used; however, these can be costly and uncomfortable, especially for those experiencing hot flashes during chemotherapy. Although CIA is often considered to be temporary, in rare cases, it can be permanent.[69] Prevention of alopecia can help to improve QOL of patients receiving chemotherapy and may allow patients to accept a therapy with potential curative or survival benefits.

Methods for Scalp Cooling

Several different methods of prevention have been explored in the realm of CIA. Methods include machine-based and manual scalp cooling (SC), intravenous administration of ammonium trichloro (dioxoethylene-O,O') tellurate (AS101), immunomodulatory tellurium, and topical application of vitamin D3.[70-73]

Of these potential treatments, only SC has demonstrated measured success in preventing alopecia because of chemotherapy.[69,74-76] Importantly, although SC has been used for decades in Europe, it was not until 2015 that the DigniCap received FDA approval as the first machine-based SC device in the United States. Similar to cryotherapy for CIPN, SC is thought to prevent hair loss through vasoconstriction, which reduces blood perfusion and substantially decreases the amount of chemotherapy taken up into follicular cells. Cold temperatures also reduce cellular metabolic activity, which lessens the effects of cytotoxic chemotherapeutic agents on follicular cells.[77,78]

SC can be achieved through different techniques; one such method includes manual cooling caps, such as Penguin Cold Caps, Chemo Cold Caps, and Arctic Cold Caps, which require chilling/freezing in an ice chest and frequent changes throughout treatment to maintain the cool temperature of the scalp. This method can be very labor-intensive and provoke anxiety to maintain a constant cool temperature. An alternative technique uses an automatic, machine-based cooling system consisting of a fitted cap connected to a device that circulates coolant throughout the cap and gradually cools the scalp to a preset fixed temperature throughout treatment. The two FDA-approved machine-based systems currently available are DigniCap (Dignitana, Dallas, TX) and the Paxman Scalp Cooling System (Paxman Coolers Limited, Huddersfield, UK).[79]

Regardless of the specific device, it is recommended that SC start 30 minutes before treatment and continue for the duration of the treatment. Postcooling times are highly variable, depending on the institution and manufacturer. In a recent prospective trial, Komen et al[80] demonstrated that extending the duration of postcooling from 90 minutes to 150 minutes in patients receiving adjuvant 5-fluorouacil, epirubicin, and cyclophosphamide chemotherapy did not significantly improve hair preservation as measured by need to wear a hair covering, but did result in less evidence of grade 2 and 3 alopecia. In this study, SC was well tolerated with only 3% of patients stopping because of intolerance.

Efficacy of SC in the Prevention of CIA

SC's efficacy depends on many factors, including chemotherapy regimen, dose, dose interval, hair type, correct cap size, race/ethnicity, SC temperature, postcooling time, and SC system.[81] Most studies assessing SC use the WHO Criteria for hair loss to grade alopecia. Hair loss grading is rated from grade 0 (no significant hair loss) through grade 4 (nonreversible alopecia). Success of SC is generally defined as the patient not requiring a wig.

In the pivotal prospective cohort trial by Rugo et al,[82] 106 patients with stage I or II BC across five US medical centers receiving adjuvant or neoadjuvant chemotherapy regimens received SC using the DigniCap device compared with 16 who did not. Among these patients, hair loss of 50% or less was seen in 66% of women compared with the control group where all participants experienced significant hair loss.[81] Importantly, although the trial did not include anthracycline (AC)-based regimens, several combination regimens, including docetaxel and cyclophosphamide and docetaxel and carboplatin with human epidermal growth factor receptor 2–targeted therapy, were included.

Although SC has been shown to be effective in patients receiving taxane-based regimens, the technology is not nearly effective at preventing alopecia in patients receiving AC-based regimens.[83] In a randomized multicentered control trial of SC versus control, Nangia et al[82] demonstrated a success rate of only 16% in those receiving AC-based chemotherapy (95% CI, 4 to 46) versus 59% in those receiving taxanes (95% CI, 27 to 84). Across seven sites in the United States, 182 patients who were undergoing chemotherapy with taxane, AC, or both were randomly assigned to SC using the Paxman device or a control group of no SC (without sham placebo). Alopecia assessments were conducted using CTCAE v4.0. The team found that patients who underwent SC had <50% hair loss after completion of treatment compared with the control group. QOL assessments were completed at baseline and after four cycles of chemotherapy using the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire (EQRTC-QLQ-C30), Hospital Anxiety and Depression Scale, and Body Image Scale (BIS). There was no effect on QOL measurements although the trial was stopped early for superiority, and the power of detecting a difference in end points might have been affected.[83] Possible explanations for this observation could include the heterogeneity of chemotherapy regimens received, the timing of interviews, and, most importantly, variability in patient expectations after prestudy education.

In a large study of 1,411 patients across 28 Dutch hospitals, van Den Hurk et al[76] analyzed data from the Dutch Scalp Cooling Registry. The analysis found that 50% of the 1,411 scalp-cooled patients wore no head covering during the last SC session. Although results were most promising for those receiving single-agent taxanes with 84%-91% of patients receiving single-agent low-dose taxanes wearing no head covering, results were less promising for those receiving TAC (docetaxel, doxorubicin, and cyclophosphamide) with only 8% of those patients wearing no head covering at least treatment.[75] The team identified patients of older age as having less chance of satisfactory results and attributed this to aged skin having a diminished cold-induced vasoconstriction. They also identified differences in those with non–West-European-type hair perhaps attributed to lower maximum tolerable chemotherapeutic dose and higher toxicity rates.[75]

Despite SC's promising results with many different treatment regimens, data continue to be lacking regarding the efficacy of SC in the African American population. Data suggest that hair thickness can prevent the scalp's skin temperature from reaching the temperature goal, perhaps resulting in lower effectiveness in African American women.[84] Dilawari et al[85] conducted a phase II feasibility trial looking at African American patients with stage I-III BC receiving at least four cycles of nonanthracycline (NAC) or anthracycline (AC)-based regimens. Modified Dean Scale scores were used to assess the alopecia rate and the Chemotherapy Alopecia Distress Scale (CADS) to measure patient distress. The trial was closed early because of lack of efficacy, with success seen in only one of 15 patients, most of whom had grade 3 alopecia. The regimen did not affect the efficacy of SC or CADS.[84] Although SC can prevent CIA, hair texture affects its efficacy. Further studies are needed to determine whether a different approach in hair preparation before cold cap application may make a difference.

Although machine-based SC represents a promising option, Rice et al[86] looked at the efficacy of hair preservation using a manual Penguin cold cap in 97 evaluable patients with early-stage BC receiving various types of chemotherapy. The manual cold caps prevented CIA in 61% of patients overall with efficacy varying on the basis of the regimen with improved success for those receiving shorter, NAC-based regimens.[86]

SC's Impact on QOL

In the same prospective, multicenter study that led to FDA approval of the DigniCap device, Rugo et al[81] assessed SC's effect on QOL in patients with BC. The study found improvement in three of five QOL measurements one month after completion of chemotherapy. Women in the SC group felt less upset about losing their hair and were less dissatisfied with their bodies compared with women in the control group.[82]

van den Hurk et al[87] conducted a prospective multicenter study looking at the effect of SC on the well-being of patients with BC. The study included 98 of possible 266 patients across 13 hospitals who used the Paxman SC device. Multiple questionnaires including EORTC-QLQ-30, EORTC-QLQ-BR23 (breast cancer–specific module), and the BIS were each assessed at 3 weeks and 6 months after the last chemotherapy cycle. The results showed effectiveness of SC in 52% of patients receiving it and a trend toward higher scores in overall well-being, including QOL and body image, in those successfully scalp-cooled patients compared with those who were unsuccessfully scalp-cooled. Investigators identified a correlation between unsuccessful SC and significantly more complaints about alopecia.[87]

Practical Considerations When Using SC

Overall, SC is effective in the reduction or prevention of alopecia with many chemotherapeutic regimens for patients with BC. It is now the standard of care and has been recommended by the NCCN, ESMO, and Cancer Australia.

SC is reasonably well-tolerated by patients with minimal to no adverse events. The most common adverse events include headache, dizziness, pruritus, chills, nausea, and skin ulceration.[82,83,86] Supportive measures such as anti-anxiety or pain medications can also improve tolerability and thus improve efficacy. An important side effect to be aware of includes cold thermal injury, which, although likely an infrequent event, may result in mild persistent alopecia.[88] One concern related to the potential for development of scalp metastasis has been shown to be unfounded on the basis of low rates of scalp metastases regardless of SC without an apparent increase in those who received SC.[89]

To achieve the optimal outcome, a collaborative effort is required from medical and nursing professionals and patients. When implementing SC, every institution should consider issues such as cost, chair time, cap fitting, patient expectations, and the need for educational materials for both patients and families.

Cost continues to be one of the most important issues for patients. The cost of SC treatment is different according to the type of system being used and the number of chemotherapy cycles. In general, the cost is estimated to be somewhere between $1,500 in US dollars (USD) and $3,000 USD. As on January 1, 2022, the US Center of Medicare and Medicaid has reassigned the repayment for SC for Medicare claims filed with 0662T CPT code. The national average Medicare payment is currently $1,850.50 USD. Although patients may consider using flexible spending accounts for payment, there are also nonprofit organizations such as Hair To Stay, which helps subsidize the cost of SC in addition to raising awareness and providing information on SC to patients.[90]

In addition to cost, implementing a SC workflow according to institutional guidelines is key. Many institutions are using a precooling time while patients are receiving premedications, and some have developed a separate area for the post-cooling time. In the setting of manual cold caps, patients can continue with the postcooling time outside of the institute, which is an advantage compared with the Paxman and DigniCap SC devices.

Future Research Involving SC

To date, most studies in SC have focused on preventing hair loss and improving QOL in patients undergoing treatment for early-stage BC. Data about the efficacy of SC in patients with BC undergoing treatment for metastatic disease using novel therapies such as newer

antibody drug conjugates are not well known, despite rates of alopecia ranging from 37% with trastuzumab deruxtecan to 46% with sacituzumab govitecan.[54,91] Currently, there is an rrongoing prospective, controlled, nonrandomized trial (ClinicalTrials.gov identifier: NCT04986579) using the Paxman Scalp Cooling device, looking at the efficacy and QOL of SC when using trastuzumab, sacituzumab, and eribulin in the metastatic setting.[92]

There is hope that the use of supportive care therapies such as SC will not only help improve the patient experience of receiving anticancer therapies but also improve overall efficacy outcomes by increasing the number of patients who successfully complete recommended systemic therapy for their disease.

CONCLUSIONS

Although we continue to make great strides in improving survival across oncologic fields, we must match these strides with improvements in QOL. This review has focused on some of the progress that has been made with the use of SC for CIA, which has proven to be quite effective with taxane-based chemotherapy and cannabis-based medications for CINV. Small studies have illustrated that compression, cryotherapy, and cryocompression devices may further improve QOL by preventing CIPN although larger studies are needed to solidify this finding. Overall, there have been significant advances in managing the symptomatic burden of chemotherapy in patients living with cancer, but more research is needed to continue this trajectory.

Aligning Germline Cancer Predisposition With Tumor-Based Next-Generation Sequencing for Modern Oncology Diagnosis, Interception, and Therapeutic Development

Timothy A. Yap, MD, PhD[1]; Zsofia K. Stadler, MD[2]; Leigh Anne Stout, MS[3]; and Bryan P. Schneider, MD[3]

overview

In the era of precision medicine, genomic interrogation for identification of both germline and somatic genetic alterations has become increasingly important. While such germline testing was usually undertaken via a phenotype-driven single-gene approach, with the advent of next-generation sequencing (NGS) technologies, the widespread utilization of multigene panels, often agnostic of cancer phenotype, has become a commonplace in many different cancer types. At the same time, somatic tumor testing in oncology performed for the purpose of guiding therapeutic decisions for targeted therapies has also rapidly expanded, recently starting to incorporate not just patients with recurrent or metastatic cancer but even patients with early-stage disease. An integrated approach may be the best approach for the optimal management of patients with different cancers. The lack of complete congruence between germline and somatic NGS tests does not minimize the power or importance of either, but highlights the need to understand their limitations so as not to overlook an important finding or omission. NGS tests built to more uniformly and comprehensively evaluate both the germline and tumor simultaneously are urgently required and are in development. In this article, we discuss approaches to somatic and germline analyses in patients with cancer and the knowledge gained from integration of tumor-normal sequencing. We also detail strategies for the incorporation of genomic analysis into oncology care delivery models and the important emergence of poly(ADP-ribose) polymerase and other DNA Damage Response inhibitors in the clinic for patients with cancer with germline and somatic *BRCA1* and *BRCA2* mutations.

INTRODUCTION

In the era of precision medicine, genomic interrogation for identification of both germline and somatic genetic alterations has become increasingly important. Traditionally, the purpose of germline genetic cancer risk assessment has been to identify individuals at an increased risk for an inherited cancer who could benefit from tailored cancer surveillance and risk-reducing measures, as well as testing of at-risk family members.[1] While such germline testing was usually undertaken via a phenotype-driven single-gene approach, with the advent of next-generation sequencing (NGS) technologies, the widespread utilization of multigene panels, often agnostic of cancer phenotype, has become a commonplace in many different cancer types.[2-4] At the same time, somatic tumor testing in oncology performed for the purpose of guiding therapeutic decisions for targeted therapies has also rapidly expanded, recently starting to incorporate not just patients with recurrent or metastatic cancer but even patients with early-stage disease.[5,6] For example, the NCI-MATCH trial demonstrated the feasibility of pan-cancer tumor testing at a large scale with identification of actionable mutations for genotype-targeted treatments in both the clinical and research settings.[7] Notably, germline testing and tumor testing were traditionally performed independently, often by different specialists (ie, geneticists versus medical oncologists); however, we are beginning to recognize that an integrated approach may be the best approach for the optimal management of patients with different cancers.[8]

APPROACHES TO SOMATIC AND GERMLINE ANALYSES IN ONCOLOGY PATIENTS

Approaches to germline and somatic genomic analyses differ across institutions. Understanding the benefits and limitations of each approach is important (Fig 1; adapted from the study by Liu and Stadler[8]). If tumor-only assessment is undertaken, tumor sequencing will result in the identification of both somatic (acquired) and germline (inherited) genomic variants. As discussed in more detail later, tumor-only assessment has the potential of uncovering inherited risk

PRACTICAL APPLICATIONS

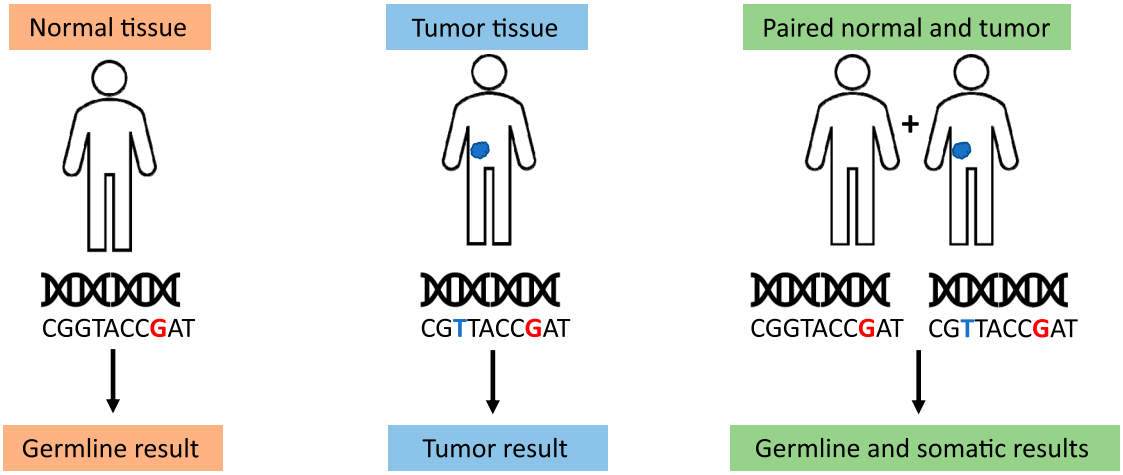
- While germline testing was usually undertaken via a phenotype-driven single-gene approach, with the advent of next-generation sequencing (NGS) technologies, the widespread utilization of multigene panels, often agnostic of cancer phenotype, has become a commonplace in many different cancer types.
- At the same time, somatic tumor testing in oncology performed for the purpose of guiding therapeutic decisions for targeted therapies has also rapidly expanded, recently starting to incorporate not just patients with recurrent or metastatic cancer but even patients with early-stage disease.
- An integrated approach may be the best approach for the optimal management of patients with different cancers.
- The lack of complete congruence between germline and somatic NGS tests does not minimize the power or importance of either, but highlights the need to understand their limitations so as not to overlook an important finding or omission.
- NGS tests built to more uniformly and comprehensively evaluate both the germline and tumor simultaneously are urgently required and are in development.

variants, yet, at the same time, it should not be a replacement test for germline analysis. In parallel tumor-normal sequencing, simultaneous sequencing of both normal and tumor tissues results in the ability to directly discriminate germline versus somatic alterations usually performed through subtracting out of germline variants from somatic variants. As such, only somatic variants are generally reported under the tumor assessment, but direct analysis of the germline with clinical return of results is possible with necessary informed consent procedures and pretest genetic counseling. Limitations of this technology are increased costs of sequencing of both normal and tumor DNA, need for genetic consent and pretest counseling, and molecular pathologist(s) designated as specialists in the curation and interpretation of both somatic and germline findings.[8] If somatic-only variants are reported and the germline is not directly interrogated, the subtracted-out germline findings may be of significant clinical importance, potentially with direct therapeutic implications, and may be missed. Many institutions have undertaken tumor testing and germline genetic testing using separate platforms often involving different commercial laboratories. This approach has the benefit of ensuring that all treatment relevant alterations in the tumor are identified, whether germline or somatic, yet also ensure that if the patient meets germline genetic testing criteria, the needed germline assessment is also performed. Disadvantages of such separate tumor and germline assessments are limited ability to assess whether a germline variant is a driver of the cancer and difficulty in assessing cases of somatic mosaicism or clonal hematopoiesis (CH).

KNOWLEDGE GAINED FROM INTEGRATION OF TUMOR-NORMAL SEQUENCING

Integrated tumor-germline analysis may help to inform whether a tumor is driven by the germline findings or whether the germline variant is simply an incidental observation. For example, in a recent assessment by Srinivasan et al[9] of >17,000 patients undergoing parallel-tumor normal sequencing, the dependency of the tumors on pathogenic germline variants was dictated by both tumor lineage and gene penetrance. Specifically, somatic biallelic inactivation, namely, either a somatic mutation or loss of heterozygosity in the gene or gene region implicated by the germline event, was identified in 40% of all patients with cancer harboring a germline pathogenic variant. Higher rates of biallelic inactivation, at 65%, were observed in patients with germline pathogenic variants in high-penetrance genes, with an increase to 85% when assessment was limited to tumor types known to be associated with the germline cancer risk variant. Beyond an increased understanding of oncogenesis, these results might also have therapeutic implications. For example, in patients with *BRCA1/2* germline variants, initial evidence suggests that poly (ADP-ribose) polymerase (PARP) inhibitor sensitivity may be linked to biallelic inactivation and tumor lineage, whereas in non–BRCA-associated cancer types, tumor pathogenesis appeared to be independent of the mutant *BRCA1/2* alteration.[10] As such, pathogenic germline variants may inform somatic alterations, helping to optimize genotype-directed therapies, yet at the same time, certainly not all patients with high-penetrance germline variants demonstrate biallelic inactivation, highlighting the complexity of selecting genotype-directed therapies.

Beyond traditional sequencing for genetic variants, tumor molecular phenotype or tumor signature as assessed by somatic tumor profiling may also be important. Traditionally, the hallmark of Lynch syndrome, a well-described high-penetrance cancer predisposition syndrome, has been associated with tumors exhibiting microsatellite instability (MSI). Interestingly, tumor-germline integration has helped to better understand this syndrome helping to optimize patient management. In a study of MSI in the pan-cancer population of >15,000 patients undergoing parallel tumor-normal sequencing, Lynch syndrome was identified in 16.3% of



Pros	Assess inherited risk Cancer screening Counseling for families Reproductive planning	Inform diagnosis and prognosis Guide therapeutic decisions for targeted therapies Assess MSI for immunotherapies	Differentiation and integration of germline *v* somatic variants Guides therapy Allows genetic counseling, screening, and reproductive planning
Cons	Limited to patients who meet guidelines Testing difficulties (eg, clonal hematopoiesis and mosaicism)	Inability to distinguish somatic *v* germline variants Inadequate surrogate for direct germline testing Need for further genetic testing and potential delays in care	Increased costs and resources, particularly related to genetic consents and counseling Specialized curation and interpretation by molecular pathologist

FIG 1. Pros and cons of tumor-only versus paired tumor-normal genetic testing.[8] This figure depicts the results of germline, tumor, and paired tumor-normal sequencing and displays how paired sequencing allows the differentiation of germline (red) versus somatic (blue) results. MSI, microsatellite instability.

high-frequency MSI tumors, 1.9% of MSI-indeterminate tumors, and 0.3% of microsatellite-stable (MSS) tumors.[11] Notably, among patients with Lynch syndrome, 50% had tumors other than the canonical colorectal and endometrial cancers, with 45% of these patients not meeting clinical criteria for germline testing on the basis of personal/family history. As such, the presence of MSI in the tumor helped to direct germline testing. On the other hand, Lynch syndrome was present in some patients even with an MSS tumor. In fact, the 0.3% prevalence of Lynch syndrome in this cohort was equivalent to the estimated prevalence of Lynch syndrome in the general population (1 in 270 individuals). In these patients, the cancer diagnosis was not driven by the Lynch syndrome, and the associated response to the immune checkpoint blockade on the basis of MSI status would not be expected in these patients. More recently, Ranganathan et al observed that even in patients with Lynch syndrome and colorectal cancer, the classic tumor associated with Lynch syndrome, 11% of colorectal tumors were MSS, predominantly consisting of the lower-penetrance *PMS2* and *MSH6* germline carriers (Ranganathan et al). Beyond MSI, other tumor phenotypes such as an ultra-hypermutated phenotype or homologous recombination deficiency (HRD) signature may help to point to the underlying presence of germline alterations in DNA polymerase genes (*POLE, POLD1*) genes or *BRCA1/2* and associated genes, respectively.

Increased understanding of both the somatic and germline landscapes in an individual patient with cancer can help differentiate germline alterations from CH, also referred to a CH of indeterminate potential or somatic mosaicism. When germline analysis using the standard source of blood for normal DNA analysis is used, DNA alterations may represent not just germline findings but also potential mosaic alterations or somatic alterations present in the hematopoietic lineages only, namely, CH.[12] CH alterations, a fairly common finding both in patients with cancer and associated with advancing age, smoking, and radiation therapy, may carry a potential risk factor for hematologic malignancies and for cardiovascular disease risk.[13] Germline analysis alone is often unable to distinguish germline variants from CH even when variant allele fraction is assessed. The resulting misinterpretation of a CH variant such as a *TP53* alteration for a germline finding has significant clinical management implications. Although variants in *TP53* because of CH imply an increased risk for hematologic malignancies, the pan-cancer risks and high-risk surveillance recommendations are dramatically different in Li-Fraumeni syndrome, the condition associated with germline TP53

alterations. Somatic mosaicism refers to the presence of a variant in some but not all cells of an individual and may be present at varying levels in different tissues.[14] The presence of a somatic pathogenic variant in the APC gene in all cells of the colon, but at decreased frequency (<50%) in the blood, may lead to a clinical diagnosis of Familial Adenomatous Polyposis. Matched tumor analysis may help inform the blood DNA–derived variant as being CH or mosaic in etiology.[12] A CH variant would not be expected to be present in tumor DNA, whereas a variant detected at lower levels in the blood but present at a higher frequency in the tumor may represent a mosaic finding. Although further confirmation analysis may be needed, matched tumor-normal analysis greatly helps with this evaluation.[12]

INCORPORATION OF GENOMIC ANALYSIS INTO ONCOLOGY CARE DELIVERY MODELS

Although no one model is perfect, it has become apparent that better integration of germline and somatic genomic findings is needed. This is inclusive of using novel care delivery models within oncology, wherein both germline assessment and somatic assessment are initiated promptly at cancer diagnosis. This is paramount given the increasing evidence for the therapeutic implications of germline finding in oncology.[15] Barriers to referral and access to genetics clinics for standard genetic testing are a commonplace, with well-documented underutilization of germline testing even in cancers such as ovarian cancer, wherein universal germline testing has been recommended by ASCO, the US Preventive Services Task Force, and National Comprehensive Cancer Network.[16-19] Moreover, existing disparities in cancer treatment and outcomes may be even further exacerbated if genomic molecular assessments are not implemented using standard procedures across all populations.[19] While precision medicine in oncology has revolutionized our field, increased flexibility with modification of existing care delivery pathways will ensure that all patients have equal access to these dramatic advancements.

TUMOR SEQUENCING TO RULE OUT INHERITED CANCER PREDISPOSITION

Tumor testing with NGS has become standard practice for patients with advanced cancer.[20,21] The overarching goal of NGS testing is to uncover potential drug targets. This often includes US Food and Drug Administration (FDA)–approved targeted therapies and molecules being tested in trials. The ASCO guidelines support testing for patients with advanced solid tumors and now several tumor types in the earlier curative settings.[22] Since the backbone of genetic variability in the tumor is shaped by the host patient's own unique blueprint, it should be of no surprise that somatic tumor testing can uncover important, risk-conferring, germline variants. Although the likelihood of identifying a germline variant is clearly affected by the disease type and the patient's personal and family history, previous data have shown that 4.3%-16% of patients undergoing NGS for tumor testing were found to harbor a germline variant, with many having not met guidelines for germline testing.[23-30] Properly identifying patients with a germline mutation is clinically relevant as it may open additional targeted therapy options for the patient and may highlight an increased risk of malignancy for the patient and related family members. Therefore, ASCO supports disclosing medically relevant incidental germline findings arising from somatic testing to patients who wish to receive this information.[31]

Although providers must be cognizant of the implications of uncovering germline mutations in the context of tumor testing, it is crucial to reinforce that this is not a replacement test or even an adequate surrogate. There are two scenarios centered around risk-conferring genes that may be clinically challenging. First, a somatic NGS test may not identify a germline mutation in a risk-conferring gene carried by the patient. Second, the somatic test may highlight a somatic mutation in a risk-conferring gene that simply arose during the development of the cancer. With regard to the latter, mutations seen in risk-conferring genes may represent stochastic somatic mutations in a patient with an inherited wild-type allele or, as previously mentioned, may represent CH rather than an inherited event.[32] When identified in a tumor test, the variant allele frequency (VAF) can be helpful in determining the likelihood that the mutation was inherited, rather than acquired. Previous work has shown that mutations with the VAF frequency between 40%-60% were very commonly found to be germline in origin, with the notable exception of *TP53* and *APC* mutations.[33-35] While mutations outside this range should never preclude germline testing when clinically appropriate, using VAF can be another tool in identifying germline carriers, especially when a patient's personal or family history is uninformative. Current guidelines support talking to the patient about germline testing when a risk-conferring variant is detected, even when the patient's personal and/or family history are not suggestive of a hereditary cancer syndrome.[31] Thus, it is important that the ordering provider actively considers this possibility across the risk-conferring variants with close attention to pathogenicity. As outlined below, a tumor test's definition of pathogenicity does not always match the germline test's definition for conferring risk.

Of equal importance, germline cancer risk-conferring mutations can be missed on tumor testing. The frequency of missed mutations is not insignificant, with previous data demonstrating a range of 8.1%-18.3%.[36,37] The reasons for this are multifactorial, but clearly include differences between somatic and germline testing assays and the downstream bioinformatic processes. There are many commercially available somatic tests, many of which have

differences in the mutations that can be detected and which mutations are ultimately selected as candidates to be listed on the summary report. The number of genes and variants tested is variable across testing platforms, and obviously less comprehensive tumor somatic tests will not detect all cancer risk-conferring variants. Another reason for not identifying a germline mutation on a tumor test is related to differences in the chemistry of sequencing. Many somatic tumor tests are not designed to detect important structural alterations, including small deletions or duplications. In addition, some germline mutations are missed because of informatic processing by somatic laboratories. For example, although somatic laboratories may be able to detect mutations in the *PMS2* gene within regions of homology with the *PMS2CL* pseudogene, in some instances, those mutations are filtered off the clinical report. Relying on these tumors to exhibit MSI may miss individuals with Lynch syndrome as previous studies have shown an enrichment of MSS tumors in individuals with germline *PMS2* mutations.[38] Furthermore, some mutations that are almost exclusively germline in origin (eg, *MITF* p.E318K) are filtered off using some somatic test results, even in the absence of a paired normal test, because they may be less likely to be driving cancer growth. Finally, some mutations are not highlighted because of differences in the interpretation of pathogenicity between somatic and germline laboratories. Germline mutations causative of high-risk cancer syndromes, including Lynch syndrome, have been listed on the variants of unknown significance page of somatic test results, which may be buried deep within the final report. A pathogenic mutation on a tumor NGS test is meant to uncover drug targets, whereas uncovering risk-conferring germline mutations is an incidental finding. For the latter, we recommend evaluating the pathogenicity of all variants in a germline setting using a quality germline database (eg, ClinVar).

Not identifying a germline variant has two potential significant consequences for the patient. The first centers on the evolving intersection of somatic and germline mutations as important drug targets. Mutations in the DNA-repair pathway appear to predict benefit for therapeutic inhibition of PARP.[39-49] The degree of benefit appears to depend on the disease type, gene mutated, and whether the mutation is germline or somatic in origin. PARP inhibitors are FDA-approved for ovarian cancer, breast cancer, prostate cancer, and pancreatic cancer. Although somatic mutations across DNA repair genes predict some degree of benefit (and even FDA-approved for prostate cancer), the most robust activity across disease types appears to be seen in patients with germline mutations in *BRCA1* or *BRCA2*.[50] More recently, the HIF-2alpha inhibitor, belzutifan, has been FDA-approved for patients with renal cell cancer who carry germline mutations in VHL.[51] The activity of this drug, and others in the class, is still undergoing investigation for patients with somatic *VHL* mutations. The second consequence of missing germline variants is having the opportunity to optimally address the risk for malignancy in the affected patient and at-risk relatives. The benefit to at-risk relatives is both obvious and potentially substantial in terms of scope and significance. The early days of tumor NGS were usually confined to patients with refractory metastatic disease, making the implications of uncovering a hereditary cancer syndrome less impactful for the patient. As tumor NGS testing moves into earlier disease settings, the potential to also affect the index patient's screening and risk reduction for additional primary cancers begins to increase as well.

EMERGENCE OF PARP INHIBITORS IN THE CLINIC

The added importance of both somatic and germline profiling lies in molecular matching with rational antitumor therapies.[52] The FDA approval of PARP inhibitors in patients with advanced ovarian cancer harboring deleterious or suspected deleterious germline *BRCA* mutations after $\geq$3 previous lines of chemotherapy represented the first proof-of-concept for exploiting a synthetic lethal approach in the clinic.[53] This is especially important given that 10% to 15% of ovarian cancer cases in the United States are due to germline or somatic *BRCA1/2* mutations. After the approval of olaparib, three other PARP inhibitors rucaparib, niraparib, and talazoparib have since obtained FDA approval in different indications in patients with ovarian, breast, prostate, and pancreatic cancer in different settings.[54] Although PARP inhibitors have successfully shifted therapeutic paradigms in cancers harboring HRD, drug resistance is nearly inevitable, leading to eventual disease progression. PARP inhibitor resistance is complex and multifactorial, including different underlying mechanisms such as the restoration of HR repair, replication stress, and other diverse mechanisms.

Given the success of PARP inhibitors, the DNA damage response (DDR) therapeutic landscape has rapidly expanded, in part facilitated by the discovery of novel precision targets enabled by cancer genome sequencing and modern CRISPR technologies.[54] Beyond PARP inhibitors, there are now multiple agents targeting the DDR pathway, including ATR, WEE1, ATM, DNA-PK, CHK1/2, POLQ, PKMYT1, USP1, and PARG inhibitors that are in clinical testing. There is also a myriad of DDR clinical candidates in preclinical testing, including ALC1, FEN1, MRN, MLH1/2, APEX2, CIP2A, DNA nucleases, and many more. Many of these agents are particularly effective in DDR biomarker–driven tumors, which provides a molecularly based patient selection strategy to optimize and guide their clinical development. Such predictive biomarkers of response are critical to the success of the different DDR agents, as evidenced by

the biomarker-driven FDA approval of PARP inhibitors in cancers with *BRCA1/2* and other mutations.

GOING BEYOND BRCA1/2-ASSOCIATED TUMOR TYPES

A key question now is how to expand the approval of PARP inhibitors beyond the traditional hereditary breast ovarian cancer (HBOC) types (ie, breast, ovarian, prostate, and pancreatic cancers), where the phenotypic and therapeutic relevance of *BRCA1/2* mutations remains poorly defined in most cancer types. Jonsson et al[10] showed that in 2.7% and 1.8% of patients with advanced-stage cancer and germline pathogenic or somatic loss-of-function alterations in *BRCA1/2*, respectively, selective pressure for biallelic inactivation, zygosity-dependent phenotype penetrance, and sensitivity to PARP inhibitors was only observed in HBOC tumors. In addition, among patients with non–BRCA-associated cancer types, most carriers of these *BRCA1/2* mutation types had evidence for tumor pathogenesis that was independent of *BRCA1/2* mutations. Overall, although it is evident that *BRCA1/2* mutations represent indispensable founding events for certain cancers, they are likely biologically neutral in other cancer types, suggesting a difference predominantly driven by tumor lineage. This, in turn, has important implications for disease pathogenesis, screening, clinical trial design, and therapeutic decision making.

A recent trial of the PARP inhibitor talazoparib and the PD-L1 inhibitor sought to address the question if such a PARP inhibitor–based combination is effective in patients with pathogenic *BRCA1/2* mutations, regardless of the tumor type.[55] In this pan-cancer tumor-agnostic phase 2b nonrandomized controlled trial, 200 patients at 42 institutions in nine countries with advanced *BRCA1/2*-altered or ATM-altered solid tumors were enrolled into two respective parallel cohorts. Interestingly, neither the *BRCA1/2* nor *ATM* mutation cohort met the prespecified target of an objective response rate of 40% across cancer types. Durable clinical activity was observed in patients with BRCA1/2-associated tumor types (eg, ovarian, breast, prostate, and pancreatic cancers), rather than those with non–BRCA-associated cancer types. A notable exception was patients with *BRCA1/2*-altered advanced uterine leiomyosarcoma (uLMS), who had prolonged responses to treatment.

In the BRCA1/2 cohort, 119 patients had BRCA1/2-associated tumor types (defined as breast, ovarian, prostate, and pancreatic cancers), whereas 40 patients had non–BRCA1/2-associated cancer types.[55] Within this BRCA1/2 cohort, the ORR was 30.3% for BRCA1/2-associated tumor types versus 15.0% for patients with non–BRCA1/2-associated tumor types, including three of three responses in patients with advanced uLMS. In an exploratory analysis, patients with uLMS were combined with the patients with BRCA1/2-associated tumor types to form one subset of patients, defined collectively as *BRCA1/2*-dependent cancer types. In the *BRCA1/2*-dependent versus non–*BRCA1/2*-dependent groups, ORRs were 32.0% versus 8.1%, the median DOR was 12.5 months versus 5.8 months, and the median PFS was 5.3 months versus 1.9 months, respectively. The ORRs were 40.0% versus 9.7% in patients with blinded independent central review (BICR)–assessed measurable disease, respectively. Overall, these findings suggest that a pan-cancer, tumor-agnostic approach with this PARP inhibitor combination is not an optimal clinical strategy for treating patients with *BRCA1/2*-altered tumors.

In the clinic, there have been anecdotal reports of PARP inhibitor activity in non–*BRCA1/2*-associated tumors, such as urothelial, biliary tract, and small cell lung cancers, and other tumors.[53] However, in general, none have led to sufficient success in larger suitably powered clinical trials to warrant FDA drug approval in specific subsets of patients. For example, on the basis of the findings that DDR and DNA repair gene mutations were associated with improved outcomes to platinum-based chemotherapy in metastatic urothelial cancer,[56] several studies have been undertaken to evaluate the efficacy of PARP inhibitors in metastatic urothelial carcinoma. This included a phase II trial of rucaparib in patients with advanced urothelial cancer who progressed on one or two lines of systemic therapy.[57] This study enrolled patients with both HRR-deficient and HRR-proficient tumors. However, the study was terminated after preliminary review by an independent data monitoring committee did not show adequate objective response rate and met the criteria for study discontinuation. Additional studies evaluating the efficacy of PARP inhibitors in a cohort of urothelial cancers that is selected for HRR deficiency are ongoing.

Another trial is ATLANTIS, which is a multicenter, umbrella trial in the United Kingdom that screened patients with advanced urothelial cancer for biomarkers while receiving first-line chemotherapy.[58] Patients were eligible to participate in multiple phase II studies evaluating targeted agents as maintenance therapy in biomarker-defined subgroups. The trial showed that maintenance therapy with the PARP inhibitor rucaparib extended progression-free survival in a cohort of patients with DNA repair deficiency, biomarker-positive metastatic urothelial cancer, defined as 10% or greater genome-wide loss of heterozygosity; alteration in any of 15 different genes associated with DNA repair; or *BRCA1/2* germline alteration. However, rucaparib did not significantly improve the secondary end point of overall survival. Patients were randomly assigned 1:1 to receive maintenance treatment within 10 weeks of completion of chemotherapy with either rucaparib at 600 mg twice daily or placebo until disease progression. The study was shut down after 40 patients were recruited for two reasons: the COVID pandemic and data from the JAVELIN Bladder 100 trial

showing a survival advantage for avelumab immunotherapy in this treatment setting. Treatment with rucaparib achieved a median progression-free survival of 35.3 weeks versus 15.1 weeks with placebo. For the secondary end point of overall survival, median overall survival was not reached in the rucaparib arm versus 72.3 weeks in the placebo arm, but this difference was not statistically significant.

The BAYOU trial enrolled treatment-naive, platinum-ineligible patients with metastatic urothelial cancer.[59] They were randomly assigned 1:1 to first-line treatment with durvalumab plus olaparib or durvalumab plus placebo. The BAYOU trial assessed the combination of olaparib and durvalumab, but did not improve progression-free survival in previously untreated, platinum-ineligible patients with metastatic urothelial cancer compared with durvalumab plus placebo, missing the primary end point of the trial. This trial used the FoundationOne assay to test tumor samples for aberrations in 15 HRR genes: *ATM*, *BARD1*, *CHEK1*, *PALB2*, *RAD51C*, *BRCA1*, *BRIP1*, *CHEK2*, *PPP2R2A*, *RAD51D*, *BRCA2*, *CDK12*, *FANCL*, *RAD51B*, and *RAD54L*, with HRR mutations found in seven of the 15 genes analyzed. The *BRCA2* mutation was found in 4.6% of all tumors and in 22.6% of the HRR-mutated subgroup.

An alternative strategy currently being explored clinically is the use of DDR agents beyond PARP inhibitors, such as WEE1 or ATR inhibitors.[54] For example, with the WEE1 inhibitor adavosertib, a confirmed partial response was observed in a patient with head and neck squamous cell cancer (HNSCC) harboring a *BRCA1* mutation.[60] With ATR inhibitors, early RECIST responses have been observed in *BRCA1/2*-mutated patients with melanoma and HNSCC.[61] Given that PARP binding to Chk1 at stalled replication forks is necessary for S-phase checkpoint activation and following these preliminary observations of anecdotal monotherapy antitumor activity with WEE1 and ATR inhibitors in patients with *BRCA1/2* mutations, PARP inhibitor combinatorial approaches should also be considered in the future.

CONCLUSIONS

In summary, as tumor NGS becomes a more commonplace, it is important to understand the potential implications for uncovering germline mutations. Specifically, we recommend providers pursue germline testing for patients with mutations in a cancer risk-conferring gene that could explain the patient's personal/family history or if the mutation VAF is near 50% allele frequency even if their personal/family history does not support testing. We also recommend offering germline testing to all patients who meet current established guidelines for testing even in the absence of a mutation in a risk-conferring gene on a tumor NGS test. The lack of complete congruence between germline and somatic NGS tests does not minimize the power or importance of either, but highlights the need to understand the limitations so as not to overlook an important finding or omission. NGS tests built to more uniformly and comprehensively evaluate both the germline and tumor simultaneously are urgently required and are in development.

Team-Based Care in Oncology: The Impact of the Advanced Practice Provider

Todd Pickard, MMSc, PA-C, DFAAPA, FASCO[1]; Stephanie Williams, MD[2]; Eric Tetzlaff, PA-C[3,4]; Camille Petraitis, DNP, FNP-BC[4]; and Heather Hylton, MS, PA-C, FASCO, DFAAPA[5]

overview

Integration of APPs into care teams affects quality and safety for the oncology patient. Learn the best practices and understand the concepts of onboarding, orientation, mentorship, scope of practice, and top of license. Review how productivity and other incentive programs can be adapted to integrate APPs and focus on team-based metrics.

INTRODUCTION

The incorporation of Advanced Practice Providers (APPs) into the care of the oncology patient has been transformational to team-based care. APPs provide care and services that would otherwise require a physician to complete. Physicians Assistants (PAs) and Advanced Practice Registered Nurses (APRNs) were developed in the United States in the mid-1960s to address physician shortages and expand access to health care. Since that time, APPs have entered practice in all disciplines and specialties. Despite more than 50 years since their creation, there remains a considerable amount of misunderstanding and questions around how to recruit, onboard, orient, and team with APPs so that they function at the top of their license and train within a full scope of practice.

ASCO has committed substantial resources in exploring the oncology workforce and the delivery of high-quality, patient-centered, team-based care.[1-4] The team approach in oncology has become a necessity as our health care system and cancer treatment have grown ever more complicated. To successfully address the needs of oncology patients, a well-integrated approach is required. This relies on the skills and competencies of many committed interprofessional team members, including APPs.[5-9] Describing the oncology workforce, including the role of the APP, has been a commitment from ASCO for several decades. The body of work developed by ASCO has found that APPs are positioned to provide care to oncology patients who would traditionally require physician time and effort. Collaboration with physicians to provide patient evaluations, diagnostic workup, consultation, patient management, systemic therapy ordering, toxicity management, patient education, and the delivery of survivorship care is one of the defining hallmarks of the APP. The APP research completed by ASCO reflects some common themes including the following: there is more work required for patients in oncology than can be performed by physicians alone; APPs are recognized by both patients and physicians as integral members of the team; and a well-coordinated team is required for the delivery of high-quality care across the cancer care continuum.[4,10-14]

APP INSIGHTS—ASCO'S ONGOING WORK

Although APPs are an integral part of the oncology care team, there remains a need to explore their role and scope of practice. In addition to the research that has been completed, ASCO has committed significant resources to further define and describe the APP. The ASCO Clinical Practice Committee's APP Task Force is charged with helping all oncology health care professionals better understand the important role that APPs play in oncology care teams in practices and clinics. This Task Force is dedicated to developing tools, resources, and educational opportunities to support oncology APPs and the team members working alongside them. The APP Task Force was established in June 2019 and comprises APPs, clinic administrators, and physicians from various practice settings and geographic locations across the United States. The Task Force's diverse membership brings together a wide array of perspectives to advance its important work.

This Task Force builds on some of the team-based care work led by ASCO's now-sunset Workforce Advisory Group (WAG), which focused on broader oncology workforce issues. The WAG developed and launched one of the first large-scale surveys of oncology APPs in 2018 and a subsequent contribution to *JCO Oncology Practice*.[11] This work helped ASCO and other organizations more clearly understand the role of the APP and the benefits of appropriately integrating APPs into a collaborative team-based oncology practice model to promote high-quality cancer care.[15,16]

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Advanced Practice Providers (APPs) are critical members of the oncology care team that affect access, quality, and safety of care.
- Integration of APPs into practice requires an intentional effort around onboarding, orientation, and mentorship.
- Scope of practice and top of license are concepts that are critical to understand to fully engage APPs in oncology care teams.

Since its inception, the Task Force has developed an APP onboarding and practice guide to help provide basic guidance, comprehensive integration of new team members, and best practices for onboarding APPs into an oncology practice. This guide is meant to supplement a practice's current onboarding processes. The Task Force has developed a designated webpage that can serve as a user-friendly clearinghouse for APP and team-based oncology care information and resources currently available from ASCO. In addition, The Task Force has created ASCO Education podcast episodes on APPs 101," covering a wide array of topics, including what and who APPs are in today's oncology practice, their role and responsibilities, understanding their full scope of practice, and how to foster positive and beneficial working relationships between APPs and physicians. The taskforce has completed the following podcasts to provide insights into the APP: Episode 1: What and Who Are APPs? Episode 2: PAs and APRNs in Oncology, Episode 3: APP's Scope of Practice, and Episode 4: APPs in Oncology. Additional podcasts are planned to explore other areas of interest such as APPs in rural oncology practices.

EDUCATION AND TRAINING

Although the educational preparation of Nurse Practitioners (NPs) and PAs differs, their role within the cancer care team and at the bedside is analogous. Both NP educational preparation and PA educational preparation are at the graduate level. NPs acquire their Bachelor of Science in Nursing first and become licensed Registered Nurses (RNs). Many NPs work as RNs before becoming an NP. To become an NP, they complete a specific population-focused (eg, Family, Women's Health, etc) NP training program, which includes didactic and clinical practicum coursework. NPs must pass a board certification examination within their population focus and acquire their license to practice as a NP within that population focus.

Most PAs hold a baccalaureate degree before pursuing their educational preparation as a PA. Many PA training programs require as part of their prerequisites that a prospective PA student has hands-on clinical experience before acceptance into a PA training program. PAs are trained in the medical model, and most are trained as generalists as opposed to having a specific population focus. PA training includes didactic and clinical rotation coursework. On completion of their training, PAs must also pass a board certification examination (which spans the focus of their education as generalists) and acquire their license to practice as a PA.

APP BASICS FOR CLINICAL INTEGRATION

Before integrating APPs into the clinical team, it is important to understand several basic concepts. These include onboarding, orientation, scope of practice, and physician mentorship. With this basic knowledge, it will provide clarity on how the APP can be most effectively empowered and supported to serve the patient and partner with physicians.

The term onboarding refers to the initial time that an APP is brought into and introduced to the team. The APP entering oncology practice should have an onboarding process and commitment from the practice to ensure that they obtain the necessary medical knowledge and patient care knowledge and understand team workflows, team members, roles, responsibilities, and national guidelines. This investment enables the APP to assume care of the oncology patient in a team-based care model.

Unlike onboarding, the orientation is a much longer period where the APP is assigned a mentor and given a schedule that will be focused on a deep understanding of the details of the practice and how care is delivered. This can include assigned reading, e-learning, conferences, training on medical procedures, and any required credentialing and privilege processes. This is a much deeper dive than onboarding and requires a sustained commitment over several months to ensure that the APP will be effectively integrated into the practice.

The role of the physician and other experienced APPs in a team-based oncology model is to share best practices and collaborate on patient care by serving as a mentor for the new APP. Although APPs are trained across a broad range of general medical practices and/or populations, they require specialized knowledge in oncology that is specific to the practice and the individual team. This role of mentorship is critical in the successful formation of teams and is a necessary commitment to support APPs in team-based oncology practice.

SCOPE OF PRACTICE

Scope of practice is a critically important concept to understand. This sets the entire framework for how an APP can function in the team. Unlike physicians, the APP scope of practice can vary significantly from state to state. The scope

of practice is the statutory and regulatory standards that define what clinical activity is permitted, authority is granted, and physician collaboration is required. Team-based practice in oncology requires each health care provider to practice at the fullest scope to enhance patient safety and quality of care. Understanding the scope of practice will empower the physician and APP to work synergistically.

It is important for each licensed professional to be familiar with and understand the practice act for each state in which they are licensed. It is particularly important to be vigilant about differences in practice acts when providing medical care across state lines, especially if that care is provided within the same medical practice. For example, if a clinic has sites in two cities that span a state border, who can deliver a particular medical service and how that service is to be delivered may be different within each state.

When the care team includes NPs and PAs, the American Academy of Nurse Practitioners and the American Academy of Physician Associates are helpful resources for state-related information in addition to a state's practice act. State practice acts may vary widely in how they are written, and practicing clinicians need to have a working knowledge of the provisions of the practice act for each state in which they are licensed. Some states may include laundry lists of permitted clinical activities, whereas other states focus on the language of the practice act on restricted clinical activities. State practice acts, nursing boards, physician assistant boards, and medical boards can provide additional insight into the degree of autonomous practice permitted by the practice act and the conditions that must be met for the autonomous practice to be authorized.

TOP OF LICENSE: EMPOWERING THE TEAM AND SERVING THE PATIENT

With the complexity of oncology care, sharing and appropriately distributing the growing volume of tasks required to safely care for the patient is important for optimizing efficiency. A key tenet of this is top of license practice. Top of license means that each member of the team performs routine activities that should use the full extent of their education, training, experience, and competency to deliver the best possible care to the patient.[17] This typically results in the most cost-effective structuring of the team while ensuring that the patient's and caregiver's needs are being met by the appropriate member of the team.[8] To optimize top of license practice, it is important to remember the scope of practice of each individual of the patient's cancer care team. Scope of practice is shaped by the following: federal law (in some cases), state laws and regulations, facility or institutional policy, clinical privileges granted to a provider by a facility, and, at times, payer policy with the final determination occurring at the practice level.[18]

APP VISIT MODELS: SHARED OR INDEPENDENT

APPs are highly educated individuals who enhance organizational ability to provide cost-efficient and quality care through a multidisciplinary approach to hematologic and oncologic patient-centric care. Many health care institutions struggle with best practices and optimal APP utilization, particularly in specialty care.[19] Definition of care team roles, coordinated onboarding and orientation, departmental education regarding the APP scope of practice, and identification of practice models all can improve optimization efforts for APP integration.[19] There are several different types of practice models that exist within health care settings. The two most common visit types in the various models are independent versus shared visits. The terminology is confusing as both visit types still involve collaborative work between physicians and APPs given the complexity of this specialty; this can differ significantly from practice models implemented in primary care settings.[11]

Independent or supervised wrap models have physicians initially see patients and formulate a plan of care and then alternate future visits with the APP depending on medical complexity of the visit.[11] APPs have their own roster or template of patients, and all providers bill independently in this model. Shared visit models involve physicians often seeing patients on the same calendar day as APPs. When completing shared visits, APPs and physicians often work off the same templates in the clinic setting. Providers may use split/shared billing or independent billing procedures in this model. It should be noted that independent models in a collaborative setting are reported to increase APP satisfaction rates and visit volumes per provider compared with shared-only visit models.[11]

Although care team models affect return on investment for APPs, practice environments can also enhance or inhibit success of APPs in the clinical setting. Positive characteristics that may facilitate top of scope practice include encouragement of autonomy and positive APP-physician relationships.[20] Through an integrative review, barriers to effective APP practice models included the following: poor administrative and physician relationships with APPs, physician opposition to independent practice models, policy restrictions on APP practice, and lack of understanding of the APP role.[20] All the above influence advanced practice outcomes and should be considered when expanding the provider workforce.

APP SCRIBES—THERE IS A BETTER WAY

Provider burnout is at an all-time high; data entry and documentation in the electronic medical record (EMR) are two contributing factors.[21-23] Several studies have cited increased documentation times versus the delivery of patient care resulting in dissatisfaction of their role, which may be partially responsible for the growing number of

physicians leaving medicine overall.[23] Unfortunately, oncologists are at higher risk of burnout compared with other specialties because of complicated history and treatment plans, which may shift documentation work to others in the care team.[22] While APPs may assist with documentation, one should question if it is the best use of their role. Consideration of clinical needs, scope of medically trained individuals, improving access, and cost of resources should be used to inform decisions.

Misunderstanding the APP role is often a costly mistake and misuse of talent. APPs are highly trained clinicians who can assist in medical decision making and are recognized by Centers for Medicare & Medicaid services as billing providers. Their contributions can mitigate physician burnout in hematology and oncology in other ways such as triaging patients, managing toxicity or sick visits, offloading follow-up visits, procedures such as bone marrows, completing benign hematology consultations, and covering infusion units. Therefore, the use of APPs as scribes is an inefficient use of their skillset both clinically and financially.[21] Scribes are a part of the care team that specializes in the following: prepare medical history from charts, document patient-clinician encounters in real time, and prepare pending orders in the EMR for clinicians.[21] Several studies increasingly recommend scribes because of documented improved workplace satisfaction, decreased screen time for providers, and increased and enhanced quality patient facing time.[22] Medical practices appropriately using scribes were also able to increase volumes of patients per day because of efficiencies in workflow.[22] Both APPs and scribes are important roles that can support medical practices in a variety of ways to boost patient and teammate satisfaction. Ultimately, roles should align with training and will prove to be cost-effective if aligned with top of license and full scope of practice.

DEFINING AND MEASURING CARE TEAM DELIVERY

Thoughtfully and purposefully defining care team delivery at the practice level is critically important. To empower care team delivery and recognize the contributions of the entire care team it is key for practices to (1) establish buy-in from the administrative and clinical enterprises and (2) create compensation models that are flexible and transparent.[24,25]

To establish buy-in, practices should establish committees consisting of multidisciplinary and interprofessional team members to optimize team-based care and develop team-based compensation models. Efforts to optimize ambulatory APP collaborative practice have shown to increase APP clinical productivity and increase time that APPs are working at the top of their license without affecting physician-generated relative value units (RVUs) or patient satisfaction.[26] Having participation of all team members in shaping care delivery will make it clear that team-based care is a valued priority while empowering them to directly contribute to compensation model development. Committees can be tasked with identifying the service categories to be included in compensation models and determining the importance of each service and the metrics by which they will be measured.[24] In addition, committees should be tasked with identifying benefits and incentives beyond financial compensation to engage employees. Incentives such as increased flexibility in provider work schedules (working remotely) or increased protected time to pursue work-related activities that provide the most meaning can provide motivation greater than financial compensation alone.[27] Finally, the committees will be key in ensuring alignment of values between the center, team, provider, and patient.

To ensure that compensation models are fair and transparent, it will be vital to have an ongoing process for the evaluation. The chosen productivity goals, value metrics, provider success in meeting benchmarks, and the overall impact of the compensation models will need ongoing evaluation and revision. As noted previously, productivity metrics can be challenging to attribute in collaborative practice. However, opportunities to leverage the EMR to improve the tracking of APP clinical productivity and practice efficiency have been successful and provided transparency in data reporting, identifying or validating requests for additional staffing, and assessing performance expectations.[28] In addition to measuring quality-of-care metrics, novel strategies using the EMR to identify and track nonrevenue generating activities such as patient phone calls, prescription refills, and previous authorizations will be important to develop. Objective metrics are needed for recognition of the entire interdisciplinary team. The success of the compensation models and efforts to improve team-based care can and should be assessed through employee retention data and ongoing monitoring of employee satisfaction with work-life integration.

FINANCIAL INCENTIVES AND CARE DELIVERY

The complexity of oncologic care requires the expertise of multiple disciplines practicing within a team-based model of care delivery. Each team must manage numerous interdependent tasks to achieve the common goal of providing the best care for each patient. Teams must leverage the expertise of each professional discipline and use their unique background and training to successfully meet the shared goals of team-based care.[29] However, as the management of patients living with cancer has changed to team-based, so has the reimbursement models from payers prompting organizations to reconsider the provider compensation and incentive models. Importantly, as the health care landscapes change from a volume-based (fee for service) model to a value-based model, it will be vital to have

compensation and incentive models for providers that reflect the team-based practice of oncology.

Ideally, the goal of compensation and incentives will be to encourage the highest quality of care for the greatest number of patients. It will be important for compensation models to reflect the goals of the health system and align with the values of the workforce. Within the oncology team, the compensation models should encourage collaboration among team members working toward the shared goal of patient-centered care. Well-designed compensation models should acknowledge the individual's productivity and contributions to quality of care while also recognizing that the collective success of the team should be rewarded. To successfully accomplish these goals, compensation models will need to balance the incentives tied to productivity and the incentives related to quality of care and influencing the behavior of the provider and the team.[30] This will require deliberate work of providers, administrators, and practice leadership to (1) identify and establish the work performed by the clinical team, (2) rank the importance of the work, and (3) develop a compensation model that reflects the organization goals.[24] When properly aligned, each member of the team will be incentivized to achieve maximal results for their patients and the team. Importantly, individuals should have a sense of control over their ability to meet compensation goals and contribute to the success of other members of the team.

MISALIGNMENT OF INCENTIVES

When compensation models do not align with the goals and values of the individual, team, or health system, there is significant risk to the entire health care enterprise. When the values of an individual do not align with the goals of the compensation model, they may be at risk of suffering from moral distress, decreased engagement at work, or simply leaving the institution entirely. In addition, when compensation models too heavily favor productivity metrics, individuals and teams may be more focused on increasing the episodes of care and procedures and be less focused on improving the quality or value of care delivered.[31]

Within the team context, compensation models that heavily focus on individual metrics (especially productivity) are at risk of creating competition between team members to increase their individual productivity. This requires detailed attention when examining compensation models that include collaborative practice between physicians, NPs, and PAs. For example, standardized work RVUs have the benefit of providing a value for a level of care independent of the provider providing the care.[32] When an independent visit model is used in collaborative practice, this is less of an issue. However, shared visit models and incident to billing are often used in oncology and result in RVUs being attributed to the physician alone. This results in the time and effort of the APP being hidden.[11] The limitations of RVU metrics for APPs are further challenged in the surgical oncology setting where services provided by an APP during the perioperative period are hidden in the overall global surgical package.

Group or team goals may help encourage collaboration among team members. However, there is also the risk that individuals may sense lack of control related to their role and ability to meet incentive metrics, which can lead to further frustration and potentially burnout. For APPs, they might not have control over their schedule and might have to rely on their collaborating physician(s) to establish practice volumes and referral patterns. There may also be scope of practice limitations that affect collaborative practice and the ability of APPs to work to the top of their degree and training. Not only will this affect their ability to meet productivity targets but may also lead to increased rates of APP or oncologist burnout.[33,34] There is a significant amount of time that the clinical team dedicates to providing care for patients that is not revenue-generating (phone calls, patient education, coordination of care, treatment planning, etc).[35] Much of this work is often delegated to APPs and other nonphysician members of the team. If compensation models are not able to account for nonrevenue-generating activities, the value and contributions of APPs will be significantly under-represented. The APP value to patient experience, safety, and quality will be overlooked.

COLLABORATION NOT COMPETITION

No compensation and incentive model will be perfect, and institutions should be tasked with establishing a deliberate process for ongoing evaluation of the selected model. Ideally, compensation models will include incentives that reflect the mission of the center such as clinical productivity, quality of care, citizenship, and, when applicable, research, education, and administrative responsibilities. As noted previously, there are challenges with using individual RVU metrics for APPs. One possible solution would be to establish RVU goals for the individual and the clinical team as a whole.[36] This would ensure not only some degree of responsibility and ownership of individual productivity but also recognizing the contribution to clinical productivity that may not be reflected in individual RVUs. The individual goal and team goal could be weighted (60% individual and 40% team for example) to reflect an overall productivity score. This would enable an incentive in support of the individual and encouraging productivity of highly functioning teams. In addition, by distributing productivity metrics between individual and team goals, there would be less of a focus on extremely high levels of individual production and institutions would be conveying a message that they value hard work but in a more modern team-based environment.[37]

Although productivity-based compensation incentives remain the most common and heavily weighted form of compensation, quality-of-care metrics have been successfully incorporated in oncology.[38] One large integrated health care system reported their experience with developing a matrixed incentive plan in their division of hematology-oncology on the basis of clinical productivity (50%), patient-center goals (10%), academic goals (10%), quality measures (20%), and overall performance of the health system (10%).[38] They noted that providers responded well to the quality measures outcomes, but interestingly, the other variables were met with variable success. Within a team-based care delivery system, the use of quality metrics to help guide compensation for providers is likely to require work of the entire team to achieve the selected metric. For example, a compensation model that used the ASCO Quality Oncology Practice Initiative core measures related to documentation and monitoring of oral chemotherapy would rely on multiple members of the oncology team to be sucessful.[39] In addition, although select metrics may be attributable to an individual for a given visit (such as documentation of oral chemotherapy plan), other metrics may be more longitudinal in nature (medication adherence assessed and addressed) in which both the APP and the physician may contribute to the success in quality care. In addition, because of the nature of the quality metrics, there will be opportunities for the team to identify problematic areas in clinical care to improve practice efficiency and workflows that encourage teamwork and collaboration.

CONCLUSION

The creation of the APP more than 50 years ago continues to have a profound impact on the health care system in the United States. Although APPs have moved into every aspect of patient care, there remains a need for better understanding of these professionals, their role, integration into clinical practice, models of care, and incentives that recognize the work of the team. ASCO has contributed to exploring the APP workforce in oncology and understanding the collaborative relationship between physicians, APRNs, and PAs. It is clear that team-based care is required for providing safe, timely, and quality care of the individual with cancer. Patients benefit from this collaboration and when the entire team works at the highest levels. Ongoing exploration and refinement of models of care, incentives, and collaboration with APPs will enhance and empower care teams.

Implementing Innovation: Informatics-Based Technologies to Improve Care Delivery and Clinical Research

Travis J. Osterman, DO, MS[1]; James C. Yao, MD[2]; and Monika K. Krzyzanowska, MD, MPH[3]

Overview

Improving technology has promised to improved health care delivery and the lives of patients. The realized benefits of technology, however, are delayed or less than anticipated. Three recent technology initiatives are reviewed: the Clinical Trials Rapid Activation Consortium (CTRAC), minimal Common Oncology Data Elements (mCODE), and electronic Patient-Reported Outcomes. Each initiative is at a different stage of maturity but promises to improve the delivery of cancer care. CTRAC is an ambitious initiative funded by the National Cancer Institute (NCI) to develop processes across multiple NCI-supported cancer centers to facilitate the development of centralized electronic health record (EHR) treatment plans. Facilitating interoperability of treatment regimens has the potential to improve sharing between centers and decrease the time to begin clinical trials. The mCODE initiative began in 2019 and is currently Standard for Trial Use version 2. This data standard provides an abstraction layer on top of EHR data and has been implemented across more than 60 organizations. Patient-reported outcomes have been shown to improve patient care in numerous studies. Best practices for how to leverage these in an oncology practice continue to evolve. These three examples show how innovative has diffused into practice and evolved cancer care delivery and highlight a movement toward patient-centered data and interoperability.

INTRODUCTION

The practice of oncology has seen a steady stream of technological advances over the past several decades, including tracking quality metrics, the concept of the Learning Healthcare System, CancerLinQ, and others.[1-3] These improvements in health care delivery have come as a direct result of the increasing adoption of electronic health records (EHRs). Here, we focus on three contemporary informatics-based initiatives that have the potential to continue transforming how oncologists provide care to patients with care: minimal Common Oncology Data Elements (mCODE),[4] Clinical Trials Rapid Activation Consortium (CTRAC), and electronic Patient-Reported Outcomes (ePROs). Here, we describe the current state of these three practice innovations.

The EHR has its roots in the 1960s when medical facilities first began using computers to store patient data.[5] However, it was not until the late 1990s and early 2000s that the widespread use of EHRs in health care became a reality. Several factors, including increasing consumer demand for access to health information and advances in information technology, have driven the growth of the EHR. However, one of the most significant drivers of EHR adoption has been government policy.

The first major policy effort to promote the use of EHRs in the United States was the Health Insurance Portability and Accountability Act (HIPAA) of 1996.[6] HIPAA established national standards for the privacy and security of patient health information, making it possible for health information to be shared electronically between providers and patients. In 2004, the Office of the National Coordinator for Health Information Technology was established to promote the widespread use of health IT, including EHRs.

The American Recovery and Reinvestment Act (ARRA) of 2009 marked a turning point in adopting EHRs in the United States. ARRA provided funding for the implementation of EHRs and incentivized providers to adopt them through the Medicare and Medicaid EHR incentive programs.[7] As a result of these incentives, the use of EHRs in the United States increased dramatically over the next several years.[8]

The adoption of EHRs has promised opportunities to further leverage technology to improve cancer care delivery. CTRAC, mCODE, and ePROs are three examples of initiatives building on this information technology infrastructure.

CTRAC AND PROTOCOL INTEROPERABILITY

The construction of treatment plans in the EHR can greatly support quality care delivery through standardization. Although efficient for standard-of-care

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- The Clinical Trials Rapid Activation Consortium project aims to provide a method to electronically share cancer treatment protocols between organizations.
- Released in 2019, minimal Common Oncology Data Elements is a data abstraction layer that leverages Fast Healthcare Interoperability Resources and currently implemented at more than sixty institutions.
- Electronic Patient-Reported Outcomes have been shown to improve outcomes in oncology care, but key challenges with these systems are alert fatigue, management of false positives, and identification and deployment of effective response strategies.

treatment, EHR treatment plans for clinical trials must be built uniquely for each participating site within its own instance of the EHR. To address this current costly, complex, and inefficient paradigm, the University of Texas MD Anderson Cancer Center (MD Anderson) has served as the coordinating site for the CTRAC, one of the consortia funded by the National Cancer Institute (NCI) to develop processes across multiple NCI-supported cancer centers to facilitate the development of centralized EHR treatment plan builds that can be deployed at multiple institutions. Here, we describe the inefficiencies of the current process, challenges underlying the necessity of repetitive builds, and work underway to enable our vision of a single build that can be shared across multiple sites.

EHR build components consist of medication builds and treatment plan builds; they require configurations for novel medications, numerous ancillary procedures, and research finance requirements. For example, each investigational medication may consist of multiple electronic medication records (ERXs), and each ERX in Epic (the most deployed EHR among large cancer centers) has hundreds of configurable fields. Each clinical trial may also require multiple treatment plans to implement different arms, cohorts, or phases of the study. In the current state, EHR treatment plans for clinical trials must be built uniquely for each instance of an EHR. Differences in workflow, standard operating procedures, and medication formularies, and the lack of standardization for site-specific procedures and laboratories all contribute to differences in workflow.

These problems are amplified in precision medicine studies with numerous arms. For example, the NCI-MATCH Precision Medicine Cancer Trial boasts 37 arms and is active at nearly 1,100 sites according to ECOG-ACRIN. If each site activated all arms, >40,000 EHR treatment plan builds could potentially be needed to support this single important study.[9] Compounding these costly inefficiencies, many studies and treatment plan builds may not be used because of a small eligible patient population, early study terminations, or changes in development priorities.

How We Currently Build Clinical Trial Treatment Plans in EHRs

The EHR build of research protocols follows a similar multistep process at most sites (Fig 1) that includes (1) clinical content extraction, (2) construction of build documents, (3) EHR build by technical teams, and (4) validation by clinical team.

This process requires participation from site investigators, pharmacists, research staff, and EHR technical teams. It often also requires frequent back and forth between these teams and with the study sponsors. We outline some of challenges that often consume resources and delay protocol activation here.

First, there is lack of standardization and structure for the provision of clinical content. Information can be represented to various degree of completeness in numerous protocol and ancillary documents, including the protocol text, study calendar, pharmacy manual, laboratory manual, investigative brochure, and other appendices. Second, clinical decisions are almost always needed by site investigators and clinical personnel before technical build. For example, although some studies include recommendations for antiemetics, many studies are silent about their use. Thus, sites may need to make decisions about whether to include antiemetics as premedication and, if used, which antiemetics is to be included. Decisions are also needed when several permissive choices are available. For example, if the protocol states that drug ABC123 can be diluted in D5W or NS to a final concentration between 1 mg/mL and 5 mg/mL and a final volume of 100 mL or 250 mL is recommended, site clinical or investigational pharmacist will need to make decision about diluent and volume before technical build. Finally, most clinical trials are written in a task-oriented manner specifying a task and when it needs to be performed. EHR builds are oriented to cycle day structure specifying what tasks are to be performed during a specific patient encounter necessitating a pivot that can be laborious.

Key Challenges Facing Centralization of EHR Builds

Lack of standardization in how protocols are written and local differences in formularies, practices, roles, workflows, and policies are challenges for an efficient centralized EHR build process. These differences proliferated as site implementation of EHR often tailored to legacy processes. CTRAC cataloged relevant challenges by comparing builds

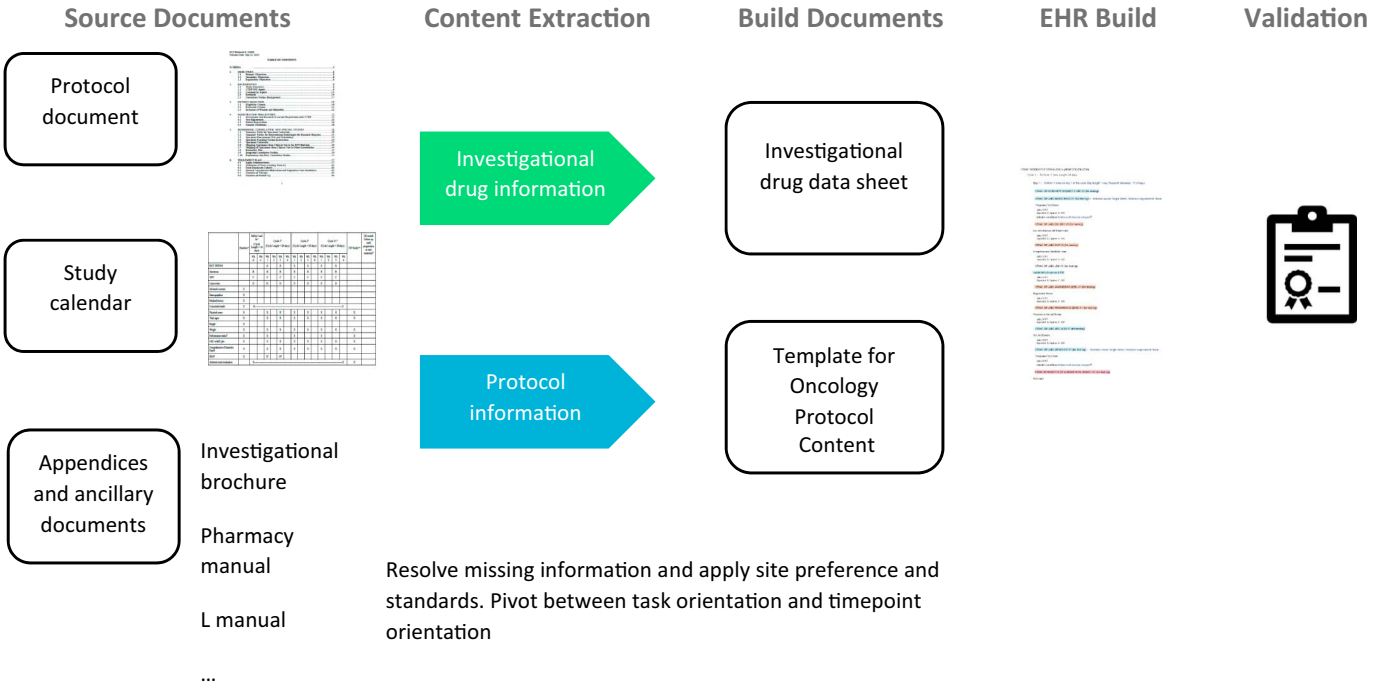

FIG 1. Clinical Trials Rapid Activation Consortium current state: EHR build process repeated at each site. EHR, electronic health record.

and build processes across its member sites and is working on solutions to enable centralized build.

Clinical content extraction. CTRAC developed standardized processes and tools for the extraction of both investigational drug information and clinical protocol information. Missing or incomplete information is clarified centrally by CTRAC or protocol sponsor. Subsequently, build documents are completed before technical build.

Heterogeneity in site formularies, practices, roles, and workflows. Protocol tasks can be generally categorized as protocol-specific or general tasks. Protocol-specific tasks, such as delivery of investigational medication, are generally fully specified by the protocol and allow little to no variation from site to site. General tasks are often supportive and may contain high degree of variation from site to site. Examples include antiemetic or hypersensitivity orders. We developed a library of standardized tasks along with specifications what each task must accomplish. Site can specify how it will accomplish the task conforming to CTRAC specifications and site policy by building groups of orders that can be called upon by a master protocol build. These building blocks act as a translation layer and a documentation layer for site clinic decisions, such as how a site handles antiemetics or hypersensitivity (Fig 2).

Progress to date and future directions. Using the methodology outline discussed here, CTRAC has completed successful proof of concept. We successfully built protocols using CTRAC standards, exported them into packages, and subsequently imported them at member sites. Although we have iteratively refined the process, most sites still need to do substantial adjustments to the build after import. Causes for postimport adjustments include the following:

1. Rigid site standards for style, wording, and naming.
2. Heterogeneity in what sites include in their treatment plan builds. For example, some sites perform certain categories of tasks outside of EHR treatment plan workflow.
3. Site preference in the sequence of how orders are presented.

With substantial progress, the work of CTRAC will continue under the newly expanded, NCI-supported, pilot EHR consortium and will work to innovate and create solutions with the goal of delivering more tailored builds that will further decrease the work of protocol activation. Our goal is to create a seamless process from protocol authoring, centralized build, and delivery of builds conforming to site needs in a speedy and efficient process.

mCODE AND DATA INTEROPERABILITY

The mCODE project began in 2018 with a working group within American Society of Clinical Oncology (ASCO). The group of informaticians worked with two use cases to conceive and propose a set of minimal set of data elements to describe patients with cancer and their journey from diagnosis to treatment. The ambitious goal was that this set

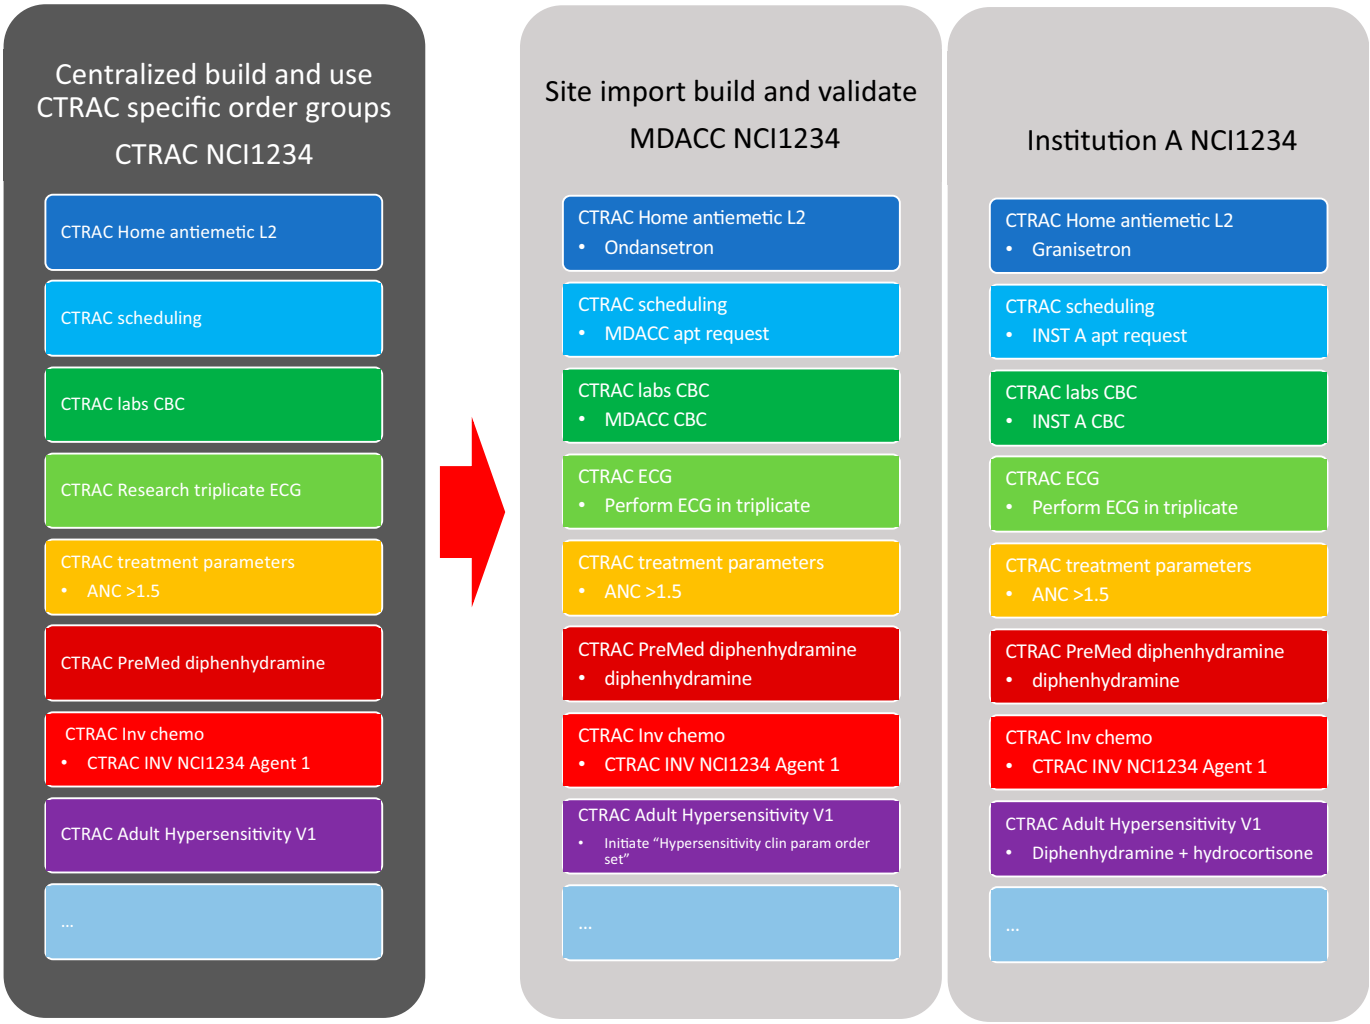

FIG 2. CTRAC use of order groups as translation layer across clinical sites. ANC, absolute neutrophil count; CBC, complete blood count; CTRAC, Clinical Trials Rapid Activation Consortium; INST, institution; INV, investigational; MDACC, MD Anderson Cancer Center.

of data elements would be an interoperable layer sitting above the EHR.

The initial public release of mCODE occurred at the 2019 ASCO Annual Meeting.[10] This was considered version 0.9 and contained 73 data elements across six domains: patient, disease, laboratory results/vitals, genomics, treatment, and outcomes. The governance of the mCODE project transitioned early from ASCO to the mCODE Executive Committee (EC). The EC is composed of four to seven entities, each entitled to appoint one representative and one alternate. The EC is chaired by the ASCO representative. EC members are voting unless they decide to be nonvoting members. The current EC members are ASCO, Alliance Foundation of the Alliance for Clinical Trials in Oncology (Alliance), the MITRE Corporation (MITRE), American Society for Radiation Oncology (ASTRO), and the Society of Surgical Oncology (SSO).

The mCODE EC formed the mCODE Technology Review Group (TRG) to manage the mCODE data dictionary. The TRG worked closely with the MITRE Corporation to respond to public comments and comments from the Heath Level 7 (HL7) community, and on March 18, 2020, Standard for Trial Use version 1 (STU1) was released.

Although the TRG largely focuses on maintaining the data dictionary, CodeX was created as a member-driven HL7 Fast Healthcare Interoperability (FHIR) Accelerator.[11] CodeX has the vision to collect patient data once and reuse those data to enable a range of critical workflows. CodeX currently supports six active community projects that use mCODE: Cancer Registry Reporting, EHR Endpoints for Cancer Clinical Trials (ICAREdata), Integrated Trial Matching for Cancer Patients and Providers, mCODE++ Extraction, Radiation Therapy Treatment Data for Cancer, and Prior Authorization in Oncology. Several other projects are planned.

Organizations also find implementation support through the Community of Practice (CoP).[12] The CoP holds monthly meetings highlighting mCODE implementations and providing a venue for organizations to ask questions and learn from one another.

The mCODE ecosystem relies on implementors to provide feedback, which is used to evolve the mCODE data dictionary. For example, the mCODE Standard for Trial Use version 2 (STU2) was released on January 18, 2022, and contained significant changes expanding the representation of radiation oncology concepts.

Today mCODE is implemented at more than 60 institutions across several countries. The data standard is currently STU2, and changes for the next version are being actively considered. Furthermore, the project has garnered interest from other groups with similar problems. Cardiology has begun to create a CardX group, for instance, on the basis of lessons learned from the mCODE project.[13]

Implementing ePROs in Real-World Oncology Practice

The growing body of evidence supporting the benefits of using patient-reported outcomes (PROs) in oncology settings has led to substantial interest in the implementation of PROs into routine practice. Studies have shown that systematic symptom assessment using PROs is better at capturing patients' symptoms and experience than clinical assessment.[14] Furthermore, their utilization to facilitate clinic assessments[15-17] or to remotely monitor patients during treatment[18-21] has been associated with improved outcomes in multiple studies. PROs can be administered using a variety of approaches ranging from paper-based forms through phone-based systems to fully integrated EHR-based systems with interactive capabilities and self-management support. Currently, the two main use cases in routine oncology practice are to support real-time assessment by a clinician during a scheduled visit or to facilitate remote monitoring during treatment. Although the evidence base on the benefits of using PROs in oncology care has grown substantially over the past decade, experience with implementation into real-world oncology practice has been limited, albeit accelerating.

EVIDENCE FOR UTILIZATION OF PROS IN ONCOLOGY

Most of the early studies in oncology focused on using PROs to support patient-clinician communication regarding quality of life and symptom management. Multiple randomized trials showed that the routine use of PROs before an outpatient oncology visit helps to identify key symptom concerns and improve quality of communication without negatively affecting visit duration.[15-17]

The ambulatory nature of oncology practice coupled with the high symptom needs between visits to the cancer center sparked interest in using PROs to facilitate the remote monitoring of patients during treatment. There have now been several randomized studies that have evaluated remote monitoring using PROs in the oncology setting.[18-24] The majority of these studies have focused on patients with solid tumors undergoing systemic treatment using a variety of PROs administered at different frequencies ranging from daily to every few weeks either by phone or electronically. Compliance with reporting has generally been high in these mostly proof-of-concept studies, as has been acceptability to both patients and providers. These studies have consistently shown that remote monitoring improves symptom control and quality of life. Two of the studies showed improvement in survival.[25,26] A key finding from one of the studies was the importance of having a robust response system with dedicated roles to manage symptom alerts, as opposed to leaving the response to the discretion of the treating team.[23] Only two of these studies examined the impact on health system outcomes, such as emergency department (ED) visits and hospitalizations. In one individually randomized study, there were fewer ED visits in patients with advanced cancer randomly assigned to remote monitoring.[18] However, in a pragmatic cluster RCT in early-stage breast cancer, there was no difference in ED visits or hospitalizations in the intervention arm.[24] Therefore, although it is clear that remote monitoring of patients with cancer improves patient outcomes, the impact on health system outcomes is less clear.

REAL-WORLD EXPERIENCE

A number of institutions and health systems have worked on integration of PROs, including electronic PROs into routine practice.

To Facilitate Clinic Assessment

The longest experience with the utilization of PROs in routine practice in the oncology setting has been in the province of Ontario, Canada. Ontario has a universal health system with standards for cancer care set by the provincial cancer agency Cancer Care Ontario. The Cancer Care Ontario implementation started with a quality improvement project focusing on improving symptom control in patients with lung cancer but led to province wide rollout starting in 2008. The focus of this implementation was on utilization of the Edmonton Symptom Assessment System (ESAS) PRO before clinic visits to facilitate patient-clinician communication. Although there was a provincial mandate for implementation, the approach to institution-level implementation was left at the discretion of the institution. Some centers did mostly paper-based implementation, but several did a successful integration into their electronic medical record (EMR) with features for trending and addition of other questions or symptom measures (Fig 3).[27] Monitoring of uptake focused on screening rates, and chart audits showed challenges with response to symptoms, which may have

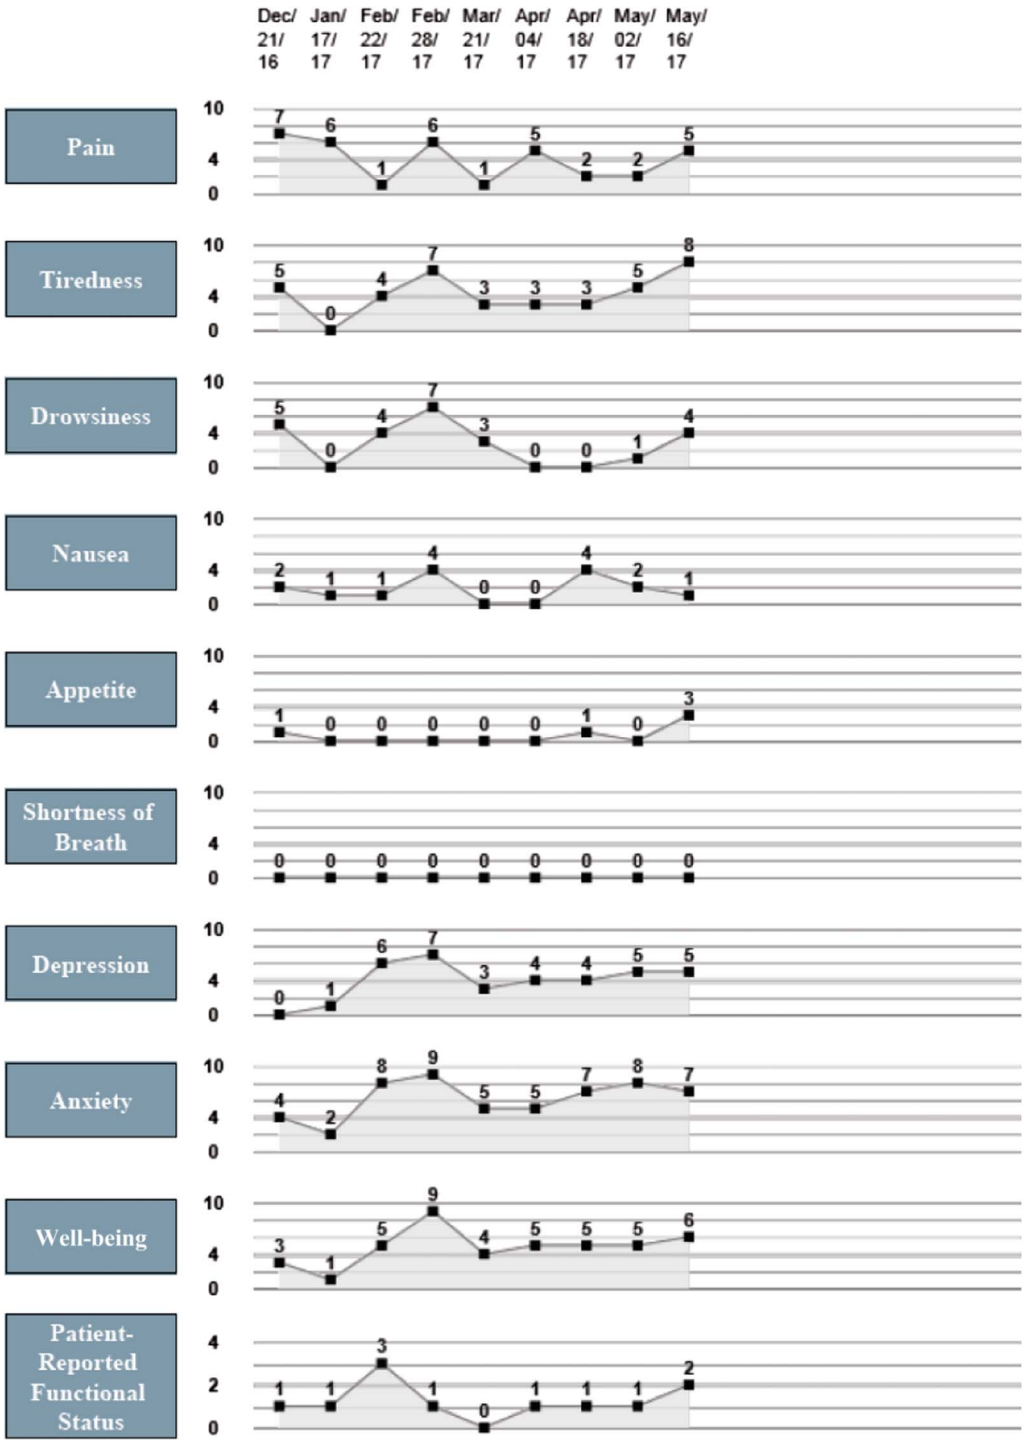

FIG 3. Example of patient-reported outcome integration into the electronic health record.

negative impact on patient engagement ("why am I filling this out if no one is looking at it"). Key learnings from the Cancer Care Ontario experience were the importance of clinician engagement and the need to pay attention to sustainability after initial implementation as compliance with screening can decrease with time.

Remote Monitoring

Published experience with implementation of remote monitoring in routine oncology practice is growing.[28-30] Some of the groups have used vendor-based applications,[28,29] whereas the SIMPRO consortium[30] is focusing on developing an

EHR-based solution in partnership with the EHR vendor. The target population in the majority of these implementations consists of patients initiating systemic therapy; the SIMPRO group has also included patients after surgery. The reported experience thus far has focused on recruitment, retention, frequency of alerting, and early barriers. The recruitment rates appear reasonable, but retention has been quite variable with one practice reporting an 88% retention rate at 6 months,[29] whereas another system-wide implementation reported 52% at approximately 3 months.[28] The available reports suggest that generated alerts are manageable, but technical, practice-level, and patient-level barriers impede uptake and sustainability.

At present, there is limited information on the system-level outcomes of PRO integration into routine practice. Data from Ontario have shown that province-wide ESAS implementation has been associated with improved system outcomes,[31] but formal financial analyses are lacking. Patient- or system-level impact of remote monitoring in real-world settings is not yet known and should be evaluated as part of the ongoing implementation efforts.

PLANNING FOR A SUCCESSFUL IMPLEMENTATION: KEY IMPLEMENTATION CONSIDERATIONS

On the basis of the experiences reported thus far, there are a number of implementation considerations that practices or health systems need to consider when implementing ePROs. Although leadership buy-in and conducive reimbursement models are essential to ensure appropriate resources for implementation, the biggest challenges, to date, to successful adoption are effective clinical integration, EMR integration, and sustainability beyond initial implementation. Systematic reviews of strategies to support ePRO implementation that include nononcology settings are emerging.[32]

Clinical Integration

The importance of response to PROs cannot be underestimated, and patient disengagement can occur if patients perceive that no one is looking at this. It is essential to engage clinical teams early to clearly articulate the objectives and potential benefits and to codesign the PRO collection and response process with the clinical team. The process should be designed to meet the needs of patients and fit the clinical resources. Identifying clinical champions has been shown to be a key component of an effective implementation strategy.[33] Importantly, practices should consider and define workflows following PRO completion. This includes developing algorithms and guidelines to support the response, training and education of clinicians, and assigning dedicated time to do this work. As the sophistication of the ePRO collection systems has increased over time, there are opportunities for automation and self-management support on some of the platforms, but a live clinician is still needed for management of more severe symptoms or to support patients with low self-efficacy.

PRO Selection—Tool and System

Many different validated PROs are available ranging from broad symptom screening tools, such as ESAS, to disease-specific ones, such as the Expanded Prostate Cancer Index Composite for Clinical Practice (EPIC-CP). The advantages of a broad PRO, such as ESAS, are that it can work across multiple settings and can be a good screening tool, but it may not be specific enough for a certain clinical scenario which may affect patient and clinician adoption. Another key consideration is the response burden, especially if multiple PROs are being considered for a particular patient. It is important to establish a governance process for PRO selection that considers the local context early in the implementation process.[34] The PROs can either be integrated into the existing EMR or come as part of stand-alone systems. Either approach has pros and cons.

Supporting Adoption

Like any complex intervention, implementation of PROs requires implementation support in the form of project management and ongoing audits of uptake and response. Planning for staff turnover with ongoing education and training at the time of joining a practice is also a key consideration.

Equity Considerations

A concern with implementation of ePROs is the risk of not reaching certain patient populations, such as patients without access to an appropriate device or Internet, those with low digital health literacy, those who are not primary English speakers, or older patients. Interestingly, the data suggest that age or low digital literacy may not be as much of a barrier, as was previously considered.[18] Regardless, access needs to be considered at the design phase and may vary depending on local context and the population served by the practice or system. Several of the PROs have been validated in other languages. Giving patients a choice (electronic completion versus via the phone) is also important. In the PRO-TECT trial of 52 community practices across the United States of which 26 were cluster randomized to remote monitoring, approximately one third of patients chose automated telephone-based administration rather than the web-based system.[22]

DISCUSSION

Here, three initiatives have been highlighted to show examples of innovation currently being implemented in cancer care deliver. CTRAC offers the potential to transform how treatment protocols are electronically shared. This has the opportunity to transform the currently siloed process of translating a narrative treatment protocol to electronic form. Although complexities such as local drug preference,

treatment plan format, and underlying EHR are not fully solved, the progress of this initiative offers hope that the burden of translating and transcribing treatment protocols will soon be reduced. A primary benefit of CTRAC is for multisite clinical trials. If successful, CTRAC may offer sites the opportunity to download an electronic version of the treatment protocol into the site's EHR, thus decreasing both local build resources and potentially decreasing activation time.

The mCODE project has seen incredible adoption since its announcement at the 2019 ASCO Annual Meeting. One key to the project's success is the focus on being the minimal set of clinical data elements to describe patients with cancer and their journey through the cancer care continuum. Additionally, mCODE has created an ecosystem to support implementers through CodeX and the Community of Practice. This setting not only provides benefits to new mCODE adopters but also facilitates feedback to the mCODE Technology Review Group on which portions of the data dictionary may need to be expanded to accommodate new use cases. mCODE also focuses on integrating with other national and international data standards while providing specialty-specific expertise in areas, such as cancer staging and tumor genomics.

There is strong evidence for the use of PROs in oncology settings, but real-world implementation is underway. Attention to key implementation considerations, especially early focus on clinical integration, has the potential to improve adoption at the practice level. Future studies of real-world implementation should focus on testing of implementation strategies and evaluation of impact on patient- and system-level outcomes.

Additional EHR elements, wearable data, and other parameters may integrate ePROs to identify and predict adverse outcomes prompting early intervention. With substantial interest to move more care into the home, PROs may also help facilitate the hospital@home model for patients who would otherwise have been managed in the inpatient setting. Key challenges with these systems are alert fatigue, management of false positives, and identification and deployment of effective response strategies.

CONCLUSION

There are several exciting evolving opportunities for data standards such as mCODE, interoperable clinical trial protocols such as CTRAC, and implementation of ePROs into routine oncology care. Each of these initiatives is rooted in fundamental clinical informatics principles. The success of these highlighted initiatives is, however, based largely on a shared process. First, identify key problems and opportunities in the field of oncology. Second, bring stakeholders together to discuss approaches to address the given problem. Next, implement one or more solutions and share the results with the community. Finally, learn from each other and continue to refine the solutions while decreasing implementation burden for future organizations. This approach can be leveraged by other informatics projects aiming to implement innovation in cancer care delivery.

Molecular Profiling in Neuro-Oncology: Where We Are, Where We're Heading, and How We Ensure Everyone Can Come Along

Alyx B. Porter, MD[1]; Patrick Y. Wen, MD[2]; and Mei-Yin C. Polley, PhD[3]

Overview

Advances in molecular profiling have led to improved understanding of glioma heterogeneity. Results have been used to inform diagnostic classification and targeted treatment strategies. Validation of these tests is necessary in the development of biomarkers that can aid in treatment decision, allowing for personalized medicine in neuro-oncologic diseases. Although not all populations have benefitted equally from awareness of and access to testing, opportunities arise regarding incorporating this testing into the standard of care for patients with glioma.

BACKGROUND

Over the last decade, there have been major advances in our ability to profile tumors molecularly with next-generation sequencing and DNA methylation analysis.[1,2] These techniques have significantly improved our understanding of the major molecular drivers in brain tumors and the identification of novel tumor types.[1,3,4] They provide the opportunity to improve the classification and diagnosis of brain tumors and identify potential targeted therapies. Nonetheless, to date, these advances have not translated into better outcomes for most patients.[5,6]

2021 WHO CLASSIFICATION OF CNS TUMORS

Undoubtedly the most important role of molecular profiling in brain tumors currently is the classification of these tumors. Beginning with the 2016 WHO CNS Tumor Classification update,[7] and expanded in the 2021 WHO CNS Tumor Classification,[8] molecular profiling now plays a crucial role in the diagnosis and classification of brain tumors (Fig 1).

Diffuse gliomas are now separated into adult-type and pediatric-type with different biology and molecular drivers.[8] Adult-type gliomas have been condensed into just three types (isocitrate dehydrogenase [*IDH*]–mutated astrocytomas and oligodendrogliomas, and *IDH* wild-type glioblastomas).[8] Glioblastomas now include not only tumors with the classical histologic findings of necrosis and microvascular proliferation but also tumors without these findings but with *TERT* promoter mutation, epidermal growth factor receptor (EGFR) amplification, or gain of chromosome 7 and loss of chromosome 10 (molecular glioblastomas).[8] For pediatric-type diffuse gliomas, there is differentiation into low-grade tumors, such as those with MAP kinase alterations, and high-grade gliomas with H3K27M alterations and infantile hemispheric gliomas, which are often associated with fusions, offering potential targets for therapies.[9]

Molecular classification of medulloblastomas also allows the identification of good prognostic groups with WNT alterations that may allow for reduction in radiotherapy dose and potential neurotoxicity and groups that have alterations in the sonic hedgehog pathway that may respond to smoothened inhibitors.[10] In contrast, those patients in other groups have a much poorer prognosis and require aggressive therapy.[8,10,11]

DNA methylation profiling enables quantitative interrogation of selected methylation sites across the genome, offering high-throughput capabilities.[2,12,13] It has improved the classification of brain tumors and allowed the identification of several previously unknown tumor types. Although it is currently not widely available, it offers the potential for a relatively cost-effective method to diagnose brain tumors, providing O^6-methylguanine–DNA methyltransferase (MGMT) methylation status and copy number information. Methylation of the MGMT promoter and silencing of the gene are predictive of improved response to alkylating chemotherapy (temozolomide and lomustine) in patients with glioblastoma.[14,15] MGMT promoter methylation status is being used increasingly to stratify patients in glioblastoma clinical trials and select patients without MGMT promoter methylation for trials omitting temozolomide, allowing the agent under investigation to be used at full dose or to avoid immunosuppression.[16]

The improved classification of CNS tumors with molecular profiling allows for better understanding of the

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Molecular profiling plays a critical role in diagnosis, classification, and outcomes of brain tumors.
- The greatest advances have been seen in children, allowing targeted therapy for SEGA in tuberous sclerosis, low-grade glioma, and plexiform neurofibroma.
- Methylation of O^6-methylguanine–DNA methyltransferase promoter enzyme is predictive of improved response to alkylating chemotherapy in patients with glioblastoma and is being used to stratify patients in clinical trials.
- Developing a predictive biomarker for widespread use in patients with glioma requires validation.
- Improving access and awareness of advanced molecular testing will broaden understanding regarding the spectrum of diseases in patients with various elements of diversity.

prognosis and optimal therapy for patients.[9,17] It also allows more homogeneous populations of patients to be enrolled into clinical trials, facilitating the evaluation of novel therapies, and increases the potential for identifying more molecular targets for therapy. However, there is now a much greater requirement for neuropathology laboratories to have access to adequate molecular testing and to provide the results in a timely manner. There is also the need for payors to be educated on the importance of these tests and provide appropriate reimbursement.

THERAPY ON THE BASIS OF MOLECULAR PROFILING

Although there has been major progress in understanding the molecular pathogenesis of brain tumors, these advances have only recently started to be translated into improved outcomes for patients, primarily in the pediatric population.

Therapy for systemic cancers has been effective with agents able to achieve therapeutic concentrations against well-validated therapeutic targets. For many brain tumors, targets are often not well-validated and there are uncertain ability of the agents to cross the blood-brain barrier (BBB) and achieve adequate concentrations in tumor and uncertain information regarding the ability of these agents to adequately inhibit the targeted pathways.[6] Other challenges to developing effective molecular therapies include the poorly predictive preclinical models, the limited number of agents under development that can effectively cross the BBB, redundancy of signaling pathways, tumor heterogeneity and plasticity of cellular states, the relative rarity of easy targets, such as *BRAFV600E* mutations and fusions, the poorly organized and funded infrastructure for early phase (phase I and surgical window of opportunity) clinical trials in neuro-oncology, the need for improved response criteria and trial design, and the relative lack of funding and interest from the pharmaceutical industry.[6]

Despite these challenges, there has been some recent progress (Table 1). In adults, the combination of dabrafenib (RAF inhibitor) and trametinib (MEK inhibitor) produced durable responses in 32% of *BRAFV600E*-mutated glioblastomas and 69% of lower-grade gliomas and contributed to the US Food and Drug Administration approval of the combination for all solid tumors in 2022.[18] Single-agent vemurafenib (BRAF inhibitor) produced a lower 25% objective response rate (ORR) and a 5.5-month median progression-free survival (PFS) in *BRAFV600E*-mutated gliomas.[19] Retrospective studies have also shown similar benefits.[36] In adults, durable response rates of 30% have been observed with larotrectinib for neurotrophic tyrosine receptor kinase fusion–positive brain tumors,[20] 20.7% with erdafitinib for high-grade gliomas with fibroblast growth factor receptor mutations or fusions,[21] and 20% with dordaviprone (ONC201), a dopamine receptor D2 inhibitor and ClpP agonist, in H3K27M-mutated diffuse midline gliomas.[22,23] In IDH-mutated gliomas, several IDH inhibitors have shown prolonged stabilization of disease and vorasidenib has shown response rates of up to 40%.[24-28,37,38]

However, the greatest advances have been seen in children. The first targeted therapy that received regulatory approval for brain tumors was the mammalian target of rapamycin inhibitor everolimus for subependymal giant cell astrocytoma associated with tuberous sclerosis.[29] A durable response rate of 35% was observed and associated with a reduction in seizure frequency. The combination of dabrafenib and trametinib has produced a response rate of 25% in children with recurrent low-grade gliomas with *BRAFV600E* mutations[30] and increased responses and prolonged progression-free survival compared with standard chemotherapy with newly diagnosed low-grade gliomas with these mutations (an ORR of 47% and a median PFS of 20.1 months with dabrafenib/trametinib *v* an ORR of 11% and a median PFS of 7.4 months with chemotherapy).[30] MEK inhibitors, such as selumetinib,[31,39] and type 2 RAF inhibitors, such as tovorafenib (day 101), also show high response rates in children with low-grade gliomas, including those with BRAF-KIAA fusions. Infants with hemispheric gliomas often have fusions, and responses have been seen with a variety of agents.[40] Dordaviprone (ONC201) has also shown activity in children with H3K27M-mutated midline gliomas,[32] and encouraging responses have been observed with GD2 CAR-T-cell therapy for these tumors.[33] Selumetinib has also shown encouraging activity for malignant plexiform neurofibromas.[34]

General Changes in Nomenclature

Use of Arabic numerals (1, 2, 3, 4) rather than Roman numerals (I/II/III/IV)

Not Otherwise Specified (NOS) indicates that the molecular and/or immunohistochemical testing needed to precisely classify a particular CNS tumor by the new scheme is not available.

Not Elsewhere Classified (NEC) refers to cases in which advanced molecular testing was done, but still failed to classify the tumor.

Adult-Type Diffuse Gliomas

- Astrocytomas, IDH-mutant
- Oligodendrogliomas, IDH-mutant, 1p/19q codeleted
- Glioblastoma, IDH wild-type

Pediatric-Type Diffuse Gliomas

Pediatric-Type Diffuse Low-Grade Gliomas

- Diffuse astrocytomas, MYB- or MYB-L1–altered
- Angiocentric glioma
- Polymorphous low-grade neuroepithelial tumor of the young
- Diffuse low-grade glioma, MAPK pathway–altered

Pediatric-Type Diffuse High-Grade Gliomas

- Diffuse midline gliomas, H3K27-altered
- Diffuse hemispheric gliomas, H3G34-mutant
- Diffuse pediatric-type high-grade glioma, H3 wild-type and IDH wild-type
- Infant-type hemispheric glioma

Circumscribed Astrocytic Gliomas

- Pilocytic astrocytoma
- High-grade astrocytoma with piloid features
- Pleomorphic xanthoastrocytoma
- Subependymal giant cell astrocytoma
- Chordoid glioma
- Astroblastoma, *MN1*–altered

Glioneuronal and Neuronal Tumors

- Ganglioglioma
- Desmoplastic infantile ganglioglioma/desmoplastic infantile astrocytoma
- Dysembryoplastic neuroepithelial tumor
- Diffuse glioneuronal tumor with oligodendroglioma-like features and nuclear clusters
- Papillary glioneuronal tumor
- Rosette-forming glioneuronal tumor
- Myxoid glioneuronal tumor
- Diffuse leptomeningeal glioneuronal tumor
- Gangliocytoma
- Multinodular and vacuolating neuronal tumor
- Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease)
- Central neurocytoma
- Extraventricular neurocytoma
- Cerebellar liponeurocytoma

Ependymal Tumors

- Supratentorial ependymoma
- Supratentorial ependymoma, *ZFTA* fusion–positive
- Supratentorial ependymoma, *YAP1* fusion–positive
- Posterior fossa ependymoma
- Posterior fossa ependymoma, group PFA
- Posterior fossa ependymoma, group PFB
- Spinal ependymoma
- Spinal ependymoma, *MYCN*-amplified
- Myxopapillary ependymoma
- Subependymoma

FIG 1. Major changes on the basis of the 2021 WHO CNS Tumor Classification of Glial Tumors.[8,9] H3, histone H3; *IDH*, isocitrate dehydrogenase; MAPK, mitogen-activated protein kinase; *MN1*, MN1 proto-oncogene transcriptional regulator; *MYB*, MYB proto-oncogene transcription factor; *MYCN*, MYCN proto-oncogene, bHLH transcription factor; *YAP1*, yes1-associated transcriptional regulator; *ZFTA*, zinc finger translocation–associated.

TABLE 1. Table Summarizing Molecular Targets Responding to Therapy

Molecular Target	Agent	Activity (ORR)	Reference
Adults			
BRAFV600E	Vemurafenib	25%	19
BRAFV600E	Dabrafenib/trametinib	32% GBM; 69% LGG	18
NTRK	Larotrectinib	30%	20
FGFR mutation/FGFRTACC fusion	Erdafitinib	20.9%	21
H3K27M	Dordaviprone (ONC201)	20%	22,23
IDH	Ivosidenib, vorasidenib Olutasidenib, BAY 1436032 Safusidenib	5%-40%	24-28
Children			
TSC1/2	Everolimus	35%	29
BRAFV600E	Dabrafenib/trametinib	25%-47%	30,35
BRAF/KIAA fusion	Selumetinib	35%-40%	31
BRAF/KIAA fusion	Tovorafenib	64%[a]	
H3K27M	Dordaviprone (ONC201)		32
H3K27M	GD2 CAR-T cell	50%	33
NF1	Selumetinib	70%	34

Abbreviations: CAR, chimeric antigen receptor; GBM, glioblastoma; LGG, low-grade glioma; ORR, objective response rate.
[a]Not yet published in peer review journal.

These recent examples of activity with targeted molecular therapies suggest that despite the concerns regarding tumor heterogeneity, plasticity of cellular states, and redundancy of signaling pathways, in small subsets of brain tumors, targeting of oncogenic drivers can be effective. Whether targeting of the more common molecular drivers involving the EGFR, the cyclin-dependent kinase (CDK) 4/6 pathway, and the phosphatidylinositol-3-kinase (PI3kinase) pathways will be effective remains to be seen. Trials with targeted therapies against these pathways, for example, abemaciclib for glioblastomas with CDKN2A/B loss, buparlisib for tumors with PI3K activation, and numerous agents against EGFR, have been ineffective. Paxalisib, a pI3 kinase inhibitor, did not graduate to stage 2 in GBM Agile, although the patients in that trial were not specifically selected for PI3 kinase pathway activation. Newer agents against EGFR directed at the molecular alterations specific for glioblastomas with good BBB penetration such as BDX1535 and ERAS-801 are in clinical trials. Whether they will be more effective remains to be determined. In addition, progress in evaluating sensitive and reliable blood and cerebrospinal fluid biomarkers will help with less invasive profiling of tumors and the selection and monitoring of molecular therapies.[41]

ESTABLISHING PREDICTIVE BIOMARKERS IN NEURO-ONCOLOGY

Predictive biomarkers, also known as treatment selection biomarkers, typically represent some characteristics related to the study drug's mechanism of action. Successful identification and deployment of predictive biomarkers are crucial toward the goal of precision oncology as its central tenet lies in delivering the right cancer therapy to the right patients at the right time. However, to date, few molecular changes detected in brain tumors have risen to the level of being clinically useful. The reasons for the paucity of clinically useful biomarkers in neuro-oncology are multifaceted. In this section, we highlight several methodological challenges associated with identifying predictive biomarkers. Using examples in neuro-oncology, we first underscore the need for well-validated and reproducible biomarker assays for routine clinical use. Second, we illustrate some difficulties arising from evaluating the predictive value of a biomarker on the basis of data collected from previous randomized clinical trials (RCTs). Although these discussions are framed primarily around predictive biomarkers, many methodological principles apply generally to other types of biomarkers (diagnostic and prognostic biomarkers).

Biomarker Assay Validity and Reproducibility

Uncertainty around the performance characteristics of the biomarker assay can pose significant challenges in clinical implementation. In a newly diagnosed glioblastoma, for example, *MGMT* promotor methylation status has emerged as a biomarker for prognosis and for predicting response to alkylating agents, such as temozolomide and

lomustine.[14,42,43] Although *MGMT* status has been used in clinical trials for some time, the implementation of this biomarker in clinical practice is challenging. One reason is that there is currently no consensus regarding the best assay to evaluate *MGMT* methylation status. The use of different assay methods has led to discordant *MGMT* results in some patients, leading to ambiguous treatment recommendations.[44,45] A study by Lassman et al[46] analyzed the concordance of *MGMT* methylation results between local and central laboratories using tissue specimens collected from a randomized phase III trial RTOG 3508 and found that the interlaboratory concordance was only 61%. At present, several assays are in use to determine *MGMT* promoter methylation status in patient samples. A comprehensive review of the various methods is beyond the scope of this article; readers are referred to a review by Weller et al.[47]

Another considerable limitation is the lack of standard cutoff values for determining *MGMT* status from quantitative methods, such as methylation and expression assays. A group of investigators conducted an international survey regarding the use of *MGMT* assays in 25 countries. The survey results revealed that there is considerable variability with respect to the assays used and the cutoff values for *MGMT* methylation status.[48] Considering the potential of this biomarker in treatment decisions in clinical trials and routine practice for glioblastoma, there is a pressing need for an international consensus guideline to standardize the *MGMT* methylation assay and define a reliable cutoff for clinical deployment. Furthermore, appropriate quality measures need to be established to ensure comparable assay results across different laboratories.

Challenges in Evaluating The Predictive Value of A Biomarker On The Basis of Completed Clinical Trials

Modern clinical trials frequently evaluate the predictive value of a biomarker for an experimental therapy using previously completed RCTs of the experimental therapy vs. the standard treatment, where the biomarker status is ascertained on patients with available biologic specimens but not used to direct therapies on the trial.[49-51] Simon et al[52] designated these types of biomarker studies as prospective-retrospective (P-R) studies to distinguish them from nonexperimental observational biomarker studies. A prime example of a prospective-retrospective predictive biomarker study is the one by Hegi et al, which examined *MGMT* promoter methylation status in a subset of patients with available tissue specimens and assay results in the practice setting trial EORTC/NCIC 22981/26981, which compared radiotherapy + temozolomide versus radiotherapy alone for newly diagnosed glioblastoma.[14,42] The investigators reported that there was a statistically significant survival benefit from temozolomide in the *MGMT*-methylated subgroup (P = .007), but this benefit did not reach statistical significance in the *MGMT*-unmethylated subgroup (P = .06). On the basis of these observations, they concluded that *patients with glioblastoma containing a methylated MGMT promoter benefited from temozolomide, whereas those who did not have a methylated MGMT promoter did not have such a benefit*.

It is important to note that in these retrospective evaluations of predictive biomarkers, the parent treatment trial is powered to discern a clinically meaningful treatment effect for all trial patients (regardless of their biomarker status). Consequently, the statistical power to detect treatment benefit from the experimental therapy in a biomarker-defined subgroup is limited because of the reduced sample size. This issue of low power is especially exacerbated in the biomarker subgroup that is not expected to derive benefit from the experimental therapy or to derive a much lesser degree of benefit, compared with the other biomarker subgroup. In a study by Hegi et al, the consequence of the reduced sample size and resultant uncertainty around the benefit from temozolomide were reflected in the wide confidence interval for the treatment hazard ratio in the *MGMT*-unmethylated subgroup (hazard ratio [HR], 0.69; 95% CI, 0.47 to 1.02). Of note, failure to demonstrate a statistically significant treatment benefit in a biomarker subgroup does not imply the lack of benefit in that subgroup since P values are highly influenced by the sample size and number of observed events. Relatedly, achieving statistical significance in one biomarker subgroup but not in the other is not sufficient to establish the predictive value of a biomarker. As such, the data presented by Hegi et al do not lend conclusive evidence for *MGMT* methylation as a predictive biomarker for benefit from temozolomide in patients with glioblastoma. In fact, among *MGMT*-unmethylated patients, PFS was significantly improved with temozolomide (HR, 0.62; 95% CI, 0.42 to 0.92). With further clinical follow-up, a subsequent analysis reported a statistically significant survival benefit in *MGMT*-unmethylated patients (HR, 0.6; 95% CI, 0.4 to 0.8).[43]

This example underscores the challenges associated with establishing the predictive value of a biomarker using data from completed clinical trials. Retrospective evaluations of the predictive value of a biomarker frequently lack adequate statistical power to reliably discern a treatment effect, especially in the biomarker subgroup that is not expected to respond to the experimental therapy. In this setting, of critical relevance are the biomarker subgroup–specific treatment hazard ratio estimates and their confidence intervals, the width of which reflects the certainty that one should place around the estimated treatment benefit. Specifically, when the confidence interval around a treatment hazard ratio is too wide in a biomarker subgroup, it would be impossible to make a definitive conclusion about

whether patients in that subgroup benefit from the experimental therapy. In turn, the clinical utility of the predictive biomarker cannot be confidently established. Possible solutions to this problem include pooling data from similar trials or increasing the clinical follow-up of the trial to obtain more events although the latter may be infeasible if the parent trial has been terminated. Furthermore, biologic insights into the biomarker and mechanism of action of the study agent from preclinical and clinical studies may increase confidence on the predictive value of the biomarker.

LEVELING THE PLAYING FIELD: ADDRESSING RACIAL, GEOGRAPHIC, AND SOCIOECONOMIC DISPARITIES IN IMPLEMENTATION OF BRAIN TUMOR DIAGNOSTICS

Nearly universally fatal, there are more than 13,000 new cases of glioblastoma identified annually. Typically affecting men more than women age 55-65 years, aggressive multimodal treatment leads to an average survival of 2 years.[53] On the basis of SEER data, incidence of glioma is highest in non-Hispanic White (NHW) populations and has been associated with increased socioeconomic status.[54,55] Similar to other reports, Ostrom et al[54] found that NHW populations have reduced overall survival compared with other racial and ethnic groups after diagnosis of glioblastoma. Black patients, Hispanic patients, and patients with lower socioeconomic status have been found to have increased risk of non–glioblastoma-related mortality. Death from other cancer, cardiac, and cerebrovascular events is reported disproportionately in these populations.[56]

Limited reporting of race and ethnicity in glioblastoma-related clinical trials has led to an incomplete understanding of the impact of treatment and outcomes in varied populations.[57] Although it is believed that nearly 15% and 13% of patients with cancer are Black and Hispanic, these populations typically are under-represented in clinical trials at 6% collectively.[58] There are several challenges leading to poor enrollment in clinical trials, including stringent eligibility criteria, geographic distribution of access to trials, inefficient activation processes, limited consumer-friendly information, and an inadequate pipeline of novel therapies.[53] Barriers to clinical trial enrollment span the clinical care pathway from diagnosis to end of life. Issues of unconscious bias, cultural barriers, cost, healthy literacy, transportation, insurance, and patient/physician factors perpetuate these disparities including lack of advanced molecular testing on tumor tissue and limited pathologic interpretation.[59,60]

Testing Disparities

Advanced molecular testing has provided deeper understanding as to the heterogeneity in high-grade glioma and is less likely to be offered to certain groups and often underutilized in clinical decision making.[61] While some patients are being offered testing up front to stratify clinical trial enrollment, others are using the results to determine treatment strategies after first or second recurrence. Understanding of promoter methylation status of MGMT is often an inclusion criterion in clinical trials, which aids in decision making regarding elderly and frail populations who may not tolerate multimodal treatment.[5] The importance of this nuance has reached the threshold to allow inclusion in National Comprehensive Cancer Network guidelines in the treatment of glioblastoma.[62]

Chukwueke et al found that patients with newly diagnosed glioblastoma who were from lower socioeconomic status, uninsured or insured through Medicaid, were less likely to receive MGMT testing.[63] Patients from these backgrounds are also noted to frequently present later in the course of disease with larger tumors, incomplete resection, and are less frequently recipients of multimodal therapy ultimately leading to reduction in survival.[64] Similarly, patients who were diagnosed at community hospitals were less likely to receive advanced testing and multimodal care. The authors note that despite the increasing incidence of testing across the United States, the populations with varied elements of diversity continued to experience disparity in testing frequency.[63] Data to direct the clinical management were also underutilized with undertreatment of populations that could have benefited from temozolomide.

Opportunities for Improvement

Limitations in referral for advanced testing in diverse populations have led to an incomplete understanding in the spectrum of diseases. The US Food and Drug Administration published guidelines in 2020 to enhance clinical trial diversity including broadening eligibility criteria and adopting enrollment and retention practices that enhance inclusiveness.[65] Efforts to reduce disparities in diagnostics are multilayered, ranging from governmental and institutional policies to individual provider behavior and patient education. As testing becomes more widely available, increased coverage by insurers is essential. While patient assistance programs are available, the addition of this recommendation to National Comprehensive Cancer Network guidelines should lead to consideration of advanced testing becoming standard of care.[62] Patient education through advocacy groups and community engagement can help raise awareness among patients and caregivers regarding the relevance and importance of the additional information this testing provides.[59] In addition to provision of resource for advanced testing as part of the protocol, behavior modification in care teams to offer advanced testing to all patients is necessary to attempt to bridge this gap.

CONCLUSION

Advances in molecular profiling have introduced a growing number of biomarkers in neuro-oncology. Comprehensive characterization of molecular alterations in brain tumors has the potential to provide more accurate disease classification, risk stratification, and tailored treatments for individual patients. The future of molecular profiling in neuro-oncology, particularly concerning the utility of treatment selection biomarkers, will depend on the availability of robust biomarker assays and effective therapeutic options to allow tailored treatment choices for individual patients. Although a burgeoning field, opportunities remain for validation of testing and improved awareness and accessibility for widespread use. Failure to pursue molecular profiling not only contributes to disparate understanding of the spectrum of diseases and populations affected but also perpetuates disparities in treatment and outcome.

Immune Resistance Mechanisms and the Road to Personalized Immunotherapy

Miles Piper, BS[1]; Harriet Kluger, MD[2]; Eytan Ruppin, MD, PhD[3]; and Siwen Hu-Lieskovan, MD, PhD[1,4]

overview

Despite decades of clinical and preclinical studies, the markers and mechanisms of resistance to cancer immunotherapy, particularly immune checkpoint blockade (ICB), remain elusive. In this review, we address the current clinical challenges regarding ICB treatment by examining the underlying cellular and molecular contributors to resistance and newly developed agents to target them. Furthermore, we discuss emerging computational tools to consolidate genomic data and provide examples of how these tools can guide clinical decision making in the context of immuno-oncology. Finally, we examine the shortcomings and clinical limitations of current predictive biomarkers of response to ICB treatment and provide details on next-generation biomarker research, including prospective genomic profiling on the basis of known biomarkers and personalized immunotherapy.

Since its implementation over a decade ago,[1] immunotherapy has quickly ascended through the ranks of approval to join radiotherapy, chemotherapy, and surgery as a mainstay in oncologic treatment. However, clinical trials have repeatedly shown that only a subset of patients respond to immunotherapy.[2] As such, extensive research work has gone into understanding the factors governing the balance between response and resistance, with efforts yielding a complex network of viable treatment targets. Here, we summarize the current thought regarding cancer cell–intrinsic and cancer cell–extrinsic resistance mechanisms to immune checkpoint blockade (ICB).

MECHANISMS OF RESISTANCE TO ICB

Tumor-Intrinsic Resistance

Lack of tumor immunogenicity. Like any other immunotherapy, response to ICB is contingent on immune cell recognition of tumor cells. To evade immune recognition, cancer cells can develop mechanisms to effectively disguise themselves and avoid CD8-mediated killing. Many of such mechanisms rely on the alteration or downregulation of the HLA antigen presentation complex, a group of proteins required for adaptive immune clearing of pathogens and differentiating between self and non-self cells.[3] Cancer cells hijack this system and cause HLA downregulation through mechanisms that include genetic silencing via NF-kB dysregulation,[4] epigenetic alteration by hypermethylation and deacetylation of the HLA promoter,[5,6] post-transcriptional silencing by noncoding microRNAs[7], and translational suppression through the downregulation of chaperone proteins,[8] resulting in immune evasion. Genetic mutations in the HLA complex are also common in tumors, with one of the most important being a mutation in the b2-microglobulin (B2M) subunit. B2M plays a critical physiologic role in immune surveillance and regulation,[9] and its loss has been shown to reduce folding and transport of HLA to the cell surface,[10] resulting in acquired resistance to ICB.[9]

After intact and functional antigen presentation machinery, the next hurdle that immunotherapeutic strategies face is the ability to discriminate between normal tissue and cancer cells. This process relies heavily on neoantigens or antigens generated by mutations expressed only in tumor cells.[11] Response to ICB is intrinsically tied to neoantigen load,[12,13] but methods of accurately quantifying antigenicity remain elusive. For years, tumor mutational burden (TMB), or the composite of all tumors' mutations, was pursued as a surrogate of tumor antigenicity, with a low TMB having been thought to confer resistance to ICB. However, those ventures have yielded highly discrepant results, with an elevated TMB having been detected in both ICB-responsive and nonresponsive patients.[14,15] Recent evidence suggests that resistance to ICB could instead be related to a low tumor *neoantigen* burden (TNB), but techniques designed to assay and enhance TNB are still in their early stages.[16-18] One strategy of promoting neoantigen cross-presentation to overcome resistance to ICB is the combination of radiotherapy and immunotherapy treatment, under the guiding principle that radiation-induced cell death releases neoantigens, which can then be used to prime T cells and initiate a specific and systemic antitumor immune response.[19-21] As immunotherapy advances into the next generation, identification of tumor neoantigens will undoubtedly be a

PRACTICAL APPLICATIONS

- A systematic approach to understanding the underlying cellular and molecular contributors to resistance in ICB treatment.
- Analysis of novel clinically actionable targets of resistance currently in clinical and preclinical trials.
- Examination of emerging computational tools to analyze vast genomic data and the power they hold in guiding clinical decision making.
- An overview of the clinical shortcomings of historical biomarkers of response such as PD-L1 expression and tumor mutational burden.
- Discussion of next-generation biomarker research including prospective genomic profiling on the basis of known biomarkers and personalized immunotherapy.

driving force in the development of novel immunotherapeutic approaches such as personalized neoantigen peptides and mRNA vaccines and novel cell therapy targeting these neoantigens.[22]

Aberrations in the IFNg/JAK/STAT pathway. Cancer cells have also devised ways to avoid immune-mediated killing by crippling critical immune response pathways. For example, the interferon-gamma (IFNg)/janus kinase (JAK)/signal transducer and activator of transcription (STAT) signaling axis is one of the primary pathways in mediating resistance to ICB. Under normal physiologic conditions, the JAK/STAT cascade is activated by cytokines and growth factors and plays a vital role in hematopoiesis, immune fitness, tissue repair, inflammation, and apoptosis.[23] Because effective immunotherapy relies on the production of IFNg by activated T cells and the subsequent JAK/STAT-mediated upregulation of genes involved in antitumor immune responses,[24] the role of this pathway is magnified in the context of ICB resistance. As anticipated, mutations in interferon (IFN) receptors have been linked to poorer treatment outcomes and have been shown to confer resistance to ICB. For example, Gao et al[25] found that ICB nonresponsive tumors were enriched for specific mutations in the IFNg receptor genes *IFNGR1* and *IFNGR2*. To demonstrate the causality of this relationship, the group then performed an IFNGR1 shRNA knockdown in the B16/BL16 melanoma cell line and found that IFNGR1-deficient tumors had an impaired response to anti-CTLA4 treatment in vivo.[25] Similarly, JAK mutations have also been implicated in resistance to ICB. JAK signaling has been widely known to contribute to T-cell chemotaxis, and targeted inhibition has been shown to dimmish T-cell recruitment by reducing expression of the chemokine CXCL10.[26] Moreover, in a genome-wide analysis of four patients who demonstrated acquired resistance to anti-PD1 therapy, two were found to harbor JAK1/2 loss-of-function mutations with significantly decreased sensitivity to IFN signaling.[27] Importantly, these JAK-deficient tumor cells were found to be clonally selected for from baseline to progression, suggesting a critical role for JAK activity in mediating resistance to ICB. On the other hand, hyperactive JAK also contributes to treatment resistance and JAK inhibition has also been shown to attenuate the response to ICB,[28-30] suggesting that more work will need to be performed to determine the exact contexts in which JAK inhibition is clinically beneficial.

The role of the STAT family of proteins in mediating response to ICB is even more ambiguous. Although currently considered oncogenes, STATs are essential for the transfer of information for dozens of immunostimulatory cytokines, including IFNs, interleukins (ILs), and colony-stimulating factors (CSFs).[31] The dichotomous effect of STAT signaling lies in the promiscuous and pleiotropic nature of this family of proteins, with some groups reporting a robust antitumor effect of STAT activity while others describing a more nefarious role in STAT function. For example, analyses of the cancer genome atlas (TCGA) database have suggested that PD-L1 expression is intrinsically regulated by STAT3 activity.[32-34] As such, overexpression of STAT3 may result in response to ICB. However, STAT3 activity has been shown to downregulate MHCII expression on dendritic cells and CD4 T cells while simultaneously promoting the development and maturation of regulatory T cells (Tregs) and myeloid-derived suppressive cells (MDSCs), two immunosuppressive cell types.[35,36] Clinical trials testing the efficacy of STAT inhibition in combination with ICB are currently ongoing.[37] Although these complex interactions seem to illustrate highly variant effects of the IFN/JAK/STAT pathway in different cell types, it is clear that this foundational signaling pathway plays an important role in regulating the response to ICB treatment.

Alterations to RAF and RAS. Another commonly mutated pathway contributing to cancer progression is the RAS/RAF signaling axis. RAF signaling in tumors has been shown to contribute to immune tolerance and evasion by both downregulating MHCI[38] and upregulating PD-L1 expression.[39] RAF mutations, particularly BRAF, have proven to be particularly significant in the progression and treatment of melanoma. Approximately 50% of melanomas harbor a BRAF mutation, and abhorrent BRAF signaling has been correlated with a more aggressive tumor phenotype.[40] Several clinical trials have explored the efficacy of BRAF and MEK inhibition in combination with ICB because of the paradoxical immune activation and sensitization by BRAF inhibitors in mouse models.[41] Initial results of these trials showed improved clinical activity

with a manageable safety profile,[42] leading to the Food and Drug Administration (FDA) approval of the combination of vemurafenib, cobimetinib, and atezolizumab for BRAF-mutant melanoma. In addition, a recently completed phase I/II clinical trial assessed the efficacy of the combination of durvalumab and trametinib on patients with metastatic colorectal cancer and found a clinical benefit in the growth of lung metastases.[43] Similar clinical trials exploring MEK-induced immunotherapy resistance are currently ongoing.[44] Once thought of as an undruggable target, trials such as these provide great rationale and optimism for combinatorial ICB approaches in aggressive RAF-mutant tumors.

Meanwhile, RAS is a molecular target of therapy that oncologists have gravitated toward since it was first isolated from the sarcoma-inducing virus MSV in the 1960s.[45] RAS has been shown to induce expression of PD-L1,[46] promote the conversion of conventional T cells into Tregs,[47] and prevent T lymphocyte intratumoral infiltration,[48] prompting the clinical investigation of its inhibition in combination with ICB. In a syngeneic murine model of colon cancer,[48] the RAS G12C inhibitor combined with anti–PD-1 therapy led to enhanced T-cell tumor infiltration, activation, and killing. In fact, the combination of these agents is currently the subject of an ongoing clinical trial (ClinicalTrials.gov identifier: NCT04185883), with preliminary results showing a tolerable toxicity profile and improved response rates after treatment with the KRAS inhibitor sotorasib in combination with pembrolizumab over sotorasib alone.[49]

Abnormal phosphatidylinositol 3-Kinase and PTEN. Cancer cells also frequently mutate to usurp control of the phosphatidylinositol 3-kinase (PI3K) signaling cascade involving PI3K, protein kinase B (AKT), and mammalian target of rapamycin to promote unrestricted cell survival.[50] However, the development of targeted therapies against different elements of this pathway has thus far yielded underwhelming results. As these molecular targets not only play an active role in cancer but also are important in homeostasis, targeted inhibition has proven to be difficult and when inhibition is achieved, compensatory resistance mechanisms are commonly observed.[51,52]

Although their direct cytotoxic activities have been disappointing, recent evidence has shown that various targeted agents of the PI3K signaling axis have a dual immunostimulatory effect on the tumor microenvironment (TME). For instance, pan-PI3K inhibition has been shown to provide a survival benefit in preclinical models by enhancing CD8 T-cell infiltration into the tumor,[53] and AKT inhibitors have been found to enhance tumor immunosurveillance by selectively inhibiting Tregs.[54] Meanwhile, loss-of-function mutations in PTEN, a negative regulator of the PI3K pathway, are associated with increased production of immunosuppressive cytokines including IL-6 and IL-10[53] and increased expression of PD-L1.[55] These observations suggest a synergistic effect between PI3K inhibition and immunotherapy, and indeed, the combination of PI3K inhibition and ICB in preclinical mouse models has been shown to augment effector T-cell function through Treg inhibition, promote memory CD8 T-cell differentiation, and elicit a strong and durable inhibition of tumor growth.[56] Clinical trials aimed at validating this relationship are currently underway.[57] This growing body of data provides yet another lens to view intrinsic resistance to ICB and identifies molecular mediators that can augment response to immunotherapeutic modalities.

Tumor-Extrinsic Resistance

Adaptative immunity Tregs. Resistance to ICB poses a complex clinical problem primarily because it is a multicompartmental phenomenon mediated by several different cellular populations (Fig 1). One such population is Tregs. Perhaps the most prominent and extensively characterized immune population within the TME, Tregs are a subpopulation of CD4 T cells that normally play an important role in autoimmunity, homeostasis, and self-tolerance by inhibiting the activation and differentiation of CD4 and CD8 effector T cells.[58] In the context of cancer, Tregs exhibit strong immunosuppressive activity and function to inhibit antitumor immunity and promote tumor immune evasion.[59]

Treg function is governed primarily by the regulatory transcription factor FoxP3, a known promoter of immunosuppression, and the production of various anti-inflammatory signaling molecules including IL-10,[60,61] a cytokine necessary for Treg maturation.[62] IL-10 plays a central role in controlling inflammatory processes and maintaining peripheral tolerance.[63] In cancer, however, IL-10 attenuates the antitumor immune response by downregulating MHCII on antigen-presenting cells[64] and decreasing the production of proinflammatory cytokines such as IL-2, TNFa, and IFNg.[65,66] Indeed, IL-10 levels have been correlated with poorer clinical outcomes in multiple disease types[67,68] and improved immune activation after IL-10 signaling inhibition has been observed in both virus- and tumor-derived preclinical models.[69,70]

Another mechanism by which Tregs suppress immune activation is by monopolizing the available IL-2 in the TME. Because of its role in the survival, proliferation, and differentiation of activated T and NK cells,[71] IL-2 has become a hallmark of immune stimulation. To our knowledge, exogenous high-dose IL-2 treatment was even the first approved cancer immunotherapy.[72] However, Tregs are also heavily dependent on IL-2 for maturation[73] and constitutively express the high-affinity IL-2 receptor subunits CD25, CD122, and CD132, allowing them to consume IL-2 more efficiently than conventional T cells.[74] Furthermore, FoxP3 has been

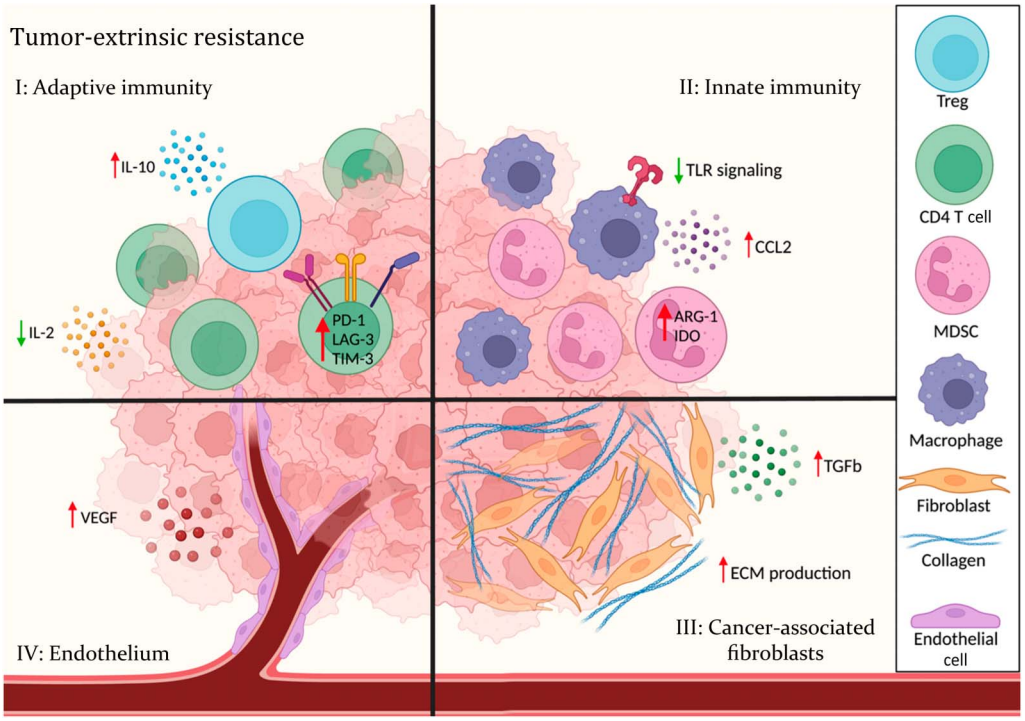

FIG 1. Mechanisms of tumor-extrinsic and cell-mediated resistance to ICB therapy. ARG-1, arginase-1; CCL2, chemokine ligand 2; ECM, extracellular matrix; ICB, immune checkpoint blockade; IDO, indoleamine 2,3-dioxygenase; IL, interleukin; LAG-3, lymphocyte-activation gene 3; MDSC, myeloid-derived suppressive cell; TGFb, transforming growth factor b; TIM-3, T-cell immunoglobulin and mucin-domain containing-3; TLR, toll-like receptor; VEGF, vascular endothelial growth factor.

shown to attenuate factors needed for Treg-mediated IL-2 production,[75,76] meaning that Tregs lack the self-sufficiency to meet their own high IL-2 demand. The sum of these effects is the sequestration of IL-2 by Tregs in the TME, leading to a deprivation of IL-2 from effector T cells and resulting in an inadequate antitumor immune response.[77]

T-cell exhaustion. T-cell exhaustion is broadly defined as a state of T-cell differentiation distinct from effector or memory T cells and is marked by dysfunction and apoptosis because of chronic antigen stimulation.[78] This process is partly mediated by the temporal expression of inhibitory receptors, many of which have been shown to prolong and maintain immune stimulation when selectively targeted in combination settings. Although PD-L1 inhibition is critical for overcoming exhaustion, it may be overshadowed by other mediators of exhaustion. For example, T-cell immunoreceptor with immunoglobulin and ITIM domain (TIGIT) is an inhibitory receptor expressed on the surface of CD4, CD8, and NK cells that signal to impede T-cell receptor (TCR)-mediated activation and reduce degranulation and cytotoxicity in CTLs.[79,80] Clinically, TIGIT inhibition in combination with ICB has been shown to enhance the proliferation and functionality of antigen-specific, tumor-educated CD8 T cells and improve response over ICB alone.[81] T-cell immunoglobulin and mucin-domain containing-3 (TIM-3) is a related coinhibitory protein expressed by the most terminally dysfunctional subset of CD8+ tumor-infiltrating lymphocytes (TILs).[82] In preclinical models, dual TIM-3 and PD-1 inhibition was also found to have a substantial synergistic effect on CD8 T-cell activity and tumor regression,[82] leading to the opening of several clinical trials testing the synergy between TIM-3 antagonization and ICB.[83,84] Finally, because of its role in autoimmunity and immune homeostasis, lymphocyte activation gene 3 (LAG-3) has garnered significant clinical and preclinical attention as a promising immunotherapeutic target. LAG-3 is an inhibitory receptor expressed on the surface of activated T lymphocytes, which has been shown to interfere with the binding of major histocompatibility complex II (MHCII) to the TCR[85] and prevent CD3-mediated cytokine release.[86] More recent work has demonstrated significant cooperation between targeted inhibition of LAG-3 and the blockade of immune checkpoints PD-1 and cytotoxic T-cell lymphocyte-4 (CTLA-4).[87,88] In fact, anti–LAG-3 relatlimab in combination with nivolumab has been recently approved for frontline treatment of advanced melanoma.[89] Although the details and complexities of the molecular mechanisms dictating T-cell exhaustion are still being elucidated, it is now undeniable that sustained T-cell activation is a required criterion for response to ICB, and the identification of tumor-reactive T cells and novel agonistic targets using genomic analyses[90] may be clinically useful in meeting that precondition.

Innate immunity tumor-associated macrophages. The innate immune system and cells of myeloid lineage have also been implicated in mediating resistance to checkpoint inhibitors immunotherapies.[91,92] One such cell type is tumor-associated macrophages (TAMs). Similar to conventional

macrophages, TAMs are phagocytes that proliferate in their site of action (the tumor) and contribute to the coordination of an immune response. Unlike conventional macrophages, TAMs express cytokines and chemokines that can suppress antitumor immunity and promote tumor progression.[93] Subsets of TAMs are now regarded as a negatively prognostic marker in response to therapy,[94] and several strategies to improve antitumor immunity by targeting or modulating TAMs are being developed. These strategies include blocking the recruitment of TAMs, repolarization of TAMs into an immunostimulatory phenotype, and upregulating antigen presentation machinery that can stimulate CTL activation.[93] For instance, the chemokine chemokine ligand 2 (CCL2) and toll-like receptor 8 have become the subject of multiple clinical trials to suppress macrophage accumulation in tumors and repolarize TAMs toward a proinflammatory phenotype, respectively.[93] Preclinical results have demonstrated that inhibition of these two signaling axes may operate synergistically with ICB therapy,[95,96] prompting further investigation of these combinations as viable treatment modalities.

MDSCs. Another mediator of immunosuppression and treatment resistance is MDSCs. MDSCs are a heterogeneous subpopulation of immature myeloid cells with a significant capacity to inhibit T and NK cell effector functions.[97] Clinically, their accumulation has been associated with disease progression and recurrence,[98] and their activity is correlated with diminished responses to immunotherapies.[99] MDSC-mediated immunosuppression is unique in that it is related to their metabolism.[100] For example, MDSCs express high levels of ARG1, an essential enzyme that catalyzes the conversion of L-arginine to L-ornithine as part of the urea cycle. Because L-arginine is a necessary molecule for T-cell proliferation, the increased consumption of L-arginine by MDSC-expressed ARG1 leads to cell cycle arrest and apoptosis in TILs.[101] Similarly, MDSCs produce elevated levels of the enzyme indoleamine 2,3-dioxygenase (IDO), which degrades and depletes L-tryptophan, starving T cells of another essential amino acid and promoting their differentiation into a Treg phenotype.[102,103] To counteract this effect, tadalafil (a small molecule inhibitor of MDSC function) and entinostat (a class I histone deacetylase inhibitor) have been shown to reduce ARG1 and IDO expression and demonstrated early signs of preclinical and clinical promise in combination with anti-PD1.[104] MDSC frequency and activity have also been targeted using an interesting strategy to leverage the population's immature nature. Recent evidence has shown that ATRA, a vitamin A derivative and approved drug for acute promyelocytic anemia, can bind to the retinoic acid receptor on MDSCs and force their maturation and differentiation into benign dendritic cells or monocytes.[105] In multiple clinical trials, ATRA administration has been shown to deplete MDSCs and improve the adaptive antitumor immune response in combination with immunotherapy.[106,107]

Cancer-associated fibroblasts. Perhaps the most abundant cell type in TME, stromal fibroblasts have been shown to play a protective role in cancer and have recently become a target of inhibition in relieving treatment resistance. Cancer-associated fibroblasts (CAFs) arise from quiescent tissue-resident myofibroblasts that migrate to the tumor where they adopt a transcriptionally and metabolically active phenotype and produce growth factors and cytokines that promote angiogenesis and immune evasion.[108,109] CAFs primarily enact their immune regulation through the production of transforming growth factor b (TGFb), a pleiotropic and immunosuppressive cytokine that functions in normal wound healing, extracellular matrix (ECM) remodeling, and immune cell differentiation.[110] TGFb downregulates MHCII on dendritic cells,[111] reduces CD8 T-cell activation and infiltration, and confers resistance to ICB.[112] CAFs have also been shown to recruit immunosuppressive myeloid populations through the secretion of CCL2[113] and express inhibitory receptors such as TIM-3, LAG-3, PD-1, and CTLA-4 to inhibit T-cell proliferation.[114] Finally, although simplistic, CAFs can prevent T-cell–mediated killing of tumor cells through the excessive deposition of ECM and the construction of a collagen network that serves as a physical barrier to CTL infiltration.[115]

These broad-spectrum mechanisms of suppression, coupled with the significant effects on tumor progression, have led to the development of novel therapeutic approaches aimed at inhibiting the activity of intratumoral fibroblasts. Such newly generated anti-CAF therapies have focused primarily on the targeted depletion of fibroblasts in the TME. For instance, one study demonstrated that administering a DNA-based vaccine specifically targeting stromal cells in the TME induced immune-mediated killing of CAFs and increased the bioavailability of chemotherapeutic drugs intratumorally.[116] More contemporary studies have shown that CAF-specific CAR-T-cell therapy can boost host immunity and arrest cancer growth in highly desmoplastic tumors.[117,118] Several clinical trials testing the efficacy of anti-CAF treatments alone or in combination with ICB[119] are underway, providing a new, potentially transformative treatment option for patients with fibroblast-rich tumors. Of note, recent preclinical studies have also shown that the newly developed FAP-41BB and FAP-CD40 bispecific antibodies can specifically activate intratumoral T cells while reducing toxicity and enhancing the therapeutic index when delivered systemically,[120,121] suggesting a potential role for CAFs and the tumor stroma as a scaffold for T lymphocyte activation.

Endothelium. The final major cellular composition of the TME is the endothelium. Once larger than a few cubic millimeters, solid tumors must establish blood supply to

meet their high energy and nutrient demands. However, the resulting vascular network is immature, disorganized, thin-walled, and prone to leaks.[122] This poorly constructed endothelium has many protumorigenic qualities, including promoting immune evasion and resistance to immunotherapy. In fact, endothelial cells of the tumor vasculature have been shown to induce CD8 T-cell apoptosis,[123] prevent T-cell adhesion and lymphocyte extravasation,[124] and polarize immune cells toward an anti-inflammatory phenotype.[125] Interestingly, preclinical studies have shown that vascular endothelial growth factor–modulating monoclonal antibodies (eg, Bevacizumab) can have a transient vessel normalization effect,[126] suggestive of a window of opportunity wherein the tumor is adequately perfused and can allow for improved delivery of immunotherapeutic agents and enhanced infiltration of antitumor immune cells. In light of these effects, the combination of antiangiogenesis and immunotherapy treatment is currently being tested in a wide range of clinical trials, with five such combinations already receiving FDA approval.[127] A comprehensive review of all completed and ongoing clinical trials incorporating immune checkpoint inhibition can be found here.[128]

TOOLS AND TECHNOLOGIES

Since the completion of the Human Genome Project in 2003,[129] technological advancements have made genome-wide sequencing techniques exponentially more accessible and cost-effective,[130] creating opportunity in the field of bioinformatics and the study of molecular drivers of cancer. However, the allure of whole genomic and transcriptomic sequencing is accompanied by an almost incomprehensible amount of data, and as this enormous amount of data continues to grow, more efficient, accurate, and informative methods for analyzing such data sets become progressively more imminent.[131] Here, we present novel data analysis and collection techniques developed to improve the acquisition of genomic data and discuss their potential in guiding treatment decisions (Fig 2).

Multiomics

Cellular deconvolution. The fundamental challenge facing the interpretation and extrapolation of bulk RNA sequencing data is its inherently conglomerate nature. Broad-spectrum analyses must use some approximation technique to identify and isolate specific cell types within the TME—without such a technique, it would be impossible to trace a given gene expression signal back to its cell of origin. COnfident DEconvolution For All Cell Subsets (CODEFACS) is one such deconvolving algorithm developed by Wang et al[132] that works by analyzing bulk gene expression data sets of tumor samples together with a training data set composed of estimated cellular abundances and expression profiles. CODEFACS then uses a heuristic algorithm to predict the cellular composition and maximize the number of expressed genes in each cell type across samples. The eventual output of CODEFACs is twofold: a three-dimensional gene expression matrix for which each entry represents the predicted expression of a gene in a given cell type in a specific sample and a two-dimensional matrix of confidence scores ranging from [0,1] representing the level of confidence between each gene/cell type association.[132] The creators of CODEFACS also developed a statistical framework referred to as ligand–receptor interactions between cell subsets that takes the output of CODEFACS and predicts likely cell-to-cell interactions within bulk genomic data sets by cross-referencing overexpressed receptor-ligand pairs with a database containing all plausible ligand-receptor interactions between any two cell types.[132] The results from an analysis such as this allow for the prioritization and interrogation of specific cell-to-cell interactions within the TME, a powerful tool in the field of precision oncology.

Spatial transcriptomics. Another emerging and promising technique in bioinformatics is that of spatial transcriptomics and the study of cellular gene expression patterns relative to each other and to a position in space. The notion that cellular function is irrevocably tied to spatial organization in complex tissues is not novel—imaging-based spatial techniques have been widely used to demonstrate this idea for many years.[133,134] However, the process of sequencing a cell's genome and confining it to a two-dimensional position with high spatial resolution has only recently become feasible.[135] To date, one of the most innovative techniques of spatial transcriptomics relies on single-cell sequencing of spatially barcoded tissue. In their work, Rodriques et al[136] developed a technique for transferring tissue sections to a surface precoated with 10-μm DNA-barcoded beads with known positions. The entire tissue section is subsequently sequenced, and, once the DNA barcodes are identified, the entire spatial transcriptome can be reconstructed. This revolutionary technique paves the way for the study of chromatin states, epigenetic changes, gene expression, and protein activity for thousands of genes in multiple regions of a tumor. To date, this and similar techniques have been used to identify transcriptional drivers of metastasis[137] and map the expression of tumor suppressor genes within the tumor.[138] As intratumoral heterogeneity is a known mediator of resistance and poses a significant challenge for oncologic treatment,[139-141] spatial genomic techniques such as this may aid in determining responsiveness to targeted treatments, identify prognostic factors, and guide clinical decision making.[142]

Proteomics. When considering sequencing options in a clinical setting, it becomes important to emphasize that it is not genetic mutations but the manifestation of those mutations that controls tumorigenesis. As such, the proteome, or the collection of a cell's translated proteins, has emerged

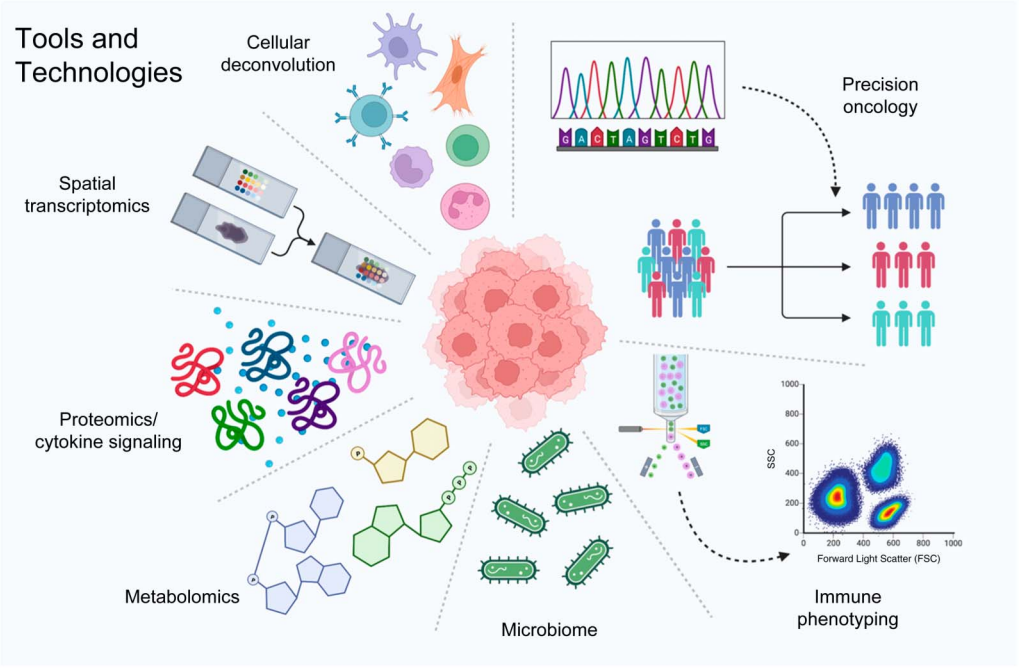

FIG 2. Current methods of omics data acquisition and computational analysis. FSC, forward light scatter; SSC, side light scatter.

as an important diagnostic and prognostic tool in many different tumor types.[143] Nucleic acids, particularly DNA, have the advantage of being thermally stable, readily amplified, and sequenced directly.[144] However, genomic sequencing approaches do not provide definitive information on a given cell's functional or activation state. Proteins, on the other hand, not only are widely accessible in solid tissues and liquids such as blood and CSF but also provide direct insight into many important biologic processes ranging from cell-cell communication to immune diversity and intratumoral heterogeneity.[145]

Recent advancements have allowed for proteomic analyses at the single-cell level, with the most commonly used methods involving antibody-based techniques.[145] For instance, antibodies conjugated to fluorophores (flow cytometry) or rare metal isotopes (mass cytometry) can be used to stain an isolated population of cells. These kinds of approaches have been widely adopted in clinical settings with applications in tumor diagnosis, tumor progression, and immunophenotyping as biomarkers of response to ICB.[146-148] However, these modalities are limited by the spectral overlap and the number of identifiable proteins in the case of flow cytometry and by throughput and sensitivity in the case of mass spectrometry.[149,150] Antibodies conjugated to enzymes, as in enzyme-linked immunosorbent assay and enzyme-linked immunosorbent spot assays, have also been used widely as a sensitive method of detecting proteins of a cell's secretome. Meanwhile, more contemporary methods can accurately quantify proteins in biologic samples even at the whole proteome level using amino acid isotope-labeling[151,152] or chemical-labeling techniques.[153-155] Although revolutionary, these novel techniques and reagents are expensive and make the large-scale implementation of these methods financially implausible. To address the high cost, researchers have developed a novel quantitative method called data-independent acquisition (DIA) that does not require expensive isotopic labels and instead relies on large-scale mass spectrometry (MS) data and protein identification to compare the signal strength of associated peptides and perform a relative quantification.[156] DIA has already made a significant clinical impact as a diagnostic tool by generating protein signatures capable of determining histologic subtypes and tissue of origin in complicated clinical scenarios such as cancers of unknown primary.[157] Techniques such as these are becoming increasingly prevalent in clinical settings and provide an attractive option for studies involving large cohorts, continuous tissue collection, and large-scale analyses such as the National Cancer Institute (NCI)'s Clinical Proteomic Tumor Analysis Consortium project.[158]

Metabolomics. Cancer cells are widely accepted to have a significantly altered metabolism, so much so that reprograming of cellular metabolism has even become one of the hallmarks of cancer.[159] However, the significance of differences in metabolite prevalence and the identification of specific products and byproducts of metabolic pathways have only recently become the topic of exploration.

In practice, circulating and intracellular metabolites are most commonly assayed using MS or nuclear magnetic resonance spectroscopy.[160] These techniques have allowed for the characterization of the most prominent metabolic pathways

to cancer maintenance and growth. For instance, while it has long been known that cancer cells display a heightened glycolytic activity compared with their nonmalignant counterparts,[161] recent studies have identified metabolites such as lactate, pyruvate, hydroxybutyrate, acetate, glutamine, and fatty acids as important catabolic and anabolic barometers of a tumor's energy requirement and biosynthetic demand.[162] To date, such novel metabolomic analyses have been used in diagnostic and prognostic settings,[163] in the grading of tumors,[164] and as biomarkers in response to treatment, including in immunotherapy.[165]

However, metabolomic analyses not only are useful in characterizing the metabolism of the tumor itself but can also be used to assess the dynamic immune-related changes that ensue after immunotherapy. The idea of using dynamic changes in metabolism as a surrogate to the antitumor immune response is a novel area of cancer research with two important advantages: (1) favorable sensitivity and specificity for metabolomic analyses in predicting clinical outcomes[163,164] and (2) biospecimens can be easily and noninvasively collected using blood or urine samples. For instance, proinflammatory cell types such as M1 macrophages, activated dendritic cells, NK cells, and effector T cells preferentially rely on glycolysis to meet their energy needs and produce elevated levels of lactate as a byproduct.[160,166,167] Meanwhile, regulatory populations such as M2 macrophages, MDSCs, and Tregs have a predilection toward fatty acid oxidation to support their functionality.[168,169] Interestingly, as effector T cells differentiate into memory T cells and then into an exhausted phenotype, they become increasingly more reliant on fatty acid oxidation and less dependent on glucose uptake,[170,171] providing a rationale for the use of glycolysis and fatty acid oxidation as biomarkers of response to ICB therapies. In fact, clinically relevant metabolomic signatures are currently being pursued as a correlative factor of clinical outcomes in multiple ongoing clinical trials.[160]

Predictive Signaling

Cytokine signals. Emerging roles for genomic data go beyond characterizing gene expression patterns of a given cell at a single point in time and instead predict how those expression patterns may change in response to an external stimulus, such as cytokine signaling.[172] However, predicting the changes in cellular activity and transcription following cytokine activation remains a significant challenge because of their inherent redundant and pleiotropic properties. To address some of the current shortcomings in cytokine signaling analysis, Jiang et al[172] developed a program called CytoSig, a predictive model of cytokine signaling interactions derived from existing transcriptomic databases. This novel model has particular advantages in that it is more effective at capturing ambiguous cell types buried in large data sets and can identify cytokine target genes even if they are only transiently expressed.[172] Technological developments such as this have allowed for the characterization of specific immune subpopulations[173] and the assessment of the spatial architecture of the TME[174] and illustrate how vast genomic databases can be leveraged into informative predictive models with many clinical and preclinical uses.

Microbiome signals. Another rapidly growing area of interest is the signaling interactions between tumor cells and the microbiome in the TME. Once overlooked, recent evidence has found that the tumor microbiome can be a potent modulator of the host antitumor immune response and induce differential gene expression in tumor cells.[175,176] It has long been known that bacteria have a significant presence in the TME—it is common practice to remove bacterial reads from RNA-seq and whole genome sequencing (WGS) of tumor samples.[177] However, in response to recent advancements and a more complete understanding of the TME, human tumor sequencing data are now being reanalyzed to retroactively include once filtered-out reads from the local tumor microbiome. The results indicate a role for microbial organisms in both prognosis and disease progression. For example, Poore et al[178] recently constructed a comprehensive pan-cancer microbiome data set derived from 18,116 WGS and RNA-seq samples within the TCGA cohort. Using this data set, the authors were able to discriminate between healthy, cancer-free, and cancer-harboring patients using only plasma-derived, cell-free microbial nucleic acids. Moreover, they showed widespread associations between diverse cancer types and specific microbiota, illustrating the diagnostic potential for microbiome sequencing. Building on this analysis, Hermida et al[177] used the same curated data set to demonstrate that microbial abundances predict prognosis, clinical outcome, and response to treatment in a subset of tumor types.

Precision Oncology

Computational approaches. As the trove of genomic data continues to accumulate and novel techniques continue to be developed, it becomes pertinent to consider where the fields of bioinformatics and big data go from here. What does a meaningful and actionable application of predictive genomic analysis look like? Today's algorithms are becoming more and more effective at providing prognoses and identifying clinically targetable molecules. Still, next-generation models will undoubtedly aim not only to predict response to treatment but also to anticipate mutations, identify mechanisms of resistance, and help guide physicians in determining and adjusting treatment regimens. Such is the goal of precision oncology.

In a recent proof-of-concept study by Ahmadi et al,[179] the authors developed a novel computational model called

MadHitter that analyzes large amounts of single-cell RNA sequencing data to identify the optimal combination of treatment targets for a given tumor sample. To make their results more clinically relevant, the group confined their analysis to cell surface proteins minimally expressed in normal tissues. Implementing these criteria allowed for the identification of molecules that can be selectively and precisely targeted by a variety of techniques, including CAR-T-cell therapy and immunoglobulin-chemotoxin conjugates, while minimizing toxicity to adjacent normal tissue. The results found that simultaneous targeting of up to four genetic targets identified by single-cell RNA sequencing was sufficient to kill at least 80% of tumor cells while sparing more than 90% of normal tissue in most disease types.[179] Combinatorial chemotherapy targeting different tumor growth mechanisms is a well-known and extensively studied aspect of cancer treatment, and with completed clinical trials demonstrating the feasibility of harvesting, sequencing, and analyzing genomic data fast enough to inform treatment decisions,[180,181] this study paves the way for robust clinical uses of genomic data. While future treatment modalities will likely use high-resolution single-cell genomic techniques such as this in tandem with systemic immune profiling, spatial analyses, and imaging modalities, this initial report demonstrates the feasibility of the personalized oncology approach in clinical care.

Attempts to implement these tools into clinical practice are already being made. For example, in a recently published study, Lee et al[182] established a framework known as synthetic lethality and rescue-mediated precision oncology via the transcriptome (SELECT) that aims to identify the most effective therapeutic drugs for a given patient on the basis of the tumor transcriptome. This computational strategy's innovativeness and novelty lie in its dependence not on the raw expression of genetic targets, but instead on specific genetic interactions subclassified into two groups: synthetic lethal interactions, wherein the simultaneous activation of two genes reduces a cancer cell's viability (as in PARP inactivation in BRCA-mutated breast malignancies[183]), and synthetic rescue (SR) interactions, defined as a change in the expression of a gene that reduces the fitness of a cancer cell, but for which viability is rescued by a concomitant alteration in a second gene (as in the rescue of Myc alterations by BCL2 activation in lymphomas[184]). The feasibility and application of this algorithm were tested by retroactively analyzing genomic data from previously published trials involving immune checkpoint inhibitors (PD-1/PD-L1 and CTLA-4) in multiple disease types. Using 21 previously published data sets and 1,021 patient samples, the group demonstrated a strong predictive power for SELECT, and specifically SR interactions, in response to treatment and overall survival.[182] The group then applied this framework to the results of the WINTHER trial, a landmark clinical trial and, to our knowledge, the first of its kind to treat patients on the basis of molecular targets identified by either genomic (WGS) or transcriptomic (RNA-seq) analysis. The study reported that SELECT would have recommended a different drug from the one prescribed in 94% of the cases, and the authors estimate that if SELECT guided treatment, 65% of patients would have responded to treatment as compared with the 27% reported in the trial, suggesting that although genomic and transcriptomic analyses do positively influence treatment decisions, SELECT and other models like it can further improve on this foundation. Of note, a recent follow-up paper has shown the predictive power of this approach on approximately 20 new additional targeted and ICB unseen (not trained on) patient cohorts.[185] Although still in their infancy, studies such as this one are making it increasingly more apparent that precision medicine tools have the potential to transform the field of personalized oncology.

BIOMARKERS OF RESPONSE

The most well-documented and problematic feature of ICB is that it is not equally beneficial to all patients. On an indication level, ICB response levels vary considerably across different cancer types. Response rates remain highly variable, and the biologic underpinnings of that variation are still poorly understood. Fortunately, in most cases, clinicians do not need an exact understanding of the mechanisms of these divergent responses; they need a more accurate way of predicting them. The emergence of the above computational and applied techniques has now allowed for comprehensive analysis of the molecular composition of both the tumor and the immune system and provides new avenues for deciphering which patients may derive benefit from ICB before the initiation of treatment. Here, we discuss the current obstacles and optimism in biomarkers of response to ICB treatment.

Shortcomings of the Past

Despite immense research and clinical efforts, PD-L1 remains the only reliable molecular marker of response to ICB treatment and the only one approved by the FDA as a companion diagnostic before initiating ICB therapy. As the most prominent mediator of immunosuppression, several diagnostic assays have been developed to establish a therapeutic PD-L1 threshold and stratify patients by predicted responsiveness.[186] Still, published results have shown that PD-L1 expression remains an incomplete and imperfect marker on its own. In a retrospective study of 45 FDA approvals of clinical trials incorporating ICB, PD-L1 expression was found to be predictive in only 28.9% of cases (53.3% were not predictive, and 17.8% were not tested), suggesting that PD-L1 as a univariate prognostic factor has significant limitations and illustrating the need for additional predictive biomarkers independent of PD-L1 status.

Meanwhile, the genetic basis for predictive biomarkers of response to ICB has historically been tied to tumor antigenicity and TMB. In preclinical models, TMB correlates with an increased probability of displaying neoantigens on the HLA molecules, eliciting CD8+ T-cell–dependent immune responses and tumor cell lysis.[2] Published clinical studies revealed a positive association between TMB and response to ICB in various disease types,[187-189] including a retrospective meta-analysis of 27 cancer subtypes that demonstrated a positive linear regression between ICB response rates and the logarithmic transformation of TMB.[190] An essential and positively prognostic genetic process that underlies neoantigen formation and TMB is microsatellite instability (MSI). MSI results from dysfunctional or deficient mismatch repair machinery, leading to the clustering of thousands of consecutive mutations along microsatellite regions.[191] Tumors that demonstrate deficiencies in MMR (MSI-high) have been shown to have improved responses to ICB treatment. For instance, in a Phase II clinical trial evaluating ICB among patients with heavily pretreated metastatic colorectal carcinoma, the objective response rate was 40% in MSI-high patients as compared with 0% in MSI-stable patients.[192] Since then, MSI-high patients have shown improved response to ICB in prostate, pancreatic, thyroid, neuroendocrine, endometrial, gastroesophageal, and biliary cancers,[193] prompting accelerated approval of pembrolizumab as second-line therapy for MMR-deficient solid malignancies. Pembrolizumab is also approved for the treatment of adult and pediatric patients with advanced solid tumors classified as TMB-high ($\geq$10 mutations/Mb) as determined by the FoundationOne CDx assay. However, similar to PD-L1, significant limitations apply to the use of TMB as a predictive biomarker because of outliers on both sides of the cutoff (responders in TMB-low and nonresponders in TMB-high populations).[194]

Finally, the most extensively studied cellular markers of response to ICB are TILs. As a correlate, the density, location, and proximity of T lymphocytes to cancer cells within the tumor have been shown to predict response to ICB in various cancer types.[195] Previous studies have attempted to quantify this effect by establishing a scoring system on the basis of the quantification cytotoxic and memory T-cell populations within tumoral cores (referred to as Immunoscore) to differentiate between immunologically hot and cold tumors.[196] Indeed, the Immunoscore has demonstrated improved accuracy in predicting prognosis and recurrence compared with MSI status or TNM staging.[197,198] By extension, tumors lacking T-cell infiltration have been shown to confer resistance, allowing them to evade immune detection and destruction. On the surface, TIL quantification seems like a promising and worthwhile potential biomarker. It is important to note, however, that pathologic analysis and the harvesting of a tissue biopsy require an invasive procedure and are not possible in all patients, highlighting the need for a surrogate marker that can reflect the composition of the tumor and be collected less invasively. Collectively, the significant limitations of even the most promising biomarkers to date illustrate the profound need for innovative identification and testing methods.

Challenges of the Present

As cancer research enters the next generation of biomarker identification and testing, several important and inescapable challenges have become increasingly apparent. Perhaps the most acute challenge is the lack of actionable markers of resistance mechanisms to guide combination immunotherapy selection. Although extensive preclinical work has identified several therapeutic targets for combination with ICB, very few have demonstrated a clinical benefit in randomized clinical trials in a nonselected patient population. This is likely due to the inter- and intrapatient variation within and among histologic cancer types. For instance, in a study of patients with metastatic melanoma, it was reported that 26% of tumors were homogenously positive for PD-L1 expression, 22% were homogenously negative for PD-L1 expression, and (most importantly) 52% of patients showed significant heterogeneity in PD-L1 expression between primary melanoma sites, locoregional disease, and distant metastases,[199] highlighting the magnitude of variation within a given tumor type (and even within the same patient) and underscoring the limitations of current biomarker testing in predicting clinical outcomes.

The degree of intratumoral heterogeneity and the diversity of subclonal cancer cells within a tumor are now also known to be significant barriers to the interpretation of predictive biomarkers.[200] Because tissue-based biopsies do not necessarily represent the entire tumor, predictive analyses reliant on pathologically harvested samples are often susceptible to sampling bias. In a study of patients with non–small-cell lung cancer, subclonal neoantigen heterogeneity was found to confer a poorer response to ICB and the neoantigen burden of subclonal populations, rather than the neoantigen burden of the tumor writ large, was more predictive of this worse clinical outcome.[201] Another important consideration in the context of biomarkers is the effect of host immunity. Factors such as baseline PD-L1 expression,[199] HLA allele polymorphism,[202] and TCR diversity[203] have been shown to contribute to ICB response rates and need to be normalized and controlled for in any effective predictive analysis.

To combat these challenges, considerable work has been performed to identify novel biomarkers that can give a more accurate representation of disease at the level of the

individual patient. One such marker gaining popularity in clinical practice is circulating tumor DNA (ctDNA). Plasma ctDNA is cell-free circulating DNA segments with previously characterized genetic, epigenetic, and chromosomal alterations corresponding to a specific cancer subtype.[204] The recent development of novel analytic platforms for ctDNA detection has generated considerable optimism that this class of biomarkers may be sensitive and specific enough to noninvasively monitor tumor growth and response to treatment.[205] Indeed, because of its ability to both profile and characterize molecular features of the tumor and serve as a surrogate for disease burden and tumor progression,[206] ctDNA has come to be known as the liquid biopsy. For example, using paired tumor and peripheral blood whole exome sequencing, a recent study in patients with advanced solid tumors treated with ICB found that a decrease in mean ctDNA concentration was highly correlated with improved clinical outcome independent of the tumor type, TMB, or PD-L1 status.[207] ctDNA monitoring has also been used to detect microscopic residual disease after curative-intent chemotherapy or surgical resection,[208] highlighting the broad clinical applications for ctDNA-based surveillance in improving patient response rates.

Promises of the Future

The unavoidable reality of biomarker research for immunotherapy is this: tumor immunobiology is far too complicated to be accurately defined at a univariate level. It is exceedingly unlikely that any single parameter will ever be predictive enough for a given disease type or treatment modality. The ideal biomarker (or collection thereof) must therefore be multifaceted and multivariable, taking into consideration individualized factors to identify patients who are most likely to derive benefit from ICB and limiting exposure and toxicity while simultaneously suggesting resistance to guide combination strategies. The ideal biomarker possesses another essential quality: it can be isolated and analyzed noninvasively.

The problem with mining previously published databases to find this optimal predictive combination is twofold: (1) the development and implementation of multivariate combinatorial biomarker algorithms quickly become a titanic mathematical undertaking and (2) most of today's immuno-oncologic clinical trials do not include considerations for upfront, prospective tumor characterization by genetic sequencing. To address these shortcomings, the immunoMATCH (iMATCH) central platform has been proposed, and the iMATCH pilot study (also referred to as the Biomarker-Stratified CaboZantinib and NivOlumab trial) has been developed and, to our knowledge, activated as the first of its kind to *prospectively* stratify participants into treatment cohorts on the basis of the expression of predefined biomarkers (ClinicalTrials.gov identifier: NCT05136196). The ultimate goal of this study is to initiate several independent trials with standardized biomarker testing to study mechanisms of response and resistance in distinct biologic

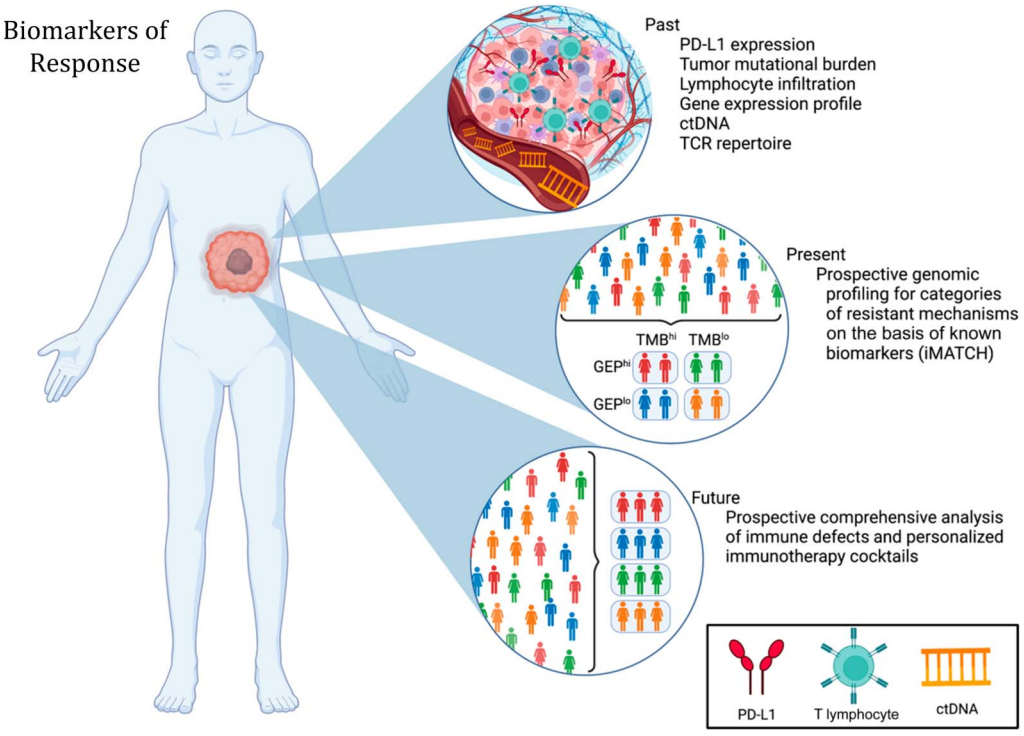

FIG 3. Evolution of biomarkers for the development of next-generation personalized immunotherapy. ctDNA, circulating tumor DNA; GEP, gene expression profile; iMATCH, immunoMATCH; TCR, T-cell receptor; TMB, tumor mutational burden.

subgroups of resistance mechanisms. To meet this end, patients will simultaneously undergo whole-exome sequencing to calculate TMB and identify treatable targets and a gene expression profiling analysis to generate a tumor inflammation score (an 18-panel gene set to quantify the immunogenicity of a patient's tumor). Patients will then be stratified by biomarker status into TMB-high (≥10 mutations/Mb) and TMB-low and gene expression profile-high (≥6) and gene expression profile-low subgroups to determine the course of treatment (Southwest Oncology Group S2101). It is believed that the robustness of these two parameters in combination can help overcome the variation of immune resistance to ICB between patients and facilitate the clinical development of combination immunotherapy (Fig 3).

Finally, what may well be the last frontier in biomarker research is the discovery of a marker that is predictive, prognostic, *and* therapeutic. One such intriguing and encouraging potential biomarker has recently made its way onto the scene. In their work, Lucca et al[209] analyze paired transcriptome and TCRαβ repertoire of both circulating and tumor-infiltrating T cells from matched tumor and blood samples in patients with metastatic melanoma at the single-cell level. They found that a small subset of clonally expanded T cells within the TME have sister clones (ie, clones with matching TCR sequences) that can be found in the periphery.[209] Using genetic profiling analyses, the group demonstrated that the degree of cytotoxicity of circulating TILs is reflective of the cytotoxicity of the tumor infiltrate and shows a positive correlation between the frequency of circulating TILs and a reduced metastatic burden,[209,210] providing a basis for the longitudinal monitoring of the antitumor immune response in situations where tumor biopsies are unfeasible. However, the presence of circulating tumor-specific T cells serves as more than just a biomarker of response and a means of viewing the immune environment of the TME. This subset of T cells can also be harnessed and invigorated with therapeutic intent. Once identified, these cells can theoretically be isolated, expanded, and reintroduced into the patient as a kind of pseudo-chimeric antigen receptor (CAR)-T-cell therapy wherein all the TCR expression and antigen priming are performed endogenously. Although this kind of technology is years away from any meaningful clinical impact, the rationale for this revolutionary personalized medicine has now been established.

CONCLUSION

Despite the challenges, immunotherapy remains the only treatment modality capable of eliciting a durable response resistant to dissemination and recurrence. As such, it naturally serves as a highly exciting launching pad in the search for novel combinations to increase its efficacy and better identify the patients most likely to benefit.

High Cost of Chimeric Antigen Receptor T-Cells: Challenges and Solutions

Edward R. Scheffer Cliff, MBBS, MPH[1,2]; Amar H. Kelkar, MD[2,3]; David A. Russler-Germain, MD, PhD[4]; Frazer A. Tessema, BA[1,2]; Adam J.N. Raymakers, PhD[1,2]; William B. Feldman, MD, DPhil, MPH[1,2,5]; and Aaron S. Kesselheim, MD, JD, MPH[1,2]

Chimeric antigen receptor (CAR) T-cells are a cellular immunotherapy with remarkable efficacy in treating multiple hematologic malignancies but they are associated with extremely high prices that are, for many countries, prohibitively expensive. As their use increases both for hematologic malignancies and other indications, and large numbers of new cellular therapies are developed, novel approaches will be needed both to reduce the cost of therapy, and to pay for them. We review the many factors that lead to the high cost of CAR T-cells and offer proposals for reform.

Advances in harnessing the immune system to treat cancer have defined the past decade of progress in oncology. Chimeric antigen receptor (CAR) T-cells are a type of cellular immunotherapy created by extracting and then genetically modifying a patient's T cells to target surface markers on—and thereby attack—malignant cells. CAR T-cells have demonstrated remarkable efficacy in treating multiple hematologic malignancies, including B-cell ALL (B-ALL), multiple subtypes of lymphoma (including the two most common types, diffuse large B-cell lymphoma [DLBCL] and follicular lymphoma), and multiple myeloma. In DLBCL, for example, trials indicate that CAR T-cells offer the possibility of cure to approximately 30%-35% of patients who would previously have had no curative therapeutic option available to them,[1] and we now have evidence that CAR T-cells can persist in vivo to maintain remissions for more than a decade.[2]

Since the first CAR T-cell therapy was approved by the US Food and Drug Administration in 2017—tisagenlecleucel (tisa-cel) for the treatment of B-ALL[3]—there are now six CAR T-cell therapies approved in the United States for the treatment of hematologic malignancies (Table 1; Fig 1).[6,7] Additionally, numerous cellular therapies, including not just CAR T-cells but also CAR-natural killer (NK) cells and CAR macrophages (among others), are being investigated across more than 500 clinical trials for a variety of malignancies,[8,9] including solid tumors such as pancreatic cancer and glioma[10] and nonmalignant conditions such as lupus and heart disease.[11,12]

However, cancer therapies are useful only to those who can access them.[13] Drug prices both in the United States and globally have increased substantially over the past two decades,[14] with the median launch price for cancer drugs in the United States now over $155,000 US dollars (USD) per year.[15] Cellular and gene therapies are among the most expensive therapies on the market.[16,17] Improving both local and global access to cancer therapies must be a priority if we want to improve cancer outcomes worldwide.[6,18] Yet, cellular therapies come with numerous logistical barriers in addition to their high cost,[6,19] including coverage limitations and insurance-required prior authorizations, lack of or delayed referrals to tertiary centers, manufacturing constraints and delays, and misperceptions around eligibility. As we sit on the precipice of a cellular therapy revolution in oncology, the high cost of CAR T-cell therapies—typically over $400,000 USD and sometimes over $1 million USD per patient[20,21]—and their logistical challenges raise concerns about their affordability and access for patients, payers, and health care systems both in the United States and globally.

Over time, increasingly disparate access to cancer therapies around the world may further exacerbate already stark inequalities in cancer outcomes.[13,22,23] Furthermore, the financial burden of CAR T-cell therapy may strain health care budgets, forcing governments and insurers to make tough decisions regarding resource allocation and coverage of different products.[24] We review the challenges of CAR T-cell pricing and evaluate the viability of various avenues for reform, including price negotiation, health technology assessment (HTA) and cost-effectiveness analyses, scientific advances such as novel CAR or costimulatory constructs and off-the-shelf allogeneic CAR T-cells, and innovative manufacturing approaches. We also consider different payment models for these high-cost therapies.

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Chimeric antigen receptor (CAR) T-cells are revolutionizing the care of many hematologic malignancies by offering an effective treatment to patients with ALL, lymphoma, and myeloma.
- However, the high cost of CAR T-cells means that uptake is limited to countries, health systems, payers, and individuals who can afford them—and a cancer treatment is only effective if a patient can access that treatment.
- Price negotiation—such as through the Inflation Reduction Act—offers a key opportunity to reduce the prices of CAR T-cells by more closely aligning them with the value that they offer patients.
- Furthermore, increasing transparency and reducing the price of the bundle of care negotiated between hospitals and insurers also has the potential to substantially affect the total cost of administering CAR T-cells.
- Autologous CAR T-cells are costly to produce because of their patient-specific nature and complex manufacturing process—novel approaches to manufacturing such as allogeneic CAR T-cells may reduce manufacturing costs.

FACTORS CONTRIBUTING TO HIGH MANUFACTURING COSTS OF CAR T-CELLS

The manufacturing and administration costs of CAR T-cell therapy represent one component of their high prices. The multistep process to manufacture CAR T-cells includes leukapheresis to obtain T cells, subsequent genetic engineering using viral vectors (or nonviral methods) to introduce CAR expression, and the expansion of modified T cells in a controlled environment.[25,26] Each of these steps can require sophisticated equipment, skilled labor, and strict quality control measures. Production costs are higher for local cell manufacturing facilities that produce trial products (compared with commercial manufacturers making cellular therapies at scale) as the reagents and lentiviral vectors, which are typically tied to each product or group of products, remain expensive.[27]

The patient-tailored nature of autologous CAR T-cell therapy raises the cost of production. Patient-specific features also impose additional logistical expenses relating to the apheresis process, cryopreservation, transportation of patient-derived cells to specialized manufacturing facilities, and the subsequent shipment of the final therapeutic product back to the clinical site. This also contributes to research and development (R&D) costs as the costs of running cellular therapy clinical trials are likely to be greater than those of small molecule therapies,[28] although it is difficult to quantify by how much.

So far, the development of many CAR T-cell products has followed a similar trajectory. In many cases, products with promising early-phase data launched by universities and/or small biotech companies have been bought by major pharmaceutical companies, who have then conducted the late-phase clinical trials and commercialized the products at scale. For example, Novartis entered into a R&D alliance with the University of Pennsylvania to develop tisagenlecleucel.[29]

PRICE VERSUS COST

Once a patient is deemed eligible for CAR T-cell therapy, the patient's insurer must then approve an entire bundle of care to enable T-cell collection and manufacturing to begin. This bundle typically includes all related patient care from collection through a specified postinfusion landmark, inclusive of expected and unexpected, inpatient and outpatient care. The price for this bundle is confidentially negotiated between the hospital and the insurer, and then a price is also confidentially negotiated with the CAR T-cell manufacturer.[30-32] Notably, the insurance approval process can take up to 2-3 weeks, exclusive of time for additional contracting between the medical center and the insurer.

Although many stakeholders, including pharmaceutical companies, argue that the extraordinary price of CAR T-cells reflects their high manufacturing cost, in fact, a large proportion of the price charged to payers represents profit for manufacturers, as suggested (but not definitively proven) by the high revenues of cell therapy manufacturers combined with their high margins across portfolios, and the collective interest in the biotech and pharma industries in cell therapies.[33] The high price charged by manufacturers is compounded by the fact that CAR T-cells are also billed as a bundle or procedure similar to stem-cell transplantation.

Definitive publicly available data about the true cost of manufacturing autologous CAR T-cells are sparse because of commercial confidentiality. University of Pennsylvania CAR T-cell pioneer Carl June suggested in 2012 that CAR T-cells cost about $20,000 USD per patient to manufacturer and that he expected this cost to decline when the product was manufactured at scale.[29] One study found that high-quality anti-CD19 CAR T-cells could be made using an automated system for approximately $35,107 USD per patient.[27] An academic group in Spain sells their product for ~€89,000, implying that their manufacturing costs are lower than this amount.[34,35] For companies manufacturing at scale, this cost may even have decreased over the past 5 years as companies may have made manufacturing processes more efficient as volume has expanded with more indications, and more centers deliver these products.

TABLE 1. List Prices of FDA-Approved CAR T-Cell Products

Generic Name	Brand Name	Approved Indication	Approval Date	Approved via Accelerated Approval	Acronym for Pivotal Trial	List Price in March 2023 (WAC, USD)
Tisagenlecleucel (tisa-cel)	Kymriah	R/R pediatric and young adult (<25) B-cell ALL	August 30, 2017	No	ELIANA	$543,828
		R/R adult DLBCL, HGBL, transformed DLBCL	May 1, 2018	No	JULIET	$427,048
		R/R FL	May 27, 2022	Yes	ELARA	$427,048
Axicabtagene ciloleucel (axi-cel)	Yescarta	R/R DLBCL	October 18, 2017	No	ZUMA-1	$424,000
		R/R FL	April 2, 2021	Yes	ZUMA-5	$424,000
Lisocabtagene maraleucel (liso-cel)	Breyanzi	R/R DLBCL, HGBL, transformed DLBCL, PMBL, FL grade 3B	February 5, 2021	No	TRANSCEND-NHL-001	$447,227
Brexucabtagene autoleucel (brexu-cel)	Tecartus	R/R MCL	July 24, 2020	Yes	ZUMA-2	$424,000
		Adult R/R B-cell ALL	October 1, 2021	No	ZUMA-3	$424,000
Idecabtagene vicleucel (ide-cel)	Abecma	R/R MM	March 26, 2021	No	KarMMa	$457,255
Ciltacabtagene autoleucel (cilta-cel)	Carvykti	R/R MM	February 28, 2022	No	CARTITUDE-1	$465,000

NOTE. List prices (WACs) include rebates and other confidential discounts, but these discounts are typically modest for oncology products (on average 2%).[4] Source: FDA Cellular and Gene Therapy Products website, Office of Tissues and Advanced Therapies and Red Book (Micromedex).
Abbreviations: CAR, chimeric antigen receptor; DLBCL, diffuse large B-cell lymphoma; FDA, US Food and Drug Administration; FL, follicular lymphoma; HGBL, high-grade B-cell lymphoma; MCL, mantle-cell lymphoma; MM, multiple myeloma; PMBL, primary mediastinal B-cell lymphoma; R/R, relapsed/refractory; USD, US dollars; WAC, wholesale acquisition cost.

If manufacturing costs represent a small component of high list prices for CAR T-cells, the opportunity to make the greatest impact on prices would be to decrease the difference between the cost of production and the price paid by the payer for the product. Of course, the reality of this calculation—the difference between the total amount paid by payers, list price, and production cost—is more complex because of the involvement of different entities in payment negotiations and agreements (eg, hospitals, public and private payers, and intermediaries). The common counterargument against negotiating lower drug prices is that these margins are needed to drive R&D. However, there are important assumptions underlying that counterargument that may not hold up to scrutiny. For example, at least for CAR-T treatments marketed thus far, substantial public funding helped support their discovery, and large companies entered later in the development process.[36] Large pharmaceutical companies spend more on marketing, administration, and stock buybacks than they do on R&D.[37] Furthermore, it is well demonstrated that there is no association between the price of a cancer therapy and the magnitude of benefit it offers to patients.[38]

HEALTH TECHNOLOGY ASSESSMENT AND DRUG PRICE NEGOTIATION

The United States pays substantially more for new therapeutics than other industrialized countries.[14] Achieving fair prices for brand name drugs is accomplished most effectively around the globe through two main mechanisms: HTAs that incorporate cost-effectiveness analysis or other assessment of a drug's value to inform price negotiation and, typically after some period of market exclusivity, entrance of direct competition from generic or biosimilar manufacturers.[39]

HTAs investigate the value of novel therapeutics and help government payers decide which therapies to reimburse and how much to offer, given the therapy's clinical value. They do this by reviewing the evidence supporting a novel agent to evaluate its incremental benefits over current standard-of-care therapies. When these assessments are subsequently used as the basis for negotiation, they are combined with a drug's proposed price to determine an incremental cost-effectiveness ratio—the amount of money it costs to deliver benefits, which can be expressed using

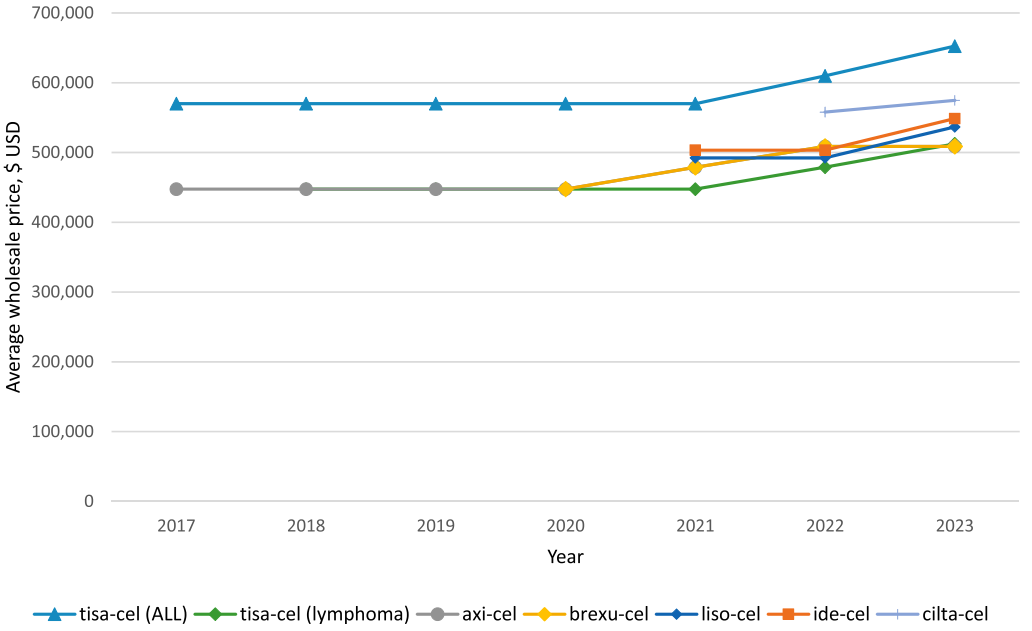

FIG 1. Prices of FDA-approved CAR T-cell products in the United States (AWP, USD). Source: Red Book (Micromedex). Average wholesale price is the price that manufacturers charge pharmacies while WAC (also known as the list price) is the price that manufacturers charge wholesalers (excluding any discounts). The AWP is generally approximately 20% higher than the WAC.[5] AWP is used in this figure as historical data are available for the AWP in the Red Book. ALL, acute lymphoblastic leukemia; CAR, chimeric antigen receptor; FDA, US Food and Drug Administration; USD, US dollars; WAC, wholesale acquisition cost.

standard measurements such as the quality-adjusted life year (QALY).[40,41,42] Through this process, the goal is to ensure that therapies offering only marginal value are less expensive than those offering larger benefits. Some countries use a willingness-to-pay threshold to enable comparisons across different disease types, essentially saying that they are only willing to fund therapies that cost less than a certain amount per QALY. For example, the United Kingdom's HTA agency, the National Institute for Health and Care Excellence, uses a threshold of £30,000.[43] To date, HTAs have made mixed recommendations on CAR T-cells, leading to differences in reimbursement and access across different countries.[44]

Although the United States does not have an HTA body,[45] the 2022 Inflation Reduction Act for the first time will enable the Secretary of the Department of Health and Human Services to negotiate the prices of certain expensive drugs in Medicare.[46] Negotiation is limited to a small number of drugs and biologics that have been on the market for a set period of time (9 years for small molecules and 13 years for biologics) and have no generic or biosimilar competition. Drugs with only a single rare disease indication and plasma-derived products (defined as a biological product that is derived from human whole blood or plasma) are excluded from negotiation. It remains to be seen whether this clause will exclude cellular therapies from negotiation since they are indeed derived from human whole blood. Another provision in the Inflation Reduction Act that could help curb price increases is the inflationary rebates, designed to prevent companies from increasing prices year-on-year beyond inflation.[47]

Given that commercially available CAR T-cell products are currently protected by multiple patents, it is difficult to predict the duration of market exclusivity for cellular therapies. Furthermore, because autologous CAR T-cells are manufactured from a patient's own cells, most patents for CAR T-cell products relate to viral vectors and manufacturing processes. Lack of clarity about the duration of protection means that it is also not yet clear whether cellular therapies will be subject to a vibrant competitive market from biosimilars.[48,49]

Negotiating Billing Agreements Between Hospitals and Payers

An additional and under-reported opportunity to reduce the price of CAR T-cells lies in reducing the total cost of the delivery of cellular therapies to patients. Because of the complexity of delivering cellular therapies, medical centers enter elaborate, multistep negotiations with payers to pay for the entire package of care, typically in a bundle. Treating a patient with a CAR T-cell therapy generally requires (1) procedural and laboratory pretesting (eg, echocardiography and pulmonary function testing), (2) suitability review by physicians and social workers, (3) placement of an apheresis catheter (typically under a local anesthetic), (4) leukapheresis, (5) CAR T-cell production and return shipment to the medical center, (6) treatment with lymphodepleting chemotherapy, (7) treatment with CAR T-cell therapy, (8) response assessments (eg, in lymphoma with fluorodeoxyglucose-positron emission tomography scans, or in ALL with bone marrow biopsy plus flow cytometry), and (9) recovery from toxicities (discussed below). Only step 5 is included in the product list prices in Table 1. Exact quantification of the costs of each step is challenging because of the confidentiality of reimbursement agreements between payers and hospitals, but it has been reported that

reimbursement of a bundle of these items may be in excess of $1-1.5 million USD, inclusive of the CAR T-cell product charge.[20,30-32,50-52] This series of studies found a wide range of total health care costs associated with CAR T-cell therapy, suggesting that these costs are underestimated in some analyses, and the wide variation reflects the methodological challenges associated with estimating these total costs.

Although centers may accept a smaller amount as reimbursement of the requested charges, part of hospitals' justification for these high bundled prices stems from their concern that they can lose large sums of money when treating patients on Medicare or Medicaid with CAR T-cell therapies. That is, often the amount paid by Medicare or Medicaid is less than the total cost of care for a patient receiving CAR T-cells. For example, in fiscal year 2022, inpatient hospital reimbursements by Medicare for CAR T-cell products were calculated on an episodic basis using a Medicare Severity Diagnosis Related Groups base payment rate adjusted for factors such as hospital geography and augmented by a new technology add-on payment and outlier payments.[52] Even with such payment adjustments, Medicare reimbursement for CAR T-cell products often failed to cover total hospital costs, which can incentivize centers to balance the books via charges to private payers.[21] Increased transparency in this area is greatly needed and could potentially build on recent policies designed to increase disclosure of hospital markups.[53,54]

STRATEGIES TO REDUCE THE PRODUCTION AND ADMINISTRATION COSTS OF CAR T-CELLS

Given that many of the aforementioned costs of CAR T-cells relate to their personalized nature, one emerging cost-saving approach is the use of allogeneic CAR T-cell products. Such products would be derived from healthy donors rather than the patient, which could reduce the manufacturing time and costs associated with autologous CAR T-cell therapy.[55] The primary concerns with this approach are the potential for graft-versus-host disease and, until recently, modest demonstrated efficacy of allogeneic products.[56] However, several allogeneic CAR T-cell products are currently in clinical development, with more promising early efficacy results than previous iterations of allogeneic products.[57,58] In December 2022, the first allogeneic cellular therapy received European Medicines Agency approval: tabelecleucel targeting the oncogenic Epstein-Barr Virus (EBV) in patients with post-transplant lymphoproliferative disease (EBV + PTLD).[59] Allogeneic CAR-NK cells, which are also under development, have a reduced risk of graft-versus-host disease than allogeneic CAR T-cells because of their lack of need for activation, shorter lifespan, and lower potency than T-cells.[60]

Innovative manufacturing approaches may also help reduce the cost of CAR T-cell therapy, such as closed-system manufacturing, which limits contamination risk and reduces the need for cleanroom facilities.[27,61] The use of serum-free or xeno-free culture media could reduce the reliance on expensive components derived from animals. Supply chain automation, from leukapheresis to CAR T-cell infusion, can help minimize the potential for human error, improve efficiency, and reduce labor costs. Automated cell processing systems, such as the CliniMACS Prodigy,[62] and more rapid production methods, such as Novartis' T-Charge,[63,64] could streamline the manufacturing process and reduce the time required for CAR T-cell production.

Decentralized manufacturing—the production of CAR T-cells at or near the point of care, currently undertaken by many university laboratories as part of clinical trials—may be able to reduce costs associated with transportation and storage. This approach may also help alleviate the logistical challenges associated with autologous therapies, such as the need for cryopreservation, strict chain-of-custody procedures, and stringent shipping requirements.

The bundled prices negotiated between hospitals and payers represent an often under-reported element of the cost of CAR T-cells. Such costs could be minimized by increasing the proportion of patients who receive CAR T-cells as outpatients, as well as reducing the frequency of complications. For example, if cytokine release syndrome or immune effector cell–associated neurological syndrome could be prevented, this may reduce the need for tocilizumab and/or intensive care unit admission for such severe adverse events. Another example is the cost-intensive need for prolonged supportive transfusions and growth factor support for patients with post-CAR-T cytopenias.[65,66] For example, use of biosimilar filgrastim can help manage post-CAR-T cytopenias. Reduced toxicity may also be achieved through novel CAR T-cell costimulatory domain constructs that may offer the possibility of T-cell expansion without the same degree of cytokine release or neurotoxicity, but the potential impact of these strategies on cost-effectiveness has yet to be formally assessed.

Assessing the Value of CAR T-Cell Therapies

To assess the relative value of novel therapeutic approaches, economic analyses are needed from HTA agencies, companies (often conducted via consulting agencies), and decision scientists. These often come in the form of cost-effectiveness analyses, in which different approaches are compared to determine which offers the best value for money. The most common cost-effectiveness analyses are conducted from the societal and health sector (eg, third party payer) perspectives, which often include budget impact analyses that consider the ramifications of the added costs on a health system. The key outcome measure used to make decisions in cost-effectiveness analyses is the incremental cost-effectiveness ratio, which is useful for comparing the difference between two approaches against a willingness-to-pay threshold.[67,68]

Cost-effectiveness analyses of CAR T-cell therapies have shown a wide variety of results, ranging from incremental cost-effectiveness ratios that would be considered cost-effective in many jurisdictions, to high incremental cost-effectiveness ratios that are nowhere near being cost-effective (Table 2). Many of these analyses have been limited by the fact that all CAR T-cell therapies were initially approved using single-arm clinical trials, which means that the comparisons inherent to cost-effectiveness analyses are hampered by the challenges of cross-trial comparison and the use of synthetic or historical control arms.[74] Similarly, the need to extrapolate treatment effects over time horizons longer than clinical trials poses important challenges and introduces considerable uncertainty for these novel therapies.[75]

Recently, the first three randomized controlled trials of CAR T-cell therapies—ZUMA-7, TRANSFORM, and BELINDA, all testing the use of CAR T-cells against autologous stem cell transplant in the second-line setting for DLBCL[1]—were published, leading to multiple cost-effectiveness analyses using this randomized data. The first three studies demonstrated cost-effectiveness over salvage chemotherapy with autologous stem-cell transplantation,[69,70,72] but the two most recent reported that CAR T-cell therapy was not cost-effective.[71,73] As shown in Table 2, one cost-effectiveness analysis has industry funding and editorial contribution; these types of studies must be interpreted with caution as industry-led cost-effectiveness analyses are more likely to report favorable results than independently-conducted analyses.[76-78]

Discrepancies in results across cost-effectiveness analyses pose a challenge in decision making. The modeled outcomes of therapies given subsequently to CAR T-cells or autologous transplantation (ie, outcomes in response to third- and fourth-line therapies and beyond) have the largest impact on the cost-effectiveness outcomes as the costs applied in the second-line therapies are very similar across the models. Other factors such as quality of life and risk of death, both while on therapy and for long-term survivors (eg, does a cured patient return to perfect quality of life?) can also influence outcomes and are based on very limited available data. By comparing various cost-effectiveness analyses, policymakers and clinicians can make informed decisions about the value of CAR T-cell therapy relative to other treatment options.

One challenge with assessing the cost-effectiveness of CAR T-cell therapy is that it may often be compared with other therapies that are already disproportionately expensive, which could make it more likely to appear cost-effective even when prices remain high.[67]

Another important consideration in assessing the value of CAR T-cell therapy is the potential for cure compared with more conventional treatments. Although some patients may achieve long-term remission or cure with CAR T-cell therapy, others may not respond or may experience relapse. Although CAR T-cells seem to offer a cure to some patients with ALL and DLBCL,[79] it is difficult to know whether they are curative in other lymphoma subtypes, and it seems unlikely that they offer a substantial proportion of myeloma patients cure. Whether patients are cured by CAR T-cells has a large impact on their subsequent life experience, but developing a better understanding of their long-term quality of life is essential to determining the treatment's value in all cases. Although CAR T-cell therapy can cause potentially life-threatening adverse events, such as cytopenias and neurotoxicity, patients who achieve long-term remission or cure may experience substantial improvements in quality of life compared with those who continue to receive conventional treatments.[80]

In children, the value of CAR T-cell therapy is particularly dependent on long-term outcomes, including cure and quality of life. If pediatric patients are cured, the benefit they gain, as measured by QALYs, will be substantial over the course of their life, which can result in improved cost-effectiveness—such as has been calculated for tisagenlecleucel in pediatric ALL.[81]

PAYMENT MODELS FOR HIGH-COST THERAPIES

Even if many of the above approaches combine to reduce the price of CAR T-cells, the cost may still be high, and innovative payment models may be required to meet remaining financial challenges.[17,82] These models aim to ensure that patients have access to life-saving treatments while mitigating the financial burden on patients and health care systems.

One potential approach to help ensure that payers only pay for treatments that provide meaningful clinical benefits is outcome-based payments, which tie the cost of a therapy to its effectiveness, with payments being contingent on the achievement of specific clinical outcomes. For example, a payer may only reimburse the full cost of a CAR T-cell therapy if the patient achieves a predefined treatment response or remains in remission for a certain period of time. As some patients initially respond to CAR T-cell therapy but then rapidly progress, it is important to ensure that the outcome measure being used reflects true clinical effectiveness.[83] Although there was some initial enthusiasm for outcome-based pricing approaches in CAR T-cells, especially in Europe,[83] current payment approaches in the United States largely do not take outcomes into account.[52] It can be difficult for payers and manufacturers to reach agreement regarding the appropriate outcome, time horizon, and adjudication approaches.[84] Outcome-based pricing models can also be complex and costly for payers and hospitals to administer. Another challenge is how to account for beneficiaries who may change insurance providers or lose their insurance coverage.

CAR T-cell payment models could borrow elements from previous models developed to pay for high-cost therapies.

TABLE 2. Comparison of Different Cost-Effectiveness Analyses of CAR T-Cells for Second-Line DLBCL

	Choe et al[69]	Kambhampati et al[70]	Kelkar et al[71]	Perales et al[72]	Vijenthira et al[73]

Is second line axi-cel cost-effective?	Yes	Yes	No	Yes	No

NOTE. This table was adapted from Kelkar et al[71] with permission from the authors.

Abbreviations: ASCT, autologous stem-cell transplantation; CAD, Canadian dollars; CADTH, Canadian Agency for Drugs and Technologies in Health; CAR, chimeric antigen receptor; DLBCL, diffuse large B-cell lymphoma; EFS, event-free survival; HSUV, health state utility value; ICER, incremental cost-effectiveness ratio; NR, not reported; PFS, progression-free survival; QALY, quality-adjusted life-years; SMR, standardized mortality ratio; USD, US dollars; WTP, willingness-to-pay.

In the mid-2010s, the Louisiana Medicaid program and the Australian health care system pioneered the use of a fixed-fee, subscription model to pay for expensive but curative hepatitis C antivirals.[85,86] In this example, the payer pays a fixed price per year for access to the treatment that does not vary with its use. This approach may prove less appealing to manufacturers of cellular therapies with higher manufacturing costs than small molecule drugs, for which the actual amount of drug produced has a much smaller impact on the profit margin. Alternatively, it could lead to a subscription model that is prohibitively expensive.

Nonexclusive licensing agreements, especially by universities and academics receiving public funding, could democratize access to transformative discoveries and in turn encourage competition.[82] Licensing agreements could also contain requirements for future pricing strategies. Just as Moderna's agreement with the United States compelled it to supply its COVID-19 vaccines preferentially to the United States, a licensing agreement at the time of public research investment could compel a manufacturer to contain prices below a certain threshold.

Because cellular and gene therapies are so expensive, health insurers have trialled new payment schemes that outsource initial payments to specialty pharmacies in a role in some ways analogous to pharmacy benefits managers. This third party—the specialty pharmacy—can help manage both high costs and the actuarial risk associated with them. For example, specialty pharmacies such as Accredo

have initiated systems in which they pay a manufacturer upfront for its gene therapy, and the specialty pharmacy is, in turn, reimbursed by a patient's health plan over time with both the rate and time period subject to negotiation.[87,88]

CONCLUSION

CAR T-cell therapies have demonstrated remarkable clinical outcomes in certain patients with cancer with otherwise limited treatment options. However, the high costs present a major obstacle for patients, health care providers, and payers. To ensure a fair price for CAR T-cell therapies and increase access to these potentially life-saving therapies, a multipronged combination of strategies is needed, including price negotiation, innovative manufacturing approaches, and the implementation of alternative payment models. Addressing these extremely high prices would help to ensure that CAR T-cell therapies are accessible to patients who may benefit from them, without placing an unsustainable burden on health care systems.

Novel Immunotherapeutics: Perspectives on Checkpoints, Bispecifics, and Vaccines in Development

Firas Y. Kreidieh, MD, ABAM[1]; Hussein A. Tawbi, MD, PhD[1]; Aikaterini Alexaki, PhD[2]; Hossein Borghaei, DO, MS[3]; and Lana E. Kandalaft, PharmD, PhD, MTR[2,4,5]

Overview

Over the past decade, the advent of molecular techniques and deeper understanding of the tumor microenvironment (TME) have enabled the development of a multitude of immunotherapy targets and approaches. Despite the revolutionary advancement in immunotherapy, treatment resistance remains a challenge leading to decreased response rate in a significant proportion of patients. As such, there has recently been an evolving focus to enhance efficacy, durability, and toxicity profiles of immunotherapy. Although immune checkpoint inhibitors have revolutionized cancer treatment with many already-approved antibodies and several others in the pipeline, bispecific antibodies build on their success in an attempt to deliver an even more potent immune response against tumor cells. On the other hand, vaccines comprise the oldest and most versatile form of immunotherapy. Peptide and nucleic acid vaccines are relatively simple to manufacture compared with oncolytic virus–based vaccines, whereas the dendritic cell vaccines are the most complex, requiring autologous cell culture. Nevertheless, a crucial question in the development of cancer vaccines is the choice of antigen whereby shared and patient-private antigen approaches are currently being pursued. There is hope that cancer vaccines will join the repertoire of successful novel immunotherapeutics in the market. Better insights into the impact of immunotherapy on effector T cells and other immune cell populations in the TME shall be a major priority across the immune-oncology discipline and can help identify predictive biomarkers to evaluate response to treatment and identify patients who would most likely benefit from immunotherapy.

INTRODUCTION

Over the past decade, the advent of molecular techniques and deeper understanding of the tumor microenvironment (TME) have enabled the development of a multitude of immunotherapy targets and approaches. Despite the revolutionary advancement in immunotherapy, treatment resistance remains a challenge leading to decreased response rate in a significant proportion of patients. Immune checkpoints are essential regulators of the immune system that can inhibit the T-cell receptor signaling pathway, thus promoting self-tolerance.[1] In 2011, ipilimumab was the first immune checkpoint inhibitor (CPI) that received US Food and Drug Administration (FDA) regulatory approval.[2] Since then, several CPIs have been approved with a continuously expanding spectrum of clinical indications. Although immune CPIs have revolutionized cancer treatment with many already-approved antibodies and several others in the pipeline, bispecific antibodies build on their success in an attempt to deliver an even more potent immune response against tumor cells by simultaneously binding two independent epitopes.[3] The field of cancer immunotherapy has been steadily growing with multitargeted approaches that exceed checkpoint inhibition to engage the various facets of the immune system.

Although vaccines were the first agents devised in an attempt at stimulating the immune system, their application as cancer immunotherapeutics has remained limited to date. Prophylactic vaccines, such as those protecting against human papilloma virus (HPV) and hepatitis B virus (HBV), are considered cancer vaccines that prevent HPV- and HBV-related malignancies. This is different from therapeutic vaccines that actively target tumor cells with therapeutic intent, whereby several platforms are underway, including cell-based, nucleic acid–based, peptide-based, and virus-based cancer vaccines, all of which carry promising potential in the field of immunotherapeutics.[4]

Cancer immunotherapeutics have been at the forefront of revolutionary advances in the field of immuno-oncology (Table 1). With the long-term remission provided by CPIs, on the one hand, and the promising results of bispecific antibodies and cancer vaccines, on the other hand, better understanding of these novel immunotherapeutic approaches ensues. In this chapter, we aim at providing an overview of advances in immunotherapeutics while focusing on their emerging game-changing role in cancer treatment.

PRACTICAL APPLICATIONS

- Despite the revolutionary advancements in immunotherapeutics and the incorporation of several checkpoint inhibitors (CPIs) in the standard practice, treatment resistance remains a challenge, leading to a decreased response rate in a significant proportion of patients.
- With evolving focus to enhance efficacy, durability, and toxicity profiles of CPIs, several other promising immune checkpoints are being studied in cancer treatment
- Although CPIs have revolutionized cancer treatment with many antibodies already-approved and several others in the pipeline, other immunotherapeutic approaches, including bispecific antibodies and cancer vaccines, are needed to deliver an even more potent immune response against tumor cells.
- More efforts are now put in investigating combinatorial approaches to improve clinical outcomes.
- Clinical trials that incorporate immune profiling of baseline tumor specimens are needed for deeper understanding of the relationship between the immune tumor microenvironment and response to treatment, resistance, and micrometastases.

INSIGHT INTO NOVEL IMMUNE CPIs

To enhance the benefit from CPIs in cancer treatment, there has recently been an evolving focus on identifying and targeting alternative novel immune checkpoints.[5]

Lymphocyte Activation Gene-3

Lymphocyte activation gene-3 (LAG-3) is a surface molecule on T cells that is related to a cluster of differentiation, CD4. It is expressed on the cell membrane of tumor-infiltrating lymphocytes, on activated CD4+ and CD8+ T cells, and on regulatory T cells.[6] LAG-3 binds to major histocompatibility complex class II on antigen-presenting cells (APC) with a great affinity that inhibits the binding of CD4 and T-cell receptor (TCR) and results in inhibition of the TCR signaling pathway. In addition, LAG-3 crosslinks with CD3, which can impair T-cell proliferation and cytokine secretion by inhibition of influx of calcium. LAG-3 has a unique cytoplasmic tail as compared with other immune checkpoints, which further supports its unique molecular characteristics and role.[7-9] Moreover, dual genetic knockdown of LAG-3 and PD-1 in murine melanoma models was associated with decreased tumor growth and improved overall survival (OS) of mice. This suggested LAG-3 as a potential target for overcoming resistance of single-agent immune-checkpoint inhibitor (ICI).[5] In addition, both LAG-3 and cytotoxic T-cell lymphocyte-4 (CTLA-4) can inhibit the TCR signaling pathway and result in tumor immune tolerance. An interesting recent finding was an increased expression of LAG-3 in tumor-infiltrating lymphocytes after treatment with ipilimumab, a CTLA-4 antibody.[10] Several clinical trials that investigate the use of a combination of ICIs targeting LAG-3, PD-1, and/or CTLA-4 are ongoing.[5,10,11]

Targeting LAG-3 results in an enhanced TCR signaling pathway, thus inhibiting the suppression of regulatory T cells. The immunomodulatory role of LAG-3 dates back to 2006 when LAG-3Ig fusion protein was used to induce an antitumor immune response. This was followed by studies that investigated its role in renal cell carcinoma, metastatic breast cancer, and melanoma.[12-14] Antibodies against LAG-3 can release the brake against the immune response targeting melanoma tumor cells. Relatlimab is the first anti-LAG-3 antibody that is under current investigation in more than 12 clinical trials in multiple tumors.[15,16]

The landmark RELATIVITY-047 trial studied the combination of relatlimab and nivolumab as compared with single-agent nivolumab for untreated advanced melanoma. This trial included 714 patients with treatment-naïve metastatic melanoma. They were randomly assigned to receive relatlimab (160 mg) and nivolumab (480 mg) once every 4 weeks or to nivolumab (480 mg) once every 4 weeks. The median progression-free survival (PFS) was 10.1 months for the combination group, which was significantly greater than that of the nivolumab group of 4.6 months ($P = .0055$). Interestingly, this improved PFS was not dependent on the expression of neither LAG-3 nor PD-L1.[17,18] At a median follow-up of 19.3 months presented at the ASCO 2022 plenary series, the PFS slightly increased to 10.2 months, as compared with 4.6 months for the combination and single-agent groups, respectively.[19] This study led to FDA approval of nivolumab-relatlimab combination on March 18, 2022, for patients with previously untreated advanced melanoma.[20] The combination is now being studied in treatment-naïve patients with advanced melanoma and active brain metastases.[21]

Following the results of RELATIVITY-047, a similar study combined relatlimab and nivolumab in the neoadjuvant setting, which enabled investigators to evaluate treatment efficacy after surgical resection. Twenty-nine patients with stage IIIB-IV resectable melanoma were enrolled in this study, and 59% of patients had complete response (CR).[22] The results from the addition of relatlimab to the CPI backbone in melanoma have led to further ongoing trials that study anti–LAG-3 therapy combinations. The phase II PLATforM trial (ClinicalTrials.gov identifier: NCT03484923) studies LaG-525 in combination with spartalizumab, which is a monoclonal antibody against PD-1.[23] There are also

TABLE 1. Approved and Most Promising Immunotherapy Agents Currently at Various Phases of Clinical Development

Agent	Target	Indication/Type of Cancer	Phase	Clinical Trial No.
Checkpoint inhibitors				
Ipilimumab	CTLA-4	Melanoma, renal cell carcinoma, colorectal cancer, HCC, NSCLC, malignant pleural mesothelioma, esophageal cancer	Approved	>380 active CTs
Tremelimumab	CTLA-4	HCC, NSCLC	Approved	>200 active CTs
Nivolumab	PD-1	Melanoma, NSCLC malignant pleural mesothelioma, renal cell carcinoma, Hodgkin lymphoma, SCCHN, urothelial carcinoma, colorectal cancer, HCC, esophageal cancer, gastric cancer	Approved	>900 active CTs
Pembrolizumab	PD-1	Melanoma, NSCLC, Hodgkin lymphoma, PMBCL, urothelial carcinoma, MSI-H or dMMR, CRC, gastric cancer, esophageal cancer, cervical cancer, HCC, MCC, RCC, endometrial carcinoma, TMB-H, cSCC, TNBC	Approved	>1,000 active CTs
Cemiplimab	PD-1	Cutaneous squamous cell carcinoma, basal cell carcinoma, NSCLC	Approved	>80 active CTs
Durvalumab	PD-L1	NSCLC, HCC, extensive-stage SCLC, biliary tract cancer	Approved	>400 active CTs
Atezolizumab	PD-L1	NSCLC, SCLC, HCC, melanoma, alveolar soft part sarcoma	Approved	>400 active CTs
Avelumab	PD-L1	Merkel cell carcinoma, urothelial carcinoma, renal cell carcinoma	Approved	>100 active CTs
Relatlimab	LAG-3	Metastatic melanoma (in combination with nivolumab)	Approved	>40 active CTs

Abbreviations: BCMA, B-cell maturation antigen; CRC, colorectal carcinoma; cSCC, cutaneous squamous cell carcinoma; CTs, clinical trials; CTLA-4, cytotoxic T-cell lymphocyte-4; DCVAC-OvCa, different approach for ovarian cancer; dMMR, deficient mismatch repair; EGFR, epidermal growth factor receptor; EpCAM, epithelial cell adhesion molecule; GI, gastrointestinal; HCC, hepatocellular carcinoma; HNSC, head and neck squamous cell carcinoma; NSCLC, non–small-cell lung cancer; HPV, human papilloma virus; HSPPC-96, heat shock protein peptide complex 96; MCC, Merkel cell carcinoma; MSI-H, microsatellite instability-high; NRG1, Neuregulin 1; OC-DC, oxidized tumor cell lysate; PAP, prostatic acid phosphatase; PEP-DC, peptide loaded dendritic cell; PMBCL, primary mediastinal large B-cell lymphoma; RCC, renal cell carcinoma; SCCHN, squamous cell carcinoma of the head and neck; SCLC, small-cell lung cancer; TICs, tumor-initiating cells; TMB-H, tumor mutational burden-high; TNBC, triple-negative breast cancer; T-VEC, talimogene laherparepvec.

around 50 studies that are currently ongoing to evaluate the role of anti–LAG-3 antibodies added to other CPIs.[24]

T-Cell Immunoglobulin and Mucin Domain–Containing Protein-3

T-Cell immunoglobulin and mucin (TIM-3), also referred to as hepatitis A virus cellular receptor 2 (HAVCR2), is a type I transmembrane protein, which is encoded by the HAVCR2 gene. Its extracellular domain consists of the N-terminal immunoglobulin variable (IgV) domain located at the distal end of the membrane followed by the membrane mucin domain that contains an O-linked glycosylation potential. It is expressed in CD4+ and CD8+ T cells, regulatory T cells, natural killer cells, dendritic cells, and Th17 cells.[25,26] When compared with other immune checkpoints, TIM-3 binds to a wider spectrum of ligands on normal and malignant cells, including galectin 9, phosphatidylserine carcinoembryonic antigen–related cell adhesion molecule 1 (CEACAM1), and high mobility group protein B1 (HMGB1).[27] Similar to LAG-3, stimulation of TIM-3 by its ligands promotes T-cell exhaustion, which entails failure of T cells to proliferate and exert their usual effector functions, including cytokine release and cytotoxicity.[28,29] There are several ongoing clinical trials for the combination of CPIs that include antibodies against TIM-3 in solid tumors.[30-32]

A phase I/II study by Curigliano et al investigated sabatolimab, an anti–TIM-3 antibody, with or without spartalizumab, an anti–PD-1 antibody. This study enrolled 219 patients with advanced solid tumors, 86 of whom received combination therapy. No response was observed in patients receiving sabatolimab, but five patients receiving combination therapy had partial response, one of whom had malignant perianal melanoma. The authors suggested that combining sabatolimab with spartalizumab showed enhanced antitumor activity.[32] Another phase II trial (ClinicalTrials.gov identifier: NCT02608268) investigated the combination of sabatolimab and spartalizumab in patients with non–small-cell lung cancer and melanoma.[33] In addition, a phase I/II trial NCT04370704 is studying the combination of antibodies against PD-1 (INCMGA00012), LAG-3 (INCAGN02385), and TIM-3 (INCAGN02390) in selected tumors.[34] Another ongoing trial is comparing dostarlimab (TSR-022), a PD-1 inhibitor, with combination therapy of TIM-3 inhibitor, cobolimab, and dostarlimab in melanoma.[35]

T-Cell Immunoglobulin and Immunoreceptor Tyrosine–Based Inhibitory Motif Domain

T-Cell immunoreceptor with immunoglobulin and tyrosine-based inhibitory motif domains (TIGIT) is a 244-amino acid transmembrane glycoprotein with an extracellular IgV domain, a transmembrane domain, and cytoplasmic tail that includes the immunoreceptor tyrosine–based inhibitory motif (ITIM) and an immunoglobulin tail tyrosine–like phosphorylation motif.[36] To our knowledge, TIGIT was first introduced by Yu et al[36] as a suppressor of T-cell activation. It is expressed on regulatory and memory T cells and natural killer (NK) cells. TIGIT binds with two main ligands, C155 and CD112, and competes with their other counterparts, namely, CD266 and CD96, thus exerting an immunosuppressive effect on T cells. CD266 delivers a positive costimulatory signaling pathway, whereas TIGIT delivers inhibitory signals.[37] Moreover, the ligation of TIGIT can result in inhibition of natural killer cells cytotoxicity through its ITIM cytoplasmic domain in human and mice models.[37]

The above data emphasized that dual inhibition of PD-1 and TIGIT is a promising combination option of CPIs for melanoma that is refractory to anti–PD-1. The first-in-human phase I study on antibody against TIGIT was conducted by Niu et al[38] and recently published. Vibostolimab, an antibody against TIGIT, showed an improved antitumor activity when combined with pembrolizumab, an anti–PD-1 antibody, with an acceptable toxicity profile in patients with solid tumors. In a phase I/II study, neoadjuvant vibostolimab plus pembrolizumab resulted in numerically higher objective response, event-free survival, and recurrence-free survival as compared with gebasaxturev plus pembrolizumab or pembrolizumab alone. The 18-month event-free survival was 85%, 70%, and 78%, respectively.[39] There are more than six antibodies targeting TIGIT that are being studied in solid tumors, including MK-7684, which is a candidate anti-TIGIT drug developed by Merck, and etigilimab (OMP-313 M32), which is a humanized monoclonal antibody that blocks TIGIT from binding CD155.[40,41] Another anti-TIGIT candidate is tiragolumab (MTIG7192A, RG-6058), which also hinders its interaction with CD155. There are two clinical trials that involve tiragolumab, namely, NCT02794571 and NCT03563716.[40]

Other Promising Immune Checkpoints

With evolving focus to enhance efficacy, durability, and toxicity profiles of CPIs, several other promising immune checkpoints are being studied in cancer treatment. Similar to TIGIT, poliovirus receptor–related immunoglobulin-containing domain (PVRIG or CD112R) also binds to CD112 and mediates comparable effects. PVRIG was first described in 2016[42] and is expressed primarily on NK and CD8+ T cells with mostly effector and memory phenotype. Activation enhances PVRIG expression on CD4+ and CD8+ T cells.[42] COM701 is a monoclonal antibody that binds to PVRIG and inhibits its interaction with CD112. Its effect, in combination with nivolumab, against advanced tumors is underway in phase I and I/II studies. Preliminary results suggest an acceptable safety profile and a promising potential therapeutic benefit.[43] It is also being investigated in combination with TIGIT inhibitors (ClinicalTrials.gov identifiers: NCT04354246, NCT04570839).[44,45]

Natural killer group protein 2A (NKG2A) is a receptor present in approximately 50% of NK cells and to a smaller extent on NKT of CD8+ T cells.[46,47] Preclinical models showed that activation by its ligand HLA-E causes a cascade of events that suppress NK and CD8+ T-cell effector function, whereas its blockade promotes antitumor immunity.[46] Monalizumab, a humanized monoclonal antibody against NKG2A, is being investigated in clinical trials with encouraging results. In addition to a phase I trial that supported its safety as monotherapy,[48] several phase III clinical trials that investigate monalizumab in combination with other CPIs in a variety of malignancies, including squamous cell carcinoma of the head and neck and non–small-cell lung cancer, are currently ongoing.[49,50]

ATP catabolism is mediated by CD73, an enzyme that is found in healthy tissue but is overexpressed in the TME, on myeloid-derived suppressor cells, tumor-associated macrophages, Tregs, exhausted T cells, and tumor cells.[51,52] Targeting CD73 and the adenosine receptors is, therefore, expected to reverse the cascade of events that lead to immunosuppression. Oleclumab, an anti-CD73 antibody, has already been shown to be well tolerated as a monotherapy in one phase I clinical trial.[53] A phase III clinical trial in patients with non–small-cell lung cancer (NSCLC) compares the combination of durvalumab/oleclumab or durvalumab/monalizumab with the combination of durvalumab/placebo. In parallel, inupadenant, an A2aR antagonist, is also under investigation in phase I, I/II, and II trials.[54,55]

BISPECIFIC ANTIBODIES

BsAbs Binding Two Tumor Antigens

Amivantamab is an FDA-approved BsAb that targets and disrupts epidermal growth factor receptor (EGFR) and MET signaling. Through this binding, amivantamab promotes targeting of tumor cells for destruction by immune effector cells, such as NK cells, by antibody-dependent cellular cytotoxicity. FDA granted accelerated approval for on May 21, 2021, for metastatic NSCLC, whose tumors harbor EGFR exon 20 insertion mutations.[56] Amivantamab is currently being investigated as monotherapy in a variety of clinical trials for salivary gland cancer, hepatocellular carcinoma, and gastroesophageal cancer.[57] On the other hand, KN026 is an antihuman epidermal growth factor receptor 2 (HER2) bispecific antibody that was produced from the structural coupling of trastuzumab and pertuzumab,[58] two

approved monoclonal antibodies for the treatment of HER2-positive cancer. Pertuzumab is, so far, only approved in combination with trastuzumab for the treatment of breast cancer, whereas trastuzumab is also approved for gastric and gastroesophageal cancers.[59] Clinical trials for single-agent KN026 have focused on the approved indications of trastuzumab and pertuzumab, in addition to combination with chemotherapy, and results from completed studies indicate that KN026 seems to be well-tolerated.[60,61]

Similarly, zanidatamab targets the same domains as trastuzumab and pertuzumab[62] and is being investigated for the same indications as KN026, in addition to biliary tract cancer and colorectal cancer. Importantly, there is an active phase III clinical trial (ClinicalTrials.gov identifier: NCT05152147) that compares zanidatamab plus chemotherapy with the standard of care, trastuzumab plus chemotherapy, as first-line treatment for patients with advanced/metastatic HER2-positive gastroesophageal adenocarcinoma.[63] This study also looks at the addition of a PD-1 inhibitor, tislelizumab, to the regimen. In parallel, zanidatamab is also being developed as an antibody drug conjugate, with the cytotoxic drug (N-acyl sulfonamide auristatin), and is currently at a phase I clinical trial (ClinicalTrials.gov identifier: NCT03821233).[64] Zenocutuzumab is an anti-HER2 and anti-HER3 BsAb developed specifically for tumors with Neuregulin 1 (NRG1) rearrangements, which are recurrent oncogenic drivers in solid tumors.[65] NRG1 binds to HER3, leading to heterodimerization with other HER/ERBB kinases, increased downstream signaling, and enhanced tumorigenesis. With results from single-patient experimental protocols[65] and a phase I clinical trial (ClinicalTrials.gov identifier: NCT03321981) showing promise, zenocutuzumab is also being investigated in ongoing phase II clinical trials.[66]

BsAbs Blocking Two Immune Checkpoints

KN046 is a recombinant humanized PD-L1/CTLA-4 BsAb that is currently investigated in multiple clinical studies, mostly phase II, for a wide range of indications with promising results.[67] Importantly, in two phase III clinical trials, KN046 is combined with first-line chemotherapy, namely, carboplatin and paclitaxel for NSCLC and gemcitabine and nab-paclitaxel for pancreatic ductal adenocarcinoma.[68] AK104, or cadonilimab, is a human tetravalent anti–PD-1/CTLA 4BsAb that was recently granted conditional approval in China for patients with relapsed or metastatic cervical cancer who have progressed on or after platinum-based chemotherapy.[69] Its investigation is underway for a range of solid tumors, including cervical cancer, lung cancer, gastric/gastroesophageal junction cancer, and liver cancer.[69]

BsAbs targeting PD-1 and other immune checkpoints are also ongoing. For example, an ongoing trial NCT03708328 studies a bispecific antibody R07121661 that targets both PD-1 and TIM-3 in metastatic melanoma and non–small-cell lung cancer.[70,71] Another trial NCT04140500 studies RO7247669, which is a BsAb against both LAG-3 and PD-1 in solid tumors refractory to previous therapy.[72] Concurrent inhibition of PD-1 and LAG-3 is explored with tebotelimab, or MGD013, a BsAb constructed from combining nivolumab and relatlimab.[73] Tebotelimab is being investigated in a phase II/III clinical trial for gastric and gastroesophageal cancers in combination with an anti-HER2 antibody.[26]

Bispecific T-Cell Engagers

This group of BsAbs binds simultaneously to T cells, through CD3, and tumor cells, through a tumor-specific antigen, thus directing the cytotoxic potential of immune cells onto tumor cells. Blinatumomab, for example, is a bispecific T-cell engager (BiTE) that binds to CD3 to engage T cells and CD19 to direct cytotoxicity to B cells. It was the first BiTE to gain FDA approval whereby it was approved in 2014 for relapsed or refractory B-cell precursor ALL.[74] Several clinical trials that combine blinatumomab with other drugs are ongoing in an effort to expand its clinical indications.[75]

Another BiTE, tebentafusp, was FDA-approved on January 25, 2022, for HLA-A*02:01–positive patients with unresectable or metastatic uveal melanoma. It is a bispecific gp100 peptide-HLA–directed CD3 T-cell engager, which continues to be investigated in clinical trials for other types of melanomas and solid cancers among patients who test positive for HLA-A*02:01. Teclistamab is a BiTE that binds to CD3 on T cells and to B-cell maturation antigen, which is expressed on the surface of multiple myeloma cells and some healthy B-lineage cells.[76] It was approved on October 25, 2022, for relapsed or refractory multiple myeloma after at least four lines of therapy and is currently in clinical trials for different combination regimens.[77]

Recently, a bispecific antibody was designed to engage CD3 on T cells and EGFR variant III (EGFRvIII) on tumor cells, and EGFRvIII is frequently expressed by glioblastoma cells while sparing healthy tissue, which makes it an attractive target for brain tumors.[78,79] This novel T-cell engager is referred to as a brain bispecific T-cell engager, BRiTE, and is the subject of several ongoing phase I clinical trials.[80]

RO6958688 recognizes CEA and CD3e and induces T-cell–mediated killing of CEA-overexpressing tumors. RO6958688 showed an acceptable safety profile in phase I clinical trials (ClinicalTrials.gov identifiers: NCT02650713, NCT02324257), and it is currently under investigation in a NSCLC phase I/II trial (ClinicalTrials.gov identifier: NCT03337698).[81] In addition to T-cell engagers, an innate cell engager was recently developed, namely, AFM24, which binds to EGFR on tumor cells and CD16 on NK cells and macrophages. In preclinical models, AFM24 was shown to be potent and effective in antibody-dependent cell-mediated

cytotoxicity via NK cells and cellular phagocytosis via macrophages.[82] AFM24 is currently under investigation in phase I/II clinical trials, alone or in combination with other immunotherapy agents.[83]

Engagement of NK cells, dendritic cells, and macrophages can also occur through the constant fragment (Fc) of antibodies. This was put into play with catumaxomab rat-mouse hybrid antibody with specificity against epithelial cell adhesion molecule and CD3. With its ability to bind innate cells as well, catumaxomab was described as being trifunctional. Although it was approved in Europe on April 20, 2009, catumaxomab was voluntarily withdrawn in 2013 for commercial reasons. It was recently reconsidered for investigation in China for its potential immunotherapeutic benefit through ongoing clinical trials for urothelial and gastric cancers.[84]

CANCER VACCINES

The advent of vaccines has introduced a promising cell-based therapeutic approach by triggering tumor antigen–specific cellular immune responses.[85,86] In this section, we will provide insight into the main cancer vaccines, namely, dendritic cell vaccines, nucleic acid vaccines, peptide vaccines, and virus-based vaccines.

Dendritic Cell Vaccines

In 2010, a dendritic cell–based vaccine, sipuleucel-T, was successfully used to treat prostate cancer, which proved the viability of cancer vaccines and created excitement in the field of cancer vaccines.[87] A major obstacle in developing other dendritic cell vaccines was the requirement for autologous dendritic cells, usually monocyte-derived, which need to be isolated and differentiated, thus significantly adding to the complexity of manufacturing. Nevertheless, a lot of progress has been made in cancer vaccines to date, particularly with the development of vaccine technology in the era of COVID-19 pandemic, which brought vaccines back to public focus.[85] So much so, a personalized vaccine, namely AV-GBM-1, which consists of autologous dendritic cells pulsed with autologous tumor antigens, was associated with promising 15-month OS in patients with newly diagnosed glioblastoma.[88]

More advanced approaches are targeting patient-specific neoantigens, which require experimental data from patient tumor samples and sophisticated algorithms for prioritization of the targets.[89] These neoantigens are delivered to the dendritic cells as long-chain peptides (ClinicalTrials.gov identifiers: NCT04147078, NCT04627246, NCT05195619).[90] To compare and combine the advantages of using oxidized tumor cell lysate and predesigned peptides for the manufacturing of dendritic cell vaccines, a phase I/II clinical trial on ovarian cancer is using peptide-loaded dendritic cells (PEP-DCs) in one arm and oxidized tumor cell lysate–loaded (OC-DC) followed by peptide-loaded DCs in the other (ClinicalTrials.gov identifier: NCT05714306).[91] Importantly, after exposure to the tumor lysate DC vaccine, a new set of peptides will be designed, on the basis of immunogenicity changes that are observed. Therefore, the contribution of each step of the vaccination will be measured and compared separately.[92]

In a different approach for ovarian cancer (DCVAC-OvCa), allogeneic tumor cells (from OV-90 and SK-OV-3 cell lines) killed by high hydrostatic pressure are used as a source of multiple tumor-associated antigens (TAAs) for loading onto autologous DCs.[93,94] This strategy provides off-the-shelf material for the preparation of dendritic cells but may lack the specificity of personalized antigens. Nevertheless, it has shown acceptable safety and promising efficacy in phase II clinical trials[94,95] and continues to be investigated (ClinicalTrials.gov identifier: NCT04834544).[96] A similar approach had been used for prostate cancer, which reached phase III clinical trials, yet did not show increased OS.[97]

Nucleic Acid Vaccines

There are several advantages for nucleic acid vaccines: amenability to the inclusion of many antigens, ability to induce both, humoral and cellular immune responses, feasibility, safety, and cost-effectiveness. However, their therapeutic potential has been modest to date.[98] The most advanced DNA vaccine in terms of clinical development is VGX-3100, which targets E6 and E7 oncogenes of HPV-16 and HPV-18 strains. This has reached phase III but is not yet able to secure regulatory approval. GX-188E, which targets the same genes as VGX-3100, has also shown promising results in phase II trials.[99,100] pTVG-HP, a plasmid DNA vaccine, produced in E. coli, that encodes the complementary DNA for human prostatic acid phosphatase had shown modest results.[101,102] Considered more immunogenic, RNA vaccines have recently gained more attention. For example, BNT111, a liposomal RNA vaccine, targets four nonmutated TAAs (NY-ESO-1, tyrosinase, MAGE-A3, and TPTE) that are prevalent in melanoma and has shown impressive preliminary results in an ongoing phase I trial.[103] More recent cancer vaccine approaches have focused on targeting neoantigens from individual tumor mutations, which are unique to cancer cells. mRNA-4157/V940 is a novel mRNA-based personalized cancer vaccine that encodes up to 34 patient-specific tumor neoantigens. In addition to encoding the target antigens, these vaccines also convey adjuvant properties that amplify the immune response. KEYNOTE-942 trial assessed the efficacy of mRNA-4157/V940 in patients with resected stage IIIB/IIIC/IIID and IV melanoma in combination with standard-of-care pembrolizumab. The vaccine was administered every 3 weeks for a total of nine doses, and pembrolizumab was administered every 3 weeks for up to 18 cycles. At 18 months, the relapse-free survival was 78.6% for the combination arm and 62.2% for the pembrolizumab arm, thus corresponding to a 44% reduction in the risk of

recurrence or death. Treatment-related and serious adverse events were mild and comparable between the two arms.[104]

Peptide Vaccines

NeoVax is a long-peptide vaccine, used with polyinosinic-polycytidylic (poly-ICLC) as adjuvant, that targets up to 20 personal neoantigens per patient.[105] It has shown very promising results in a phase I clinical trial in patients with melanoma. Long-term persistence of neoantigen-specific T-cell responses was reported, with some neoantigen-specific T cells exhibiting a memory phenotype. Phase I melanoma studies with NeoVax in combination with other therapies continue for lymphocytic leukemia, follicular lymphoma, glioblastoma, and kidney and ovarian cancers. Similarly, iNeo-Vac-P01, which was developed in China, also uses up to 20 neoantigen peptides and showed very promising results in patients with pancreatic cancer.[106]

Heat shock protein peptide complex 96 (HSPPC-96), which is purified from patient tumors, has received a lot of attention as a personalized multivalent therapeutic vaccine. In contrast to NeoVax and iNeo-Vac-P01, HSPPC-96 does not require determination a priori and synthesis of peptide targets as these are agnostically isolated, bound to gp96, from the tumor. HSPPC-96 has exhibited a safe profile in treating a variety of malignancies including recurrent and newly diagnosed glioblastoma.[107-109] After withdrawal in Europe in 2009 by the Committee for Medicinal Products for Human Use, it re-entered clinical trials in phase II/III for liver cancer (ClinicalTrials.gov identifier: NCT04206254) and in phase II, in combination with temozolomide for glioblastoma (ClinicalTrials.gov identifier: NCT03650257).[110,111]

KRAS, the most frequently mutated oncogene, has been at the core of many drug development efforts. Recently, a vaccine was developed, composed of long peptides corresponding to six common mKRAS mutations, namely, G12D, G12R, G12V, G12A, G12C, and G13D, mixed with poly-ICLC adjuvant. Three phase I trials are currently recruiting patients, one of which uses KRAS peptide vaccine prophylactically in patients with high risk for developing pancreatic cancer. KRAS vaccine is being studied in combination with nivolumab and ipilimumab for NSCLC and colorectal and pancreatic cancers.[112]

On the other hand, survivin is an important oncogene for promoting glioblastoma tumor proliferation.[113] SurVaxM (SVN53-67/M57-KLH) contains a synthetic long peptide mimic that spans amino acids 53 through 67 of the human survivin protein sequence. The amino acid alteration in this peptide (M57) leads to enhanced binding of the core survivin epitope to HLA-A*0201 molecules.[114,115] Results from a phase II clinical trial for glioblastoma, where it was used in combination with temozolomide, showed that it was very well tolerated and increased progression-free survival.[116]

Virus-Based Vaccines

Oncolytic viruses are attractive as immunotherapeutic agents, as the lysis of tumor cells leads to the release of tumor-derived antigen that can be taken up by APC, thus amplifying the antitumor immune response.

Talimogene laherparepvec (T-VEC) is a genetically modified herpes simplex virus (HSV)-1 engineered to replicate within tumors and to produce the immune stimulatory protein granulocyte-macrophage colony-stimulating factor. Approved in 2015, it is indicated for the treatment of recurrent injectable but nonresectable melanoma skin lesions.[117] The phase III clinical trial, on which the approval was based, had shown a 31.5% response rate with a 16.9% CR. Furthermore, additional data showed substantially more positive results with a response rate of up to 88.5% and a CR of rate up to 61.5%.[118] T-VEC is still actively being investigated in multiple clinical trials for various indications, including sarcoma, hepatocellular carcinoma, and pancreatic and breast cancers, and for combinations with other drugs, primarily CPIs.[119]

In a more recent approach, OH2 is a novel oncolytic virus derived through genetic modifications of HSV-2. It is currently under investigation in multiple phase I and II clinical trials for melanoma and colorectal, gastrointestinal, liver, pancreatic, bladder, and central nervous system cancers.[120] PVS-RIPO is a recombinant, live attenuated, nonpathogenic oncolytic poliovirus, in which the internal ribosomal entry site (IRES) is replaced with the IRES from human rhinovirus type 2 (HRV2), with potential antineoplastic activity. On intratumoral administration of PVS-RIPO, the poliovirus is selectively taken up by and replicates in tumor cells expressing CD155 (poliovirus receptor, PVR, or NECL5) eventually causing tumor cell lysis.[121] CD155, an oncofetal cell adhesion molecule and tumor antigen, is ectopically expressed in certain cancers, including glioblastoma multiforme, and plays an important role in tumor cell migration, invasion, and metastasis. Because of the heterologous HRV2 IRES in this recombinant virus, PVS-RIPO only propagates in susceptible, nonneuronal cells.[122,123] In a phase I clinical trial in patients with malignant glioma, the absence of neurovirulent potential of PVS-RIPO was confirmed with an improved survival rate compared with historical controls.[124] There are more ongoing trials with PVS-RIPO in phase I and II for various indications including glioblastoma, melanoma, and breast and bladder cancers, some of which combine it with a CPI.[125]

PROSTVAC is a recombinant vaccine composed of a heterologous prime-boost regimen using two different live poxviral-based vectors: PROSTVAC-V, a recombinant vaccinia virus (rilimogene galvacirepvec), and PROSTVAC-F, a recombinant fowlpox virus (rilimogene glafolivec). Both vectors contain transgenes for human prostate-specific antigen and three costimulatory molecules for T cells (B7-1, ICAM-1, and LFA-3) to enhance immune activation.

Although PROSTVAC was shown to be safe and well tolerated, it did not show an OS benefit in metastatic castration-resistant prostate cancer.[126] Combination therapies of PROSTVAC, either with nivolumab (ClinicalTrials.gov identifier: NCT02933255) or with a human fusion protein that combines a monoclonal antibody against PD-L1 and the soluble extracellular domain of transforming growth factor-β (TGF-β) receptor II, which acts as a TGF-β trap (ClinicalTrials.gov identifier: NCT03315871), are currently being explored in clinical trials.[127,128]

FUTURE PERSPECTIVE: FROM TUMOR GENOMICS TO IMMUNOGENICITY

The advent of molecular techniques, including next-generation sequencing and discovery of germline mutations, further widened the scope and complexity of genetic mutations involved in tumorigenesis.[129] An effective antitumor immune response requires recognition of tumor antigens by immune cells followed by a mounted immune-mediated tumor cell killing. It has been proposed that tumors that do not benefit from CPIs have low immunogenicity, thus having a limited antitumor T-cell response.[130] High mutation rate is associated with a greater chance in producing mutant proteins that act as neoantigens, thus increasing the tumor cell immunogenicity. This was supported by data whereby mutational burden (TMB) was associated with the efficacy of the anti–PD-1 antibody pembrolizumab.[130,131] For example, compared with other tumors, cutaneous melanoma belongs to tumors with the highest tumor mutation burden, which, in turn, is linked to high melanocytes exposure to ultraviolet radiation and accumulated mutations.[132-134] On the other hand, in rare types of melanoma, namely, acral, uveal, and mucosal melanoma, the TMB is generally lower with a lower response to CPIs. The fact that noncutaneous melanoma has much fewer mutations than cutaneous melanoma and, at the same time, is less responsive to immunotherapy further supports the close connection between TMB and tumor immunogenicity.[135] Despite the clinical efficacy of immunotherapy reported to date, the majority of patients develop resistance and the overall outcome for patients remains generally unsatisfactory. There has been a recent trend to incorporate tumor immune profiling into the design of clinical trials to correlate it with response to treatment.[136,137] Deeper understanding of the relationship between the immune TME and response to treatment, resistance, and micrometastases by analyzing baseline tumor specimens can help in the development of novel approaches to enhance the antitumor immune response.

Conclusions

Despite the revolutionary advances in immunotherapeutics, treatment resistance remains a challenge leading to decreased response rate in a significant proportion of patients. As such, there has recently been an evolving focus to enhance efficacy, durability, and toxicity profiles of immunotherapy. Although CPIs have revolutionized cancer treatment with many already-approved antibodies and several others in the pipeline, other immunotherapeutic approaches, including bispecific antibodies and cancer vaccines, build on their success in an attempt to deliver an even more potent immune response against tumor cells. Moreover, there are several ongoing trials for the combination of immunotherapeutic approaches to enhance their efficacy, yet at the expense of potential toxicity. With the long-term remission provided by CPIs, on the one hand, and the promising results of bispecific antibodies and cancer vaccines, on the other hand, better understanding of these novel immunotherapeutic approaches ensues. More clinical trials that incorporate immune profiling of baseline tumor specimens are needed for deeper understanding of the relationship between the immune TME and response to treatment, resistance, and micrometastases.

Artificial Intelligence in Clinical Oncology: From Data to Digital Pathology and Treatment

Kirthika Senthil Kumar, PhD[1,2,3]; Vanja Miskovic, PhD[4,5]; Agata Blasiak, PhD[1,2,3,6]; Raghav Sundar, MBBS, PhD[1,2,7,8,9,10]; Alessandra Laura Giulia Pedrocchi, PhD[4]; Alexander T. Pearson, MD, PhD[11,12]; Arsela Prelaj, MD[4,5]; and Dean Ho, PhD[1,2,3,6]

overview

Recently, a wide spectrum of artificial intelligence (AI)–based applications in the broader categories of digital pathology, biomarker development, and treatment have been explored. In the domain of digital pathology, these have included novel analytical strategies for realizing new information derived from standard histology to guide treatment selection and biomarker development to predict treatment selection and response. In therapeutics, these have included AI-driven drug target discovery, drug design and repurposing, combination regimen optimization, modulated dosing, and beyond. Given the continued advances that are emerging, it is important to develop workflows that seamlessly combine the various segments of AI innovation to comprehensively augment the diagnostic and interventional arsenal of the clinical oncology community. To overcome challenges that remain with regard to the ideation, validation, and deployment of AI in clinical oncology, recommendations toward bringing this workflow to fruition are also provided from clinical, engineering, implementation, and health care economics considerations. Ultimately, this work proposes frameworks that can potentially integrate these domains toward the sustainable adoption of practice-changing AI by the clinical oncology community to drive improved patient outcomes.

INTRODUCTION

Artificial intelligence (AI) is being widely explored for diverse applications in clinical oncology. Initial key work affected a broad spectrum of clinical indications including ophthalmology, radiology, dermatology, and others.[1-8] From this foundational work, broader capabilities emerged, such as digital pathology, biomarker development, treatment, and beyond. For example, the initial emergence of AI and its application to medicine were based on multiple large-scale studies pertaining to AI-based pathology as a means of supporting clinician-driven risk prediction and diagnosis.[9-18] As a specific example, this has been promising when deep learning (DL) has been paired with conventionally acquired histology toward the differentiation between primary and metastatic tumors and positive lymph node detection.[19,20] With regard to biomarker development, AI has been applied toward immune checkpoint inhibition, prediction of recurrence, ovarian cancer, and many other domains.[21-25] With regard to drug discovery and development, AI has also demonstrated promising advances. For example, target identification and the design of novel therapies for multiple disease indications are being widely explored.[26-28] These and other studies have introduced the potential of markedly increasing the speed with which drug candidates can be selected and prioritized for validation and downstream clinical trials to reduce the costs and time needed to advance new therapies toward late-stage development.[29] Importantly, additional work has shown that to truly position AI as a platform for optimizing cancer treatment, recognizing its role across the full therapeutic spectrum, from discovery (eg, new drug design or repurposing) to development (eg, combination regimen design) to dosing, is critical. Therefore, seamlessly integrating these segments has also been proposed as a strategy toward AI-augmented intervention in oncology.[30] Beyond the potential observed across these aforementioned aspects of clinical oncology, other areas of development, from data infrastructures, the type of data needed (eg, environmental factors, genomic profiles, family history, etc), matching patients to appropriate trials, and other indications, may incorporate AI.[31] Importantly, a plethora of studies have advanced to clinical trials across the globe, utilizing AI to enhance cancer screening/diagnosis and predict treatment outcomes. These studies rely on digital pathology, radiology, and genomic data to optimize the design of combination regimens and determine appropriate dosing of chemotherapy and immunotherapy (Table 1).[32-34] As the trial outcomes continue to be realized, if AI will ultimately change practice in oncology, a number of factors that extend far beyond technology and data will need to be explored. These include behavioral and implementation sciences, health care economics, reimbursement, and beyond. Therefore, in addition to highlighting promising technical advances in AI for clinical oncology, this work

PRACTICAL APPLICATIONS

- In early studies, artificial intelligence (AI) has demonstrated promise toward supporting and augmenting clinician-driven cancer diagnosis and prognosis; an example includes the emergence of digital pathology.
- With regard to cancer treatment, AI has also demonstrated promise in reducing timescales needed for drug/target discovery, the ability to personalize drug regimen design, and modulating drug dosing.
- Large-scale validation is still needed for diagnostic, prognostic, and therapeutic applications of AI, among other potential use cases.
- Potentially actionable frameworks for the seamless integration of AI into clinical workflows are proposed.
- Challenges remain with regard to the logistics of harnessing AI to empower practice-changing outcomes in clinical oncology. Outside of technical validation, a number of additional disciplines that span implementation sciences, health care economics, and other considerations are proposed.

also provides an outline of challenges that are already being or will be confronted by the continued advancement of AI in oncology. In addition, this work provides recommendations moving forward which may play a helpful role in integrating AI-based solutions into clinical workflows, with an aim of ultimately harnessing unprecedented predictive and interventional outcomes at scale.[35-37] We also convey the importance of deep collaboration across a multitude of disciplines to achieve real-world impact, demonstrate quantifiable value to health care systems, and achieve eventual adoption.

AI ADVANCES IN CANCER PATHOLOGY AND DIGITAL BIOMARKER DEVELOPMENT

Conventional cancer diagnosis and prognosis have included the use of standard pathology and other approaches.[38] These approaches have played a critical role in facilitating AI validation and beyond. This section will examine the role that AI has played in recent studies toward the continued validation of digital pathology as a prognostic platform and digital biomarker development.

DL in Cancer Pathology for Digital Biomarker Development

The identification of new molecular biomarkers to enable tailored cancer treatment options remains an enduring challenge and objective in the application of AI toward oncology. However, the limited availability of molecular assays, cost, and lengthy turnaround time hamper the practicality of unique biomarker findings. To accelerate the development of actionable biomarkers, DL methods are now being explored for advanced histology analysis of tumor cells to include inference of molecular features,[39-41] mutation prediction,[18,42,43] survival prediction,[44,45] and end-to-end prediction of therapy response.[32,46-48] Through these features, the aim is to harness DL to assign patients to optimal therapy regimes faster and more precisely compared with standard care. The implementation of DL-based genotyping in clinical workflows serves a dual purpose. First, DL biomarkers can be used to prescreen patients before conducting genetic testing. Second, these biomarkers could potentially replace the current methods of definitive testing, provided they demonstrate higher test performance than current methods. At present, challenges include the need for large-scale, prospective clinical validation of the DL systems to confirm the clinical impact of candidate biomarkers.[32]

Developing Biomarkers with Tumor Vasculature Imaging

To address these challenges, a number of studies have been conducted with promising outcomes toward the realization of imaging-based biomarker. In one such study, a tumor vasculature-based biomarker was developed. The tumor microenvironment comprises several critical elements, including the tumor vasculature, which can significantly affect invasiveness, metastatic potential, and resistance to therapeutic interventions. Several studies highlight the correlation between the twisted nature of vessels and its ability to counteract metastasis formation. Hence, quantitative vessel tortuosity (QVT) is being validated as a new imaging biomarker to predict the response and outcome prognosis of patients. In this study, 507 patients with non–small-cell lung cancer (NSCLC) treated with immune checkpoint inhibitor (ICI) therapies were analyzed for association between baseline and delta QVT features to their response to ICI therapies and overall survival (OS). This study was conducted using small cohort sizes for both training and test sets in a retrospective fashion. It was noted that there was insufficient tissue for analysis. As such, the correlation was derived with a small subset of cases. The investigators have noted that further prospective clinical validation is required. However, this study represented a promising step forward for digital biomarker development.[49]

Digital Pathology of Collagen Fibers for Breast Cancer Treatment Prediction

In another study, the digital pathology of collagen fibers was assessed and correlated with breast cancer outcomes. In invasive breast cancer, the interaction between tumor cells and surrounding extracellular matrix (ECM) can potentially predict metastatic outcomes. Specifically, because collagen is the most abundant protein in the ECM, it

Abbreviation: AI, artificial intelligence.

has been widely studied using second harmonic generation (SHG)–based microscopy or laser scanning microscopy (LSM). These studies previously showed that stiff and aligned collagen fibers were indicative of microinvasion sites by breast cancer cells and that collagen fiber analysis could potentially predict breast cancer prognosis. Unfortunately, neither SHG-based microscopy nor LSM is commonly used in clinical practice. To address this barrier, digital pathology was explored using standard hematoxylin & eosin (H&E) staining without the need for any additional specialized collagen staining or complex imaging approaches. The organization of collagen fibers from routine H&E slides were analyzed and investigated for association with disease-free survival outcome measure, with promising findings. Of note, the team noted that a small data set was used because of restricted inclusion criteria, which may be suboptimally representative of the entire population. However, these and other studies serve as important proof-of-concept validation toward downstream prospective studies.[50]

Addressing DL Accuracy and Enhancing the Reliability of Digital Pathology

Histology images are generally used by pathologists to examine and identify characteristics to categorize tumor subtypes, assess prognosis, and potentially predict response to treatments. With the emergence of digital histology, DL can be applied to identify more subtle but specific features, illuminating substantially more information from traditional histology to potentially determine clinical biomarkers, gene expression patterns, survival outcomes, and pathogenic mutations. To support this promising avenue of innovation, the Cancer Genome Atlas (TCGA) represents a substantial digital histology collection and has played a crucial role in developing DL-based histology models. It contains more than 10,000 digital slide images obtained from 24 different types of tumors and also includes relevant clinical, genomic, and radiomic data. The TCGA is among the largest biorepositories of its kind and has provided a valuable resource for researchers

to access and analyze cancer tissue samples for their studies, and its large collection of data has been crucial in advancing cancer research. Recent developments have made promising advances toward overcoming previously observed challenges and realization of widespread digital pathology usage in clinical oncology. For example, the preparation of histological specimens for digital imaging has traditionally involved multiple steps that can introduce variations in resulting images. Fixation, staining, and digitization methods can all contribute to unique site-specific digital histology signatures. Additionally, biological differences between patients that were treated across different centers can also affect histologic characteristics of tumors. Despite using color normalization and augmentation methods across sites to reduce site detection, there is significant variation in the histological features of cancer samples across different tissue submitting sites in TCGA, which can be detected by DL methods. This site-specific digital histology signature can lead to overfitting of digital histology models to site-level characteristics, resulting in biased accuracy of feature prediction. Therefore, these site-specific signatures must be considered to ensure equitable DL application and accurate predictions in cancer research.

Numerous approaches have been taken to reduce bias and improve trustworthiness in identifying patient specifics to achieve equity with DL models.[51] For example, a recent study characterized the heterogeneity between clinical and digital imaging in TCGA for more than 3,000 patients with six cancer subtypes. A quadratic programming approach was used to ensure that models are not trained and validated on samples from the same site.[53] The study recommended a set of best practices for DL studies on histology using TCGA or other data sets on the basis of the combination of multiple hospital sites.[53] First, the study described that outcomes of interest should be reported across included sites to assess the potential impact of site-specific signatures on accuracy. Second, knowledge regarding the distribution of outcomes on both training and testing sites can enable the accurate assessment of model performance. It was subsequently suggested that the area under the receiver operating characteristic (AUROC) curve is an uninformative marker for heavily imbalanced data sets and that the precision recall curve, or F1 score, may be more informative. Therefore, if outcomes of interest vary significantly across sites, it may be necessary for further validation at individual institutions before implementing the models to ensure that biases learned from institutional staining patterns do not affect the results.

The study analyzed the basic demographics and tumor-specific factors for six major solid tumor types (breast, colorectal, lung adenocarcinoma renal clear cell and lung squamous cell carcinoma, and head and neck squamous cell carcinoma) and found that multiple clinical features vary by site for all tested tumor subtypes. To predict tissue submitting sites, the study trained a DL convolutional neural network on the basis of Xception architecture[52] and used threefold cross-validation stratified by site to calculate the one versus rest AUROC for accuracy assessment. The study implemented preserved site cross-validation, optimally stratifying for k-fold cross-validation while also isolating each site to an individual k-fold by using convex optimization/quadratic programming to produce perfect stratification in 55% (32 of 58) of outcomes tested. This preserved site cross-validation represents a promising tool for identifying features that are unlikely to survive external validation testing—an important foundation for DL-based improvements in reliability of digital pathology as clinically actionable platforms for biomarker development and disease prognostication.[53]

AI ADVANCES IN CLINICAL CANCER TREATMENT

In the field of cancer treatment, the terms drug discovery and drug development are often used interchangeably, but they are different segments of the interventional pipeline. Seamless integration matters to ensure that drugs are used individually and in combination properly. In addition, diagnostic-guided modulation of treatment (eg, pharmacologic/radiation dosing) can subsequently be realized. This section will highlight the use of AI across the spectrum of drug discovery through development and dosing and outline a framework to combine these capabilities toward the potential of optimized clinical cancer treatment, guided by AI-augmented diagnostic and biomarker development capabilities (Fig 1).

Harnessing AI to Design and Discover Novel Therapies

AI has been widely explored as a catalyst to accelerate the discovery and design of new targets and drugs. For example, a recent study described the successful integration of AlphaFold, an AI-based protein structure prediction system, with two AI-driven drug discovery platforms. These included PandaOmics and Chemistry42, resulting in the identification of a new hit molecule against a novel target involved in the treatment of hepatocellular carcinoma.

The molecule was identified in a time- and cost-efficient manner within 30 days, starting from the selection of the protein target, identification of the CDK20 hit molecule, compound synthesis, and biological testing. Chemistry42 generated the molecules on the basis of the protein structure predicted by AlphaFold, and the selected molecules were then synthesized and tested in biological assays. Overall, this study demonstrates the effectiveness of integrating AlphaFold into AI-powered drug discovery pipelines.[54]

Addressing Cancer Therapy Regimen Design With AI

In standard medical practice, combination therapies are commonly prescribed, but for patients with chemotherapy-resistant conditions, these treatments often lead to low response rates. Additionally, these approaches are largely

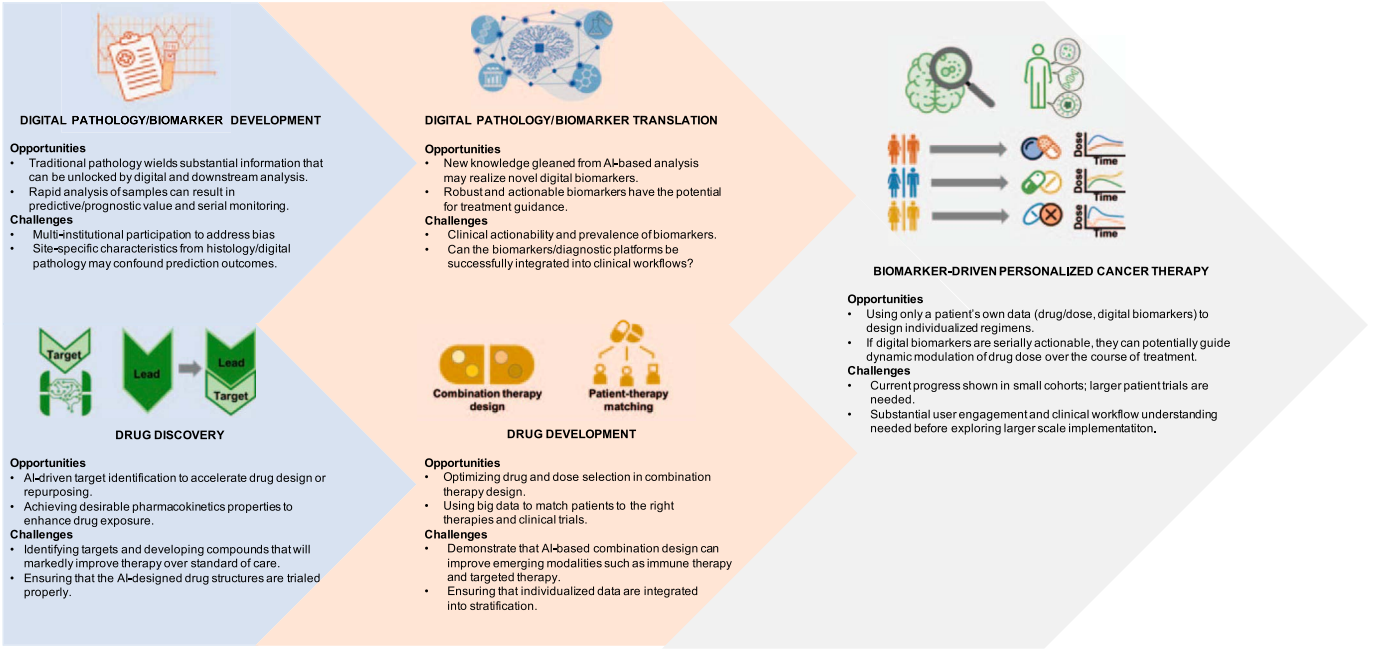

FIG 1. Technology workflow: Harnessing digital platforms to personalize treatment. This technology-centric workflow discusses opportunities and challenges in applying AI toward digital pathology, drug discovery/development, and dynamic drug dosing. AI, artificial intelligence.

based on population-level responses, ignoring interpatient heterogeneity. To address this challenge, the quadratic phenotypic optimization platform (QPOP) was developed.[55] Contrary to purely computational methods, QPOP combines prospective laboratory experimentation with optimization analysis to design patient-specific drug combination, followed by the validation of efficacy through ex vivo testing of biopsied tumor samples. As opposed to existing ex vivo drug testing that relies on single drug sensitivity, QPOP uses an orthogonal array composite design that plates drugs in a specific format to markedly reduce experimental data points from extraordinarily large parameter spaces. QPOP ideally maps individualized and unforeseen drug-drug interactions and ranks drug combinations for individual patients. A prospective study was conducted with 71 patients (75 samples) with relapsed or refractory non-Hodgkin lymphoma (RR-NHL) whose biopsies were subjected to ex vivo testing using a panel of 12 drugs with known efficacy against NHL. For 67 of 75 patient samples, individualized QPOP reports were generated within a clinically actionable timeframe within a median of 6 days from sample collection to report generation. Five of the 17 treated patients achieved complete responses using QPOP, a promising proof-of-concept study toward future large-scale validation studies.[55]

In another study, an image-based single-cell functional precision medicine (scFPM) platform was used for drug profiling of patient biopsies with singe-cell resolution. This enabled the direct quantification of drug effects.[56] scFPM platform-based ex vivo drug efficacy was identified using high-content microscopy and image analysis for patient population with progression-free survival (PFS) ratio of $\geq$1.3 as an outcome measure. Like QPOP, this method does not require population-scale data or indirect reference to genomic data for the design of treatment strategies. A prospective trial, Extended Analysis for Leukemia and Lymphoma Treatment (EXALT; NCT03096821), was conducted for 143 patients with advanced aggressive hematologic cancers who exhausted all standard therapy lines. Fifty-six of 143 patients were treated according to scFPM with 54% of patients demonstrating $\geq$1.3-fold improved PFS. The median time taken from sampling to scFPM report generation was about 5 (1-33) days.[56]

Addressing Cancer Therapy Dosing With AI

In an important previous study, evolutionary game theory was proposed to model physician therapy and cancer cell resistance strategies. In this scenario, the physician aims to guide cancer cells to better treatment outcomes over traditional treatment protocols. Specifically, the physician can rationally anticipate future events by applying game theory. The cancer cells cannot anticipate or adapt to future events and only have the ability to respond to current or past events through evolution of resistance strategies. This approach addresses a key barrier confronted by traditional treatment strategies, where the continuous application of the same regimen on the basis of maximum tolerated dose alone yields short-term success but does not anticipate the long-term evolutionary characteristics of the tumor. Hence, game theory emphasizes that cancer cells continuously evolve to

generate adaptive responses to treatments and similarly physicians should adopt more dynamic treatment protocols and modulate therapies accordingly. This study also highlights the potential need to expand cancer treatment protocols toward defining the goal of the treatment to maximize cancer cell extinction or the time to progression and include a resistance management plan to exploit evolution-based approaches to delay or suppress resistant phenotype proliferation. In this work, game theory has also been explored in understanding glucose membrane transporters such as GLUT1 production in cancer cells and its correlation with rapid proliferation and metastatic potential.[57] Game theory–based studies have also advanced to clinical trials, with a recent outcome revealing a 47% reduction from standard dosing and a markedly increased time to progression compared with standard care.[58]

Harnessing CURATE.AI to Dynamically Modulate Cancer Treatment Dosing

Cancer therapy, particularly chemotherapy, is often given at fixed and high doses. Although these doses have been established through properly powered, randomized controlled trials (RCTs), there can be a subset of patients where high/fixed drug dosing may result in a suboptimal response or nonresponse to treatment and high toxicity. Broadly speaking, patients who do not respond or stop responding to each line of therapy are then moved to other lines of treatment until they run out of options. Unfortunately, among the aforementioned subset of patients, this may also result in the misperception that therapy cannot work for certain patients. To address this challenge, the CURATE.AI platform was developed. CURATE.AI is an AI-based optimization platform that aims to pinpoint optimal doses at the right time for each patient. CURATE.AI uses only a patient's own data to manage only their own care. It does not use population data to treat individuals. CURATE.AI has previously shown that optimal dosing may be dynamic, meaning the dose needs to be modulated or changed during the course of treatment.[59-61] CURATE.AI implementation prospectively calibrates each patient by providing each patient with modulated *inputs*. These inputs include varied drug doses (all within clinically accepted safe ranges). *Outputs*, which can include quantifiable measures of efficacy and safety which correspond with each of these varied doses, are measured. Outputs can include carcinoembryonic antigen (CEA, used for colorectal and other cancers), other biomarkers that indicate cancer progression including images (computed tomography [CT], magnetic resonance imaging [MRI], and ultrasound), liquid biopsies, and markers for toxicity (liver health, kidney health, white blood cell numbers, etc). On the basis of the aforementioned calibration, CURATE.AI relates the drug dosing to treatment efficacy and safety using a quadratic algebraic series which was previously discovered via neural networks. Solving for this series constructs a two-dimensional or three-dimensional profile, which we referred to as a Digital Avatar, which then identifies the right doses to optimize treatment outcomes. This map may evolve/change over time during the course of treatment. This allows us to identify doses as treatment proceeds that can sustain optimal care. Of note, CURATE.AI does not require the use of big data, genomics, or pharmacokinetics. A CURATE.AI-centric workflow is shown in Figure 2. Instead, CURATE.AI is implemented through the use of small data sets that are carefully acquired through prospective calibration of patient response. However, approaches such as CURATE.AI can be complementary to big data or genomic approaches (eg, precision medicine) in that the initial drugs used for treatment can be selected on the basis of patient's genomic profiles. Therefore, in parallel with AI-based diagnostic approaches or the development of predictive algorithms which may require big data sets, interventional AI platforms can potentially improve treatment outcomes over standard care using small data, which are both important areas for further validation.

PRECISE CURATE.AI (ClinicalTrials.gov identifier: NCT04522284), a phase I single-arm (treatment), two-center, pilot clinical trial, was recently conducted to assess the logistical and technical feasibility of a larger RCT with CURATE.AI. Regimens covered in this study included XELOX (oxaliplatin and capecitabine), XELIRI (irinotecan and capecitabine), and single-agent capecitabine. Tumor markers used included CEA, CA125, and ctDNA (an experimental marker in the study). Individualized patient digital avatars (akin to a digital twin) were successfully constructed via CURATE.AI. Capecitabine doses were reduced on average by 19.4% ± 13.71% compared with what would have traditionally be given as standard-of-care dosing for these patients. Additional outcomes included the timely delivery of dosing recommendation (100%), clinically significant dose changes (100%), and patient adherence to the prescribed doses (independent if the dose was recommended by CURATE.AI or a medical team alone; 80%).[62] It is important to note that CURATE.AI does not aim to lower the dose to all patients with cancer. Instead, the impetus for its assessment is to potentially find more responders to treatment and provide bespoke dosing for patients who can optimize efficacy and/or prolong the period the patient is responsive to the treatment. These doses may be lower than the conventional doses that are traditionally used.[62,63] Moving forward, additional clinical trials harnessing the use of platforms such as QPOP and CURATE.AI have been launched to address other indications such as breast cancer (ClinicalTrials.gov identifier: NCT05177432), GI cancers (ClinicalTrials.gov identifier: NCT04611035), glioma (ClinicalTrials.gov identifier: NCT05532397), and sarcoma/melanoma (ClinicalTrials.gov identifier: NCT04986748), as well as modulated dosing in immunotherapy for solid tumors

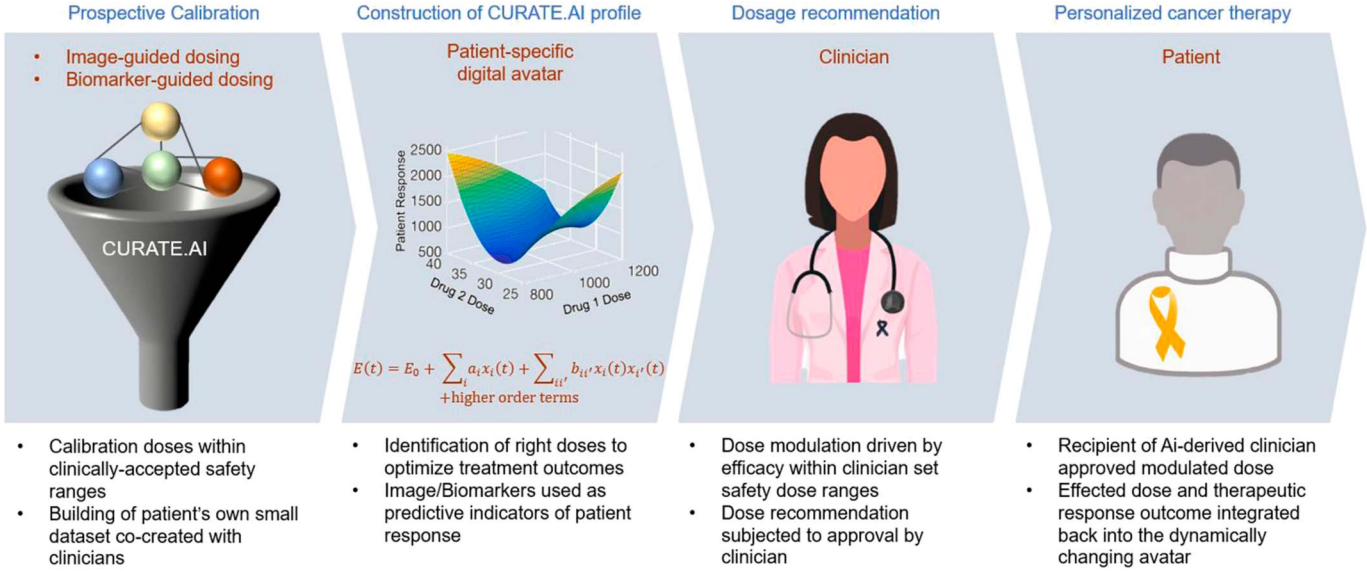

FIG 2. CURATE.AI workflow: Clinical implementation of dynamic dosing. This workflow harnesses clinician-guided, prospective calibration of patient dosing (input) and biomarker outcomes (output) to construct a digital avatar. This avatar is subsequently used to dynamically modulate cancer therapy dosing. AI, artificial intelligence.

(ClinicalTrials.gov identifier: NCT05175235), multiple myeloma (ClinicalTrials.gov identifier: NCT03759093), digital therapeutics for neuro-oncology patients (ClinicalTrials.gov identifier: NCT04848935), and an integrated regimen and dose optimization trial for gastric cancer (ClinicalTrials.gov identifier: NCT05381038). In parallel to collecting clinical outcomes additional information is gathered on the implementation aspects including physicians' perceptions.[64]

AI IN CLINICAL ONCOLOGY: A USE CASE OF INTEGRATED DATA FRAMEWORKS

Predictive algorithms have the potential to revolutionize the health care industry, especially in the field of oncology, by improving patient outcomes and optimizing treatments. However, it is essential to demonstrate the effectiveness and safety of AI-based models for clinical decision support (CDS) in oncology. Several key aspects must be considered to successfully implement AI-based models. These include the quality, source, storage, and sharing of data; the accuracy and trustworthiness of chosen models; ethical considerations and patient involvement in the use of predictive models; and the legal implications related to the use of patient data. Transparency and open communication between patients and health care providers are crucial to building trust and promoting patient-centered care. Novel data-driven trial designs need to balance progress with security while ensuring that patients' privacy and autonomy are protected. By addressing these challenges, AI-based models can be powerful tools for improving the quality of care and patient outcomes in oncology. A subsequently described international use case outlines key considerations for the integration of AI into clinical workflows.

The I3LUNG Use Case: Recommendations for Design, Methodology, and Infrastructure for Integrating AI Into Clinical Oncology Workflows

To successfully integrate AI into a clinical oncology workflow, it is crucial to develop and validate a platform that can (1) aid physicians through CDS by offering readily accessible predictive models, (2) equip patients with personalized codecision-making platforms, and (3) ensure secure access to generated data for further research purposes by using a continuum learning process. An example of such a project is the recently described EU-backed (Horizon Europe) I3LUNG Project: Integrative science, Intelligent data platform for Individualized LUNG cancer care with Immunotherapy.[64] I3LUNG aims to individualize treatment in patients with advanced non–small-cell lung cancer (aNSCLC) treated with immunotherapy. The study is international and multicentered and combines retrospective, observational, and prospective validation. The main objective of this study is to investigate the usefulness of heterogeneous data sources and the effectiveness of big data for individualized prediction for patients with NSCLC treated with immunotherapy (IO). The study uses AI-based tools to improve survival and quality of life, minimize or prevent undue toxicity, and promote efficient resource allocation by investigating the omics role by personalizing diagnostics. The final product of the project aims to yield a novel, integrated, AI-assisted data storage and CDS platform for IO-based therapy in NSCLC,

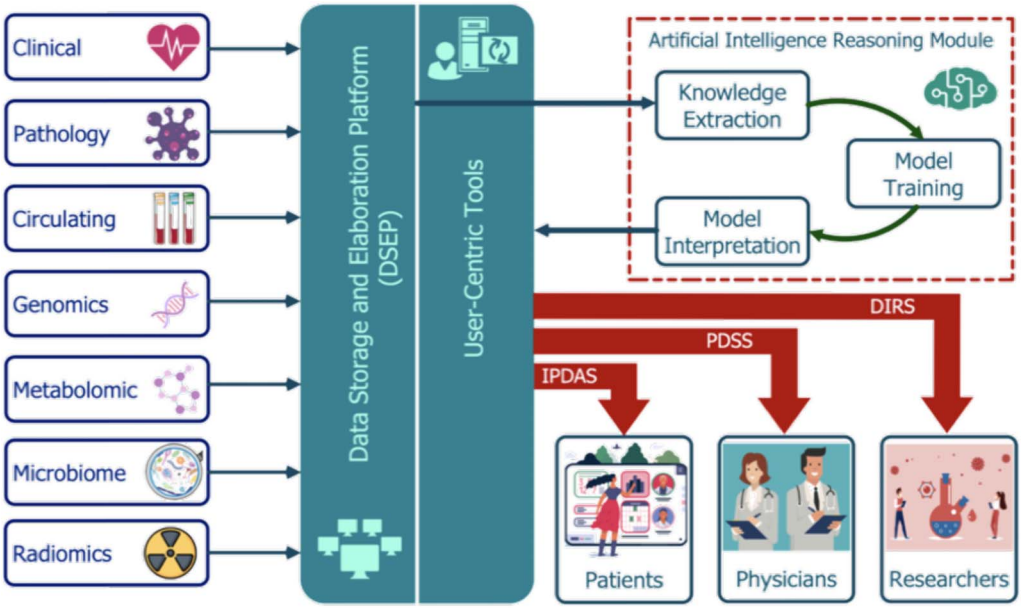

FIG 3. Data use case workflow: An integrated data framework for the I3LUNG platform use case. This use case demonstrates an integrative, omics-driven strategy to drive personalized CDS for immunotherapy toward NSCLC that is accessible and economically sustainable for health care systems and patients. AI, artificial intelligence; CDS, clinical decision support; DIRS, a tool that allows the researchers to easily access data about patients with NSCLC to be used in future clinical studies[64]; IPDAS, tools aimed at patient-physicians' shared decisions on treatment, giving information about NSCLC treatments and on the AI techniques used for prediction; ML, machine learning; NSCLC, non–small-cell lung cancer; PDSS, element to provide physicians with patients' individualized predictive model library, integrating the available data and ML algorithms for NSCLC.

ensuring easy access and cost-effective use by health care providers and patients. A data-centric workflow illustrating the I3LUNG use case is shown in Figure 3.

Framework Design and Data Collection

Fully integrating AI tools into real-world clinical oncology workflows requires the engagement of a highly multidisciplinary team, which includes medical doctors, AI experts, bioengineers, experts in ethics research, behavioral scientists and user engagement experts, psychologists, legal experts, data managers, designers and health economists, and reimbursement specialists, and patients themselves, among others. This is critical in an effort to ensure that the many users of such platforms,[65] which can span clinicians through patients and caregivers, are adequately engaged during development and implementation processes. Initiatives such as I3LUNG, the work of the Institute for Digital Medicine (WisDM), and other international stakeholders reflect the importance of deep collaboration required to empower studies that have the potential to change clinical practice.

In parallel, the development of effective AI predictive models in clinical oncology research is heavily dependent on the availability of large data sets. Therefore, multicenter studies and data are critical to generate the necessary big data for training and validating AI models. Although AI can analyze already available retrospective data from blood examinations; CT, PET, and MRI scans; and pathological slides, among others, acquiring prospective data, including multiomics data sets, will also be critical for further AI development and validation. For example, personalized multiomics data can shed previously unforeseen insights into the molecular mechanisms of cancer, potentially improving the way that treatments are designed, developed, or dosed.[66]

As an example, I3LUNG will use retrospective clinical data from CT and PET scans, digital histological diagnosis, and PDL1 slides at diagnosis from 2000 patients with NSCLC to develop retrospective (R-model) predictive models. The platform will subsequently enroll two cohorts: (1) 2,000 patients with prospective NSCLC treated with first-line IO, collecting real-world data, digital slides (both histology at diagnosis and PD-L1 slides), and CT and PET scans to validate the R-model and (2) 200 patients with NSCLC with a sufficient period of follow-up. Data collected will be similar to the previous cohorts and also include personalized bioomics analyses (eg, genomics, transcriptomics, circulating immune profiling, single-cell analysis, metabolomics, and microbiome). Prospectively collecting these omics data sets

will validate previously developed predictive models coupled with prospective trial validation and will further establish the importance of these data sets in refining the model. These models will then be integrated into the final I3LUNG platform for NSCLC CDS for downstream medical device clearance submissions.

Cross-Institutional Data Harmonization Storage

Importantly, this infrastructure will also enable data harmonization across partner institutions (six European Union [EU] cancer centers and centers in the United States and Israel). This harmonization will further support model refining and the establishment of a cross-institutional omics data dictionary. Data storage for such an initiative is envisioned to involve a collaborative, shared data platform that uses compressed binary files and a multimodel database structure capable of handling various types of data. Therefore, the I3LUNG platform has been designed to enable aggregation, compression, encryption, storage, processing, and transport of data while maintaining embedded security and privacy protections. It will support multiscale data and other semantic domains such as quality of life and behavioral measurements, which is envisioned to advance patient-specific treatment. Data included in the platform should be a multiscale and anonymized with possible future bidirectional data exchange. A multi-institutional data sharing workflow to enable predictive analytics is shown in Figure 4.

Creation of Predictive Models and Integration of Multimodal Data

The I3LUNG use case and our envisioned frameworks for AI-enhanced digital pathology, drug discovery, and cancer treatment collectively illustrate the importance of reconciling multiple classes of data as a foundation for AI-based CDS in clinical oncology. This will in turn enable new insights that were previously precluded because of limitations brought on by insurmountable amounts of clinical information. Therefore, multimodal data integration using machine learning (ML) and DL continue to gain traction in clinical oncology research.[67-69] Two recent studies[70,71] have shown that incorporating ML to integrate data of various modalities, including CT scans, digitalized PD-L1 slides, and genomics, can enhance the accuracy of predicting the effectiveness of immunotherapy in NSCLC and also aid in risk stratification of high-grade serous ovarian cancer.

CHALLENGES AND OPPORTUNITIES OF AI-BASED ONCOLOGY APPLICATIONS

Before the widespread and sustained application of AI in clinical oncology, a number of challenges and opportunities remain. These challenges span several domains, ranging from the need for continued technical validation to legal/ethical implications, as well as data infrastructure, regulatory, and economic considerations.

Technical Challenges of AI in Clinical Oncology

There are many potential applications of AI in clinical cancer diagnosis, treatment, and monitoring. The body of work in this space has been substantial and continues to gain traction. However, before the clinical implementation of AI at scale, a number of challenges remain. At the heart of these challenges is clinical validation, where clear pathways that span well-designed preclinical studies through adequately controlled RCTs continue to be needed. Recently, multiple AI-based oncology platforms have received regulatory clearance.[72] A number of clinical trials from pilot through RCT are also underway. Continued momentum in these domains will be needed to avoid the associated challenge of Pilotitis, where studies are unable to progress beyond small-scale clinical studies, which preclude the derivation of clinically actionable findings.[73]

With regard to challenges in the diagnostics space, with AI-enhanced imaging as a use case, there remains a continued need to achieve a scale of validation such that AI can be reliably integrated into clinical workflows. Progress has certainly been made, as demonstrated by a plethora of recent studies. However, factors such as trust, clinician confidence in AI-based recommendations, and AI performance that can empower the clinical community to markedly enhance clinical practice over standard care remain to be seen at scale across health care systems, regions, and indications.

With regard to biomarker development and predictive/personalized matching of patients to therapies, the clinical concordance of AI-derived predictions of matching molecular alterations to drug selection also need further validation. Although studies have illuminated the potential to achieve improved outcomes in objective response rate, PFS, OS, and other end points, the potential of tapping into AI to further improve these outcomes remains. Although molecular alteration and biomarker-driven drug selection have yielded promising results, a substantial number of patients do not respond favorably to treatment on the basis of these approaches. As discussed in this work, there are other factors such as drug-dose optimization that may be explored to bridge this gap, but they will need to be further validated.

There are also challenges confronting AI-based cancer therapy. The first is the concept that AI-driven drug discovery alone will optimize patient treatment. It is clear that the field has accelerated drug target identification, new drug design, and repurposing. AI also led to an emergency use authorization of an AI-predicted, repurposed drug during the COVID-19 pandemic within the span of approximately 8 months of initial identification.[74] However, beyond AI-designed compounds, implementing a comprehensive workflow that ensures that these compounds are properly stewarded during the subsequent development process will be important for AI to realize its full potential toward

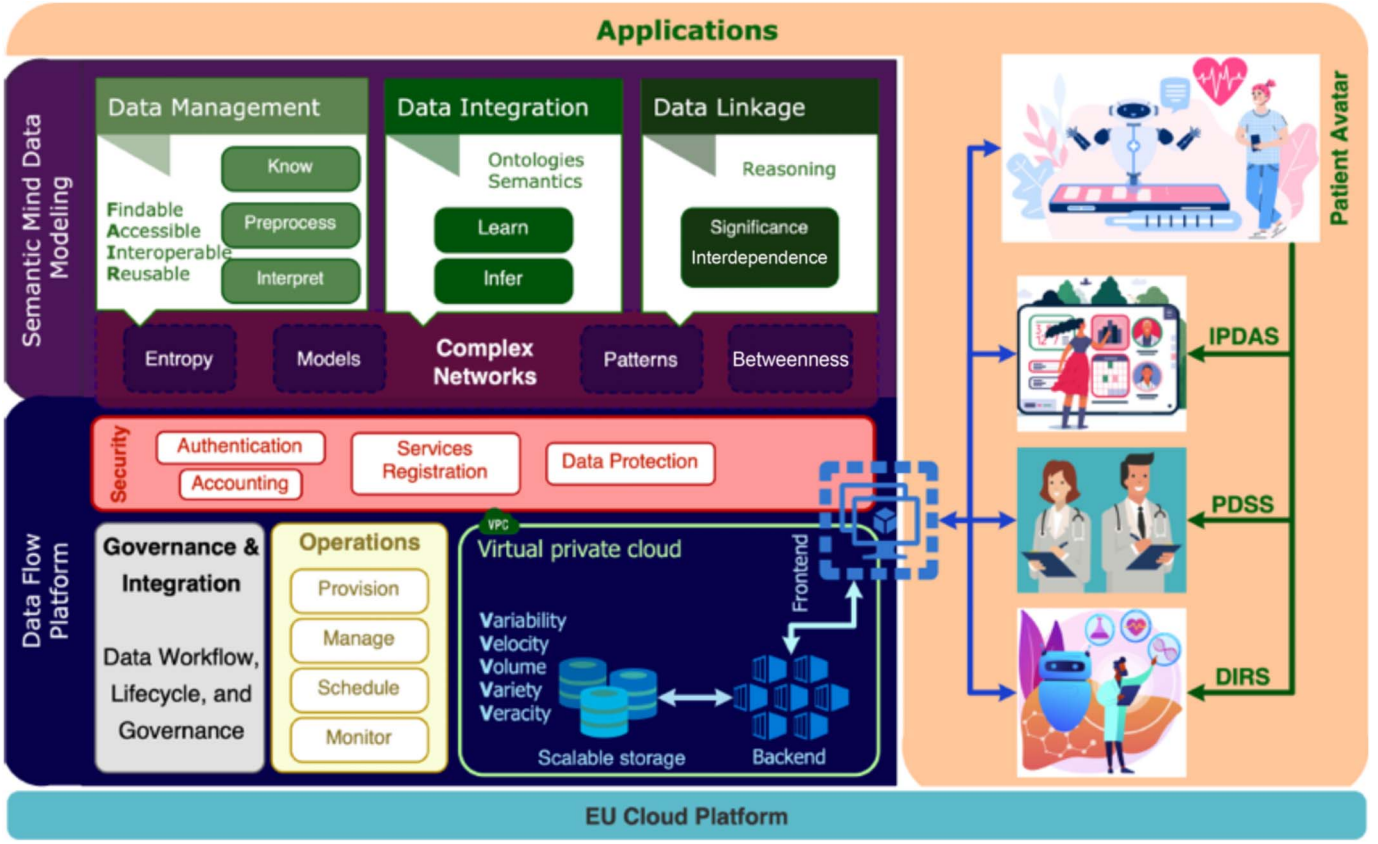

FIG 4. Predictive analytics data workflow: A multi-institutional data sharing platform for predictive AI analytics. To support international collaboration in platforms such as I3LUNG, a platform has been created to drive data harmonization and safe storage and access. AI, artificial intelligence; DIRS, a tool that allows the researchers to easily access data about patients with NSCLC to be used in future clinical studies64; IPDAS, tools aimed at patient-physicians' shared decisions on treatment, giving information about NSCLC treatments and on the AI techniques used for prediction; PDSS, element to provide physicians with patients' individualized predictive model library, integrating the available data and maching learning algorithms for non–small-cell lung cancer.

changing practice in cancer treatment. AI has reimagined how drug combinations can be designed, finding unforeseen drug interactions that have increased therapeutic efficacy compared with traditional mechanism-of-action–based combination design. However, there are substantial operational challenges to overcoming convention if mechanism independence will be integrated into common practice across the drug development through CDS domains, where mechanism of action (MOA)-based drug selection is a cornerstone of current workflows. To support the further validation of these and other AI-enabled advances, reimagining and innovating clinical trial design, adequate user engagement in the development of new clinical workflows, and other considerations will need to be addressed.[75,76] These have been discussed as part of the proposed therapeutic, data, and CDS workflows illustrated in this work.

Trustworthy AI

The complexity of ML and DL models can potentially affect their interpretability. This can in turn complicate CDS. To make these models more usable, recent efforts have harnessed post hoc explainable AI (XAI). XAI aims to make models accountable, interpretable, transparent, explainable, and trustworthy, targeting models that are not interpretable by design.[77] The goals of XAI methods are to produce more explainable models while maintaining high learning performance, enabling humans to understand, trust, and manage the emerging generation of AI partners. In oncology research, different post hoc XAI approaches are used, such as feature relevance explanation techniques like SHAP[78] and saliency maps,[79] which help explain predictions for DL models. Generative methods may also provide opportunities to create explanation-embedded visualizations of clinical states in images.[80] Despite relevant studies on XAI in oncology,[25,81,82] a significant development in the field of XAI in medicine is expected in the next few years to enhance the transparency, accountability, and trustworthiness of AI in health care.

Legal and Ethical Considerations of AI in Clinical Oncology

The use of AI in clinical research raises a number of ethical and legal questions that need to be addressed. One of the main concerns is the protection of patient privacy as vast

amounts of potentially sensitive patient data can be collected. Another consideration is data vulnerability to cyberattacks. Therefore, strict privacy policies and measures against data theft are essential. Additional considerations, ranging from data ownership to patient access to their own data, will require further consideration and debate.[83]

Health Care Economics of AI in Clinical Oncology

The sustainable deployment of clinical AI will require substantial infrastructural considerations to address the aforementioned data storage, sharing, and safety requirements. The training of AI may require new procedures in the types of tests and data we require from each patient. The implementation of AI in CDS may also change the landscape of drug-patient matching, dosing, and other factors. Therefore, the previously noted innovation in clinical trial design will also need to further consider whether the health and economic benefits of using these tools outweigh the additional implementation costs. Therefore, how AI will affect actuary modeling, quality of life (QoL), and other patient outcomes will need to be addressed.[84]

Regulatory Considerations of AI in Clinical Oncology

A number of challenges are shared by both the diagnostic and intervention spaces. When using population-based data to train models for diagnosis or CDS, the generalizability of approaches across patient populations will need to be carefully considered. Additional challenges pertain to whether relevant infrastructures (eg, data security, clinical laboratory, software/computing, etc) are in place to support new workflows. However, a number of guidelines and recommendations through the collective effort of an international community of regulatory agencies are being released, which should aid in the advancement of new platforms into clinical practice.[85-91]

Opportunities for AI in Clinical Oncology

Aside from these challenges, there remain substantial opportunities for AI to positively affect the delivery of evidence-based oncology care. At the heart of the AI oncology community interface is the potential of empowering the clinical community to accessibly improve patient outcomes. After the early and continued promise of AI-assisted image and biomarker development for potentially enhanced prognostic capabilities, the promise of improved treatment selection over standard care for more patients may greatly enhance clinical practice and save lives. AI-guided drug regimen selection and dynamic dose modulation has, in early studies, revealed the potential of improving the practice of CDS to find more responders to treatment and optimize the development of drug combinations, among other outcomes. For these opportunities to take shape at scale and to change the practice of clinical oncology more work remains across a broad spectrum of disciplines.

RECOMMENDATIONS FOR THE DEVELOPMENT OF AI SOLUTIONS FOR CLINICAL ONCOLOGY

Here, we propose a series of recommendations for the disciplined development of AI-based platforms for diagnostic and therapeutic applications. It is important to note that the categories and recommendations are not exhaustive, and AI platform developers are encouraged to consider additional factors that can support safe and rigorous technology development to enable accessible solutions to reach patients at scale. In addition, many of these recommendations may not need to be addressed chronologically. Some may also be applicable across multiple or all stages of development.

Ideation

- A critical first step is to comprehensively assess the intended use for the solution. Can conventionally acquired data (eg, histology, clinical records) drive AI development and training to enable actionable CDS?
- Aside from ensuring the solution addresses an unmet clinical need, it is critical to note who the core user(s) is/are and if data infrastructures are in place to support deployment.
- It is important to assess if the originality of the proposed solutions, supporting infrastructure, and data sharing practices have the potential of advancing practice at scale.

Validation

- The data used for model training/validation and recruited trial participant population should be representative of the downstream user population to reduce prediction bias. In addition, the model training/validation and clinical validation studies should sufficiently address the objectives needed for regulatory approvals/clearances to meet clinical implementation guidelines.
- External validation, validation with cohort from different institutions, is highly recommended to test models generalizability and should become a norm.
- User engagement studies should be considered as part of the workflow validation process. The health economics of the solutions will also be critical to demonstrate value to the health care system and users.
- Clinical trial design innovation should be strongly considered and subsequently explored.

Implementation

- The AI solution should properly consider clinical practice norms and other requirements (eg, time required for execution per user).
- Infrastructural requirements and other applicable operations considerations should be considered early on in the development process so that the AI platform can be practically integrated into clinical workflows.

- User feedback should be considered as part of early trial designs to better inform downstream implementation.

Adoption

- How does the AI developer intend to sustain the use of the solution in a health care system with regard to data infrastructure and sharing?
- When considering the user of the AI solution, what steps have been taken to address implementation sciences, user interface, and experience (UX/UI) that can support user engagement with the solution?
- Can payer considerations/engagement be addressed early on in the development process to avoid downstream challenges with reimbursement?

CONCLUDING REMARKS

At present, the potential role of AI in driving digital pathology, biomarker development, and treatment outcomes for patients is being explored using a broad spectrum of applications. As the validation of AI-based platforms continues, early and frequent consideration of the end user, which could be the doctor, nurse, pharmacist, allied health, patient, caregiver, or a combination of these stakeholders and others, along with implementation and adoption considerations will be essential. As the field continues to progress, the seamless integration of AI-based solutions across the entire health care workflow will serve as a vital catalyst toward AI-enabled change in clinical oncology practice.

Rise of Antibody-Drug Conjugates: The Present and Future

Mythili Shastry, PhD[1]; Avantika Gupta, PhD[2]; Sarat Chandarlapaty, MD, PhD[2]; Matthew Young, MD[3]; Thomas Powles, MD[3]; and Erika Hamilton, MD[1,4]

overview

Antibody-drug conjugates (ADCs) embody a simple, but elegant, vision for cancer therapy—the delivery of a potent cytotoxic agent to tumor cells with minimal damage to normal cells—so-called smart chemo. Although there were significant challenges in achieving this milestone culminating in the first Food and Drug Administration approval in 2000, subsequent advancements in technology have led to rapid drug development with regulatory approvals for ADCs targeting a variety of tumor types. The most successful application for solid tumors has been in breast cancer, with ADCs becoming the standard of care across traditional human epidermal growth factor receptor 2 (HER2)+, hormone receptor+ (HR+) and triple-negative disease subtypes. Moreover, the improved features and gains in potency with the development of ADCs have expanded the treatment-eligible population to those with low/heterogeneous expression of the target antigen on the tumor with trastuzumab deruxtecan or in the case of sacituzumab govitecan, agnostic to target expression. Despite their antibody-directed homing, these novel agents come with their share of toxicities obligating appropriate patient selection and vigilant monitoring while on treatment. As more ADCs are included in the treatment armamentarium, mechanisms of resistance need to be studied and understood for optimal sequencing. Modifying the payload to use immune-stimulating agents or combination therapies with immunotherapy and other effective targeted therapies may further extend the utility of these agents in the treatment of solid tumors.

INTRODUCTION

Antibody-drug conjugates (ADCs) are a rapidly emerging class of therapeutic agents that combine the target specificity of a monoclonal antibody (mAb) with the lethality of cytotoxic cellular poison. With ongoing advancements in drug engineering and fresh biologic insight into mechanisms of drug action, the ADC field is still early in its evolution. Despite this, there are over a 100 new ADCs in clinical trials encompassing a wide variety of tumor types. This explosion of interest is, in part, due to the spectacular success in the past 5 years, particularly in some highly treatment-refractory diseases. This review will provide a brief overview on ADC design and mechanism of action, highlighting ADCs currently in use for breast and urothelial cancer (UC) where some of the most significant clinical advancements have been achieved. The toxicity profile of these agents, development of resistance, and the potential of combination therapies with ADCs will be explored.

HISTORY OF ADC DEVELOPMENT

The idea of targeted chemotherapy was conceptualized by a German scientist, Paul Ehrlich, over a century ago. His magic bullet would target a cytotoxin to intended structures in unwanted cells but spare healthy tissues.[1] The structures were later conceptualized to be cell surface antigens to attract antibodies that could grant the desired target specificity. Ehrlich also coined the term chemotherapy, where he proposed to use chemicals to kill the pathogenic cells. Early progress in the development of chemotherapy included generation of some cellular toxins that might be too potent and toxic to administer without a targeted approach. Inception of the hybridoma technology for generation of mAbs[2] helped realize Ehrlich's vision with the first ADC trials underway in the 1980s.[3-5] The first approved ADC was gemtuzumab ozogamicin[6] in 2000, where a CD33 antibody is conjugated to an antitumor antibiotic, calicheamicin.[7] Growing understanding of the ADC mechanism of action and technological breakthroughs have heralded the approvals of over a dozen ADCs, including two on the basis of trastuzumab backbone, an antibody against human epidermal growth factor receptor 2 (HER2).

ADC DESIGN

The fundamental components of an ADC are a mAb directed against a tumor-associated antigen, a cytotoxic agent called payload, and a connecting linker. Each component and their interactions play crucial roles in determining the efficacy and toxicity profiles of an ADC.

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- The fundamental components of an antibody-drug conjugate (ADC) include an antibody, a linker, and a payload, and the choice and construction determine the clinical characteristics of the ADC.
- Recent drug development has focused on altering linker chemistry and tapping into novel cytotoxic payloads to generate high-potency ADCs that have dramatically improved outcomes, especially in breast cancer.
- Some novel ADCs demonstrate clinical efficacy regardless of the level of tumor antigen expression, enabling the treatment of tumors with heterogeneous expression of the target.
- Most ADCs are associated with unique toxicities, such as pneumonitis/interstitial lung disease, and ocular or skin toxicities that warrant careful monitoring and mitigation strategies.
- The next wave of agents looking to build on the success of ADCs include immune-stimulating antibody conjugates, engineered toxin bodies, and radioligand conjugates that aim to improve therapeutic index while minimizing toxicity.

Antibody Moiety

The antibody moiety of an ADC dictates its plasma circulation duration, immunogenicity, immune functions, and target specificity. Current ADCs are predominantly based on immunoglobulin G (IgG), particularly IgG1. IgG1 offers a long serum half-life and strong Fc-mediated immune functions, including antibody-dependent cell-mediated cytotoxicity (ADCC), antibody-dependent cellular phagocytosis, and complement-dependent cytotoxicity.[8] Murine antibodies in the early ADCs have been replaced with chimeric or humanized antibodies to minimize immunogenic side effects.[9] Selection of a suitable target antigen has also proven to be instrumental in modulating the specificity and processing of an ADC. An ideal target should exclusively, or preferentially, be expressed at high levels on the surface of tumor cells and not on normal cells. HER2 and trophoblast cell surface antigen 2 (TROP2) are two such targets being used for ADC development in breast cancer (BC) because of their overexpression on tumor cell surfaces[10,11] while sparing normal tissue.

Linkers

A linker's function is to ensure that the payload remains bound to the antibody during circulation but is released at the tumor site. Linkers can be cleavable or noncleavable.[8] Cleavable linkers release the payload on reduction, proteolysis, or hydrolysis because of tumor cell–associated factors (eg, proteases or pH), but noncleavable linkers require complete lysosomal degradation for the payload release. Of the three ADCs approved for BC, ado-trastuzumab emtansine (T-DM1) is the only one with a noncleavable linker,[12] which provides stability to the ADC during circulation and might contribute to a better safety profile compared with other trastuzumab-based ADCs. However, the noncleavable linker may also hinder the potential for bystander killing, wherein payload is released into the tumor microenvironment (TME) and can kill antigen-less cancer cells or even cancer-supporting cells.[13]

Cytotoxic Payloads

Payloads are the chemotherapeutic agents that exert cytotoxic effects on the tumor cells targeted by the ADCs. These are commonly microtubule binding or DNA damage (DNA cleavage or alkylation)-inducing agents. Because of advances in linker conjugation chemistry and our understanding of the ADC mechanism of action in vivo, an increasing breadth of anticancer agents are now being incorporated in newer ADC designs. Among all the newer payloads, however, the most effective have been topoisomerase I (Topo 1) inhibitors including camptothecin derivatives. Fam-trastuzumab deruxtecan (T-DXd) is an anti-HER2 ADC on the basis of an exatecan derivative,[14] and sacituzumab govitecan (SG) is an anti-TROP2 ADC that uses SN-38 (the active metabolite of irinotecan) as its payload.[15] Both ADCs have high drug to antibody ratios (DARs), which can enhance ADC efficacy in vivo given low hepatic clearance.[16] In the case of T-DXd, the membrane permeable deruxtecan is also proficient at diffusing to neighboring cells to exert a bystander effect. This characteristic is integral to the activity in HER2-low or HER2-heterogeneous tumors. Continuous progress is moving the field forward toward the development of more powerful ADCs with varied payloads[17,18] including even nonchemotherapeutic[19] payloads like immune-stimulating agents,[20] while improving the therapeutic window and decreasing systemic side effects to healthy cells.

MECHANISM OF ADC ACTION

The primary antitumor action of ADCs is via targeting of the cytotoxic payload to the tumor cells. On binding of the mAb to the target antigen, the ADC is internalized into the tumor cell. The eventual linker breakdown promotes intracellular release of the payload, where it exerts its microtubule- or DNA-damaging effects.[16] The process of antibody binding and internalization may be subject to further pharmacologic manipulation or enhancement. For instance, recent work has highlighted the potential to increase antigen availability through the use of statin[21] or increase internalization and

lysosomal sorting through the use of kinase inhibitors.[22] These and other studies highlight the multistep process to ADC-mediated killing, which may be enhanced through such drug combinations and may also prove to be relevant to drug resistance.

In addition to the canonical payload release mechanism of drug action, the antibody moiety can exert anticancer effects in a payload-independent manner. The binding of the antibody to its target antigen can disrupt the antigen's downstream function by preventing interaction with its binding partners[23] or promoting its degradation.[24] Furthermore, ADC antitumor action can also be mediated through antibody-dependent activation of immune response including ADCC,[25] such as trastuzumab. Indeed, some of these particular effects may be insufficient as a single agent but provide critical support to the chemotherapy combination akin to how trastuzumab combines with chemotherapy to realize synergistic antitumor effects.

TOXICITIES OF ADCs APPROVED FOR BC AND UC

A major goal of ADCs is to achieve high specificity and low toxicity, beyond the capability of traditional chemotherapeutic agents that lack tumor selectivity.[26] However, despite nuanced drug development strategies, important toxicities exist in clinical practice for approved ADCs. While the toxicities are often attributed to the payload, the target antibody and linker have important implications in determining the implicated organs of observed adverse reactions.[26] Key trial data for ADCs approved for BC and UC and the toxicities associated with them are discussed below. The most common treatment-related adverse events (TRAEs) with these ADCs and the clinical monitoring recommended during treatment are included in Tables 1 and 2, respectively.

T-DM1

T-DM1 is an ADC composed of the mAb trastuzumab, the cytotoxic payload maytansine (DM1), and a nonreducible thioether linker MCC (4-[*N*-maleimidomethyl] cyclohexane-1-carboxylate).[27] The use of a stable noncleavable linker maximizes the therapeutic index of DM1 by minimizing the systemic exposure to free DM1 and improving exposure to T-DM1.[28]

T-DM1 was the first ADC that was granted regulatory approval for solid tumors; it was Food and Drug Administration (FDA)–approved for the treatment of HER2-positive metastatic breast cancer (MBC) on the basis of results from the EMILIA trial.[29] It now has expanded use as an adjuvant therapy for residual disease in early-stage HER2-positive BC after neoadjuvant therapy, on the basis of KATHERINE trial data.[30]

The EMILIA trial also reported a superior toxicity profile associated with T-DM1 compared with capecitabine plus lapatinib (40.7% *v* 57% ≥grade 3 events). The rate of ≥grade 3 adverse events (AEs) was 41% in patients treated with T-DM1, the most common being thrombocytopenia (13%) and elevated serum concentrations of aspartate aminotransferase (4%) and alanine aminotransferase (3%; Table 1).[29]

TABLE 1. TRAEs of Antibody-Drug Conjugates

Drug	Antibody/Payload	Cancer Type	Most Common TRAEs	
			All Grade	TRAEs ≥ Grade 3
T-DXd (*DESTINY-Breast03*, *DESTINY-Breast04*)	Trastuzumab (anti-HER2)/deruxtecan	Breast, colorectal, gastric, non–small-cell lung cancers	Nausea (77%, 73%), vomiting (52%, 34%), alopecia (40%, 38%), anemia (37%, 33%), constipation (37%, 21%), fatigue (31%, 48%)	Neutropenia (16%, 14%), anemia (9%, 8%), platelet count decreased (8%, 5%), nausea (7%, 5%), fatigue (6%, 8%)
EV (*EV-301*)	Anti–nectin-4/MMAE	Urothelial carcinoma	Alopecia (45%), peripheral sensory neuropathy (34%), pruritus (32%), fatigue (31%), decreased appetite (31%)	Maculopapular rash (7%), fatigue (6%), decreased neutrophil count (6%)
T-DM1 (*EMILIA*, *KATHERINE*)	Trastuzumab (anti-HER2)/DM1	Breast cancer	Nausea (39%, 42%), fatigue (35%, 50%), thrombocytopenia (28%, 29%), elevated AST (22%, 28%)	Thrombocytopenia (13%, 4%), elevated AST (4%, 0.5%), ALT (3%, 0.4%)
SG (*ASCENT*, *TROPICS-02*)	Anti-TROP2/SN-38	Breast, urothelial carcinoma	Neutropenia (63%, 70%), diarrhea (59%, 57%), nausea (57%, 55%), alopecia (46%, 46%), fatigue (45%, 37%), anemia (34%, 34%)	Neutropenia (51%, 51%), diarrhea (10%, 9%), anemia (8%, 6%), febrile neutropenia (6%, 5%)

Abbreviations: ALT, alanine aminotransferase; AST, aspartate transferase; EV, enfortumab vedotin; HER2, human epidermal growth factor receptor 2; MMAE, monomethyl auristatin E; SG, sacituzumab govitecan; T-DM1, trastuzumab emtansine; T-DXd, trastuzumab deruxtecan; TRAEs, treatment-related adverse events; TROP2, trophoblast cell surface antigen 2.

TABLE 2. Precautions, Baseline Investigations, and Monitoring for T-DXd, EV, and T-DM1

Drug	Precautions	Baseline Investigations	Monitoring During Treatment and Prophylactic Measures
T-DXd	Pneumonitis, ILD, history of drug-induced pneumonitis Symptomatic or history of congestive heart failure	Assessment of LVEF	Assessment of LVEF clinically as indicated, consider regular assessment throughout Regular assessment of respiratory symptoms (cough, dyspnea, fever)
EV	Hyperglycemia (increased risk in baseline hyperglycemia, BMI > 30) Pre-existing peripheral neuropathy	Assessment of glycemic control (consider HbA1C)	Glucose monitoring Consider ocular prophylaxis with artificial tears Clinical assessment of neuropathy
T-DM1	Pneumonitis, ILD, history of drug-induced pneumonitis Symptomatic or history of congestive heart failure	Assessment of LVEF	Assessment of LVEF as clinically indicated, consider regular assessment throughout Platelet count Liver enzymes Regular assessment of respiratory symptoms (cough, dyspnea, fever)

Abbreviations: EV, enfortumab vedotin; HbA1C, hemoglobin A1C; ILD, interstitial lung disease; LVEF, left ventricular ejection fraction; T-DM1, trastuzumab emtansine; T-DXd, trastuzumab deruxtecan.

Trastuzumab and T-DM1 bind to FcγRIIa on megakaryocyte progenitors, but only T-DM1 is associated with thrombocytopenia, indicating that this toxicity is due to DM1 or its metabolite lys-SMCC-DM1.[26] For most patients, the first occurrence of grade 3 or 4 thrombocytopenia was observed during the first two cycles of T-DM1 treatment and, with appropriate dose modifications, did not result in treatment discontinuation.[29] Interestingly, the incidence of thrombocytopenia after treatment with T-DM1 has been reported to be higher in Asians than White patients, with grade 3 events in 45% and 12%, respectively.[26] Although rare, studies have reported left ventricular dysfunction and the appearance of interstitial lung disease (ILD) associated with the use of TDM-1.[31] Careful patient monitoring is required throughout treatment in an effort to prevent more serious toxicity, and baseline assessment of left ventricular ejection fraction (LVEF) is recommended (Table 2).

T-DXd

Fam-T-DXd is a novel ADC with a humanized HER2 antibody with the same sequence as trastuzumab, covalently linked to a Topo I inhibitor (DXd). This ADC was designed with several unique features: (1) a potent payload DXd; (2) a novel linker that permits a high DAR of 8, with reduced hydrophobicity; (3) a tumor-selective cleavable linker susceptible to lysosomal proteases in the tumor; (4) short systemic half-life to avoid systemic exposure; and (5) bystander effect caused by the high membrane permeability of DXd that enables its diffusion out of tumor cells to exert its cytotoxic effects in the TME.[32]

The FDA granted accelerated approval for T-DXd in December 2019, on the basis of the efficacy in pretreated HER2-positive MBC in DESTINY-Breast01.[33] The DESTINY-Breast03 study demonstrated an unprecedented 1.5-year improvement in median progression-free survival (PFS) with T-DXd compared with T-DM1 in predominantly second-line HER2+ MBC (25.1 *v* 7.2 months; hazard ratio [HR], 0.28; $P = 7.8 \times 10^{-22}$), earning T-DXd a confirmatory FDA approval in this patient population.[34,35] Furthermore, the DESTINY-Breast04 trial in patients with pretreated HER2-low (HER2 immunohistochemistry [IHC]1+ or HER2 IHC2+/in-situ hybridization) MBC demonstrated the superiority of T-DXd over TPC with improved median progression-free survival (HR, 0.50; $P < .0001$) and overall survival (OS; HR, 0.64; $P = .0010$).[36] T-DXd received FDA approval in HER2-low MBC on August 5, 2022, expanding the pool of patients with MBC eligible for treatment with this HER2-targeted ADC.[37]

In DESTINY-Breast01, the most common of these TRAEs associated with T-DXd were decreased neutrophil count (21%), anemia (9%), nausea (8%), and fatigue (6%). Of note, 14% of patients receiving T-DXd had ILD related to the receipt of the study drug, resulting in death among 2% (four patients) of patients. Just three patients experienced decreased LVEF (1.6%), with only one patient (0.5%) experiencing grade 3 severity, suggesting that cardiac toxicity is infrequently observed with this anti-HER2 ADC.[38]

In DESTINY-Breast03, a phase III study comparing T-DXd with T-DM1 in metastatic HER2-positive BC (Table 1), AEs were similar to those in DESTINY-Breast01 and drug-related ILD or pneumonitis occurred in 15% of patients treated with T-DXd, with no grade 4 or 5 ILD/pneumonitis events. Proactive monitoring, early diagnosis, and management were thought to have contributed to the lack of grade 4 or 5 events in this large trial.[39] Nausea and fatigue were also the most common drug-related AEs reported on the DESTINY-04 trial,[36] and a two- to three-drug prophylactic antiemetic regimen (5 Hydroxytryptamine 3, steroid ± neurokinin-1) is recommended for all patients receiving T-DXd.[40]

Drug-related ILD is an important toxicity that must be considered in patient selection and monitoring throughout

treatment with T-DXd. Of note, there seems to be increased risk with the use of T-DXd in the management of HER2-mutated non–small-cell lung cancer, with 26% of patients experiencing drug-related ILD in DESTINY-Lung01.[41] Patients with pre-existing or suspected ILD or pneumonitis should not be offered this therapy and were excluded from DESTINY-Breast01 and subsequent clinical trials investigating T-DXd.[38,42] If ILD is suspected during treatment, consultation with a pulmonologist is recommended, along with high-resolution computed tomography, testing of pulmonary function, and monitoring of oxygen saturations[38,42] (Table 3). Systemic glucocorticoids may be indicated, and further treatment with T-DXd may be contraindicated depending on the severity of toxicity.[38,42]

ENFORTUMAB VEDOTIN

Enfortumab vedotin (EV) is an ADC with proven survival benefits in the treatment of UCs.[43] EV consists of a fully human mAb specific for nectin-4, a cell adhesion molecule, and monomethyl auristatin E (MMAE), an agent that disrupts microtubule formation.[44] EV received accelerated FDA approval in 2019 and regular approval in July 2021, after the publication of EV-301.[45] EV-301 was a global phase III trial, which showed significantly prolonged survival with EV compared with standard chemotherapy in patients with advanced urothelial carcinoma who had previously received platinum-based treatment and an immune checkpoint inhibitor (ICI; HR, 0.70; 95% CI, 0.56 to 0.89).[43]

In EV-301, TRAEs of grade 3 or higher occurred in 51% of patients who received EV, which was similar to the chemotherapy control arm. The most common of these events included maculopapular rash (7%), fatigue (6%), and decreased neutrophil count (6%).[43] Skin reactions and peripheral neuropathy were the most frequent TRAEs of special interest, occurring in 44% and 46% of patients, respectively. The majority of peripheral neuropathy events were grade 1 and 2 sensory events, but they were identified as the TRAE most commonly leading to drug interruption, withdrawal, or dose reduction. This AE appears to accumulate with time and has both motor and sensory components.[43]

Postmarketing reports of severe and fatal cutaneous adverse reactions, including Steven-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN), have been reported with the use of EV.[46] Most commonly, these serious cutaneous toxicities occur during the first cycles of treatment, and therefore, careful initial monitoring with early drug interruption is recommended[47] (Table 3). In cases of severe (grade 3 or higher) dermatologic events, treatment should be withheld and referral for specialized dermatologic care should be considered. In confirmed cases of SJS or TEN, treatment with EV should be permanently discontinued. Mild skin reactions can be managed with supportive care, including topical corticosteroids and oral antihistamines, and treatment may be continued.[47] The role of oral steroids is unproven.

The precise mechanism for SJS or TEN with the use of EV remains unknown, but both the nectin-4–directed antibody and MMAE payload have been implicated. Nectin-4 is expressed in the skin, where it is involved in cell–cell adhesion[47] and may be a case where the target is not specific enough to tumor cells only. In skin biopsies of patients taken 7 days after treatment, EV has been shown to localize to healthy tissues including epidermis, epithelium, and sweat glands.[47]

In EV-301, treatment-related hyperglycemia occurred in 6% of patients, occurring more frequently in patients with hyperglycemia at baseline or with a BMI of 30 or higher,[43] and glucose monitoring is helpful. Ocular toxicities, including dry eyes, blurred vision, and keratitis, have been reported.[48] Artificial tears may be used prophylactically, treatment should be interrupted for ≥grade 3 toxicity, and consultation with ophthalmology is recommended for consideration of additional therapy, including ophthalmic topical steroids[48] (Table 3).

EV has also been investigated in a phase II study of EV plus pembrolizumab in previously untreated UC.[49] No new safety signals were reported in combination with PD-1 therapy; the toxicity profile was similar to that of EV and pembrolizumab monotherapy. However, AEs were more frequent than those with EV monotherapy. This combination is being evaluated further in a phase III study (Table 4). An ongoing clinical trial, EV-202, is investigating the efficacy of EV in the treatment of breast, lung, head and neck, and gastroesophageal cancers, all of which have been shown to express nectin-4[59] (ClinicalTrials.gov identifier: NCT04225117). Overall, EV should not be considered more toxic than chemotherapy in the treatment of UC. Rather, it has a distinct toxicity profile that requires education and awareness.

DISITAMAB VEDOTIN (RC48)

Disitamab vedotin (DV) also has MMAE as its payload but targets HER2 rather than nectin-4 (as is the case with EV).[60] It is licensed in China for advanced UC and has a single-agent response rate of over 50% in a cohort of 107 patients with HER2 positivity. ≥Grade 3 AEs occurred in 58% of patients, the most common of which were hypoesthesia (23%) and neutropenia (14%).[60] Skin toxicity appears less than that seen with EV. The differences in toxicity profile compared with EV are likely due to the distribution of the target as the payload is the same. Larger randomized trials with DV are ongoing.

TABLE 3. Management Recommendations for Important ADC Toxicities

Toxicity (*ADC*)	Severity	Management of Toxicity
Skin reactions (*EV*)	Suspected SJS or TEN	Immediately withhold EV and refer to specialized care Permanently discontinue in confirmed cases
	Grade 2	Withhold until ≤grade 1 Consider referral to specialized care Consider dose reduction if rechallenging after grade 2 toxicity
Hyperglycemia (*EV*)	Blood glucose >13.9 mmol/L (>250 mg/dL)	Withhold until elevated blood glucose has improved to ≤13.9 mmol/L (≤250 mg/dL) Resume treatment at the same dose
Peripheral neuropathy (*EV*)	Grade 2	Withhold until ≤grade 1 For first occurrence, resume treatment at the same dose level. Consider dose reduction for rechallenge after recurrences
	Grade ≥3	Permanently discontinue
Pneumonitis (*trastuzumab deruxtecan*, *trastuzumab emtansine*)	Grade ≥2	Referral to pulmonary, CT thorax, PFT if pneumonitis/ILD suspected Permanently discontinue
Ocular toxicity (*EV*)	Grade ≥2	Consider referral to specialized care Consider topical ophthalmic corticosteroids

Abbreviations: ADC, antibody-drug conjugate; CT, computed tomography; EV, enfortumab vedotin; ILD, interstitial lung disease; PFT, phenylalanine mustard, fluorouracil, tamoxifen; SJS, Stevens-Johnson syndrome; TEN, toxic epidermal necrolysis.

SACITUZUMAB GOVITECAN

SG consists of a humanized mAB specific for TROP2 linked to SN-38, the active metabolite of the Topo I inhibitor irinotecan.[15] This conjugation is achieved using a hydrolyzable, proprietary linker, CL2A, which allows for delivery of SN-38 inside tumor cells expressing TROP2. CL2A linker also allows for release of SN-38 into the nearby TME, resulting in a bystander effect killing adjacent tumor cells. SG is linked with high DAR.[15] SG has FDA approval for the treatment of metastatic triple-negative breast cancer (TNBC) and metastatic UC and most recently for the treatment of hormone receptor+ (HR+)/HER2– MBC.[61-63]

ASCENT was a phase III study comparing SG with physician's choice chemotherapy in patients with TNBC who had received two or more previous systemic therapies for metastatic disease. SG was found to improve PFS (HR, 0.41; 95% CI, 0.32 to 0.52) and OS (HR, 0.48; 95% CI, 0.38 to 0.59) compared with single-agent chemotherapy.[64] In this trial, the most common TRAEs of any grade were neutropenia (63%, ≥grade 3—51%), diarrhea (59%, ≥grade 3—10%), nausea (57%), alopecia (46%), fatigue (45%), and anemia (34%, ≥grade 3—8%); see Table 1. Febrile neutropenia was also observed (≥grade 3—6%). Low frequencies of rash (9%, any grade), ocular toxicity effects (5%; all grade 1), and neuropathy (1% ≥grade 2) were reported.[64]

TROPICS-02 randomly assigned patients with HR+/HER2– MBC 1:1 to receive SG or TPC.[65] SG demonstrated statistically significant and clinically meaningful improvements in PFS (HR, 0.66; $P < .0003$) and OS (HR, 0.79; $P = .02$) over TPC.[66] The safety profile in TROPICS-02 was consistent with previous studies (Table 1).

TROPHY-U-01 was a phase II study investigating SG in the treatment of metastatic UC in patients who experienced disease progression after platinum-based chemotherapy and ICI therapy. This study reported a very similar toxicity profile to that observed in ASCENT. There was again a low rate of TRAE involving skin (6%), ocular disorders (4%), and peripheral neuropathy (4%).[67]

There has been rapid development of ADCs in the treatment of other solid tumors as well, with promising activity compared with conventional cytotoxic chemotherapy. Tisotumab vedotin (targeting human tissue factor) is already a standard treatment for advanced cervical cancer,[68] and mirvetuximab soravtansine (targeting FRα) received FDA approval recently for FRα-expressing recurrent epithelial ovarian cancer/fallopian tube cancer/primary peritoneal carcinoma,[69] expanding the treatment options for these patients.

The therapeutic success with novel ADCs in relapsed disease is prompting their evaluation in earlier lines of treatment including the curative setting (Table 4). However, with the use of potent cytotoxic agents and imperfect mechanisms of targeting tumor cells, toxicity is an important consideration while using these agents. Patient selection and careful monitoring continue to be critical components in prescribing systemic therapy, with attention to the unique toxicities associated with these novel agents.

TABLE 4. Select Ongoing Trials With ADC Combinations

ADC	ADC Target	Trial ID (name)	Phase	Combination Therapy	Patient Population	Clinical Trial Data (if applicable)
ADC + IO combinations						
T-DM1	HER2	NCT04740918 (KATE3)	III	Atezolizumab (anti–PD-L1 antibody)	HER2-positive and PD-L1+ MBC	
		NCT04873362 (ASTEFANIA)	III	Atezolizumab (anti–PD-L1 antibody)	HER2+ BC with residual disease after NAC	
		NCT02924883 (KATE2)	II	Atezolizumab (anti–PD-L1 antibody)	HER2-positive MBC	mPFS: HR, 0.082, $P = .33$,[50] atezolizumab arm: 8.2 months, placebo arm: 6.8 months Treatment-related SAEs: atezolizumab arm: 19%, placebo arm: 3%
		NCT02605915	Ib	Atezolizumab (anti–PD-L1 antibody)	HER2-positive BC	
		NCT03032107	I	Pembrolizumab (anti–PD-1 antibody)	1-2L metastatic HER2+ MBC	ORR (N = 20): 20%[51] mPFS: 9.6 months G3 AEs: 20% Pneumonitis: 20% (n = 4; G2 = 3, G3 = 1)
T-DXd	HER2	NCT04538742 (DESTINY Breast-07)	Ib/II	Durvalumab (anti–PD-1 antibody)	1L metastatic HER2+ MBC	
		NCT04556773 (DESTINY Breast-08)	Ib/II	Durvalumab (anti–PD-1 antibody) + paclitaxel	1-2L metastatic HER2-low MBC	
		NCT03742102 (BEGONIA)	Ib/II	Durvalumab (anti–PD-1 antibody)	1L HER2-low TNBC	ORR (n = 12): 66.7%[52] (regardless of PD-L1 expression) G3/4 AE (n = 21): 38.1%, pneumonitis: two cases
		NCT03523572	Ib	Nivolumab (anti–PD-1 antibody)	≥2L HER2+ MBC	ORR (n = 32): 65.6%[53] mPFS: 11.6 months, no benefit with addition of nivolumab to T-DXd, adjudicated ILD/pneumonitis[a]: 14.6%
		NCT03523572	Ib	Nivolumab (anti–PD-1 antibody)	≥2L HER2-low MBC	ORR (n = 16): 50%[53] mPFS: 7.0 months, adjudicated ILD/pneumonitis[a]: 14.6%
		NCT04042701 (KEYNOTE KN-797)	I	Pembrolizumab (anti–PD-1 antibody)	HER2+ MBC (treated with previous T-DM1) and HER2-low MBC	
SG	TROP2	NCT04468061 (Sacı-IO TNBC)	II	Pembrolizumab (anti–PD-1 antibody)	1L mTNBC, PD-L1–negative	
		NCT04448886 (Sacı-IO hormone receptor+)	II	Pembrolizumab (anti–PD-1 antibody)	1-2L hormone receptor+/HER2– MBC	
		NCT05633654 (ASCENT-05)	III	Pembrolizumab (anti–PD-1 antibody)	TNBC with residual disease after NAC	
		NCT04434040 (ASPRIA)	II	Atezolizumab (anti–PD-L1 antibody)	TNBC with residual disease after NAC	
		NCT03971409 (InCITe)	II	Avelumab (anti–PD-1 antibody)	Metastatic TNBC	
		NCT04863885	I/II	Ipilimumab (anti-CTLA4 antibody) + nivolumab (anti–PD-1 antibody)	1L cisplatin-ineligible metastatic UC	Phase I results: ORR: 66.6% (4/6 evaluable –1 CR, 3 PR)[54] DLTs: G3 skin rash (n = 2), G3 pneumonitis (n = 1) RP2D: 8 mg/kg SG IV D1, 8 q3 weeks + 3 mg/kg Ipi IV q3 weeks + 1 mg/kg nivo IV q3 weeks

ADC	ADC Target	Trial ID (name)	Phase	Combination Therapy	Patient Population	Clinical Trial Data (if applicable)
ADC + other targeted therapy combinations						
T-DXd	HER2	NCT04556773 (DESTINY Breast-08)	Ib/II	Capivasertib (AKT inhibitor)	1-2L metastatic HER2-low MBC	
				Anastrozole (NSAI)	1-2L metastatic HER2-low MBC	
				Fulvestrant (SERD)	1-2L metastatic HER2-low MBC	
		NCT04553770 (TALENT)	II	Anastrozole (NSAI)	Hormone receptor+/HER2-low (neoadjuvant setting)	
		NCT04704661 (DASH)	I	AZD6738 (ATR inhibitor)	Advanced solid tumors with HER2 expression	
SG	TROP2	NCT05143229 (ASSET)	I	Alpelisib (a specific PI3K inhibitor)	≥2L HER2– MBC	
		NCT05006794	I	GS9716 (Mcl-1 antagonist)	Advanced solid tumors including TNBC	
Patritumab deruxtecan	HER3	NCT05569811 (VALENTINE)	II	Endocrine therapy	High-risk hormone receptor+/HER2– BC neoadjuvant	
EV	Nectin 4	NCT04963153	I	Erdafitinib (FGFR inhibitor)	Metastatic UC with FGFR2/3 genetic alterations	

Abbreviations: ADC, antibody-drug conjugate; AE, adverse event; ATR, ataxia telangiectasia and Rad3-related; BC, breast cancer; CPS, combined positive score; CR, complete response; CTLA4, cytotoxic T-lymphocyte-associated protein 4; Dato-DX, datopotamab deruxtecan; DLT, dose-limiting toxicity; EFS, event-free survival; EV, enfortumab vedotin; FGFR, fibroblast growth factor receptor; G, grade; HER2, human epidermal growth factor receptor 2; HR, hazard ratio; ILD, interstitial lung disease; irAE, immune-related adverse events; ISAC, immune-stimulating antibody conjugate; ITT, intent-to-treat; LA, locally advanced; LN, lymph node; MBC, metastatic breast cancer; Mcl-1, myeloid leukemia cell differentiation protein -1; mPFS, median progression-free survival; MRD, minimal residual disease; MTD, maximum tolerated dose; mTNBC, metastatic triple negative breast cancer; NAC, neoadjuvant chemotherapy; NSAI, nonsteroidal aromatase inhibitor; ORR, overall response rate; OS, overall survival; PARP, poly ADP-ribose polymerase; pCR, pathologic complete response; PD, progressive disease; PFS, progression-free survival; PI3K, phosphatidylinositol 3-kinase; PR, partial response; RP2D, recommended phase 2 dose; SAE, serious adverse event; SERD, selective estrogen receptor degrader; SG, sacituzumab govitecan; T-DM1, trastuzumab emtansine; T-DXd, trastuzumab deruxtecan; TKI, tyrosine kinase inhibitor; TLR, toll-like receptors; TNBC, triple-negative breast cancer; TROP2, trophoblast cell surface antigen 2; UC, urothelial cancer; uORR, unconfirmed overall response rate.
[a]ISAC consisting of an anti-HER2 monoclonal antibody conjugated to a TLR 7/8 dual agonist.

RESISTANCE TO ADC THERAPY

The advent of ADCs for the treatment of metastatic cancers over the past decade has significantly improved outcomes across different solid tumors. Nevertheless, patients on these therapies eventually experience disease progression, likely because of resistance. As ADCs are a relatively new class of drugs in oncology, the mechanisms of resistance are not fully elucidated.

Resistance may be related to the components of ADCs including altered target cell surface expression or gene mutation, upregulation of drug efflux transporters to offset payload toxicity, changes in trafficking of the ADC and internalization rates, or simple payload resistance. Some of these are discussed below with the relevant preclinical and clinical findings.

Target Modulation

Target downregulation is a common resistance mechanism; for example, HER2 downregulation is well known to lead to T-DM1 resistance in HER2+ disease.[70,71] In a neoadjuvant trial of T-DM1 + pertuzumab in HER2+ BC, there was a significant association between HER2 heterogeneity (defined as HER2 positivity by FISH in 5%-50% of tumor cells or an area of tumor that tested HER2-negative in multiple core biopsies) and lack of pCR after dual HER2-targeted therapy; none of the patients with HER2 heterogeneity achieved a pCR, in contrast to a 55% pCR rate in patients without HER2 heterogeneous tumors.[72] On the other hand, T-DXd, a next-generation ADC, has significant activity in tumors classified as HER2-low, likely because of a prominent bystander activity. However, data from DAISY revealed that a high percentage of HER2 IHC 0 tumor cells and their spatial distribution relative to HER2+ cells negatively affected response to T-DXd.[73]

Although SG outperformed chemotherapy in low–TROP2 expression settings, patients with low expression had reduced response rates (22%) versus those with medium/high expression in tumors (39%-44%).[74] A three-case autopsy series from patients treated with SG also demonstrated that there was no TROP2 expression detected (mRNA and protein) in one patient who experienced rapid progression, suggesting primary resistance.[75]

Lack of access to the target antigen can also promote resistance to ADCs. The presence of the HER3 ligand neuregulin that promotes HER2-HER3 dimerization diminished

the efficacy of T-DM1 in vitro, and combining T-DM1 with pertuzumab alleviated this inhibitory effect.[76]

Drug Efflux Transporters and Defects in Internalization and Trafficking

Upregulation of genes encoding multidrug resistance proteins (MDR) that promote DM1 efflux have been reported in-T-DM1–resistant cell lines.[77,78] Inhibiting the activity of multidrug resistance–associated protein 1 (MRP1), MRP2 and MDR1 reversed the resistance to T-DM1.

T-DM1 is dependent on lysosomal trafficking for intracellular release of the cytotoxic payload. In T-DM1–resistant gastric cancer cells, trastuzumab-ADCs were internalized into caveolin-coated vesicles/endosomes instead of colocalizing to lysosomes.[79] This cell line was also cross-resistant to an auristatin-based ADC with a noncleavable maleimide linker because of its inability to degrade the antibody in the endosomes and enable payload release. This resistance could be overcome by replacing the linker with protease cleavable linker. Thus, the modular nature of the ADCs can be exploited to generate new ADCs by swapping individual components with different functional properties to bypass resistance.

Mutations That Affect Payload Sensitivity or Antigen Binding

Whole-exome sequencing of tumor tissue from pre-SG treatment and postprogression autopsy tumor lesions identified mutually exclusive somatic mutations in *TOP1* (gene encoding topoisomerase I) and *TACSTD2* (gene encoding TROP2) in distinct lesions from the same patient.[75] TOP1 is a target of the SN-38 payload, and the $TOP1^{E418K}$ mutation prevents binding of the payload to TOP1, leading to resistance. The $TACSTD2^{T256R}$ encodes a protein that alters TROP2 binding to the antibody in SG, leading to resistance to SG. Furthermore, the mutant protein is mislocalized from the plasma membrane to the cytosol. Whether these mutations will be a frequent source of resistance to SG in the clinic remains to be seen.

Thus, diverse and numerous mechanisms likely account for the observed resistance to current ADCs in clinical use. The sequential use of ADCs with distinct mechanisms of action may offer a solution to overcoming resistance, but strong clinical trial translational work will be required to guide optimal sequencing. In addition, combinations of ADCs with other anticancer therapies can also potentially evade resistance or even overcome resistance.

COMBINATIONS WITH ADCs

Anti-HER2 Therapies

Combination of anti-HER2 ADCs and other HER2 agents that target a different epitope or function of HER2 to further improve outcomes has been explored. Although preclinical data showed synergistic activity for the T-DM1 + pertuzumab combination,[76] this was not seen in the MARIANNE trial where the addition of pertuzumab to T-DM1 did not improve PFS (stratified HR, 0.91; 97.5% CI, 0.73 to 1.13).[80] In DESTINY Breast-07, T-DXd is being combined with pertuzumab, immunotherapy, endocrine therapy, and other targeted agents. Other ADCs currently under evaluation with HER2-targeting agents are listed in Table 4.

Immunotherapy Agents

The multifaceted mechanism of action of ADCs also includes the engagement of immune effector cells with the goal of eliciting antitumor immunity.[16] This may manifest itself as the ADCC effects of the tumor-specific antibody in the ADC and direct interaction of the ADC with immune cells to modify their function.[81] In a mouse model, T-DXd + anti–PD-1 antibody was more active than T-DXd alone, potentially because of increased T-cell activity and upregulated PD-L1 expression induced by T-DXd.[82] These data formed the basis for the randomized trial of T-DM1/placebo + atezolizumab in HER2+ MBC (KATE-2) and the phase 1 trial of T-DXd with nivolumab. Disappointingly, neither trial showed significant improvement in efficacy with the combination over HER2-ADC alone.[50,53] Results from trials with ICI in TNBC suggest that setting and the line of therapy are important in BC, and there are ongoing trials in earlier lines of therapy (Table 4). On the other hand, preliminary results from T-DXd + nivolumab in HER2-expressing advanced UC reported an ORR of 37% and a medium duration of response of 13.1 months.[83]

The cytotoxic activity of Topo I inhibitors like SN-38 (payload in SG) results in the release of tumor-associated antigens into the circulation, which may upregulate PD-L1 expression on tumors and further prime the antitumor immune response. Topo I inhibitors can also alter tumor immune landscape by reducing Tregs and augmenting MHC class I–mediated tumor antigen presentation.[84] Hence, the TROP2 ADCs are under clinical investigation in combination with ICIs in TNBC (Table 4).

A phase 1 trial of SG with EV is ongoing in advanced/metastatic UC that has progressed on previous ICI therapy (ClinicalTrials.gov identifier: NCT04724018).

PARP Inhibitors

ADCs with Topo I inhibitors may be synergistic with poly ADP-ribose polymerase (PARP) inhibitors since the latter block resolution of TOP1 cleavage complexes induced by Topo I inhibitors, thus exposing the inability of remaining pathways to repair DNA damage. Unfortunately, early clinical trials exploring combinations with standard Topo I inhibitors, such as irinotecan and topotecan, were hampered by dose-limiting myelosuppression.[85,86] Preclinical models that used a temporal separation of SG and PARPi treatment demonstrated

the synergy of the combination.[58] Subsequently, a phase 1b study in TNBC revealed that staggered dosing of SG with talazoparib was well tolerated without DLTs and resulted in preliminary clinical activity.[58] Translational studies in pre- and on-treatment biopsies confirmed target inhibition. Thus, utilization of alternate dosing schedules may permit the use of promising ADC drug combinations to enhance efficacy/overcome resistance while minimizing toxicities.

CONCLUSION

It is not an understatement that the use of ADCs is revolutionizing the treatment of solid tumors, especially HER2+ BC, delaying progression and prolonging survival in one of the most aggressive subtypes of the disease. These successes have encouraged the evaluation of ADCs across a spectrum of cancers expressing a variety of tumor antigens. Advances in linker chemistry, antibody technology, and the use of potent drugs have enabled targeting of tumors regardless of the level of antigen expression, thus extending the benefit of these agents to a broader pool of patients. However, the use of these novel ADCs is associated with unique toxicities and mandates vigilance and careful monitoring of patients and continuous education on mitigation strategies. A vital practical consideration is the appropriate sequencing of these different ADCs during the course of a patient's treatment, and there are a handful of ongoing trials addressing this issue.

Understanding the mechanisms of resistance to ADC therapy and overcoming them using combination strategies or new agents are imperative. Harnessing the power of the immune system to ADC development and generating molecules that target immune cells and other components of the TME are already underway. Probody drug conjugates, immune-stimulating antibody conjugates, engineered toxin bodies, radioligand conjugates, and so on comprise the new wave of molecules in clinical development, seeking to improve efficacy and circumvent the drawbacks with existing ADCs while maintaining an acceptable safety profile.

Expanding the Benefit: Dabrafenib/Trametinib as Tissue-Agnostic Therapy for *BRAF* V600E–Positive Adult and Pediatric Solid Tumors

Mohamed A. Gouda, MD[1,2] and Vivek Subbiah, MD[1,3,4]

Overview

The recent US Food and Drug Administration (FDA) approval of the dabrafenib/trametinib combination as a tissue-agnostic treatment for solid tumors with *BRAF* V600E mutation is the result of more than 20 years of extensive research into *BRAF* mutations in human cancer, the underlying biological mechanisms that drive *BRAF*-mediated tumor growth, and the clinical testing and refinement of selective RAF and MEK kinase inhibitors. Such approval marks a significant achievement in the field of oncology and represents a major step forward in our ability to treat cancer. Early evidence supported the use of dabrafenib/trametinib combination in melanoma, non–small-cell lung cancer, and anaplastic thyroid cancer. Furthermore, data from basket trials have demonstrated consistently good response rates in various tumors, including biliary tract cancer, low-grade glioma, high-grade glioma, hairy cell leukemia, and multiple other malignancies, which has been the basis for FDA approval of a tissue-agnostic indication in adult and pediatric patients with *BRAF* V600E–positive solid tumors. From a clinical standpoint, our review delves into the efficacy of the dabrafenib/trametinib combination for *BRAF* V600E–positive tumors: examining the underlying rationale for its use, evaluating the latest evidence on its potential benefits, and discussing the possible associated adverse effects and strategies to minimize their impact. Additionally, we explore potential resistance mechanisms and future landscape of BRAF-targeted therapies.

INTRODUCTION

Genome-driven precision oncology has revolutionized the landscape of management in multiple solid tumors. With the evolving advances in next-generation sequencing technologies, the molecular heterogeneity of cancers has become apparent. Advances also led to identifying several potentially actionable oncogenic driver mutations and developing drugs that can act on them, which ushered in the era of precision oncology.[1] One of the most promising therapeutic targets is the *BRAF* proto-oncogene. *BRAF* alterations, including *BRAF* V600E, are not uncommon in cancer and can lead to ligand-independent activation of the MAPK pathway.[2,3] This results in uncontrolled phosphorylation of downstream MEK and ERK, eventually leading to unregulated cell growth and differentiation as part of oncogenesis (Fig 1).[4-6] BRAF can be targeted by BRAF inhibitors, which results in the cessation of the aberrant activation signal. Downstream MEK can also be inhibited using targeted treatment options that have demonstrated clinical benefit in different patient populations.[7,8] Currently, three BRAF plus MEK combinations are approved by the US Food and Drug Administration (FDA) for treatment of melanoma harboring *BRAF* V600 mutations: vemurafenib/cobimetinib, dabrafenib/trametinib, and encorafenib/binimetinib. In addition, the dabrafenib/trametinib combination is approved for anaplastic thyroid cancer and non–small-cell lung cancer (NSCLC) with *BRAF* V600 mutations. More recently, the combination of the BRAF inhibitor, dabrafenib, and the MEK inhibitor, trametinib, has been approved for *BRAF* V600E–altered unresectable and metastatic solid tumors with the exception of colorectal cancer.[9] This approval for a tissue-agnostic indication was based on evidence from several adult and pediatric studies (ROAR basket trial, NCI-MATCH trial, and Study X2101), demonstrating efficacy in different tumor types.[10-17,75] From a clinical standpoint, our review delves into the efficacy of the dabrafenib/trametinib combination for *BRAF* V600E–positive solid tumors: examining the underlying rationale for its use, evaluating the latest evidence on its potential benefits, and discussing the possible associated adverse effects and strategies to minimize their impact. Additionally, we explore potential resistance mechanisms and future landscape of *BRAF*-targeted therapies.

RATIONALE BEHIND COMBINATION

Despite the efficacy of BRAF inhibition monotherapy (eg, vemurafenib, dabrafenib, and encorafenib), durable clinical benefit is limited, and most patients will eventually progress.[18,19] In addition, BRAF inhibitor

PRACTICAL APPLICATIONS

- Combining the BRAF inhibitor, dabrafenib, and the MEK inhibitor, trametinib, has been practice changing in managing *BRAF* V600–mutated cancers.
- Early evidence supported using dabrafenib and trametinib in *BRAF* V600–positive melanoma and non–small-cell lung cancer. However, data from basket trials have demonstrated consistent responses in various tumors harboring *BRAF* V600 mutation, including anaplastic thyroid carcinoma, biliary tract cancer, hairy cell leukemia, low-grade glioma, high-grade glioma, and multiple other rare cancers.
- Dabrafenib and trametinib combination is currently approved for all solid tumors with *BRAF* V600E mutations, regardless of tissue of origin (except colorectal cancer).
- Understanding the adverse event profile of dabrafenib and trametinib and possible strategies to mitigate these toxicities is important.

monotherapy has been associated with paradoxical activation of the MAPK pathway, which has been linked to progression of cancer and various side effects, including the development of secondary skin cancers.[20,21] Therefore, a combination with MEK inhibitors was explored and has currently emerged as the standard of care.

The idea behind the combined targeting of different molecules in a cellular pathway is not new and has long been practiced at different levels.[22] The same concept applies to dual inhibition of upstream BRAF and downstream MEK, which can lead to a synergistic effect ending the aberrant oncogenic signal (Fig 1). Although the most feared issue with drug combinations is added toxicities, the toxicity profile shown with the dabrafenib and trametinib combination was quite manageable, and in some cases, the combination could even prevent BRAF inhibitor monotherapy-related complications. Even with a high proportion of patients experiencing any-grade toxicity, most are limited to grade 1 and grade 2 events, and even grade 3 events can resolve with appropriate management. So far, the combination of dabrafenib and trametinib has demonstrated good response rates in different tumor types harboring *BRAF* V600E (Fig 2), which was the basis for FDA drug approvals.

CURRENT INDICATIONS FOR DABRAFENIB AND TRAMETINIB

Currently, the FDA approves the use of dabrafenib and trametinib combination in patients with melanoma, NSCLC, anaplastic thyroid carcinoma, and low-grade glioma (pediatrics) who have *BRAF* V600E–mutated metastatic disease (also V600K in lung cancer, unresectable disease and early disease with nodal involvement in melanoma, and locally advanced disease in anaplastic thyroid carcinoma).

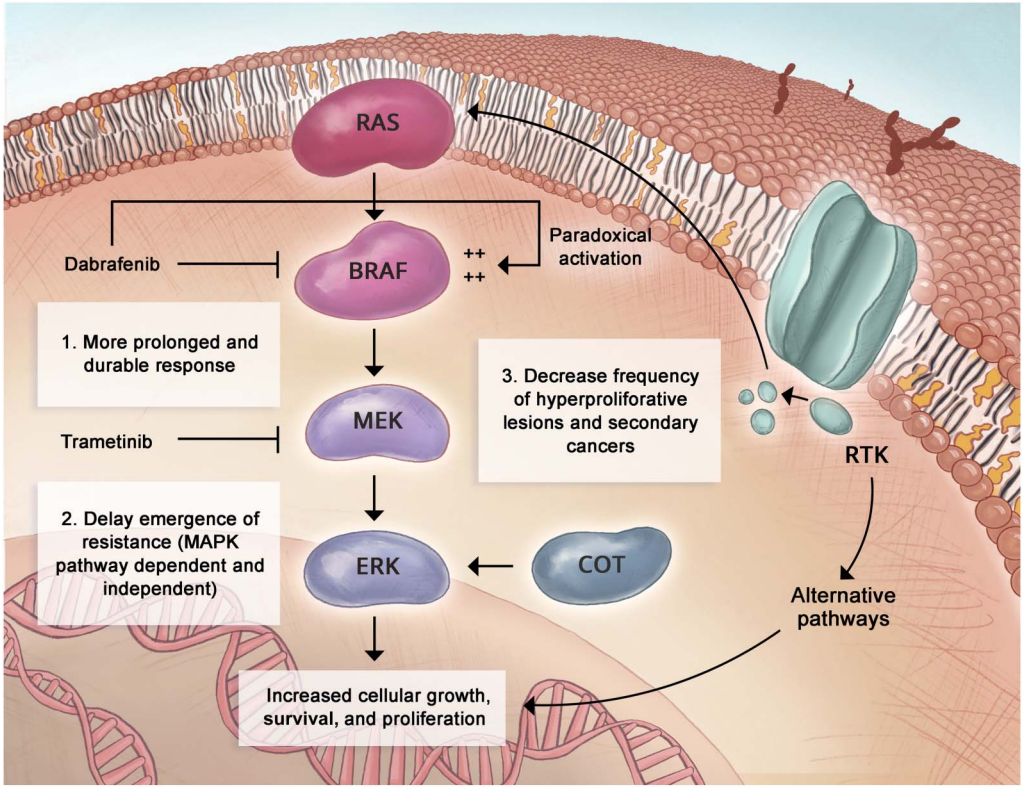

FIG 1. BRAF pathway and rationale for combination therapy. RAF isoforms, including BRAF, are activated through interaction between small G protein and N-terminal, which leads to phosphorylation of MEK and downstream ERK eventually resulting in cell survival. A serine/threonine protein kinase, COT/Tpl2, is indispensable for extracellular signal–regulated kinase (ERK) activation. Combination of BRAF inhibitor, dabrafenib, and MEK inhibitor, trametinib, leads to more prolonged and durable response, delays emergence of resistance, and decreases frequency of hyperproliferative lesions compared with monotherapy BRAF inhibition alone. MEK, mitogen-activated protein kinase; RAF, rapidly accelerated fibrosarcoma; RAS, rat sarcoma; RTK, receptor tyrosine kinase.

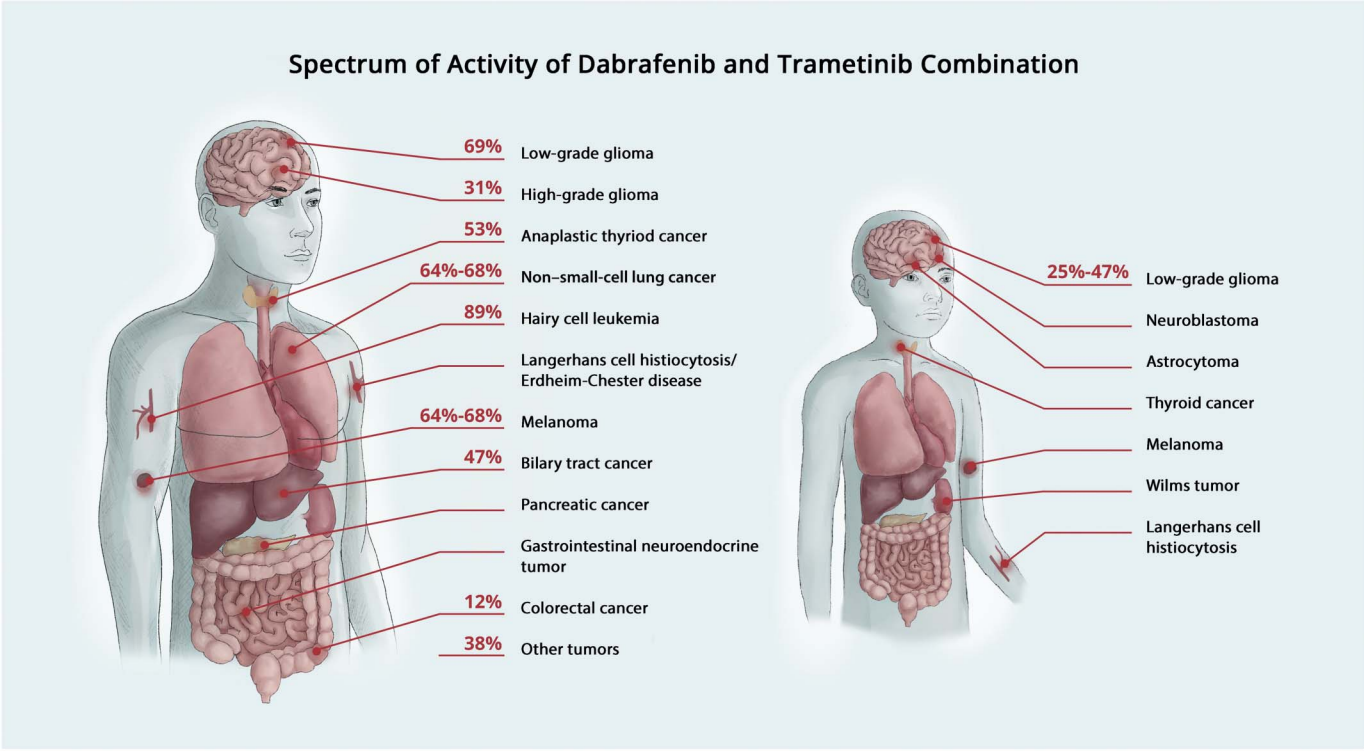

FIG 2. The depth and breadth of dabrafenib plus trametinib use in cancer. Response rates of dabrafenib plus trametinib from multiple clinical trials in different tumor types are shown. Other tumor types with anecdotal evidence of BRAF plus MEK inhibitor activity from a literature review are also shown.

In addition to these tissue-specific indications, the current FDA label also includes the treatment of adult and pediatric patients with unresectable or metastatic solid tumors who have *BRAF* V600E mutation in a tissue-agnostic indication (Table 1).[23]

Use in Melanoma

More than 50% of patients with malignant melanoma harbor *BRAF* oncogenic alterations (approximately half are V600E).[3,24,25] Evidence on the efficacy of dabrafenib and trametinib combination in patients with metastatic and unresectable melanoma is supported by data from three randomized controlled trials (COMBI-v, COMBI-d, and COMBI-MB; Table 2). The COMBI-v (ClinicalTrials.gov identifier: NCT01597908) was a phase III trial that randomly assigned patients with unresectable or metastatic V600E/K-altered melanoma to receive either the combination of dabrafenib and trametinib or vemurafenib monotherapy. The trial demonstrated improved progression-free survival (PFS) and overall survival (OS) in patients randomly

TABLE 1. Current US Food and Drug Administration Indications for the Dabrafenib and Trametinib Combination

Indication	Setting	Population	Alteration	Age	Approval Type
Melanoma	Advanced	Unresectable or metastatic disease	*BRAF* V600E or V600K	Not specified	Regular approval
Melanoma	Adjuvant	After complete resection in patients with nodal involvement	*BRAF* V600E or V600K	Not specified	Regular approval
NSCLC	Advanced	Metastatic disease	*BRAF* V600E	Not specified	Regular approval
Anaplastic thyroid carcinoma	Advanced	Locally advanced or metastatic disease and no satisfactory locoregional treatment options	*BRAF* V600E	Not specified	Regular approval
Low-grade glioma (pediatrics)	Advanced	Low-grade glioma that requires systemic therapy	*BRAF* V600E	≥1 year	Regular approval
All solid tumors	Advanced	Unresectable or metastatic disease after progression on previous treatment and no satisfactory alternative treatment options	*BRAF* V600E	Adult and pediatric patients 6 years and older	Accelerated approval

Abbreviation: NSCLC, non–small-cell lung cancer.

assigned to the combination arm compared with patients in the vemurafenib arm (median, 11.4 months *v* 7.3 months for PFS; and median, not reached *v* 17.2 months for OS). The objective response rate (ORR) was also higher in the combination group compared with the vemurafenib group (64% *v* 51%).[26] Another phase III trial (COMBI-d; ClinicalTrials.gov identifier: NCT01584648) randomly assigned patients with unresectable or metastatic V600E/K-altered melanoma to receive either the combination of dabrafenib and trametinib or dabrafenib plus placebo. Results showed longer PFS (median, 9.3 months *v* 8.8 months) and higher ORR (68% *v* 55%), although the median OS was not reached in both groups.[27,28] Both trials reported a lower incidence of secondary skin cancer in the combination group.[26-28] The third trial (COMBI-MB; ClinicalTrials.gov identifier: NCT02039947) was a phase II trial that included patients with metastatic melanoma to the brain and *BRAF* V600 mutations. Four cohorts were included in this trial: Cohorts A and B included patients with V600E mutation and asymptomatic brain disease that was subject (cohort B) or not subject (cohort A) to previous local therapy. Cohort C included patients with other *BRAF* mutations (V600D/K/R) and asymptomatic brain disease that was not previously treated. Cohort D included patients with brain disease irrespective of mutation type or local therapy. Responses were seen across different cohorts (lowest in cohort C and highest in cohort D), and the side effect profile was tolerable.[29]

Use in the adjuvant setting is supported by evidence from the phase III randomized controlled trial (COMBI-AD; ClinicalTrials.gov identifier: NCT01682083), which compared the use of the combination with placebo in patients with stage 3 *BRAF* V600E/K-altered melanoma after curative intent surgery. Data from this trial showed a lower risk of recurrence in patients in the combination arm compared with patients who received placebo (37% *v* 57%). The median recurrence-free survival was not reached in the combination arm and was 16.6 months in the placebo arm, and OS was not reached in both groups.[30]

Use in Non–Small-Cell Lung Cancer

BRAF mutations are present in nearly 1%-5% of patients with NSCLC (including 50% *BRAF* V600).[3,31] Evidence supporting the use of dabrafenib and trametinib combination in lung cancer stems from the phase II trial BRF113928 (ClinicalTrials.gov identifier: NCT01336634; Table 2). In this study, patients with pretreated metastatic NSCLC who harbored *BRAF* V600E mutation received either dabrafenib monotherapy (cohort A) or dabrafenib and trametinib combination (cohort B). In the same trial, a treatment-naïve patient cohort was included (cohort C) and received dabrafenib and trametinib combination. The ORR was 64%, 68%, and 33% in cohorts C, B, and A, respectively, demonstrating a favorability of the combination in treatment-naïve and pretreated patients. PFS was also higher in cohorts B and C (median, 10.2 months and 10.8 months) compared with cohort A (median, 5.5 months), and so was OS (median, 17.3 months, 18.2 months, and 12.6 months in cohorts C, B, and A, respectively). With a tolerable safety profile, this trial established the efficacy of the combination in NSCLC, which led to its FDA approval.[32-35]

Use in Anaplastic Thyroid Carcinoma

BRAF mutations are estimated to be present in 20%-50% of patients with anaplastic thyroid carcinoma.[36-39] Evidence of combination efficacy in anaplastic thyroid carcinoma came from the Rare Oncology Agnostic Research (ROAR) trial (BRF117019; ClinicalTrials.gov identifier: NCT02034110). ROAR was a basket trial that explored the use of dabrafenib/trametinib combination in multiple tumor types (Table 2).[10-14,75] FDA approval was based on an ORR of 61% in 23 patients with anaplastic thyroid carcinoma who were evaluable for response at the time of initial data cutoff. The complete and partial response rates were 4% and 57%, respectively. The response duration was at least 6 months in 64% of responding patients.[40] These data were very promising, considering the poor prognosis of anaplastic thyroid cancer. Recently, an updated analysis that included the full enrollment of 36 patients and around 4 years of additional study follow-up showed that investigator-assessed responses were observed in 56% of patients, with 50% of responders still in response at 12 months. The median OS was 15 months, with the 12-month OS rate of 52% being notable given the historic median OS of <6 months. This updated analysis confirmed the definitive benefit of dabrafenib plus trametinib in anaplastic thyroid carcinoma at long-term follow-up.[10,11]

Use in Biliary Tract Cancer

Around 5%-7% of patients with biliary tract cancer harbor *BRAF* alterations.[41,42] In 43 patients included in the ROAR trial with *BRAF* V600E–mutated biliary tract cancer (Table 2), there were very promising results in the form of a response rate of 47% (investigator-assessed response rate, 51%). Besides, 35% had a stable disease, which expands the proportion of patients who derived clinical benefit to 81%. The median duration of response was 9 months; with nearly 59% of responding patients having ongoing responses beyond 6 months, and 9% with ongoing responses at data cutoff.[13]

Use in Glioma

BRAF V600 mutations are present in nearly 5%-15% of patients with low-grade glioma and 3% of patients with glioblastoma.[3,43] In the ROAR trial, 45 patients with high-grade glioma (including 31 with glioblastoma) and 13 with low-grade glioma were included (Table 2). The ORR reported by the independent review committee was 31% and 69% in patients with high-grade and low-grade glioma, respectively. Interestingly, complete responses were seen in

TABLE 2. Summary of Clinical Trials of Dabrafenib (D) Plus Trametinib (T)

		PFS (mo)		OS (mo)		ORR

[a]Asymptomatic patients with *BRAF* V600E mutation who had no previous local brain therapy.

[b]Asymptomatic patients with *BRAF* V600E mutation who had previous local therapy.

[c]Asymptomatic patients with *BRAF* V600D/K/R mutations who had no previous local brain therapy.

[d]Symptomatic disease regardless of local therapy or mutation subtype.

[e]Recurrence rate.

[f]Cohort A received dabrafenib monotherapy.

[g]Previously treated.

[h]Treatment naïve.

[i]Responses seen in seven different tumor types.

three patients with high-grade glioma and one with low-grade glioma. In a post hoc analysis of the high-grade glioma cohort, ORR increased to 50% in patients age 18-39 years with a median PFS of 18.5 months and median OS of 45.2 months, which showed the relatively better clinical benefit in the adolescent and young adult population who conventionally have poor outcomes than the pediatric or older adult population. The median duration of response was 13.6 months in patients with high-grade glioma, and the median PFS was 4.5 months. In low-grade glioma, the median duration of response was 27.5 months, and the median PFS was not reached. The median OS was 17.6 months and not reached in the high-grade and low-grade cohorts, respectively.[14]

In the pediatric patient population, data supportive of using dabrafenib plus trametinib were demonstrated in the TADPOLE trial (Study CDRB436G2201; ClinicalTrials.gov identifier: NCT02684058).[23] The phase II/III randomized trial included pediatric patients with high-grade glioma and low-grade glioma who require systemic therapy. Compared with patients in the control arm who received carboplatin plus vincristine in the low-grade glioma cohort (n = 37), patients on dabrafenib plus trametinib (n = 73) showed higher ORR (46.6% *v* 10.8%) and longer median PFS (20.1 months *v* 7.4). On the basis of these promising results, FDA recently approved dabrafenib plus trametinib for treatment of pediatric patients with low-grade glioma who require systemic therapy.[23,44] This marks the first FDA approval of a systemic treatment for first-line therapy of children diagnosed with low-grade glioma harboring a *BRAF* V600E mutation. Additionally, the FDA granted approval for novel oral formulations of both medications that are appropriate for patients with difficulty in swallowing pills.[45] Similar to the TADPOLE trial, Study X2101 in the pediatric patient population (ClinicalTrials.gov identifier: NCT02124772) evaluated trametinib alone or in combination with dabrafenib in pediatric patients with *BRAF* V600–mutated solid tumors including low-grade glioma (Table 2). The multicenter, open-label, multicohort trial recruited pediatric patients with refractory or recurrent solid tumors. Encouraging data were reported in patients with low-grade glioma (n = 47) who received combination therapy, where a response rate of 25% was seen with a median PFS of 36.9 months.[9,16,17]

Use in *BRAF* V600E Mutation–Positive Unresectable or Metastatic Solid Tumors

Data on dabrafenib/trametinib combination efficacy in other tumor types originated from three basket trials (ROAR, NCI-MATCH, and Study X2101) that included a heterogeneous group of patients with multiple cancer diagnoses.[9,15-17,23] The ROAR trial (BRF117019 study; ClinicalTrials.gov identifier: NCT02034110) included adult patients with *BRAF* V600E mutation–positive tumors, such as high-grade glioma, low-grade glioma, biliary tract cancer, adenocarcinoma of the small intestine, GI stromal tumor, and anaplastic thyroid cancer. Arm H of the NCI-MATCH study (EAY131-H; ClinicalTrials.gov identifier: NCT02465060) included patients with *BRAF* V600E–mutated tumors, excluding melanoma, thyroid, and colorectal cancer. The study enrolled adult patients with various types of solid tumors, such as gastrointestinal tumors, lung tumors, gynecologic or peritoneal tumors, CNS tumors, and ameloblastoma of the mandible. In a pooled analysis of 131 patients with multiple tumor types specified in ROAR and NCI-MATCH (90% pretreated), responses were seen in multiple tumor types (Table 3).[15,23] Study X2101 reported promising data in pediatric patients with low-grade glioma while results from other cohorts are still awaited.[9,16,17]

Data in Hematological Malignancies and Histiocytic Neoplasms

Beyond solid tumors, *BRAF* alterations (primarily V600E) are observed in more than 90% of patients with hairy cell leukemia.[14,46] Data from ROAR also supported the use of the dabrafenib/trametinib combination in this patient population (Table 2). In 55 patients with *BRAF* V600E–mutated hairy cell leukemia, the investigator-assessed ORR was 89%.

TABLE 3. Pooled Data From ROAR and NCI-MATCH Expanding the Benefit of Dabrafenib/Trametinib for *BRAF* V600E Solid Tumors

Diagnosis	No.	ORR (%)	Duration of Response (mo)
Biliary tract cancer	48	46	1.8
High-grade glioma	48	33	3.9
Glioblastoma	32	25	3.9
Anaplastic pleomorphic xanthoastrocytoma	6	67	6

Adenocarcinoma of the anus	1	0	NA
GIST	1	0	NA

Abbreviations: GIST, GI stromal tumor; NA, not available; ORR, objective response rate.

Responding patients remained event-free for at least 24 months. Complete remission was reported in 65.5% of patients (including nine patients with no minimal residual disease).[14] In addition to hairy cell leukemia, dabrafenib is listed in National Comprehensive Cancer Network guidelines for Erdheim-Chester disease or Langerhans cell histiocytosis harboring *BRAF* V600 mutation, and trametinib is listed for patients with MAP kinase pathway mutations, no detectable mutation, or no available testing. The combination has been reported anecdotally in a case that demonstrated a sustained response in a patient with *BRAF* V600E–positive Langerhans cell histiocytosis.[47,48]

FDA TISSUE-AGNOSTIC APPROVAL AND BEYOND

On the basis of these data showing efficacy in more than 20 tumor types, dabrafenib plus trametinib was indicated as combination in adult and pediatric patients with advanced solid tumors that harbor *BRAF* V600E mutation.[9,23,49] The exception is patients with colorectal cancer because of known intrinsic resistance to BRAF inhibition by activation of the EGFR pathway.[23,50] Hence, adding EGFR monoclonal antibodies to BRAF/MEK combination has shown salutary effects. For example, encorafenib in combination with cetuximab is currently approved for colorectal cancer harboring *BRAF* V600 alteration.[51] Interestingly, recent data have also shown that the BRAF plus MEK combination might still be effective in patients with colorectal cancer by adding with a third therapeutic drug other than an EGFR pathway inhibitor. For example, a recent phase II trial (ClinicalTrials.gov identifier: NCT03668431) provided evidence on the efficacy of dabrafenib/trametinib combination when an anti–PD-1 antibody (spartalizumab) was added, leading to a confirmed response rate of 24.3%.[52]

DRUG ADMINISTRATION AND DOSAGE

Adults

The recommended doses of dabrafenib and trametinib are 150 mg (twice daily) and 2 mg (once daily). Both drugs should be given at least 1 hour before or 2 hours after the last meal.[23,50]

Pediatrics

The recommended doses of dabrafenib and trametinib should be based on body weight. The dose would be 75 mg/1 mg, 100 mg/1.5 mg, and 150 mg/2 mg in patients with a weight of 26-37 kg, 38-50 kg, and ≥51 kg, respectively. The drugs should be given orally twice daily for dabrafenib and once daily for trametinib.[23,50]

Oral Suspension

The recommended dosage for dabrafenib tablets for oral suspension is based on body weight ranging from 20 mg twice daily for a patient weighing 8-9 kg to 150 mg twice daily for patients >51 kg. The recommended dosage for trametinib for oral solution is based on body weight ranging from 6 mL (0.3 mg once daily) for a patient with

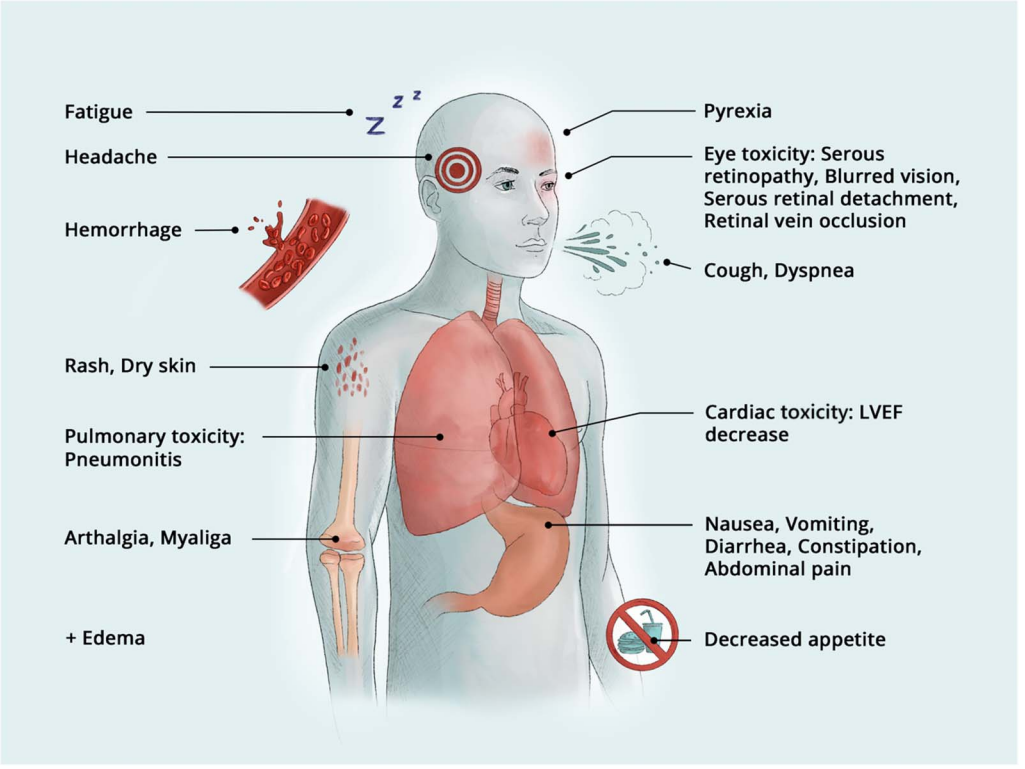

FIG 3. Common side effects of dabrafenib and trametinib. LVEF, left ventricular ejection fraction.

TABLE 4. Management of Select Adverse Events in Patients Receiving D Plus T[6,23,50,55]

Side Effect	General Management	D Plus T Use
Pyrexia	Use antipyretics (eg, acetaminophen) as appropriate A limited burst of corticosteroids may be used after 3 days (eg, prednisone 10 mg once daily for 5 days) No recommended sepsis routine workup unless localizing symptoms or other symptoms suggestive of infection exist	100.4-104°F (38-40°C) Withhold D plus T until fever resolves. Resume at same or lower dose >105°F (40.5°C) OR pyrexia complicated by rigors, hypotension, dehydration, or renal failure Withhold D plus T until fever resolves for at least 24 hours Resume at lower dose or permanently discontinue
Skin toxicities (including rash, photosensitivity, and secondary skin cancers)	Use emollients, antihistamines, and analgesics to alleviate symptoms A short course of corticosteroids may be tried in patients with persistent symptoms Dermatologic consultation before and during therapy may be helpful. Any suspicious lesions should be removed and evaluated Patient education about photosensitivity reactions. Use sunblock with high sun protection factor and UV protective clothing. Avoid UV-A exposure if possible	Intolerable grade 2 OR grade 3-4 Withhold D plus T for up to 3 weeks. Resume at lower dose If not improved, permanently discontinue Severe cutaneous adverse reactions Permanently discontinue
Noncutaneous RAS mutation–positive new primary		Permanently discontinue D
Cardiomyopathy	Assess LVEF before starting D plus T and reassess 1 month after starting therapy and regularly each 2-3 months thereafter	Asymptomatic ≥10% decrease in LVEF Withhold T for 4 weeks Resume at lower dose If not improved, permanently discontinue Symptomatic cardiomyopathy OR decrease >20% from baseline Permanently discontinue T Withhold D. Resume at lower dose. If not improved, permanently discontinue
Elevated liver enzymes	Measure liver enzymes before starting therapy and monthly afterward	Persistent or recurrent grade 2 (and any grade ≥3) events. Withhold D plus T Resume at lower dose OR same dose If not improved, permanently discontinue
Ocular toxicities	Active surveillance including ophthalmologic consultation while on therapy Patient education and instruction to promptly report any abnormal visual manifestations Some ocular toxicities (eg, iritis and uveitis) may benefit from local steroids and mydriatic eye drops	RPED Withhold T for 3 weeks Resume at lower dose If not improved, permanently discontinue or resume at lower dose Uveitis, including iritis and iridocyclitis Withhold D for up to 6 weeks If improved to grade 0-1, resume at same or lower dose If not improved, permanently discontinue RVO Permanently discontinue T
Hemorrhage	Manage hemorrhagic events with supportive care including blood transfusion as appropriate	Grade 3 Withhold T Resume at lower dose If not improved, permanently discontinue Grade 4 Permanently discontinue T
Venous thromboembolism	Provide supportive care as appropriate	Uncomplicated Withhold T for 3 weeks Resume at lower dose If not improved, permanently discontinue Life-threatening Permanently discontinue T
Interstitial lung disease	Active surveillance including consultation with pulmonologist as appropriate Patient education and instruction to promptly report any pulmonary manifestations	Permanently discontinue

Abbreviations: D, dabrafenib; LVEF, left ventricular ejection fraction; RPED, retinal pigment epithelial detachments; RVO, retinal vein occlusion; T, trametinib.

8 kg to 40 mL (2 mg once daily) for a patient over 51 kg.[23]

SIDE EFFECTS AND MANAGEMENT OF ADVERSE EVENTS

The combination of dabrafenib and trametinib can lead to high rates of adverse events, given the added toxicity of each drug. In a recent meta-analysis, the incidence of any grade toxicity was 95%, with 43% of patients having grade 3 or higher events. Dose reductions were reported in 28% of patients, and toxicities led to treatment discontinuation in 24% of participants.[53] The most common adverse events are pyrexia, chills, fatigue, rash, dry skin, headache, arthralgia, myalgia, cough, dyspnea, nausea, vomiting, diarrhea, constipation, abdominal pain, decreased appetite, edema, hemorrhage, and paronychia (in pediatrics; Fig 3).[23,50] Evidence shows that those side effects, and corresponding dose reductions or interruptions, become less frequent after 6 months of treatment,[54] which highlights the importance of understanding possible management strategies that would prevent treatment cessation because of toxicity (Table 4). Managing adverse effects can be quite challenging, given the overlapping profile of possible toxicities. However, the general rule of thumb is to try to prevent those toxicities, and if they happen to try to resume with dose reductions after toxicities resolve unless they are serious enough, which would warrant treatment discontinuation (Fig 4).

RESISTANCE MECHANISMS

After initial response to BRAF/MEK inhibition, some patients will eventually develop secondary resistance which can be driven by MAPK pathway–dependent or MAPK pathway–independent alterations. For example, *NRAS* mutations can lead to upstream activation of BRAF and paradoxical activation of MAPK pathway via CRAF dimerization. Some non-*BRAF* V600 alterations, for example, *BRAF* fusions, have been also linked to BRAF inhibitor resistance by escaping selective inhibition. Other pathway alterations in *MEK*, *ERK*, and *COT* have been shown to contribute to the possible resistance to BRAF inhibitors. MAPK-independent resistance can originate from overexpression or upregulation of receptor tyrosine kinases and upregulated PI3K/AKT pathway.[56,57] Apart from MAPK-mediated resistance, various other resistance mechanisms such as CRAF, ARAF, MET, and the P13K/AKT/mTOR pathway exist, among other intricate pathways. The VEM-PLUS study analysis to investigate the effectiveness and safety of vemurafenib monotherapy and its combination with targeted therapies (sorafenib, crizotinib, or everolimus) or carboplatin plus paclitaxel in treating advanced solid tumors with *BRAF V600* mutations revealed no significant differences in the duration of OS or PFS between vemurafenib monotherapy and combination treatments.[58] This shows that combining BRAF inhibitors with other agents (beyond BRAF plus MEK) may be quite challenging.

BEYOND DABRAFENIB PLUS TRAMETINIB IN ADVANCED SETTING

Although current evidence supports the use of dabrafenib plus trametinib in patients with advanced cancers, more data on use in other disease settings are currently awaited. For example, there is at least some evidence from the COMBI-AD trial (ClinicalTrials.gov identifier: NCT01682083) to suggest a survival benefit in patients with melanoma in the adjuvant setting.[30] Moreover, there are data in the neoadjuvant setting from the NeoCombi trial (ClinicalTrials.gov identifier: NCT01972347) demonstrating complete responses in nearly half of included patients.[59] Use in anaplastic thyroid carcinoma is currently also tested in the neoadjuvant setting in the ANAPLASTIC-NEO study (ClinicalTrials.gov identifier: NCT04739566).[60] Triplet combinations with immunotherapy have been tested and provided evidence on the efficacy of dabrafenib/trametinib/anti–PD-1 combinations in colorectal cancer.[52,61] Other disease indications and other triplet combinations, for example, with anti-EGFR, are also being explored in clinical trials.[57] Aside from dabrafenib/trametinib, other combinations for BRAF/MEK inhibitors are also being explored in the same context.[2]

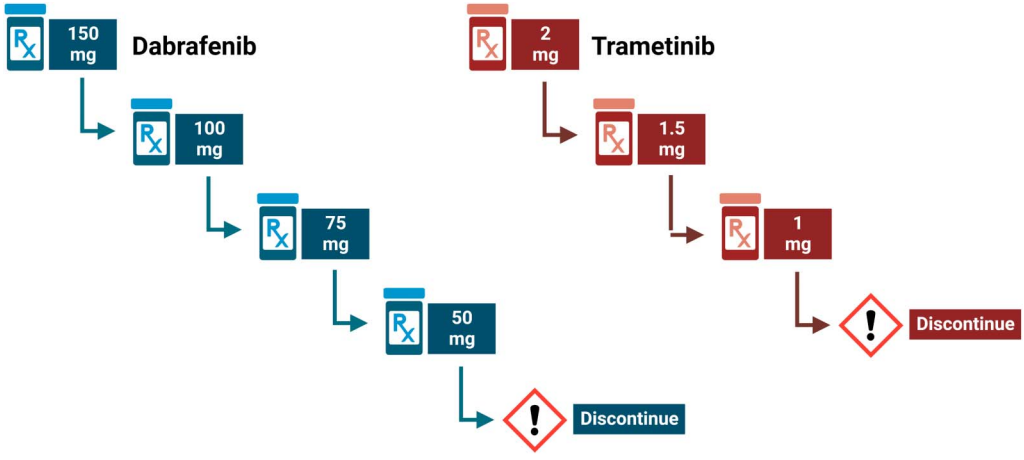

FIG 4. Dose reductions in dabrafenib and trametinib.

For example, vemurafenib plus cobimetinib is currently approved in patients with advanced melanoma on the basis of data from the coBRIM trial (ClinicalTrials.gov identifier: NCT01689519).[62-64] Similarly, encorafenib plus binimetinib is currently approved in patients with advanced melanoma on the basis of data from the COLUMBUS trial (ClinicalTrials.gov identifier: NCT01909453).[65-67] In addition to those combinations, more novel drugs are being explored in therapeutic drug development field as well. Those include novel brain penetrant BRAF inhibitors, BRAF paradox breakers, BRAF dimer inhibitors using an allosteric site, BRAF selective degraders, and mutant-selective degradation by BRAF-targeting proteolysis targeting chimeras (PROTACS).[2,68-74]

CONCLUSIONS

Dabrafenib and trametinib combination has transformed clinical care in *BRAF* V600E–altered cancers by providing an additional option for biomarker-driven therapy in patients with multiple tumor types, especially rare cancers. *BRAF* V600E alterations across solid tumors add to the tissue agnostic precision medicine list of targetable alterations that include neurotrophic tyrosine receptor kinase (NTRK) fusion, microsatellite instability-high phenotype, high tumor mutational burden (≥10 mutations/megabase), and rearranged during transfection (RET) fusions. Evidence supporting the efficacy of dabrafenib/trametinib is substantial in multiple tumor types, including melanoma, NSCLC, anaplastic thyroid cancer, biliary tract cancer, high-grade glioma, low-grade glioma, pediatric cancers, and other tumor types. To ensure that patients with *BRAF* V600E solid tumors who could potentially benefit from dabrafenib plus trametinib are identified, it will be essential to identify these alterations by comprehensive genomic testing.

Equitable Access to Clinical Trials: How Do We Achieve It?

Ana Acuña-Villaorduña, MD[1]; Joaquina Celebre Baranda, MD[2]; Jessica Boehmer, MBA[3]; Lola Fashoyin-Aje, MD, MPH[4]; and Steven D. Gore, MD[5]

overview

The mismatch between the study populations participating in oncology clinical trials and the composition of the targeted cancer population requires urgent amelioration. Regulatory requirements can mandate that trial sponsors enroll diverse study populations and ensure that regulatory revue prioritizes equity and inclusivity. A variety of projects directed at increasing accrual of underserved populations to oncology clinical trials emphasize best practices: broadened eligibility requirements for trials, simplification of trial procedures, community outreach through patient navigators, decentralization of clinical trial procedures and institution of telehealth, and funding to offset costs of travel and lodging. Substantial improvement will require major changes in culture in the educational and professional practice, research, and regulatory communities and will require major increases in public, corporate, and philanthropic funding.

Clinical trials are pivotal for testing novel drugs and establishing new standard-of-care treatments for patients with cancer. The advent of immunotherapy and cellular therapy and the broad use of sequencing techniques allowing the identification of subpopulations more likely to respond to targeted agents have led to an impressive change in the oncology treatment landscape[1] and a decrease in cancer-related mortality.[2] However, there is a noticeable mismatch between populations participating in trials and real-world oncology patients.[3] Data generalizability is jeopardized by the unequal representation of certain groups (ie, racial minorities, elderly, females, patients living in rural areas, and patients with comorbidities, such as HIV, hepatitis, autoimmune disorders, cirrhosis, and renal dysfunction). Thus, the effectiveness of drugs for groups under-represented in pivotal oncology trials is either extrapolated or assessed retrospectively using institutional cohorts or national databases, which is limited by biases and incomplete information.[4-7] Similarly, unequal participation in early-phase cancer clinical trials affects the effective delivery of potentially efficacious investigational therapies to patients with cancer without other available treatment options.[8-14]

Previous reports have extensively summarized barriers affecting access to clinical trials at the patient level (distrust, unawareness, financial status, geography, social support, and logistics issues), provider level (lack of awareness, lack of research workforce, innate bias), study level (restrictive inclusion criteria, complex processes with multiple study visits), and institutional level (deficient screening and trial matching, lack of periodic institutional self-assessments).[15] Equitable access to participation in oncology clinical trials is a crucial step to improve health equity through access to care.[16] Consequently, efforts have focused on identifying and developing tools, resources, and programs to overcome some of these barriers.[17] However, as we face a high-priority, public health problem, there is an urgent need to implement interventions with nationwide outreach. This review focuses on projects and interventions aimed at increasing diversity in the access to cancer clinical trials at regional and national levels.

DIVERSITY IN CANCER CLINICAL TRIALS—US FOOD AND DRUG ADMINISTRATION ONCOLOGY CENTER OF EXCELLENCE PROJECT EQUITY

The US Food and Drug Administration (FDA) has had a long-standing policy recommending that clinical trial sponsors implement measures that help enroll members of historically under-represented populations on the basis of demographic and clinical characteristics.[18-21] Drugs should be evaluated in populations for which they are intended to be used in clinical practice once approved. Enrolling diverse study populations in clinical trials, in a representative fashion, helps improve study results generalizability. In addition, it allows members of all populations to contribute to scientific and clinical discoveries related to the drug under investigation and the disease under study and offers the opportunity for early access to potentially efficacious investigational therapies. A clinical trial may provide the best patient care option for those with serious or life-threatening diseases like

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICE APPLICATIONS

- Study populations for cancer clinical trials do not match the composition of targeted populations for cancer therapies.
- A variety of changes to clinical trial requirements can improve the accrual of patients from underserved populations to cancer clinical trials.
- Linguistic and culturally appropriate patient navigators and simplification of clinical trial procedures, including the use of telehealth, constitute best practices to increase diversity in clinical trial accrual.
- Increased equity and diversity in cancer clinical trials will require substantial changes in oncology culture and will require major investment in appropriate personnel and education.

cancer, many of whom do not have effective approved therapies. Thus, the FDA Oncology Center of Excellence launched Project Equity,[22] a public health initiative aimed at addressing disparities in cancer trials intended to support marketing applications.

Racial and ethnic minorities and older adults have historically been under-represented in cancer research, including clinical trials submitted to the FDA as part of oncology drug development and approval.[11,23,24] The many barriers to clinical trial participation include failure to invite members of racial and ethnic minority populations and older adults to participate in clinical trials, because of bias, socioeconomic factors, and other factors.[25] Gender identity information is not currently routinely collected in cancer trials submitted to the FDA[26]; thus, the extent to which sexual and gender minority patients with cancer are enrolled in oncology clinical trials remains unknown. Geographic location may also be a significant barrier to clinical trial access particularly for those who reside in rural parts of the country and patients living in health professional shortage areas lacking access to large cancer centers.[27,28] In the United States, a study reported that 38%-52% of patients with commonly diagnosed cancer types have commute times longer than an hour to participate in clinical trials, with longer travel times for those residing in Central United States.[28] Geographic accessibility disproportionally affects racial minority groups, with lower rates of clinical trial participation among Black patients living in rural than urban areas.[27] Improving clinical trial accessibility in rural areas is crucial as worse clinical outcomes of patients living in rural areas compared with urban areas dissipate when disparities in access to clinical trials are uniform.[27]

Consequently, the evidence base generated to support the safe and effective use of medical products might have limited external validity, particularly when certain clinical characteristics occur more commonly in the excluded populations. In addition to missing an opportunity to learn about drug effects in a population more reflective of the diversity of patients likely to use the approved drug, the lack of participant diversity can also curtail collection of data that could provide insight on how the disease manifests across the population. Project Equity aims to facilitate improvement in the clinical trial participation rates by focusing on historically under-represented populations in oncology trials on the basis of demographic characteristics, such as race, ethnicity, sex, age, gender, and geographic location.

Project Equity objectives are met through three focus areas: outreach and engagement, policy development, and regulatory science research. Through outreach and engagement efforts with stakeholders (ie, the pharmaceutical and biotechnology industry, patient advocacy, academia), Project Equity provides a regulatory perspective on initiatives to promote health equity and diversity in clinical research, oncology drug development, and regulatory policy. Project Equity priorities are informed by and may be developed and adapted in response to these stakeholder interactions. Inclusive enrollment practices intended to improve diversity in clinical trials can include measures such as designing trials that maximize inclusivity while maintaining patient safety. Broadening eligibility criteria at the outset of a clinical development program, on the basis of known and unknown safety assumptions, may be coupled with re-examination of the need for the previously necessary restrictive criteria as more data accumulate over time. Strategies that enrich for select populations or that allow for extending trial accrual to ensure that a representative population is enrolled may also improve study participant diversity. Additional measures to improve clinical trial diversity can include decreasing the burden of trial recruitment and trial participation by decentralizing some or all aspects of the clinical trial to community settings with fewer access barriers. Decreasing the frequency of study visits could improve clinical trial retention, particularly for those clinical trial participants who face resource barriers. Addressing known barriers (eg, financial reimbursement for travel and lodging); implementing public outreach, education, community engagement, and strategic site selection; and providing language access to participants with limited English language proficiency can also reduce barriers.[21]

Project Equity policy initiatives involve facilitating the integration of an inclusive approach in the review practices of FDA oncology staff. For example, FDA oncology review templates have been revised to ensure that the FDA review process consistently considers representativeness of study

populations enrolled in trials that support approval of oncology medical products. In addition, Project Equity has fostered more comprehensive descriptions of the study population demographic characteristics in oncology product labeling to promote transparency regarding populations enrolled in trials that support drug approval. Project Equity also provides technical assistance on various policy and legislative efforts that support enrollment of underrepresented and special populations in clinical trials. Of note, a major focus of Project Equity policy measures has been ensuring that diversity and inclusion are prioritized as highly as other aspects of drug development during clinical development. This position was outlined previously in a published framework for integrating diversity in the clinical and operational strategy for drug development.[29] On the basis of this framework, the FDA issued a draft guidance for industry on *Diversity Plans to Improve Enrollment of Participants from Underrepresented Racial and Ethnic Populations in Clinical Trials*.[30] The draft guidance provides recommendations to sponsors developing medical products on developing Race and Ethnicity Diversity Plans to enroll representative numbers of participants from underrepresented racial and ethnic populations in the United States, such as Black or African American patients, Hispanic/Latino patients, Indigenous and Native American patients, Asian patients, Native Hawaiian and Other Pacific Islander patients, and other persons of color in clinical trials. The draft guidance outlines the types of medical products for which a diversity plan is recommended, timelines and processes for submitting a diversity plan, and the recommended plan content. While this guidance focuses on racial and ethnic minorities, the FDA encourages the application of these principles to other under-represented populations.

In December 2022, the Food and Drug Omnibus Reform Act of 2022 (FDORA) was enacted, as part of the Consolidated Appropriations Act, 2023.[31] It contains provisions codifying the principles of the draft guidance on Diversity Plans by requiring drug and medical device sponsors to submit Diversity Action Plans for pivotal trials to include sex and age groups. Under FDORA, drug sponsors are required to submit a Diversity Action Plan to FDA, not later than the date on which sponsors submit protocols for the phase III or other pivotal trial. The plan should include goals for enrollment and supporting rationale and an explanation of how the sponsor intends to meet those goals. FDA policy emphasizes implementation of inclusive practices early in clinical development as these measures are likely more effective when the evidence base that informs subsequent clinical trials derives from a diverse population. Despite best efforts, when the planned diversity goals are not achieved, trials conducted once a drug is marketed may provide opportunities in some case to evaluate new therapies in diverse populations.

A plan of action to enroll and retain diverse participants requires a multipronged approach that includes clinical considerations such as broadening eligibility criteria and should also incorporate operational measures and strategies that foster such engagement and collaboration with key stakeholders including global regulatory authorities and community cancer centers. The plan of action includes investment in infrastructure to collect data that will inform understanding of the population receiving care,[32] improve enrollment performance at clinical sites, and sustain community engagement. In addition to site location and access considerations (eg, language assistance for persons with limited English proficiency, reasonable modifications for persons with disabilities, etc), sponsors should consider measures that help reduce potentially burdensome elements of clinical trial design and conduct (eg, reducing the number and frequency of study-related procedures, permitting use of local laboratory/imaging facilities and telehealth, etc).

Clinical trials provide patients the opportunity to access potentially promising investigational treatments, which may be especially important when standard treatment options provide limited benefit or no standard treatments exist. For patients with serious and life-threatening diseases, such as cancer, quick access is important. Policies that improve access are critical to address inequities for historically underserved and under-represented populations.

ENSURING ACCESS TO PRECISION MEDICINE TRIALS FOR UNDER-REPRESENTED POPULATIONS: THE ETCTN CATCH-UP.2020 PROGRAM

Access to quality care including clinical trials leading to paradigm-changing treatments is critical for cancer care and equity in society. Clinical trial participation has been associated with longer 1-year survival in specific cancer types, such as acute myeloid leukemia, prostate, lung, and pancreatic cancers.[33] A report from the SWOG Cancer Research Network suggested that access to clinical trials may bridge the urban and rural divide in cancer care. In line with the FDA policy that acknowledges that the primary aim of phase I trials is to find early evidence of effectiveness, American Society of Clinical Oncology (ASCO) reaffirms its position that phase I trials provide trial participants potential clinical benefit including improved quality of life and psychological and direct medical benefit.[34,35] Disproportionate access to high-quality cancer care, including access to novel therapies through early-phase clinical trials among racial/ethnic minorities and socioeconomically disadvantaged and geographically isolated members of our society, continues to exist. In fact, disparities are worsening in early-phase clinical trial participation among patients from racial and ethnic minority groups.[36]

CATCH-UP.2020: CREATE ACCESS TO TARGETED CANCER THERAPY FOR UNDERSERVED POPULATIONS

In September 2020, the National Cancer Institute's (NCI) Experimental Therapeutics Clinical Trial Network (ETCTN) awarded CATCH-UP.2020, a congressionally budgeted administrative supplement to NCI P30 Cancer Center Support Grants, to 8 NCI-designated cancer centers that were not network members to provide enhanced access to targeted cancer therapy for minority/underserved populations. This 1-year grant, launched during the height of the COVID-19 pandemic, required each site to accrue 24 patients with 50% from underserved populations. Over 18 months (including necessary ramp-up time to set up infrastructure and activate studies), 246 patients were accrued by CATCH-UP centers, including 127 from racial and ethnic, rural, socioeconomic, and Health Professional Shortage Areas (HPSA) under-represented populations, as recently reported.[37] This report will focus on best practices adopted to address barriers in accrual to ETCTN trials in CATCH-UP.2020.

STRATEGIES TO ENHANCE ACCESS AND ACCRUAL TO ETCTN TRIALS IN UNDER-REPRESENTED POPULATIONS

ETCTN clinical trials include phase I, phase I/II, or phase II trials associated with challenges inherent to early-phase trials such as slot availability and enrollment pauses for dose-escalation safety reviews. Sites developed and implemented program-based, investigator-based, and patient-based strategies, some of which were adopted across CATCH-UP sites, whereas others were site-specific.

Program-Based Approaches

Cancer center catchment area demographics, common and uncommon cancers, and gaps in clinical trial portfolio were considered in trial selection. Sites that implemented programmatic changes for rapid activation (such as priority or expedited review by protocol review committees) and increase in number of trials resulted in increased access and accrual. A change in culture was associated with invitation to trial participation to patients from under-represented populations that were historically not offered trials. Less complicated ETCTN trials were opened in community and outreach sites, bringing them closer to patients. Program leaders sought additional funding from cancer centers, local government, and philanthropic resources to offset high-cost research-related procedures such as tumor biopsies and histologic testing where grant funding was insufficient. Progress reports from each site were presented during a monthly virtual conference. NCI program leaders assisted in addressing trial-related questions, and the sites exchanged best practices. Clinical and nonclinical linguistically appropriate patient navigators were successfully used by several sites. By contrast, the bulk screening of genomics studies on patients with cancer for identification of patients did not prove to be an effective strategy.

Investigator-Based Approaches

Each site had a program leader with early-phase research experience and an outreach investigator as a coleader. Disease-Focused Clinical Investigators (DFCI) were selected as local principal investigators (PIs) with effort included in the grant budget to encourage ownership. In each site, one or two early career DFCI were paired with mentors with expertise in drug development. Academic PIs built strong relationship with PIs in community and outreach sites. Investigators prioritized accrual of patients from under-represented populations to ETCTN trials. Training and education of research staff in clinical trial conduct and engagement of under-represented populations were provided by the lead academic organizations.

Patient-Based Approaches

To increase public awareness of this program, many CATCH-UP sites held press releases and outreach events emphasizing the importance of clinical trial participation and the need to promote equity in access. Patient advocacy groups were engaged to understand barriers to accrual to ETCTN. Telehealth was used to prescreen patients, and, in some sites, e-consenting was performed. Financial counseling was offered to patients.

Inadequate access to electronic devices and connectivity by patients, rigidity of trial requirements, initial lack of clarity of e-consenting guidelines, and changes in requirement for practitioners to practice medicine outside the state where they are licensed contributed to underutilization of telehealth. For some trials with complicated study procedures, patients continued to travel long distances. Although industry-sponsored trials often provide travel vouchers, only a couple of CATCH-UP.2020 sites were able to offer full or even partial reimbursement for patients' travel expenses.

Lessons Learned

The successful accrual of large numbers of patients from underserved populations to complex NCI-sponsored early-phase clinical trials despite the COVID-19 pandemic highlights important resource requiring features of future equity-/inclusion-focused clinical trial enhancement programs. These include dedicated clinical investigators compensated for the additional effort required; community-based patient navigators, outreach coordinators, and educators dedicated to the clinical trial mission; novel approaches to longer-distance accrual including telemedicine and the engagement of community oncology treatment centers; and ability to compensate patients and families for the additional expenses involved in participating in high-impact clinical trials.

ADDITIONAL INITIATIVES TO INCREASE ENROLLMENT AMONG UNDER-REPRESENTED POPULATIONS

Educational Modules and Programs for Staff Members

The Association of Community Cancer Centers (ACCC) in collaborating with ASCO supported the assessment of two independent interventions across multiple sites in the United States, including 50-65 academic centers, hospital/health systems, and private practices: Just Ask and Site Self-Assessments. Just Ask included an online training program containing five electronic modules developed using a curriculum offered by the Duke Cancer Institute, followed by evaluations and peer-to-peer discussions. These modules could be completed independently in a timeframe of 60-90 minutes. This training program aimed to address implicit bias among research team members, including study investigators, enrolling clinical staff members, and nonresearch staff members engaging in clinical trials at 50 sites in the country. With over 90% of enrollees completing the training modules and evaluations and an increase in knowledge scores that was sustained over 6 weeks, Just Ask successfully facilitated the process of asking patients about their interest in clinical trials and decreasing implicit bias in this population.[25] Cancer sites conducting research should be encouraged to implement this intervention once a publicly available version becomes available.

Another ongoing initiative launched by the Bristol Myers Squibb Foundation in partnership with Virginia Commonwealth University and the American Association for Cancer Research has focused on increasing diversity in the oncology research workforce by training a new generation of researchers to develop research skills along with a deep sense of community engagement. The educational program Robert A. Winn Diversity in Clinical Trials Program is offered to medical students and early-career investigators from minority groups committed to increasing diversity in clinical trials.[38] The expectation of the program is to train researchers, which will expand the number of community-based sites in the country and diversity in clinical trials.

Site Self-Assessments

Another intervention supported by ASCO-ACCC is a Site Self-Assessment intervention, which used a Plan-Do-Study-Act strategy to assess site performances and identify strategies to overcome deficiencies in the screening process. The first part of the intervention aimed to collect performance measure data. For this, participant sites had to track the number of patients screened, offered, and enrolled in clinical trials by race/ethnicity across 65 sites in the country. In the second part, 36 questions with Likert scale options were used to evaluate opportunities for improvement in several domains. Although the majority of participants identified opportunities for improvement and up to 63% of participants agreed that collecting data of performance measure would increase diversity, most participating sites were unable to provide data in the first part of this intervention. This study reinforced the importance of conducting self-assessment evaluations as a tool to identify strategies to increase the enrollment of under-represented populations.[39] Importantly, it evidenced the urgent need for a standardized, screening tool that could substitute our current screening practices entailing manual review of charts to identify trial participants.

Implementation of a Geriatric Assessment Tool

Adults older than 70 years have been under-represented in cancer clinical trials. Despite constituting 42% of the total cancer population, only 24% of participants in clinical trials are 70 years or older.[40] Historically, several clinical trials have excluded older patients on the basis of an age cutoff rather than a comprehensive functional and cognitive assessment. A study reported that clinical trials were more often discussed with patients with breast cancer younger than 65 years.[41] This might result from unconscious biases or concerns of poor tolerability in this population.[40] Although screening tools should not substitute geriatric assessments, these could serve to discriminate patients who do not require a full assessment and to follow up elderly patients participating in clinical trials.[42] Several geriatric assessment tools have been validated, and most consist of self-administered questionnaires on paper forms. Recently, an electronic geriatric assessment embedded in a data capture system and offered to elderly patients using tablets showed feasibility in a multi-institutional study,[43,44] with 81% of completion rates without help. Notably, 28% of patients were non-Hispanic Black patients. As this tool was only available in English, only 6% of participants identified as Hispanic patients.[43] The implementation of electronic geriatric tools is a promising intervention that could increase the enrollment of elderly patients, and the validation of the tool could allow expansion to other under-represented groups.

Reimbursement Programs

Most clinical trials, and more specifically early-phase studies, may incur additional out-of-pocket costs, leading to financial burden. In a survey among 230 patients enrolled in phase I clinical trials, nearly half of the participants reported unanticipated costs, generally not related to medical care. Financial burden was more prominent among Hispanics and non-Whites.[45] Logistic and financial burden, mainly associated with longer commutes, was identified as an important barrier for participation in clinical trials in a qualitative study. Decentralization of study activities, including treatment, laboratory, or follow-up visits to facilities in their communities, and financial assistance were strategies proposed by participants of this study.[46] An intervention to reimburse travel and lodging expenses among participants in cancer clinical trials who expressed concerns about nonmedical costs at baseline was conducted in a single institution in Massachusetts and

showed improvements in travel-related concerns over time, which was encouraging. However, there were no improvements in general financial well-being, which highlighted the need for a more comprehensive program.[47] This led to further collaboration and an ongoing study supported by the Lazarex Foundation with the Cancer Prevention and Research Institute of Texas to evaluate the effectiveness of a financial reimbursement program aimed to enhance the representation of racial minorities in therapeutic clinical trials by supporting expenses associated with study participation including transportation, lodging, parking, meals, and/or childcare costs across three institutions in the United States.[48]

Moving Equitable Access to Clinical Trials Forward

The experiences summarized here provide reasons to be optimistic and simultaneously remain sobering. Well-funded, intentional projects can facilitate enrollment of populations that face innate racism, structural barriers, and historical distrust and populations for which clinical trial enrollment involves treatment at long distances from academic medical centers. Each of the demonstration projects described here received resources from public and philanthropic funding. They illustrate the importance of several principles that can drive or facilitate enrollment of underserved populations to clinical trials:

1. Regulatory expectations of inclusion and congruence of the constitution of clinical trial cohorts with the targeted treatment population
2. Active change of culture in the research community, which requires education of all personnel interfacing with patients and families
3. Broadened eligibility requirements for trials
4. Simplification of trial procedures to minimize patient travel and inconvenience
5. Community outreach through cultural and linguistically appropriate advocacy groups, patient navigators, and study coordinators
6. Increased use of telehealth and decentralization of clinical trial procedures; facilitation of the delivery of clinical trial procedures at local sites
7. Funding to offset travel costs and lodging. This may require a change in IRB and other regulatory culture in terms of what is considered coercive
8. Each of these principles require significant funding

Although some of these principles appear concrete and can be easily implemented if funding is available, the necessary changes in culture require long-term commitment and willingness among educators, administrators, and practitioners. While many efforts may be bottom-up, locally developed and funded, public-private partnerships to incentivize and enable the necessary changes in culture and practice will be needed for larger impact on our national cancer research infrastructure. An inclusive, diverse clinical trial patient population will lead to cancer treatments that will be feasible across communities.

New Opportunities for Minimizing Toxicity in Rectal Cancer Management

Alice M. Couwenberg, MD, PhD[1]; Dimitrios N. Varvoglis, MD[2]; Brian C. Grieb, MD, PhD[3]; Corrie A.M. Marijnen, MD, PhD[1,4]; Kristen K. Ciombor, MD, MSCI[3]; and Jose G. Guillem, MD, MPH, MBA[5]

overview

Advances in multimodal management of locally advanced rectal cancer (LARC), consisting of preoperative chemotherapy and/or radiotherapy followed by surgery with or without adjuvant chemotherapy, have improved local disease control and patient survival but are associated with significant risk for acute and long-term morbidity. Recently published trials, evaluating treatment dose intensification via the addition of preoperative induction or consolidation chemotherapy (total neoadjuvant therapy [TNT]), have demonstrated improved tumor response rates while maintaining acceptable toxicity. In addition, TNT has led to an increased number of patients achieving a clinical complete response and thus eligible to pursue a nonoperative, organ-preserving, watch and wait approach, thereby avoiding toxicities associated with surgery, such as bowel dysfunction and stoma-related complications. Ongoing trials using immune checkpoint inhibitors in patients with mismatch repair-deficient tumors suggest that this subgroup of patients with LARC could potentially be treated with immunotherapy alone, sparing them the toxicity associated with preoperative treatment and surgery. However, the majority of rectal cancers are mismatch repair-proficient and less responsive to immune checkpoint inhibitors and require multimodal management. The synergy noted in preclinical studies between immunotherapy and radiotherapy on immunogenic tumor cell death has led to the design of ongoing clinical trials that explore the benefit of combining radiotherapy, chemotherapy, and immunotherapy (mainly of immune checkpoint inhibitors) and aim to increase the number of patients eligible for organ preservation.

INTRODUCTION

During the past decades, improvements in the diagnosis and treatment of locally advanced rectal cancer (LARC) have led to improved local control and survival.[1] Currently, the standard of care for LARC includes multimodality treatment with radiotherapy, chemotherapy, and surgery.[2,3] Preoperative management includes the administration short-course radiotherapy (SCRT) or long-course chemoradiotherapy (CRT) which may be proceeded or followed by chemotherapy (total neoadjuvant therapy [TNT]). Surgical options include a sphincter-preserving low anterior resection (LAR) with partial or total mesorectal excision (TME), depending on the distal distance of the rectal cancer from the upper part of the anal sphincters or an abdominoperineal resection (APR) with a resultant permanent colostomy.[4]

Although successful in controlling locoregional disease, this multimodality treatment approach is associated with significant risk for short- and long-term morbidity and a decline in patient's quality of life (QoL).[5-8] For example, the LAR procedure has been associated with a substantial risk for acute and chronic anastomotic complications[5,9] and long-term bowel dysfunction,[10] such as urgency, fecal incontinence, clustering, and frequent bowel movements known as the LAR syndrome (LARS).[11] After an APR, perineal wound infection and delayed closure are not uncommon.[12,13] Furthermore, a permanent colostomy has been associated with a negative effect on patient's body image and well-being.[14] In addition, urogenital and sexual dysfunction issues are often reported after curative rectal cancer surgery.[15] Neoadjuvant radiotherapy further increases the rates of toxicity noted with surgery alone including (1) postoperative perineal complications,[16] (2) LARS,[17-19] and (3) sexual dysfunction.[15,20] Similarly, the addition of induction or consolidation systemic chemotherapy therapy (often including oxaliplatin) to neoadjuvant radiotherapy increases the risk of chemotherapy-related toxicity, such as neurotoxicity.[21]

In this review, we discuss therapeutic treatment options for patients with LARC that have the potential to minimize toxicity including the watch and wait (WW) approach and the evolving role of radiotherapy and immunotherapy in LARC management.

WW AFTER TNT

Until recently, the standard of care for LARC consisted of neoadjuvant CRT, which induces tumor downsizing and thereby increases the chance of radical resection,

PRACTICAL APPLICATIONS

- Total neoadjuvant therapy results in excellent oncological outcomes, with current evidence favoring consolidation over induction chemotherapy.
- Local regrowth in patients after a WW approach may be resected with negative margins in most cases but may compromise sphincter preservation.
- Improved techniques facilitate dose escalation, and doses above 70 Gy may result in increased organ preservation rates.
- Combining immunotherapy and chemoradiotherapy may enhance tumor response and improve organ preservation rates in microsatellite-stable/mismatch repair-proficient patients.
- Neoadjuvant immune therapy demonstrates great promise in the management of MSI-H/mismatch repair-deficient locally advanced rectal cancer and may allow for omission of chemotherapy, radiation, and surgery.

followed by surgery according to the TME principles. This strategy minimized the rates of local recurrences below 10% at 5 years.[22,23] For intermediate-risk tumors in whom downsizing may not be required, SCRT followed by immediate surgery can be considered. Using SCRT in this cohort of patients may be beneficial because SCRT leads to lower early toxicity and similar rates of postoperative complications, late toxicity, health-related QoL, and anorectal and sexual function compared with CRT.[24-28] In addition, SCRT leads to noninferior oncological outcomes compared with CRT.[29] However, several studies demonstrate higher rates of complete response post-CRT compared with post-SCRT even if the interval between completion of SCRT and surgery is prolonged.[29-32] Still, prolongation of this waiting period is seemingly safe as, according to the results of the Stockholm III trial, the chances of radical resection and the risk of postoperative complications are not compromised.[33]

Unfortunately, distant metastases (DM) remain a problem, with 5-year disease-free survival (DFS) rates of about 65% for patients with LARC.[34] The beneficial effect of postoperative adjuvant chemotherapy (aCT) in rectal cancer is limited, especially after CRT.[34] This could be due, in part, to the poor compliance to chemotherapy after major surgery and the possible outgrowth of micrometastatic disease in the time interval between diagnosis and commencement of aCT. Thus, introducing chemotherapy before surgery, in the form of TNT, may improve compliance and efficacy.

According to the National Comprehensive Cancer Network (NCCN) guidelines, TNT is the preferred neoadjuvant treatment modality for most patients with LARC[3] including those with (1) T_3N_{any} lesions with clear mesorectal fascia (MRF) by magnetic resonance imaging (MRI), (2) $T_{1\text{-}2}N_{1\text{-}2}$ lesions, (3) T_3N_{any} lesions with involved or threatened CRM by MRI, and (4) T_4N_{any} lesions with locally unresectable disease or who are medically inoperable. However, the European Society of Medical Oncology (ESMO) guidelines for neoadjuvant treatment differ as they use preoperative MRI to identify risk factors to distinguish between intermediate disease ($cT_{3a/b}$ [very low, levators clear, MRF clear] or $cT_{3a/b}$ in mid or high rectum with $cN_{1\text{-}2}$ [not extranodal, no extramural venous invasion]) and locally advanced disease (>cT_{3b}, extramural venous invasion+ or threatened MRF on MRI).[2] According to ESMO, preoperative radiotherapy, either CRT or SCRT, for patients with intermediate disease is not routinely advised on the basis of the fact that the local recurrence risk should be low if a good-quality TME is performed.[35,36] For patients with a high local recurrence risk, CRT is recommended, whereas for patients with an added risk for DM, TNT is advised.[2] Although these guidelines are designed to risk-stratify and identify patients suitable for TNT, it is important to recognize that there will be cases that on the basis of patient comorbidities, patient preference (sphincter preservation, organ preservation, avoidance of CRT, etc), and tumor location (upper *v* lower) where the decision to pursue TNT versus conventional CRT or up-front surgery will be best made at the multidisciplinary team level, taking all factors into consideration.

The first report on TNT, published in 2006,[37] demonstrated that the addition of capecitabine and oxaliplatin (CAPOX) before the commencement of CRT resulted in a 24% pathological complete response (pCR) rate which was superior to the 15% pCR achieved with standard fluorouracil (FU)–based CRT.[38] The GCR3 randomized phase II trial demonstrated noninferiority regarding pCR rates, increased compliance, and improved toxicity profile with induction CAPOX, followed by CRT and surgery compared with CRT plus surgery.[39] During that time, the group from Memorial Sloan Kettering Cancer Center (MSKCC) gradually altered their treatment paradigm for patients with LARC and noted that approximately 36% of patients treated with TNT were able to achieve a clinical response (CR), defined as either a pCR or a clinical complete response (cCR).[40] The MSKCC group subsequently reported on a larger sample size with 36% CR rate in patients who received TNT compared with 21% CR rate in patients receiving standard CRT.[41] A recent pooled analysis of patients receiving TNT demonstrated that pCR rate for patients undergoing TNT was 22.4%.[42] In addition, a meta-analysis of studies comparing TNT with CRT demonstrated a pCR rate of 29.9% in the TNT group versus 14.9% in the CRT.[43]

The superiority of TNT with respect to pCR rates has recently been confirmed by phase III clinical trials (Tables 1 and 2). The RAPIDO trial, which compared SCRT, followed by consolidation chemotherapy consisting of either six cycles of CAPOX or nine cycles of FOLFOX4 and surgery (TNT arm) with CRT, followed by surgery with or without aCT, demonstrated that patients in the TNT arm achieved higher pCR rates and lower 3- and 5-year DM rates.[21,44] However, the 5-year locoregional recurrence rate was higher in the TNT arm when compared with the CRT arm (10.2% *v* 6.1%).[44] Whether this difference will be confirmed in other studies remains to be determined. The PRODIGE 23 study, which compared induction chemotherapy consisting of six cycles of FOLFIRINOX (oxaliplatin, irinotecan, leucovorin, and fluorouracil), followed by CRT plus surgery with CRT followed by surgery and aCT, demonstrated higher pCR rates, improved 3-year DFS, and lower DM rates in the TNT arm.[45] The results from the CAO/AIO/ARO-12 trial, a study comparing three cycles of induction mFOLFOX6 (modified scheme with fluorouracil, leucovorin, and oxaliplatin) followed by CRT to CRT (with oxaliplatin in both arms) followed by three cycles of consolidation mFOLFOX6, demonstrated that consolidation resulted in better pCR rates when compared with induction chemotherapy.[46] However, 3-year DFS, toxicity, QoL, and stool incontinence were similar between the two groups.[47] The STELLAR study, which compared SCRT followed by four cycles of CAPOX, surgery, and adjuvant two cycles of CAPOX with CRT, followed by surgery and adjuvant six cycles of CAPOX, demonstrated better CR rates and overall survival (OS) in the TNT group compared with the CRT group, but similar 3-year DFS.[48] Of note, the Polish Study, which compared SCRT, followed by three cycles of FOLFOX4 and surgery with CRT (including oxaliplatin) and surgery, failed to demonstrate a significant difference in pCR rates and 3-year DFS.[49] Currently, it is not clear if the better pCR outcomes noted with consolidation are due to the prolonged time interval between TNT completion and surgery or the effect of the chemotherapy itself since it has been demonstrated that waiting more than 10-11 weeks after CRT completion does not improve pCR rates.[50,51]

The recently published Organ Preservation for Rectal Adenocarcinoma (OPRA) trial, a prospective, randomized phase II trial, demonstrated a 3-year DFS of 76% for both consolidation- and induction-based TNT which was similar to historical controls treated with CRT, surgery, and aCT.[52] In addition, organ preservation was achieved in 50% of the entire cohort. The secondary aim of the OPRA trial was to compare consolidation versus induction chemotherapy approaches with respect to organ preservation. In total, 225 patients demonstrating a cCR or near clinical complete response (ncCR; 76% in the consolidation *v* 71% in the induction group) were offered a standardized WW approach. As in the CAO/AIO/ARO-12 trial that demonstrated the superiority of consolidation over induction chemotherapy on the basis of pCR rates, the OPRA trial noted organ preservation to be more likely with the consolidation versus the induction chemotherapy approach (53% *v* 41% respectively).[52]

It appears that one of the first descriptions of what we currently refer to as WW was a case report published in 1929 highlighting significant tumor downsizing and symptom resolution in a patient with rectal cancer treated with radiation therapy alone and careful follow-up.[53] In 2004, to our knowledge, Habr-Gama et al[54] were the first to demonstrate in a group of carefully selected patients who achieved a cCR after CRT and adhered to a very strict follow-up regimen equivalent to 5-year OS and DFS (100% and 92%, respectively) to patients who had undergone surgery after CRT and experienced a pCR. Subsequent reports from multiple international centers[55-59] and a meta-analysis[60] confirmed that patients classified as cCR who pursued a WW approach had similar OS and DFS to patients treated with surgery after CRT. Furthermore, a recent meta-analysis of individual patient data[61] and an analysis of the International WW Database,[62] a multicenter, multinational database that contains data on patients with cCR managed with a WW protocol,[63] demonstrated a 5-year OS ranging between 84.6% and 87%.

Although not uniformly accepted as standard of care, the NCCN guidelines suggest that the WW approach may be considered in centers with experienced multidisciplinary teams[3] after a careful discussion with the patient about their risk tolerance and need for adherence to an extended surveillance program. Reservations with pursuing a WW approach include current limitations with detecting residual disease[64-66] and concerns with leaving behind occult residual disease after the completion of CRT or TNT that may ultimately go on to present as local tumor regrowth. The local regrowth rates in patients who experience a cCR after CRT and pursue WW range from 21.6% to 24.9% at 3-years- follow-up[61,67] and approximately 28% at 5-year follow-up,[61] with the majority occurring within the first 3 years of follow-up (93.4%-96.1%).[61,67] However, the percentage of patients with a local regrowth who can undergo a salvage operation is high (82.5%-95.4%),[60,61,67,68] with the majority achieving an R_0 resection (approximately 79%).[61,67] Furthermore, through conditional survival analyses, it appears that the longer the patient sustains a cCR (ie, the longer they do not develop a local regrowth), the greater the probability of remaining local regrowth free during future follow-up.[69] Another perceived limitation with the WW approach has been the concern for the development of DM. However, the DM rates for patients classified as cCR who pursue WW range between 6.8% and 9.1% at 3-year follow-up[61,62,67] and 10.7% at 5-year follow-up,[69,70] with 71.8% to 78.6% of the DM occurring within the first 3

TABLE 1. Management of Patients Receiving TNT in Phase III Clinical Trials

Study	INCT	SCRT or CRT	CNCT	aCT
RAPIDO[21,44]	NA	Five times × 5 Gy over a maximum of 8 days	Six cycles of CAPOX: (1) capecitabine 1,000 mg/m^2 orally twice per day on days 1-14 and (2) oxaliplatin 130 mg/m^2 IV on day 1, with a chemotherapy-free interval between days 15 and 21 OR nine cycles of FOLFOX4: (1) oxaliplatin 85 mg/m^2 IV on day 1; (2) leucovorin (folinic acid) 200 mg/m^2 IV on days 1 and 2; (3) bolus FU 400 mg/m^2 IV; and (4) FU 600 mg/m^2 IV for 22 hours on days 1 and 2, with a chemotherapy-free interval between days 3 and 14	NA
PRODIGE 23[45]	Six cycles of FOLFIRINOX: (1) oxaliplatin 85 mg/m^2 delivered as 2-hour IV infusion; (2) leucovorin (folinic acid) 400 mg/m^2 delivered as 2-hour IV infusion followed by (3) irinotecan 180 mg/m^2 as a 90-minute IV infusion; and (4) FU 2,400 mg/m^2 continuous IV infusion over 46 hours every 14 days	50 Gy over 5 weeks (2 Gy five times/wk, with a reduction of fields after 44 Gy) and capecitabine 800 mg/m^2 oral twice daily for 5 days/wk	NA	Six cycles of mFOLFOX6: (1) oxaliplatin 85 mg/m^2 given as 2-hour IV infusion; (2) leucovorin (folinic acid) 400 mg/m^2 given as 2-hour IV infusion and followed by (3) FU 400 mg/m^2 given as an IV bolus; and (4) FU 2,4000 mg/m^2 over 46 hours every 14 days OR four cycles of capecitabine 1,250 mg/m^2 twice daily orally on days 1-14 every 21 days
CAO/AIO/ARO-12[46-47,a]	Three cycles of (1) oxaliplatin 100 mg/m^2 delivered as a 2-hour IV infusion; (2) leucovorin (folinic acid) 400 mg/m^2 delivered as a 2-hour IV infusion followed by (3) FU 2,400 mg/m^2 delivered as a continuous infusion over 46 hours repeated on days 1, 15, and 29 for a total of three cycles	50.4 Gy in 28 fractions and continuous infusion of (1) FU 250 mg/m^2 on days 1-14 and days 22-35; (2) oxaliplatin 50 mg/m^2 2-hour IV infusion on days 1, 8, 22, and 29 of radiotherapy	Three cycles of (1) oxaliplatin 100 mg/m^2 delivered as a 2-hour IV infusion; (2) leucovorin (folinic acid) 400 mg/m^2 delivered as a 2-hour IV infusion followed by (3) FU 2,400 mg/m^2 delivered as a continuous infusion over 46 hours repeated on days 57, 71, and 85 for a total of three cycle	NA
STELLAR[48]	NA	Five times × 5 Gy	Four cycles of CAPOX: (1) oxaliplatin 130 mg/m^2 once a day on day 1 and (2) capecitabine 1,000 mg/m^2 twice/d from day 1 to day 14, 7-14 days after the completion of radiotherapy	Two cycles of CAPOX: (1) oxaliplatin 130 mg/m^2 once a day on day 1 and (2) capecitabine 1,000 mg/m^2 twice/d from day 1 to day 14, 7-14 days after the completion of radiotherapy
Polish III[49]		Five times × 5 Gy	Three cycles of FOLFOX4	
OPRA[52,a]	Eight cycles of FOLFOX: (1) oxaliplatin 85 mg/m^2 delivered as IV infusion; (2) leucovorin (folinic acid) 400 mg/m^2 delivered as IV infusion followed by (3) FU 400 mg/m^2 IV push; and (4) FU 2,400 mg/m^2 over 46-48 hours by continuous infusion on a 14-day cycle OR five cycles of CAPOX: (1) oxaliplatin 130 mg/m^2 on day 1 and (2) capecitabine 1,000 mg/m^2 twice a day on days 1-14 repeated on a 21 day cycle	45 Gy in 1.8 Gy over 25 fractions to regional pelvic nodes 50-56 Gy delivered at the primary tumor either as simultaneous integrated boost and/or a sequential boost AND capecitabine 825 mg/m^2 twice a day orally OR FU 225 mg/m^2/d delivered as a continuous infusion during radiotherapy	Eight cycles of FOLFOX: (1) oxaliplatin 85 mg/m^2 delivered as an IV infusion; (2) leucovorin (folinic acid) 400 mg/m^2 delivered as an IV infusion followed by (3) FU 400 mg/m^2 IV push; and (4) FU 2,400 mg/m^2 over 46-48 hours by continuous infusion on a 14-day cycle OR five cycles of CAPOX: (1) oxaliplatin 130 mg/m^2 on day 1 and (2) capecitabine 1,000 mg/m^2 twice a day on days 1-14 repeated on a 21 day cycle	NA

Abbreviations: aCT, adjuvant chemotherapy; CAPOX, capecitabine and oxaliplatin; CNCT, consolidation chemotherapy; CRT, chemoradiotherapy; d, day; FOLFOX, fluorouracil and oxaliplatin; FU, fluorouracil; INCT, induction chemotherapy; IV, intravenously; NA, not applicable; OPRA, Organ Preservation for Rectal Adenocarcinoma; SCRT, short-course radiotherapy.

[a]CAO/AIO/ARO-12 and OPRA compared INCT with CNCT. Patients received either INCT or CNCT, not both.

years of follow-up.[67,70] Since approximately 2%-9%[38,71] of patients who achieve a pCR after CRT and undergo surgery develop a DM at 5-year follow-up, the added risk for DM development in patients pursuing a WW approach may be minimal.

Overall, it appears that current results with a WW approach in patients experiencing a cCR seem acceptable. However, the decision to pursue WW should be shared between the physician and the patient fully informed of the fact that the opportunity for cure may be lost even if a cCR is achieved. Further improvements to WW may be achieved with research dedicated to (1) increasing cCR rates; (2) identifying ncCR patients who will not convert to cCR; (3) identifying cCR patients likely to develop a local regrowth; (4) clarifying the potential role of circulating tumor DNA (ctDNA) to detect persistent disease; (5) overcoming the paucity of long-term outcome data, particularly in younger patients; (6) identifying failure patterns other than endoluminal; (7) accurately capturing QoL in this unique population; and (8) minimizing the burden of surveillance and inequalities in care delivery with a WW approach.

ncCR Conversion to cCR

It appears that patients who experience a ncCR (Table 3) do not fare as well since organ preservation is feasible in only 52% of patients classified as ncCR compared with 79% classified as cCR at 3-year follow-up.[73] Because patients experiencing a ncCR represent a heterogeneous population, half of whom do not progress to cCR, pursuing a WW approach in this population exposes those ultimately requiring an operation to the risks associated with delayed surgery including inferior quality of the mesorectal excision,[74] increased pelvic fibrosis,[51] compromised sphincter preservation,[75] and need for perineal reconstruction.[76] This heterogeneity highlights the urgent need for research dedicated to improving our ability to identify ncCR patients unlikely to achieve a cCR.

cCR and Local Regrowth Development

Similarly, early identification and resection of cCR patients with an increased tendency to develop a local regrowth could potentially benefit this subset of cCR patients since the development of a local regrowth is associated with a decreased likelihood of achieving organ preservation. In fact, in the OPRA trial, patients who underwent surgery after initial restaging had a numerically higher, albeit statistically not significant, rate of sphincter preservation compared with patients who underwent surgery after a local regrowth (55% *v* 44% respectively).[52] Furthermore, two meta-analyses of patients with distally located rectal cancers classified as cCR after CRT who pursued WW demonstrate that in approximately 55% of salvage procedures performed for local regrowth, an APR was required.[61,67]

ctDNA

ctDNA, a marker of residual micrometastatic disease, has recently been demonstrated to identify a subset of patients with colon cancer who would benefit from aCT on the basis of their postoperative ctDNA levels.[77] Although not yet proven, ctDNA may also increase risk stratification and management of patients with LARC. Measurement of ctDNA levels pretreatment and after completion of CRT/TNT may help determine eligibility and improve surveillance of patients pursuing a WW approach. However, the current literature exploring the utility of ctDNA in LARC management remains scarce.[78,79]

Early Age at Onset and WW

The implementation of WW in patients with early age-at-onset rectal cancer should be further investigated, especially given the increasing number of cases noted worldwide.[80-82] Although an analysis demonstrated that patients younger or older than 50 years managed with WW after cCR did not differ in terms of local regrowth and DM rates after 3-year follow-up,[83] long-term follow-up data in this young population with an anticipated long lifespan are needed to accurately assess the long-term incidence of local regrowth and DM and local effects of TNT on pelvic fibrosis and function.

Patterns of Failure

Although after 3 years of follow-up most of the local regrowths appear to be luminal,[62] concerns exist regarding pelvic/regional failures that may become evident with long-term follow-up. These concerns arise from the observation that the rate of downstaging may be greater in the primary tumor than in the regional lymph nodes (LNs).[84,85] In addition, a prospective pathological analysis of patients with LARC undergoing CRT demonstrated that approximately 18% of LNs are located in the region above the current standard field of external beam radiation therapy (EBRT), suggesting that a fraction of LN in patients pursuing a WW approach after TNT will have only been treated with systemic chemotherapy and not EBRT.[86] Long-term results on patterns of failure (either pathological confirmation on those who undergo surgery or serial imaging demonstrating progressive growth) after a WW approach could potentially lead to modifications in the radiotherapy target volumes.

QoL

In addition to achieving good oncological outcomes, a parallel goal of the WW approach is the improvement of patients' QoL. Although the literature is limited, it appears that one third of patients who follow a WW approach report symptoms consistent with a LARS, despite not undergoing surgery, a finding that highlights the late effects of radiation therapy to the rectum and pelvic floor musculature.[87,88] The development of a validated instrument that accurately

TABLE 3. Criteria for Patient Classification as cCR, ncCR, and iCR According to the International Consensus Recommendations[72]

Modality	cCR[a]	ncCR	iCR
DRE	Absence of palpable tumor material	Presence of small and smooth regular irregularities	The presence of a palpable tumor mass
Endoscopy	No residual tumor material or only a small erythematous ulcer or a scar	Presence of small and smooth regular irregularities, including residual ulcer or small mucosal modules or minor mucosal abnormalities, with mild persisting erythema of the scar	Presence of a visible macroscopic tumor
MRI[b]	Substantial downsizing with no observable residual tumor material or residual fibrosis only (with limited signal on DWI), sometimes associated with residual wall thickening because of edema, no suspicious lymph nodes	Obvious downstaging with residual fibrosis but heterogeneous or irregular aspects and signal regression or regression of lymph nodes with no malignant enhancement features, but with a size of >5 mm	Patients not fulfilling criteria for cCR nor ncCR

Abbreviations: cCR, complete clinical response; DRE, digital rectal examination; DWI, diffusion-weighted imaging; iCR, incomplete clinical response; MRI, magnetic resonance imaging; ncCR, near complete clinical response.

[a]All criteria including DRE, endoscopy, and MRI should be fulfilled to define a cCR.

[b]Gadolinium contrast medium is no longer compulsory for MRI conducted with the aim of defining a cCR.

measures sexual, bowel, and urinary dysfunctional issues after a nonoperative WW approach is needed to accurately capture the QoL in this unique patient population.[72]

Burden of Surveillance and Equity in Care

The current follow-up regimen of the WW approach (Table 4) translates into 16 outpatient visits over the course of at least 60 months, assuming optimal coordination of single-day scheduling of all five assessment modalities (carcinoembryonic antigen, digital rectal examination, MRI, endoscopy, and computed tomography).[72] This intensive follow-up regimen may be challenging to adhere to and highlights the need to carefully advise patients and families of the long-term commitment of time and resources required to be compliant with a WW surveillance approach. The fact that different sectors of our patient population may not have the resources to support this follow-up regimen suggests that a WW approach may potentially propagate the existing disparities in the treatment of LARC. Thus, research on the feasibility of the WW approach in areas that are limited in resources should be pursued and encouraged.

ADVANCES IN RADIOTHERAPY

Radiotherapy Dose Escalation

In the past, radiotherapy dose escalation was considered impossible because of technical constraints and fear of grave toxicity. However, in the past decades, the technique of external beam radiotherapy for rectal cancer has emerged, and it has been shown that high doses of radiotherapy increase the number of patients achieving a pCR or cCR.[89] In addition, the conventional three- or four-field technique, leading to a large high-dose volume, has been replaced by intensity-modulated radiotherapy or volumetric-modulated arc therapy, which allows for a more conformal coverage of the target volume. The introduction of image-guided radiotherapy enables further reduction of the required safety margins. Novel radiotherapy techniques, such as magnetic ressonance (MR)-guided radiotherapy, facilitate daily delineation of the target volume with adaptation of the dose distribution. This may permit a 30% reduction of the high-dose volume, a gain which facilitates dose escalation allowing for higher response rates. The smaller treatment margins and better visibility of the pelvic anatomy may therefore enhance sparing of the sphincter complex and pelvic floor musculature.[90,91]

The recently published phase III randomized controlled OPERA trial demonstrated a 3-year organ preservation rate of 81% after a contact x-ray brachytherapy boost (3 × 30 Gy combined with 45 Gy CRT) in early- and intermediate-stage rectal cancers.[92] The effects of contact x-ray brachytherapy boost on LARC are currently investigated in the OPAXX study, where ncCR patients after SCRT or CRT are randomly assigned to receive either contact therapy boost or undergo prolonged observation with local excision, if needed.[93]

Although radiotherapy dose escalation holds great promise for organ preservation, its long-term toxicity remains a concern since the high radiation doses delivered to the tumor and adjacent bowel wall increase the risk of long-term toxicity.[94] In the aforementioned OPERA trial, despite the lack of late grade 3-5 toxicities, 19% of the patients reported major LARS at 1-year follow-up and 63% experienced late grade 1-2 rectal bleeding caused by telangiectasia.[92] Similarly, late proctitis and bleeding complications were observed in the HERBERT trial which evaluated high-dose rate endorectal brachytherapy boost post-EBRT in the elderly patients.[95] In addition, the RECTAL-BOOST trial, a randomized phase II trial comparing external radiation boost before CRT, followed by TME with standard CRT, followed by TME, demonstrated that patients in the boost group reported worse global health, physical role, and social functioning compared with the standard CRT group at 3 and

6 months of follow-up. However, despite more fecal blood/mucous reported in the boost group, the QoL was similar between the groups after 12 months of follow-up.[96]

Radiotherapy and Immunotherapy

It is hypothesized that the addition of immunotherapy, primarily checkpoint inhibitors, in the neoadjuvant setting may improve tumor response and thereby facilitates organ preservation while reducing the risk of DMs. A small subset of patients with LARC are found to be microsatellite instability-high (MSI-H) defined via polymerase chain reaction sequencing or mismatch repair-deficient (dMMR) on immunohistochemistry testing. In these patients, neoadjuvant immunotherapy has resulted in incredibly high cCR rates, as described below.[97,98] However, most patients with LARC have microsatellite stable (MSS) or mismatch repair-proficient (pMMR) tumors and therefore are more likely to potentially benefit from a multimodal (chemo) radioimmunotherapy approach than immunotherapy monotherapy, a claim supported by ongoing clinical trials demonstrating promising pCR and cCR rates (Table 5).[99,106.]

The effects of radiotherapy on the increase of T cells and PD-L1/PD-1 and CTLA-4 expression provide a rationale for the combination of radiation therapy with immune checkpoint inhibitors.[109] Preclinical studies in various tumor models have shown synergy with this combination.[110-112] However, the heterogeneity of results highlights the complex balance between immune stimulation and suppression induced by radiation, which may be dependent on (1) patient and tumor factors, (2) timing and sequencing of radiotherapy with immunotherapy, (3) radiation dose and fractionation, and (4) radiotherapy technique, planning, dose rate, and target volume. For example, in mouse models that received fractionated radiotherapy, PD-L1 expression was upregulated with concurrent (but not sequential) administration of anti–PD-1/PD-L1 antibodies, leading to enhanced immune response, immune memory, and better OS.[113] Conversely, the administration of anti–CTLA-4 agents several days before the administration of high-fraction radiotherapy seems to facilitate the synergy between the two modalities via T-regulatory cell depletion.[114] Furthermore, hypofractionated schedules, such as 24 Gy in three fractions, may be more immunogenic than conventional schedules or a single high-dose fraction.[115-119] In addition, the implementation of smaller radiation fields, shorter treatment duration, and

TABLE 5. Response Rates to Immunotherapy-Containing Treatment Regimens in MMR Proficient Locally Advanced Rectal Cancer

Study	Patient Population	Treatment Regimen	Sample Size	Tumor Response
Lin et al[99]	cT3-4N0M0 or cT1-4N + M0	SCRT followed by two cycles of CAPOX with camrelizumab followed by surgery after 1 week	N = 30 (28 pMMR, one dMMR, one unknown), 27 for evaluation	pCR rate: 48.1% (13/27, one patient with dMMR)
AVERECTAL trial (meeting abstract ESMO 2021)[100]	cT2 N1-3, cT3 N0-3, evidence of extramural vascular or MRF involvement	SCRT followed by six cycles of mFOLFOX-6 plus avelumab followed by surgery after 3-4 weeks	N = 44, 40 patients for evaluation	pCR rate: 37.5% (15/40); near complete response rate (TRG 1): 30% (12/40)
TORCH (meeting abstract ASCO 2022)[101]	T3-4/N + M0, distance from anus ≤10 cm	Randomly assigned to receive consolidation arm (A) SCRT followed by six cycles of ToriCAPOX or induction arm (B) two cycles of ToriCAPOX followed by SCRT followed by four cycles of ToriCAPOX Both groups receive curative surgery or WW strategy	N = 67, 11 patients for evaluation (all pMMR)	CR rate (pCR + cCR): 81.8% (9/11); pCR rate: 77.8% (7/9)
NRG-GI002, Rahma et al[102]	Stage II/III with distal location (cT3-4 ≤5 cm from anal verge, any N), with bulky disease (any cT4 or tumor within 3 mm of MRF), at high risk for metastatic disease (cN2), and/or who were not candidates for sphincter-sparing surgery	Randomly assigned to receive six cycles of FOLFOX followed by CRT (control arm) or the same dosage of FOLFOX followed by CRT with concurrent pembrolizumab (pembro arm). Surgery was performed 8-12 weeks after the last dose of radiotherapy	N = 185 (95 patients in control arm and 95 in pembro arm), 137 for evaluation	Mean (SD) NAR score: 11.53 (12.43) for the pembro arm *v* 14.08 (13.82) for the control arm ($P = .26$); pCR rate: 31.9% in the pembro arm *v* 29.4% in the control arm ($P = .75$); cCR rate: 13.9% in the pembro arm *v* 13.6% in the control arm ($P = .95$).
NCRT-PD-1-LARC trial, Gao et al[103]	Mid-to-low cT3-4a N0M0 or cT1-4a N1-2M0	CRT with concurrent three 21-day cycles of tislelizumab followed by a radical surgery 6-8 weeks after radiotherapy	N = 26 (all pMMR)	pCR rate: 50% (13/26); TRG 0: 53.8% (14/26); TRG 1: 26.9% (7/26); TRG 2: 19.2% (5/26); NAR score 7.2 ± 10.4
R-IMMUNE trial (meeting abstract ESMO 2021)[104]	cT3-T4 N0 or T any or N1-2, M0	CRT with concurrent atezolizumab (four infusions at weeks 3, 6, 9, and 12). Surgery planned at week 15	N = 26 (interim analysis), 25 patients for evaluation	pCR rate: 24% (6/25)
AVANA trial (meeting abstract ASCO 2021)[105]	At least one of the following features: cN+, cT4, high risk cT3	CRT with concurrent six cycles of avelumab followed by surgery at 8-10 weeks after the end of CRT	N = 101, 96 patients (one patient with dMMR) for evaluation	pCR rate: 23% (22/96); major pathological response: 61.5% (59/96)
VOLTAGE trial, Bando et al[106]	cT3-4 N0-2 M0	CRT followed by five cycles of nivolumab and surgery	N = 39 (pMMR), 37 patients for evaluation	pCR rate: 30% (11/37); TRG: 0-1 38% (14/37); median NAR score: 8.4 (0.0-50.4)
NSABP FR-2 trial (meeting abstract ASCO 2022)[107]	Stage II-IV, pMMR	CRT followed by durvalumab within 3-7 days after CRT completion followed by surgery within 8-12 weeks after CRT	N = 45, 40 patients for evaluation	Mean modified NAR score: 12.03; pCR rate: 22.2%; cCR rate: 31.1%
PANDORA (meeting abstract ASCO 2022)[108]	cT3/4N0/M0 or Tx N1-2/M0	CRT followed by durvalumab and surgery after 10-12 weeks from neoadjuvant therapy	N = 60, 55 patients for evaluation	pCR rate: 32.7% (18/55); near complete regression, moderate and minimal regression in 14 (25.5%), 9 (16.4%) and 11 (20.0%) patients, respectively

Abbreviations: CAPOX, capecitabine plus oxaliplatin; cCR, clinical complete response; CR, complete response; CRT, chemoradiation; dMMR, deficient mismatch repair; LARC, locally advanced rectal cancer; mFOLFOX, modified fluorouracil and oxaliplatin; MMR, mismatch repair; MRF, mesorectal fascia; NAR score, neoadjuvant rectal score; pCR, pathological complete response; pMMR, proficient mismatch repair; SCRT, short-course radiotherapy; SD, standard deviation; ToriCAPOX, toripalimab plus capecitabine and oxaliplatin; TRG, tumor regression grade; WW, watch and wait.

avoidance of low dose baths may save the extremely radiation-sensitive T cells and thereby enhance immune response.[120] Overall, these results suggest that for each tumor type there might be an optimal combination of radiation dose and checkpoint inhibitors for inducing antitumor immunity.

For patients with LARC, ongoing (chemo)radiotherapy-immunotherapy studies evaluating multiple sequencing options, including TNT (using conventional SCRT or CRT schemes) with concurrent or sequential immunotherapy (mainly PD-1 or PD-L1 checkpoint inhibitors) and with or without chemotherapy such as CAPOX and fluorouracil and oxaliplatin (FOLFOX),[121] will provide new insights in how to optimize immunotherapy with radiotherapy. Below, we describe (preliminary) outcomes of the first trials in LARC with pMMR/MSS tumors.

Radiotherapy-Immunotherapy Trials in Locally Advanced Rectal Cancer

Three studies evaluating SCRT and induction or consolidation immunotherapy have presented toxicity outcomes and response rates.[99-101] A single-arm, phase II trial evaluated SCRT followed by CAPOX with camrelizumab (anti-PD-1) followed by surgery after 1 week in patients with $T_{3\text{-}4}N_0M_0$ or $T_{1\text{-}4}N_+M_0$ rectal cancer.[99] Of the 30 patients enrolled (of note, one had MSI-H disease), 27 received at least one dose of CAPOX plus camrelizumab. The pCR rate was 48.1%. Grade 1-2 immune-related adverse events (AEs), which consisted mostly of skin reactions, occurred in 88.9% of the population. Any grade 3 AE occurred in 26.7% and consisted mainly of hematological toxicity. None of the patients demonstrated grade 4/5 AEs. The AVERECTAL study, a single-arm, multicenter, phase II two-stage trial evaluated SCRT, followed by mFOLFOX-6 plus avelumab (anti-PD-L1) and surgery 3-4 weeks after in patients with LARC ($cT_2N_{1\text{-}3}$, $cT_3N_{0\text{-}3}$, evidence of extramural vascular, or MRF involvement), presented the outcomes of 44 patients at ESMO 2021.[100] The pCR rate was 37.5%, and ncCR was 30%. Grade 3, 4, and 5 AEs were 58.1%, 11.6%, and 2.3% (one patient died of cardiopulmonary arrest), respectively, none of which were related to acute effects of avelumab. The TORCH trial, a multicenter phase II trial, randomly assigned patients with LARC ($T_{3\text{-}4}/N_+M_0$, distance from anus $\leq$10 cm) to a consolidation arm including SCRT followed by toripalimab (anti-PD-1) plus capecitabine and oxaliplatin (ToriCAPOX) or an induction arm including ToriCAPOX followed by SCRT followed by ToriCAPOX and presented the first outcomes of 11 patients at ASCO 2022.[101] Both groups receive curative surgery or WW. In this small group of patients, a high complete response rate (pCR + cCRT) was observed (81% of which the pCR rate was 77.8%). Grade 3 AE included thrombocytopenia in 36.4% of the patients. No grade 4-5 AEs were observed (Table 5).

TABLE 6. Clinical Trial Results in Patients With dMMR Localized Colorectal Cancer

Study	Patient Population	Treatment Regimen	Sample Size	Study End Point
Cercek et al[123]	Patients with pMMR and dMMR LARC undergoing neoadjuvant therapy	Neoadjuvant chemotherapy (FOLFOX)	N = 21 (dMMR); N = 63 (pMMR)	6/21 (29%) dMMR with disease progression; 0/63 pMMR with disease progression
De Rosa et al[124]	Patients with dMMR LARC undergoing neoadjuvant therapy	Neoadjuvant chemotherapy and long-course radiation followed by surgical resection	N = 29	8/29 (27.6%) with pCR (one additional patient had cCR and declined surgery)
Cercek et al (ASCO 2022)[125]	Patients with dMMR LARC undergoing neoadjuvant immunotherapy	Dostarlimab × 6 months	N = 14	14/14 (100%) with cCR
NICHE-1; Chalabi et al[97]	Patients with dMMR and pMMR colon cancer undergoing neoadjuvant immunotherapy and surgery	Nivolumab/ipilimumab × 1, then nivolumab × 1, then surgical resection; pMMR patients ± celecoxib	N = 35 patients (20 dMMR, 15 pMMR)	12/20 (60%) dMMR with pCR, 2/15 (13.3%) pMMR with pCR
NICHE-2; Chalabi et al[126]	Patients with dMMR colon cancer undergoing neoadjuvant immunotherapy and surgery	Nivolumab/ipilimumab × 1, then nivolumab × 1, then surgical resection	N = 107	72/107 (67%) dMMR with pCR
Ludford et al[127]	Patients with localized unresectable or high-risk resectable dMMR tumors	Pembrolizumab ± surgical resection	N = 35 (19 colon, 8 rectal, 8 noncolorectal); 33 evaluable; 17 underwent surgery	11/17 (65%) with pCR; 27/33 (82%) ORR

Abbreviations: cCR, clinical complete response; dMMR, deficient mismatch repair; FOLFOX, fluorouracil and oxaliplatin; LARC, locally advanced rectal cancer; ORR, overall response rate; pCR, pathologic complete response; pMMR, proficient mismatch repair.

Four studies evaluated CRT with concurrent immunotherapy.[102-105] The NRG-GI002 trial, a phase II randomized trial, compared FOLFOX followed by CRT (control arm) with FOLFOX followed by CRT with concurrent pembrolizumab in patients with stage II/III rectal cancer.[102] Surgery was performed 8-12 weeks after CRT. The neoadjuvant rectal (NAR) score (on the basis of clinical T stage and pathologic T and N stages), the primary outcome evaluated in 137 patients (95 patients in the control arm and 95 in the intervention arm), was comparable between the groups, as well as the pCR rate and the cCR rate. Grade 3-4 AEs were observed in 48.2% of the patients in the intervention arm and 37.3% in the control arm during CRT. Two patients died during FOLFOX treatment because of sepsis (control arm) and pneumonia (intervention arm). The NCRT-PD-1-LARC trial evaluated CRT with concurrent tislelizumab (anti-PD-1) followed by a radical surgery 6-8 weeks after CRT in a multicenter, single-arm phase II trial.[103] On the basis of the interim analysis of the first 26 patients, the pCR rate was 50%. Immune-related AEs occurred in 19.2%, including one grade 3 event (immune-related colitis) and no grade 4-5. The R-IMMUNE trial, a multicenter phase Ib/II single-arm trial, evaluated CRT with concurrent atezolizumab followed by surgery and presented the interim results of 26 patients at ESMO 2021.[104] The pCR rate was 24% (on the basis of 25 patients). Grade 3-4 AEs were observed in 34.6% (mostly postoperative complications). The AVANA study, presented at ASCO 2021, is a multicenter phase II study in LARC (with at least one of the following features: cN_+, cT_4, and high-risk cT_3) whiche-valuated CRT with concurrent avelumab followed by surgery at 8-10 weeks after CRT.[105] Of the 101 study patients, including one MSI-H tumor, 96 were evaluable for pathological response. The pCR rate was 23%, and major pathological response was observed in 61.5%. Grade 3-4 nonimmune and immune-related AEs were observed in 8% and 4% of the patients, respectively.

Three studies have evaluated CRT with sequential immunotherapy.[106-108] The VOLTAGE study, a phase I-II trial evaluated CRT followed by nivolumab (anti–PD-1) and surgery in patients with MSS and MSI-H LARC, that is, $T_{3-4}N_{0-2}M_0$.[106] Among the 37 MSS patients, pCR was noted in 30%, near-pCR in 8%, and cCR in 3% who adopted the WW approach. Serious AEs related to nivolumab or surgery were reported in eight patients, and immune-related severe AEs were observed in three patients (grade 3 myasthenia, grade 3 interstitial nephritis, and grade 2 peripheral motor neuropathy). During the follow-up period, one patient developed grade 2 colitis. The NSABP FR-2 study is a phase II trial in stage II/III evaluating neoadjuvant CRT followed by durvalumab (anti–PDL-1) within 3-7 days after CRT completion followed by surgery within 8-12 weeks after CRT. Preliminary results demonstrated a mean modified NAR score of 12.03 in 40 patients, pCR in 22.2%, and cCR in 31.1%.[107] Most common grade 3 AEs included diarrhea, lymphopenia, and back pain. There was one grade 4 AE (elevated amylase/lipase) and no grade 5. The PANDORA study is a phase II multicenter trial in patients with LARC evaluating CRT followed by durvalumab and surgery after 10-12 weeks from neoadjuvant therapy and was presented at ASCO 2022. Preliminary results on 55 patients demonstrated a pCR rate of 32.7% and a near complete regression of 25.5%.[108] Grade 1-2 immune-related AE was observed in 36.4%, whereas grade 3 toxicity was seen in 7.3% and included diarrhea, skin toxicity, transaminase and lipase increase, and pancolitis. No grade 4-5 AEs were observed. Although promising, more confirmatory data are needed before immunotherapy can be considered standard of care.

NEOADJUVANT IMMUNOTHERAPY IN MSI-H/dMMR LOCALLY ADVANCED RECTAL CANCER

Although patients with MSI-H/dMMR LARC can have a limited response to FU and oxaliplatin chemotherapy,[123] these dMMR tumors often respond well to chemoradiation. In fact, one retrospective study of patients with dMMR LARC undergoing fluoropyrimidine-based neoadjuvant chemoradiation followed by surgery demonstrated a 27.6% pCR rate with one additional patient achieving cCR and declining surgery.[124] Although not a head-to-head comparison, these results compare favorably with historical pCR rates of approximately 15% in patients with MSS/pMMR disease who undergo neoadjuvant chemoradiation (Table 6).[27]

Concerns regarding inefficacy and toxicities with standard treatment in this population along with high response rates and survival benefit in the metastatic setting for MSI-H/dMMR colorectal cancer (CRC) treated with immunotherapy led to the design of a single-institution study evaluating the use of neoadjuvant immunotherapy for MSI-H/dMMR LARC.[98,128-132] This single-arm phase II study is enrolling patients with stage II and III dMMR/MSI-H rectal adenocarcinoma. Eligible patients are treated with dostarlimab, an anti–PD-1 antibody, every 3 weeks for 6 months. At the completion of therapy, tumor response is assessed by DRE, endoscopy, and MRI. If a cCR is detected (defined as visual disappearance of the rectal primary on endoscopy, a normal DRE, and lack of primary tumor signal and disappearance of pathologically enlarged LNs on pelvic MRI), patients are eligible to pursue a WW approach. Otherwise, patients proceed to standard CRT, followed by surgery. The majority of the first 18 patients treated had T_3/T_4 tumors and node-positive disease (78% and 94%, respectively). Of interest, 59% had evidence of MMR germline mutations in *MSH2*, *MLH1*, *MSH6*, or *PMS2*, with no concomitant *BRAF V600E* mutations noted. With a median follow-up of 6.8 months (0.7-23.8 months), all 14 consecutively treated patients who completed 6 months of dostarlimab therapy achieved a cCR.

Grade 1 and 2 AEs included rash, dermatitis, pruritus, nausea, and thyroid function abnormalities. Thus far, none of the treated patients have required chemotherapy, radiation, or surgery, and no grade 3 or 4 AEs have been observed.[98] In another study of anti–PD-1 therapy in patients with MSI-H/dMMR LARC in China, 17 patients were treated initially with neoadjuvant sintilimab monotherapy.[133] Of 16 evaluable patients, nine achieved a cCR with sintilimab alone and refused surgery, and three of six patients who underwent surgery had a pCR. Although most patients did well with neoadjuvant immunotherapy, unfortunately one patient had a serious AE of grade 3 encephalitis, and one patient had primary progression on neoadjuvant sintilimab therapy.

Although the sample sizes of these two MSI-H/dMMR LARC studies are small and confirmatory studies with larger sample sizes and longer follow-up are needed, these preliminary results of neoadjuvant immunotherapy in rectal cancer are promising. These findings are also supported by other recent studies in colon cancer, which together suggest that neoadjuvant immunotherapy in localized CRC may be more promising than even as definitive therapy in the metastatic setting, in which overall tumor burden and systemic immunosuppression may dampen treatment responses.

For instance, building on intriguing efficacy noted in the NICHE trial which combined nivolumab (anti-PD1 antibody) and ipilimumab (anti-CTLA4 antibody) in the neoadjuvant setting for colon cancer,[97] the NICHE-2 trial examined the efficacy of nivolumab/ipilimumab in patients with MSI-H/dMMR localized colon cancer.[126] Of 112 patients in the intention-to-treat population, 74% were considered to have high-risk stage III disease, with 48% having cT_4 and N_2 on radiologic staging. Overall, 31% of patients were known to have Lynch syndrome. Doublet immunotherapy, albeit with a limited course of c1d1 nivolumab/ipilimumab and c1d15 nivolumab, resulted in any AEs in 61% of the patients. However, only 4% experienced grade 3 or 4 toxicities, such as elevated amylase/lipase, hepatitis, myositis, or rash. Of the 107 patients included in the efficacy analysis, 67% had a pCR, and 95% had a major pathologic response, defined as 10% or less residual viable tumor at surgical resection.

A recent study investigating the use of pembrolizumab in patients with localized unresectable or high-risk MSI-H/dMMR solid tumors demonstrated in the subset of patients with CRC receiving varying amounts of pembrolizumab a pCR rate of 79%.[127] However, with a median follow-up of almost 9.5 months (range, 0-26 months) among 17 patients with GI tumors managed with a nonoperative approach, two patients in this study (one colon and one rectal) demonstrated disease progression events. It should be noted that the eight patients with rectal cancer demonstrated heterogeneous responses with one displaying innate resistance to treatment and disease progression after two cycles of pembrolizumab and one with adaptive resistance and disease progression at 9 months. Although this approach was overall promising in the majority of patients, these results do raise some concern and illustrate the need for additional studies investigating the underlying biological basis for response and resistance to immunotherapy in this specialized cohort of patients and in localized CRC in general.

Currently, the optimal duration and regimen of immunotherapy (anti-PD1 monotherapy *v* anti–PD-1/anti-CTLA4 doublet) remain unclear. The results of ongoing studies including the dostarlimab study and EA2201, a phase II trial of neoadjuvant nivolumab and ipilimumab in MSI-H/dMMR LARC with or without SCRT therapy depending on response to immunotherapy,[134] and ongoing correlative studies exploring the utility of ctDNA are eagerly awaited. Nevertheless, on the basis of published reports, neoadjuvant immunotherapy in the treatment of MSI-H/dMMR LARC holds significant promise to simplify the therapeutic landscape and minimize toxicities for patients who would have previously received trimodality therapy, thereby providing an opportunity for personalized therapy, reduction of toxicity, and improvement in QoL.

CONCLUSION

The development of TNT has resulted in improved oncological outcomes with current evidence favoring consolidation over induction chemotherapy. In addition, TNT has resulted in increased response rates such that with careful patient selection and follow-up, organ preservation may be feasible in approximately half of the patients pursuing a WW approach. Although patients developing a local regrowth may undergo a salvage resection, in some cases, sphincter preservation and/or resection margins may be compromised. On the basis of current nonrandomized, highly heterogeneous data, it appears that rates of DM approximate those in patients undergoing surgery and achieving a pCR suggesting that a WW approach in carefully selected, highly informed patients with long-term follow-up by experienced multidisciplinary teams may be safely pursued.

Advances in radiotherapy techniques have facilitated dose escalation and allow for safe administration of doses over 70 Gy which may result in increased organ preservation rates. The synergism noted, in preclinical studies, between immmunotherapy and chemoradiotherapy on immunogenic cell death may also enhance tumor response and improve organ preservation rates for patients with MSS/pMMR tumors. Although patients with MSI-H/dMMR tumors may respond poorly to neoadjuvant chemotherapy, they often respond well to concurrent chemoradiation. In

addition, neoadjuvant immunotherapy demonstrates great promise in the management of MSI-H/dMMR LARC and may allow for omission of chemotherapy, radiation, and surgery. Therefore, identification of patients with MSI-H/dMMR LARC is critical to optimize treatment decision making.

Early-Onset GI Cancers: Rising Trends, Genetic Risks, Novel Strategies, and Special Considerations

Emily Harrold, MB, BCH, BAO, MRCPI[1]; Alicia Latham, MD, MS[1]; Naveen Pemmaraju, MD[2]; and Christopher H. Lieu, MD, FASCO[3]

Overview

Cancers in young adults (commonly described as early-onset [EO] cancer) represent a group of malignancies that have unique and challenging biology and genetic, treatment, social, and psychological implications. Even more concerning is a rising trend of EO cancers in multiple tumor types. Research and investigation in EO cancers will help elucidate mechanisms of carcinogenesis, differences in biology and response to treatment, and the need for multidisciplinary care to ensure comprehensive treatment and support for young patients.

INTRODUCTION

Historically, cancer has been considered predominantly a disease associated with aging with multifactorial etiology.[1] Early-onset (EO) cancer has conventionally been defined as cancer occurring in adults age between 18 and 49 years. Across a number of global analyses, we are seeing a paradigm shift in the ages at which some of the most common cancers are being diagnosed for reasons that are not entirely clear.[2-5] GLOBOCAN data analyses demonstrate rising incidence of cancers of the colorectum, extrahepatic bile duct, gallbladder, liver, pancreas, stomach, breast, endometrium, bone marrow, thyroid, head and neck, kidney, and prostate.[6] This concerning emerging trend has been listed as a research priority by the US National Cancer Institute, and global research efforts are being made to determine the relative contributions of both known and unknown risk factors to this EO epidemic, particularly with regard to EO colorectal cancer (EO-CRC).[4] Recent evidence also recapitulates this worrying trend across the GI cancer spectrum including gastric, pancreatic, and biliary tract cancers,[7] and for the purposes of this review, we have focused on this spectrum of EO GI malignancies. One prevailing theory is that the significantly altered early life exposome which includes dietary and lifestyle factors, environmental carcinogens, obesity, and antibiotic exposure among others that is characteristic of the 20th century living is playing a central role in this EO cancer epidemic.[3] The influence of the microbiome on immune system development, and indeed carcinogenesis, is being increasingly recognized, and ongoing research may help to further elucidate the relationship between host and exogenous factors and implications for EO cancers (Fig 1).[8,9]

EO-CRC: RISING INCIDENCE AND OPPORTUNITIES FOR PREVENTION AND TREATMENT

CRC is the third most common cancer worldwide, and the second leading cause of cancer-related deaths.[10] EO-CRC refers to CRC diagnosed in individuals younger than 45 years. Incidence rates in individuals younger than 45 years have been increasing since the mid-1990s, driven largely by an increasing incidence in rectal cancer.[11] On the basis of data from the North American Association of Central Cancer Registries, which includes 47 states and the District of Columbia, there has been a 1.1% increase per year (95% CI, 0.3 to 2.0) from 2006 to 2015. This includes an increase of 0.7% per year (95% CI, 0.5 to 0.9) for colon tumors and 1.7% per year (95% CI, 1.4 to 2.0) increase for rectal tumors.[12] By the year 2030, 10% of all colon cancers and 22% of all rectal cancers in the United States are expected to be diagnosed in patients younger than 50 years.[13] Recent evidence reveals a similar rapidly rising incidence of EO-CRC in other developed countries worldwide indicating that this increase is not specific to the United States.[14] This pattern is even more worrisome when placed against the backdrop of a significant decline in the incidence of CRC in patients older than 45 years. This decrease has been attributed to multiple factors, including screening programs and reductions in risk factors such as smoking, diet, and anti-inflammatory medications.[15]

Racial Differences in EO-CRC

Between the year 2000 and 2013, EO-CRC incidence increased 2.5% in American Indian/Alaskan Native patients, 2.3% in non-Hispanic White patients, 1.0% in non-Hispanic Black patients, and 0.2% in Asian/Pacific Islander patients.[16] In an analysis of

PRACTICAL APPLICATIONS

- Awareness of the early-onset (EO) cancer epidemic should prompt heightened vigilance among health care providers caring for patients who would not be historically considered at high risk for cancer.
- Early detection of symptoms with appropriate diagnostic testing is critical to obtaining a cancer diagnosis in earlier stages which may allow for a greater chance of curative approaches.
- Multidisciplinary management of patients with EO cancers is critical to address unique and challenging issues that younger populations must navigate, including family, social, career, and financial stress.
- Genetic counseling and testing are critical components to multidisciplinary care and may elucidate mechanisms of EO cancer development.

SEER data, from 1992 to 2014, the incidence of EO-CRC increased from 7.5 to 11.0 per 100,000 in White individuals and from 11.7 to 12.7 per 100,000 in African American individuals. The increase in rectal cancer was larger in White (from 2.7 to 4.5 per 100,000) than in African American patients (from 3.4 to 4.0 per 100,000).[17] During this period, in African American patients, mortality declined by 0.4%-1.1% annually, but African American patients still have a higher absolute mortality rate than other populations (6.1/100,000).[18] These racial disparities are likely multifactorial, stemming from a combination of socioeconomic, access to care, dietary, environmental, and biologic factors.[19] In the Hispanic population, CRC incidence rates from 2001 to 2014 have increased among younger (age, 20-49 years) adults.[20] Interestingly, the largest relative increases in incidence occurred in Hispanic patients age 20-29 years (90% *v* 50% relative increase among White patients), suggesting that opposing incidence trends in younger versus older Hispanic patients may reflect generational differences in CRC risk by birth cohort, as well as environmental exposures and lifestyle-related risk factors associated with immigration and acculturation.[20]

Clinical and Pathologic Features

Given that screening is not recommended for adults younger than 45 years, the majority of CRCs in young patients are identified because of signs and symptoms, and diagnosis can be delayed significantly. In a series of more than 1000 EO-CRCs, the most common presenting symptom was rectal bleeding (50.8%), followed by abdominal pain (32.5%) and change in bowel habits (18.0%).[21] When compared with symptomatic older patients with CRC, younger patients are more likely to present with symptoms of hematochezia (28.8% *v* 23.2%) and abdominal pain (41.2% *v* 27.2%).

Patients with EO-CRC experience symptoms for longer (243 *v* 154 days) and have a longer delay to diagnosis (152 *v* 87 days), compared with older patients.[22,23] In addition, younger patients more commonly present with left-sided cancers and are more likely to have rectal cancer (31.2% *v* 22.4%; $P < .001$).[24] EO-CRCs also appear to have more aggressive histopathology than older patients. Overall, mucinous and signet ring histologies were seen in 10.0%-14.5%[25-28] and 2.0%-13.0%[25,26,28] of EO-CRCs, respectively, and up to 27.9% of EO-CRC cancers are poorly differentiated or undifferentiated compared with just 10.8% in average-onset CRC (AO-CRC).[22,29]

EO-CRC tends to present at a more advanced stage with a relative risk of 1.37 (1.33-1.41) and 1.58 (1.53-1.63) for younger patients to present with regional or distant metastasis, respectively, compared with older patients.[24] A retrospective review of EO-CRC revealed a clear association between time from onset of symptoms and stage at diagnosis highlighting the critical need to establish the diagnosis in a timely manner.[22,23]

Molecular Characteristics of EO-CRC

Microsatellite and chromosomally stable (MACS) tumors are near-diploid tumors without the aneuploidy that characterizes chromosomal instability (CIN) and without microsatellite instability (MSI). In a prospectively collected series of 84 microsatellite-stable (MSS) EO-CRCs (younger than 50 years) compared with 90 MSS later-onset CRCs (older than 65 years), EO-CRC had higher frequencies of MACS tumors, and tumors in the EO-CRC were more frequently diploid (46%) than the older-onset group (26%; $P = .006$).[30] The pathological processes that drive MACS may be simply reflective of the distal colorectal location, and it is unclear if this is a characteristic that is unique to EO-CRC. In addition, another large genomic analysis of EO left-sided CRC revealed that younger patients (n = 350), when compared with older patients (n = 776), showed higher mutation rates in genes associated with cancer-predisposing syndromes (eg, Lynch syndrome [LS]), such as MSH6, MSH2, POLE, NF1, SMAD4, and BRCA2.

Somatic Alterations

Evaluation of comprehensive genomic landscapes in EO-CRC has been limited because of relatively small sample sets. Comparisons in the molecular and clinical findings of sporadic CRC of 39 young patients (younger than 45 years) versus 36 older patients (older than 60 years) revealed a

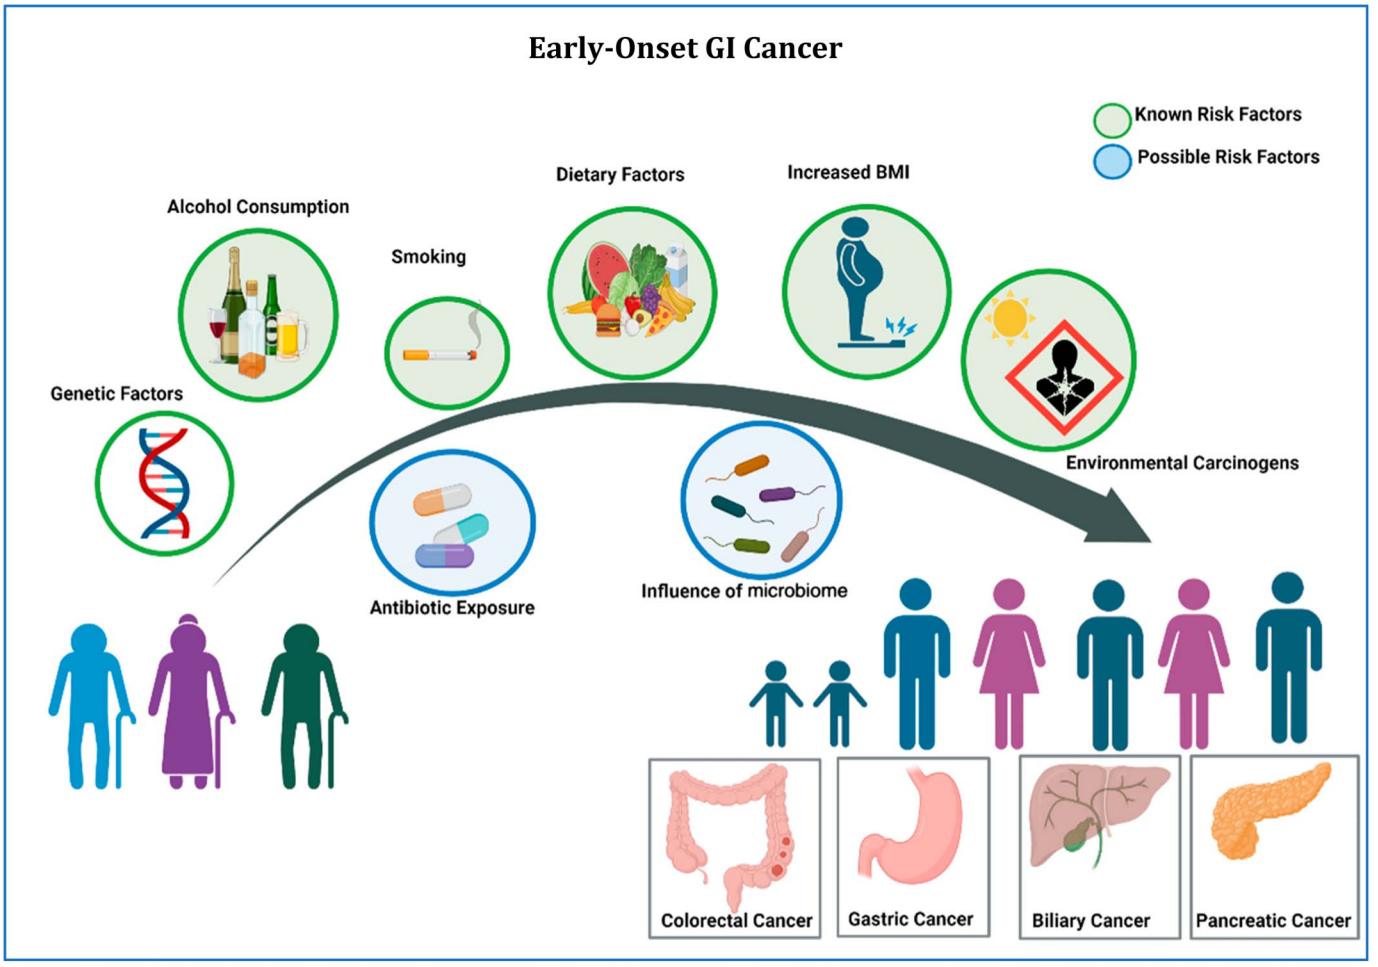

FIG 1. Established and potential risk factors for early-onset GI cancers. Schematic was created with BioRender.com.

higher incidence of distal tumors, synchronous metastases, BRAF V600E wild type, absence of a methylator phenotype, and evidence of CIN in EO-CRC.[31] In 2019, a multicenter study of 18,218 CRC samples with next-generation sequencing was published showing differences in genomic alterations between EO and later-onset CRC. When substratified into EO (younger than 40 years), intermediate group (40-49 years), and older (50 years and older),[32] *TP53* and *CTNNB1* alterations were more common in the EO cohort, whereas *APC*, *KRAS*, *BRAF*, and *FAM123B* variants more frequent in the older cohort.

The observation of genetic heterogeneity across EO-CRC tumors reveals the need to leverage data from next-generation sequencing to define molecular phenotypes. An integrated European multiomics study included tumor transcriptome, plasma proteome, and metabolome-implicated deregulated redox homeostasis, through perturbation of *NRF2*-mediated oxidative stress response, the CXCL12-CXCR4 signaling pathway, and glutathione metabolism, as a molecular hallmark of EO-CRC.[33] Further analysis in diverse populations[34] will be required to better understand and validate these data.

EO-CRC Treatment and Survivorship

Despite seemingly later stage and more aggressive histology at presentation, patients with EO-CRC appear to have similar stage-specific outcomes. In a SEER database analysis, the stage-adjusted, cancer-specific survival was improved in younger patients compared with those diagnosed older than 50 years (local: 95.1% *v* 91.9%; regional: 76% *v* 70.3%; distant: 21.3% *v* 14.1%).[24] However, another analysis in stage IV CRC showed an increased risk of progression and death in younger patients (22% increased risk of progression and 19% increased risk of death), suggesting a reduced benefit of frontline therapy in EO-CRC.[35]

Although there appears to be a different pattern of molecular profile in EO-CRCs and treatment regimens are routinely modified on the basis of the molecular features of CRCs,

these cancers are still a heterogeneous group, and there is currently no specific tailored approach to treatment on the basis of age alone.[32] Secondary to their young age and presumed improved performance status compared with older adults, younger patients tend to be treated more aggressively than older adults without clear survival benefit. Matched for stage and tumor characteristics, younger patients are more likely to be treated with systemic chemotherapy and multiagent regimens compared with older patients.[36,37] This more aggressive approach to therapy has not been associated with survival gain in patients with stage II disease (rate ratio [RR], 0.90; 95% CI, 0.69 to 1.17) but led to a marginal gain for patients with stage III (RR, 0.89; 95% CI, 0.81 to 0.97) and IV (RR, 0.84; 95% CI, 0.79 to 0.90) disease.[37] In addition, an analysis of extended colon resection showed no benefit in younger patients.[38] Another analysis of 6,284 patients from nine phase III studies in stage IV CRC showed that young age was modestly associated with poorer progression-free survival but not overall survival (OS) or RR in treated patients with advanced CRC, and young patients had more nausea but less diarrhea and neutropenia with chemotherapy in general.[39] Given the association of EO-CRC and LS, a higher proportion of young patients will have high MSI which may affect the use of chemotherapy in patients with stage II disease, as well as the use of immunotherapy for patients with stage IV disease which is expected to improve outcomes in this cohort of patients.[40]

Non-CRC EO-GI Cancers: Current Trends

EO gastric cancer. Despite falling overall, gastric cancer incidence conversely appears to be rising in younger generations.[2,41] Using SEER data in a study of 158,599 patients, this rising incidence appears to disproportionately affect Black, Hispanic, and Asian populations.[42] Similar to CRC, EO gastric cancer is more likely to present with multifocal disease, higher grade, and diffuse histology.[43] Additionally, EO gastric cancer is less likely to have MSI compared with later-onset gastric cancer.[44]

EO pancreatic cancer. In considering pancreatic cancer, Sung et al[2] analyzed data sets from 25 US state registries from 1995 to 2014 and identified increasing pancreatic cancer incidence with decreasing age, noting a 2.47% (95% CI, 1.77 to 3.18) annual increase for age 30-34 years and a 4.34% (95% CI, 3.19 to 5.50) increase for age 25-29 years compared with 0.77% (95% CI, 0.57 to 0.98) for patients age 45-49 years. This has been further corroborated by large population-based studies using SEER registry data,[7] and more recently, Jayakrishnan et al[45] demonstrated a relative percentage increase of 33.3% in pancreaticobiliary cancer in patients younger than 50 years from 2004 to 2017. Younger patients are more likely to be diagnosed with stage IV cancer and with a more aggressive phenotype.[46,47] Although the majority of data sets have focused on pancreatic adenocarcinoma, there is also evidence of increased pancreatic neuroendocrine tumors (PNETs); these patients with EO PNETs are more likely to be Black, Hispanic, and female and additionally have improved OS when compared with average-onset PNETs.[48]

EO biliary cancers. Biliary tract cancers also appear to be rising in younger adults across diverse geographical regions, and this again contrasts with the trends in older adults.[49] The unique biological and genomic characteristics of these tumors have been less well elucidated given that this represents a novel phenomenon. However, some of the data that are available specific to this population suggest possibly poorer OS with enrichment of genes associated with poorer differentiation, deubiquination, and WNT signaling pathway.[50] This association with poorer survival was not seen when the US National Cancer database was analyzed from 2004 to 2017 and pancreaticobiliary tumors were analyzed as a group.[61]

EO-GI CANCERS AND GENETIC PREDISPOSITION: KNOWNS AND UNKNOWNS

Classic Model of Genetic Testing

Evaluating the contribution of germline pathogenic variants (gPVs) to the risk of EO-GI cancers is critical not only for the appropriate estimation of lifetime cancer risks but also increasingly for treatment decision making among patients already affected with cancer. Herein, we describe the historical model of genetic testing and its evolution, define the most common high-risk genetic predispositions to GI cancers, and describe how germline genetics has grown to be pivotal in the routine care of oncologic patients and their at-risk relatives.

The classic models of genetic testing for cancer historically hinge on three basic factors: patients' age at diagnosis, rarity of tumor type, and/or family cancer history. The aim of this approach is to identify those with the highest pretest probability of having a gPV while reducing the likelihood of obtaining uncertain results with limited clinical utility (eg, variant of uncertain significance). This is typically conducted by a pretest genetic counseling session in which a certified genetic counselor takes the family history and completes a three-generation pedigree to assess if the patient and/or family meets clinical criteria for genetic testing. Such criteria may be established by national guidelines by cancer type, such as the National Comprehensive Cancer Network (NCCN) for Colorectal Cancer,[51] or syndrome-specific criteria, such as the Amsterdam Criteria and Bethesda Guidelines[52,53] for assessment of and tumor screening for LS.

Although these methods typically capture those at *highest* risk for having a gPV, over the past several years, an

increasing amount of data have demonstrated that a significant portion of patients with gPVs in high penetrance cancer risk genes, such as the mismatch repair (MMR) genes diagnostic of LS, are missed through such stringent criteria. LS is a pan-cancer syndrome with up to an approximate 60% lifetime risk of cancer, with CRC and endometrial cancer (EC) carrying the highest risk. Given that it has been reported that underlying LS is found in approximately 3%-5% of all CRC and ECs, universal screening for LS via assessment for MSI-high and or MMR-deficiency has been recommended for these canonical tumor types for the nearly 2 decades.[52,54,55] One 2019 publication in the *Journal of Clinical Oncology* demonstrated that among 15,000 patients representing a pan-cancer cohort of MSI tumors (>50 cancer types), LS was identified in approximately 16% of cases.[56] Moreover, of patients with LS presenting with cancers other than CRC or EC, only half met clinical testing criteria on the basis of personal and/or family cancer history,[56] highlighting that relying on this classic testing model misses nearly half of LS diagnoses. Importantly, this is not unique to LS as multiple studies have demonstrated a significant incremental pickup rate for gPV in cancer susceptibility genes when classic testing criteria are relaxed.[57-59]

Rising Incidence of EO-GI Cancer and Relative Contribution of Genetic Risk: The Known

Historically, the application of family history has been important in identification of patients for germline testing and potential primary prevention of CRC.[60] Approximately 28% of patients with EO-CRC will have family history of CRC, and the risk conferred by a history of CRC in FDR is greatest in younger individuals.[61] In contrast to studies assessing gPVs among MSI tumors, a large comparison of EO-CRC to AO-CRC MSS cancer found that 17.5% patients with EO-CRC harbored a gPV (3) with the highest mutation prevalence in the cohort with those younger than 35 years (23.2%) compared with 14% in the AO-CRC cohort and that this appeared to be driven by an enrichment of gPVs in high penetrance genes.[62] The majority of gPVs were in known CRC-associated cancer predisposition genes including DNA MMR genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) *EPCAM* terminal deletions, *APC*, and *POLD1*.[62] When assessing all-comers (MSI and MSS EO-CRC), rates of gPVs range from 9% to 26.4%.[63,64] Although LS is the most common genetic syndrome associated with EO-CRC, there is increasing evidence of the association of other high penetrance gPVs with CRC which include TP53, *BRCA1/2*, *ATM*, and *PALB2*, although whether or not these findings are causative of the cancer or incidental findings remain to be fully elucidated.[64-68]

As a result of this increasing appreciation of the potential contribution of gPVs to EO-CRC, the Delphi initiative released the DIRECt recommendations in 2022[69] which have been endorsed by four scientific societies: the Collaborative Group of the Americas on Inherited Gastrointestinal Cancers, the European hereditary Tumor group, the International Society for Gastrointestinal Hereditary Tumors, and the Association Italiana Familirita Ereditarieta Tumori. These recommendations mandate multigene panel testing (MGPT) for all patients younger than 50 years (Fig 2).

NCCN guidelines[70] now recommend germline genetic testing for all patients diagnosed with pancreatic cancer in view of the potential clinical actionability on the basis of the POLO study for maintenance olaparib among g*BRCA* carriers.[71] Importantly, in a cohort of 450 patients with EO pancreatic cancer diagnosed between 2008 and 2018 at a large academic institution,[72] approximately 32% were found to harbor at least one gPV, with 27.5% of gPVs identified in high and moderate penetrance genes.[72] A large study from another large tertiary center demonstrated that patients with EO pancreatic cancer had a significantly higher odds of testing positive than older patients for germline mutations (odds ratio, 1.93; 95% CI, 1.03 to 3.7) although the definition of EO pancreatic cancer for the purposes of this study was defined as age younger than 60 years.[73]

Approximately 1%-3% of gastric cancers are associated with gPVs,[74] and genetically driven tumors are more common among patients with EO disease. The most common syndrome is hereditary diffuse gastric cancer associated with mutations in the *CDH1* gene.[75-77] Beyond *CDH1* gPVs, hereditary diffuse gastric cancer can also be seen in the setting of truncating mutations in the *CTNNA1* (α catenin) gene inferring a genocopy of *CDH1*[76,78] although this represents a minority of diffuse gastric cancer families.[75] Additionally, an autosomal dominant syndrome has been identified characterized by gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS) without duodenal or colonic involvement in most individuals reported.[79,80] GAPPS arises in the context of APC promoter 1B mutations (c.-191T>C, c.-192A>G, and c.-195A>C) which reduce the binding activity of the transcription factor Yin Yang 1 and transcriptional activity of the promoter.[81] EO gastric cancer (nondiffuse type) may also occur in the setting of LS (caused by gPVs *in MLH1*, *MSH2*, *MSH6*, *PMS2*, and terminal deletions in *EPCAM*),[82] Li Fraumeni syndrome (caused by gPVs in *TP53*),[83] familial adenomatous polyposis (caused by gPVs in *APC*),[82,84,85] Peutz Jeghers (caused by gPVs in *STK11*),[86,87] and juvenile polyposis syndrome (caused by gPVs in *SMAD4* or *BMPR1A*).[88,89] Importantly, many of the above syndromes have classic, well-described phenotypic presentations, allowing for better estimations of pretest probability of a true positive result in such cases.

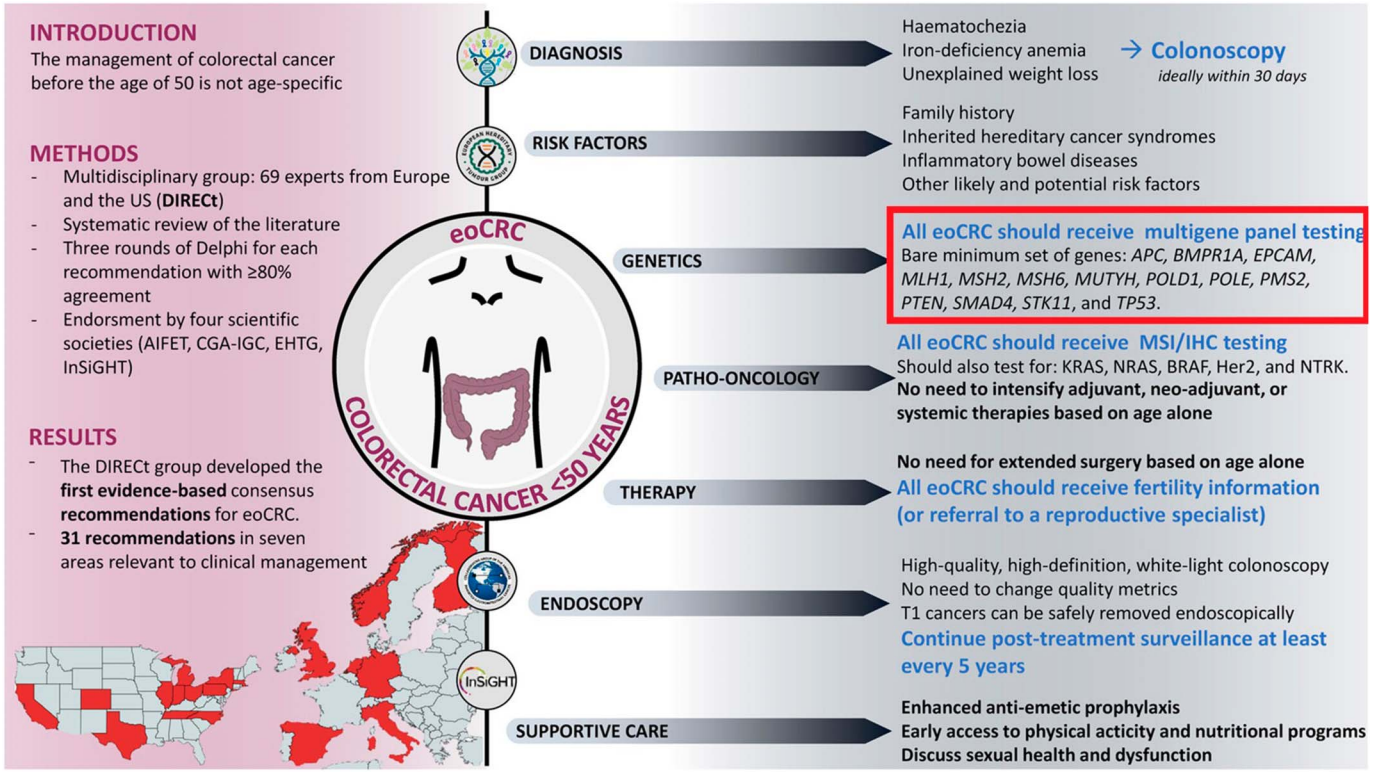

FIG 2. Delphi Initiative for EO-CRC. Red box indicates recommendation that all patients with EO-CRC should receive MGPT. AIFET, Association Italiana Familirita Ereditarieta Tumori; CGA-IGC, Collaborative Group of the Americas on Inherited Gastrointestinal Cancers; DIRECt, Delphi Initiatve for Early Onset Colorectal Cancer; EHTG, European Hereditary Tumor Group; EO-CRC, early-onset colorectal cancer; HER2, human epidermal growth factor receptor 2; IHC, immunohistochemistry; InSiGHT, International Society for Gastrointestinal Hereditary Tumors; MGPT, multigene panel testing; MSI, microsatellite instability.

What is less clearly defined is the association of gastric cancer with pathogenic germline variants in the homologous recombination DNA repair pathway. In a large cohort of more than 5,000 BRCA families, the relative risk of gastric cancer was increased in both *BRCA1* and *BRCA2* carriers, 2.17 (95% CI, 1.25 to 3.77) and 3.69 (95% CI, 2.4 to 5.67), respectively.[90] This association appears to be stronger with *BRCA2* than with *BRCA1*.[91-94] At the present time, these data are not robust enough to recommend routine surveillance gastroscopy in all carriers of gPVs in *BRCA* but could be a consideration in the setting of both gPVs and a family history of gastric cancer.[95]

gPVs on Multipanel Testing and Causality: The Unknown

With the increasing availability of commercial MGPT and expansion of the cancer types in which MGPT is recommended particularly in patients with EO cancer, we will undoubtedly detect more gPVs which are of clinical relevance for the patient as well as at-risk relatives. Although MGPT is recommended for patients with ovarian, pancreatic, and high-risk/or metastatic prostate cancer, the debate about universal germline testing for patients with CRC remains unresolved. In a cohort of nearly 35,000 patients, Coughlin et al[96] reported detection of at least one pathogenic/likely pathogenic germline variant; the majority of which were in genes classically associated with CRC. The rates of gPVs were highest in the youngest age groups, 25.7% in patients younger than 30 years, 17% in patients age 30-39 years, and 14.1% in those age 40-49 years. The rate of clinically actionable variants in individuals younger than 30 years was approximately double than that of patients age between 50-59, 60-69, and 70-79 years, 23.4% versus 13% and 11.7% and 8.9%, respectively. With increased genetic testing, appreciation of novel associations may further evolve and become more clearly defined.

However, what cannot be deduced from germline MGPT alone is the contribution of a particular gPV to causation of the index cancer particularly in the setting of genes not classically associated with that cancer subtype. As such, integration of germline and somatic analysis is critical to elucidate the role of germline variants in GI carcinogenesis by evaluating biallelic loss which when assessed seems to be consistently higher among patients with EO cancer than in average-onset cancer,[62,68] suggesting that these gPVs are driving cancer development at least in proportion of these

cancers. Determination of causality is imperative to identify novel treatment approaches exploiting underlying germline drivers implicated in carcinogenesis. Importantly, although the prevalence of gPVs are consistently higher among patients with EO cancers, decisions regarding germline genetic testing should not be restricted by age alone, particularly as the therapeutic implication of gPVs expands.[71,97]

NOVEL STRATEGIES IN EO GI MALIGNANCIES

Novel Targeted Treatment Strategies

Two potentially paradigm altering trials were presented in 2022 demonstrating a novel targeted approach to MSI colorectal tumors. Building on the total neoadjuvant approach for MSS locally advanced rectal cancers gaining traction globally, Cercek et al[98] demonstrated the potential for the complete omission of both surgery and radiotherapy for locally advanced MSI rectal cancers treated with immunotherapy alone with the interim analysis, demonstrating a 100% response rate. In a similar fashion without the omission of surgery, Chalabi et al[99] demonstrated a 95% major pathological response rate among MSI locally advanced colon cancers treated with combination immunotherapy. The potential to avoid the toxicities of chemotherapy and radiotherapy will have particular relevance among patients with EO-CRC among whom LS is the most commonly seen genetic syndrome and is characterized by near universal MSI status of the associated tumors. In 2023, Andre et al[100] published the interim results of another similar study evaluating the use of neoadjuvant ipilimumab and nivolumab in resectable gastric and gastroesophageal junction tumors demonstrating a high pathological complete response rate and allowing for the omission of surgery in 3 of 32 patients. The OS data from these and other ongoing prospective studies will confirm the utility of this approach.

Novel Research Approaches

To fully elucidate the etiology of EO cancers and evaluate the complex interaction between environmental factors, prospective life-course cohort studies that enable biomarker/omics analyses of specimens obtained during early life in parallel with the collection of epidemiological information will be critical.[2] The pooling of existing data sets is a consideration particularly when evaluating rarer GI malignancies such as biliary tract cancers to develop improved prevention and treatment strategies. Funding research endeavors of this magnitude will require significant cross border and international collaboration.

SPECIAL CONSIDERATIONS

The rise in EO cancers has significant implications on a personal level beyond the physical level for patients whose families are not yet complete and who are often working full time at the time of their diagnosis and more broadly has significant societal impacts both financial and structural with escalating health care costs, reduction of the workforce, and often fragmentation of young families in the event of cancer diagnosis in a parent. Focusing on EO-CRC because of the high rate of diagnosis at later stages of disease, patients with EO-CRC are much more likely to face long-term functional deficits, higher rates of anxiety, poor body image, and difficulties associated with alterations in bowel habits.[101] Recognition of the unique supportive care and developmental and psychosocial needs of patients with EO cancer to inform development of a framework to address the needs of this expanding population in parallel with research into the underlying etiological factors is critical.[102]

Oncofertility

In contrast to average-onset cancers, discussion regarding fertility preservation is critical before the initiation of treatment among patients with EOC. Although recognition of the impact of systemic anticancer therapies on fertility among patients with EO breast cancer has been robustly elucidated, data specific to fluorouracil-based regimens which form the backbone of numerous regimens across the GI caner spectrum are more limited.[14] The effect of fluorouracil on fertility is lower than with agents such as cyclophosphamide; data also suggest that amenorrhea, which may be persistent, is associated with increasing age at the time of chemotherapy receipt, mirroring what has been described in perimenopausal patients with breast cancer receiving chemotherapy.[103,104] The addition of oxaliplatin can induce transient gonadotoxicity in both men and women.[105] The use of gonadotropin-releasing hormone agonists which is commonplace in the treatment of premenopausal patients with breast cancer on chemotherapy is less widespread among patients with EO GI cancers but should be considered to prevent chemotherapy-induced ovarian failure.[41]

A distinct consideration with regard to the management of rectal cancer which appears to be rising in premenopausal patients is the risk of premature menopause induced by pelvic radiation[40]; doses of 45-50 Gy induce premature menopause in >90% of patients.[106] Ovarian transposition may reduce but not eliminate the damaging effect of radiation on the ovaries.[107] It should, however, be considered especially for women age 40 years or younger to avoid premature menopause and associated sequelae. Current clinical guidelines recommend offering cryopreservation of sperm to all patients undergoing gonadotoxic chemotherapy and embryo cryopreservation or preservation of unfertilized oocytes.[108] Referral to fertility preservation specialists should be considered for all patients with EO cancers.

Survivorship and Longer-Term Health Consequences

Patients with EO cancer are particularly susceptible to the financial toxicity associated with cancer care.[109] Patients with EO disease are often early in their careers, and maintaining financial security and employment is often challenging, and additionally they may have minimal savings or assets[8] and may be dependent on the support of family members to cover the costs associated with treatment exacerbated by work absence.

Survivors of EO cancers also have a higher risk of other long-term health problems including secondary cancers and cardiovascular disease.[110,111] Specific to CRC, a large study among older survivors indicated that the 10-year cumulative incidence of new-onset cardiovascular disease and heart failure to be more than double than that of the controls.[112] The magnitude of risk for patients with young-onset CRC has not been clearly elucidated.

CONCLUSION

Despite increasing understanding of genetic contributions to EO cancer, known gPVs only account for a small proportion of these cancers. Emerging data demonstrate the importance of the microbiome in cancer-modulating interactions and indeed response to therapy.[113,114] In addition, the association of obesity with EO cancer is also increasingly being elucidated.[14,115] Dietary factors have also been found to influence the development of colorectal adenomas in patients with LS, highlighting a potentiated, incremental risk in patients who already have up to a 60% lifetime risk of CRC on the basis of their germline status alone.[51,116] Understanding the complex interplay between host factors such as gPVs, gut microbiome, and extrinsic environmental factors will be critical to mitigate the rising incidence of EO cancer globally, particularly across the spectrum of GI cancers.

Next-Generation Approaches to Immuno-Oncology in GI Cancers

J. Randolph Hecht, MD[1]; Jasmine Mitchell, MD, MS[1]; Maria Pia Morelli, MD, PhD[2]; Gayathri Anandappa, MBBS, MPhil, MRCP[2]; and James C. Yang, MD[3]

overview

Immunotherapy has only had a modest impact on the treatment of advanced GI malignancies. Microsatellite-stable colorectal cancer and pancreatic adenocarcinoma, the most common GI tumors, have not benefited from treatment with standard immune checkpoint inhibitors. With this huge unmet need, multiple approaches are being tried to overcome barriers to better anticancer outcomes. This article reviews a number of novel approaches to immunotherapy for these tumors. These include the use of novel checkpoint inhibitors such as a modified anti–cytotoxic T lymphocyte–associated antigen-4 antibody and antibodies to lymphocyte-activation gene 3, T cell immunoreceptor with immunoglobulin and ITIM domains, T-cell immunoglobulin-3, CD47, and combinations with signal transduction inhibitors. We will discuss other trials that aim to elicit an antitumor T-cell response using cancer vaccines and oncolytic viruses. Finally, we review attempts to replicate in GI cancers the frequent and durable responses seen in hematologic malignancies with immune cell therapies.

INTRODUCTION

Although immunotherapy with standard PD(L)-1 or cytotoxic T lymphocyte–associated antigen-4 (CTLA-4) immune checkpoint inhibitors (ICIs) has revolutionized the treatment of melanoma[1] and non–small-cell lung cancer (NSCLC),[2] the benefits in GI cancers have been relatively limited. The most efficacy has been demonstrated in patients with GI tumors with deficient DNA mismatch repair (dMMR)[3] although these are only a small portion of patients with GI cancer particularly in pancreatic adenocarcinoma.[4] Furthermore, not all dMMR cancers respond to therapy with standard ICIs and some that do eventually progress. ICIs have become standard of care in metastatic upper GI malignancies,[5] hepatocellular carcinoma,[6] and bile duct cancers[7] although the benefits are not as great as those seen in more immunosensitive tumors. The most common GI cancers, proficient MMR colorectal cancer (CRC), and pancreatic adenocarcinoma remain resistant to these agents.[3] Therefore, new approaches to immunotherapy are needed. The most mature of these are novel checkpoint inhibitors, tumor vaccines, oncolytic viruses (OVs), and immune cell therapies. The data for their use in GI cancers will be reviewed.

NOVEL ICIs AND COMBINATIONS IN GI TUMORS

ICIs, notably anti–CTLA-4 and PD-1 and PD-L1 inhibitors, have improved treatment for solid tumors, including GI.[3,8-10] Combinations with chemotherapy[5,11] and the anti–human epidermal growth factor receptor 2 antibody trastuzumab are standard of care in cancers of the upper GI tract.[12] Unfortunately, outside of patients with dMMR, these benefits are rarely durable and are nonexistent in colorectal and pancreatic cancers. Therefore, researchers are looking at new versions of standard ICIs, new combinations with other agents to overcome immunosuppression, and finally inhibitors of novel checkpoints (Table 1).

Botensilimab, an Fc-enhanced next-generation anti–CTLA-4 antibody, in combination with balstilimab, a novel anti–PD-1 antibody, showed promising results in patients with microsatellite-stable (MSS), heavily pretreated metastatic CRC (NTC03860272).[16] Data presented by El-Khoueiry et al[17] recently showed that the objective response rate (ORR) was 24% (95% CI, 14 to 39), the disease control rate was 76% (95% CI, 60 to 84), and median duration of response was not reached. The 12-month overall survival (OS) rate was 63% (95% CI, 42 to 75). The patients who did benefit the most from treatment were those without liver metastases. About 12% of the patients had treatment-related adverse events resulting in treatment discontinuation. A phase II trial is currently enrolling (ClinicalTrials.gov identifier: NCT05608044).[18]

The presence of various immunosuppressive cells in GI tumors such as tumor-associated macrophages and regulatory T cells (Tregs) may limit the effectiveness of ICIs. In preclinical models, small-molecule tyrosine kinase inhibitors (TKIs) such as regorafenib can reduce this immunosuppression by inhibiting colony stimulating factor 1 receptor, vascular endothelial growth factor receptor, and other potentially immunosuppressive pathways.[19] The relatively small Japanese REGONIVO

PRACTICAL APPLICATIONS

- Further studies testing antibodies against LAG-3, TIGIT, T-cell immunoglobulin-3, and CD47 should be performed in GI malignancies as they have shown promising results in preclinical studies and phase I/II trials in other cancer types.
- Fc-enhanced cytotoxic T lymphocyte–associated antigen-4 inhibitor botensilimab in combination with an anti–PD-1 has shown remarkable activity in proficient MMR (microsatellite-stable) metastatic colorectal cancer in a phase I study, and results of further trials could have a major impact in standard-of-care treatments.
- Although cancer vaccines and oncolytic viruses have shown limited responses in early phase trials in GI cancers, there are still many unknowns in terms of which cancer types will respond and which combinations of chemotherapy/immunotherapy will improve efficacy.
- T-Cell receptor therapy may prove to be more advantageous than chimeric antigen receptor-T therapy in solid malignancies, but further research in this area is needed.
- Solving the problems of antigen selection and intrinsic tumor immune evasion will allow advances in genetic engineering of T-cell fitness to better promote durable antitumor responses.

trial combining regorafenib with the anti–PD-1 nivolumab showed encouraging results with the response rate (RR) of 44% in gastric cancer and 33% in MSS CRC. Many of these responses appeared to be durable.[13] A phase II North American trial, however, only showed a 7% RR with regorafenib and nivolumab, all in patients without liver metastases. In that small group, interestingly, the RR was 22%. Similar early data have been seen with newer small-molecule TKIs such as lenvatinib and cabozantinib that may inhibit additional immunosuppressive pathways.[20,21] Large-phase trials combining ICIs with lenvatinib (LEAP-017; ClinicalTrials.gov identifier: NCT04776148)[22] and zanzalintinib (XL092; STELLAR-303; ClinicalTrials.gov identifier: NCT05425940)[23] in metastatic CRC are currently underway.

There are multiple other immune checkpoints, and inhibitors of these alone and in combination with anti–PD(L)-1 inhibitors are the subject of active research in GI cancers. Lymphocyte-activation gene 3 (LAG-3) (CD223) is a cell surface molecule expressed on activated CD4 and CD8 T cells, Tregs, natural killer (NK) cells, B cells, and plasmacytoid dendritic cells (DCs).[24] In preclinical studies, the combination of LAG-3/PD-1 blockade resulted in synergistic activity, providing a strong rationale for a combinatorial strategy. In the randomized, phase II/III, RELATIVITY 047 study in patients with untreated or unresectable, advanced melanoma, the combination of relatlimab, a first-in-class, anti–LAG-3 antibody, with the PD-1 inhibitor nivolumab showed improvements in median progression-free survival (mPFS) compared with nivolumab alone (10.1 *v* 4.6 months [hazard ratio, 0.75; 95% CI, 0.62 to 0.92; $P = .006$]).[25] This combination is now approved for treatment by the Food and Drug Administration (FDA). A phase I trial with the anti–LAG-3 antibody favezelimab with pembrolizumab in metastatic CRC had an 11% RR. Combination trials with other LAG-3 antibodies are ongoing in GI cancers.[26]

T cell immunoreceptor with immunoglobulin and ITIM domains (TIGIT), a member of the Ig superfamily and an immune inhibitory receptor, plays a key role in the suppression of T-cell proliferation and activation.[27] Among its functions, TIGIT inhibits NK cell–mediated tumor killing, suppresses CD8 T-cell priming and differentiation, and prevents CD8 T-cell–mediated killing.[28] Preclinical studies showed that TIGIT is coexpressed and associated with PD-1 expression and dual blockade of TIGIT and PD-1 in the restoration of T-cell[29] and NK cell immunity, providing a good rational for this combination.[30] The CITYSCAPE trial evaluated the efficacy and safety of tiragolumab in combination with atezolizumab as first-line treatment for NSCLC. The primary analysis from this randomized, double-blind, phase II trial showed clinically meaningful improvement in ORR and PFS compared with placebo plus atezolizumab in patients with chemotherapy-naive, PD-L1–positive, recurrent or metastatic NSCLC.[31,32] Unfortunately, these results were not confirmed by the SKYSCRAPER trial, which failed to confirm PFS and OS benefits in the tiragolumab arm.[33] There are ongoing trials of tiragolumab in combination with atezolizumab, chemotherapy, and targeted therapies in upper GI and CRCs (ClinicalTrials.gov identifier: NCT03281369, NCT04929223).[34,35] In the CITRINO study (ClinicalTrials.gov identifier: NCT03250832),[36] encelimab (TSR-033) was combined with dostarlimab and bevacizumab and chemotherapies in patients with CRC, but results are still pending. Vibostolimab (MK-7684), another anti-TIGIT antibody, was evaluated in combination with pembrolizumab in a phase I trial, showing a safe profile and a promising antitumor activity,[37] and is being looked at in MSI-high CRC (ClinicalTrials.gov identifier: NCT04895722).[38]

T-cell immunoglobulin-3 (TIM-3) is an immune checkpoint that promotes immune tolerance.[39] TIM-3 blockade results in decreased myeloid-derived suppressor cells (MDSCs) and increased proliferation and cytokine production by T cells.[40] Given its expression in a variety of T cells and its synergistic effects with other anti–PD-1 agents, several trials are ongoing to evaluate safety and activity of TIM-3 inhibitors in combination with anti–PD-1 antibody. In a

TABLE 1. Novel Immune Checkpoint Inhibitors and Combinations

Target	Mechanism of Action	Ongoing/Completed Trials in GI
Fc-enhanced anti–CTLA-4	Anti–CTLA-4 ab with enhanced FcγR-dependent functionality Promotes superior T-cell priming, memory responses, and depletion of intratumoral Tregs	Phase II of botensilimab with balstilimab in CRC (NCT05608044)
TKIs Regorafenib Zanzalintinib Lenvatinib	TKIs block potentially immunosuppressive pathways	REGONIVO Japanese trial combining regorafenib with nivolumab 11[13] Phase II trial regorafenib/nivolumab in North America (NCT04126733) Phase III zanzalintinib + atezolizumab in mCRC (NCT05425940) Phase III lenvatinib + pembrolizumab in mCRC (NCT04776148)
LAG-3	A cell surface molecule expressed on activated CD4/CD8 T cells, Tregs, NK cells, B cells, and DCs	Phase I trial with favezelimab with pembrolizumab in mCRC (NCT05064059)
TIGIT	Inhibits NK cell–mediated tumor killing Suppresses CD8 T-cell priming/differentiation Prevents CD8 T cell–mediated killing	Phase I trials in combination with ICI (NCT03281369, NCT04929223, NCT03250832, NCT04895722)
TIM-3	Blockade results in decreased MDSCs and increased proliferation and cytokine production by T cells	Phase Ib study of sabatolimab and spartalizumab 11[14]
CD47	Binds to SIRPα that inhibits macrophage phagocytosis	ELEVATE trial in combination with FOLFIRI and bevacizumab (NCT04827576)
ICOS (CD278)	Binds to an ICOS ligand expressed by B cells, macrophages, and DCs Costimulatory for T-cell proliferation and cytokine production Inhibition decreases intratumoral Tregs and increases T effector cells	Phase I/II trial in combination with atezolizumab in advanced malignancies (NCT03829501)
B7-H3 (CD276)	Inhibits CD4/CD8 T-cell activation, proliferation, and cytokine production	Phase I/II trial in advanced solid tumors with enoblituzumab 11[15]

Abbreviations: ab, antibody; CRC, colorectal cancer; CTLA-4, cytotoxic T lymphocyte–associated antigen-4; DCs, dendritic cells; FcγR, Fc gamma receptor; FOLFIRI, folinic acid, fluoruoracil, and irinotecan; ICI, immune checkpoint inhibitor; ICOS, inducible T cell costimulator; LAG-3, lymphocyte-activation gene 3; mCRC, metastatic colorectal cancer; MDSC, myeloid-derived suppressor cell; NK, natural killer; SIRPα, signal receptor protein-α; TIGIT, T cell immunoreceptor with immunoglobulin and ITIM domains; TIM-3, T-cell immunoglobulin-3; TKI, tyrosine kinase inhibitor; Treg, regulatory T cell.

phase Ib study, sabatolimab (MBG453), a TIM-3 antibody, and spartalizumab, a PD-1 ICI, generated partial responses in two patients with CRC.[14]

CD47 is a don't-eat-me signal that is a truly novel checkpoint for macrophages and DCs. It binds to signal receptor protein-α that inhibits phagocytosis.[41] Studies with the anti-CD47 antibody magrolimab have shown promising activity in hematologic malignancies.[42] The randomized phase II ELEVATE trial is currently underway in second-line CRC in combination with FOLFIRI and bevacizumab (ClinicalTrials.gov identifier: NCT04827576).[43]

Other novel checkpoints such as V-domain immunoglobulin suppressor of T-cell activation (VISTA), inducible T cell costimulator (ICOS), and B7-H3 have not been closely examined in GI cancer. VISTA is an immunoregulatory molecule involved in maintaining T-cell and myeloid quiescence.[44] It is expressed on resting T cells, indicating its regulatory role in earlier stages, and is more abundant in MDSCs in the tumor microenvironment (TME). The nonoverlapping mechanisms of VISTA and PD-L1 make their combination an ideal treatment strategy to overcome immune suppression. ICOS (CD278) is a member of the CD28 coreceptor family, which includes costimulatory CD28 and coinhibitory receptor CTLA-4.[45] Yap et al[46] evaluated an ICOS agonist, vopratelimab, alone and in combination with nivolumab in patients with advanced solid tumors. The study showed a safe drug profile and efficacy only in a subset of patients, with potential biomarkers to be evaluated in prospective studies. B7-H3 (CD276) is a member of the B7 family, a family of transmembrane proteins that interact with CD28 receptors family and modulate wither stimulatory or inhibitory immune signals.[47] Several agents targeting B7-H3 are currently under investigation in clinical trials. The anti–B7-H3 monoclonal antibody, enoblituzumab (MGA271), was evaluated in combination with pembrolizumab in a phase I/II trial in advanced solid tumors, showing a safe profile and promising antitumor activity in checkpoint inhibitor–naïve patients.[15]

In summary, there are multiple approaches being examined to try to overcome resistance to standard CTLA-4 and PD(L)-1 inhibitors in GI cancers. These promise to improve outcomes in malignancies that have had little improvement over the past two decades. Further development will require more translational research and identification of robust biomarkers of activity.

CANCER VACCINES IN GI MALIGNANCIES

Adaptive immunity is mediated by cytotoxic CD8+ T cells, CD4+ helper T cells, and B cells. In cellular immunity, T cells can recognize and eliminate diseased cells.[48] Vaccines work by inducing an immune response to the antigen(s) encoded by the vaccine. Subsequently, immunologic memory and adaptive immunity elicited against the immunizing antigen can protect an individual against the pathogen from which the antigen was derived.[49] Cancer vaccines are designed with the intent to elicit an immunologic therapeutic response against tumor antigens. Tumor antigens can be divided into tumor-specific antigens (TSAs) and tumor-associated antigens (TAAs). TSAs are expressed only by cancer cells, not normal cells, whereas TAAs are overexpressed in tumor cells compared with normal cells.[50]

Despite numerous attempts over the past century, only two therapeutic vaccines have been approved to date, sipuleucel-T, a DC-based vaccine for the treatment of castrate-resistant prostate cancer,[51] and the Bacillus Calmette-Guerin (BCG) vaccine for early bladder cancer. Despite this track record, vaccines continue to be developed in GI malignancies because of the huge unmet need. There are multiple different vaccine approaches to stimulate anticancer immunity such as autologous or allogenic cancer cells, DCs, and vaccine vectors encoding tumor antigens.[52]

Early studies used whole cancer cells to induce an immune response. OncoVAX combined BCG with autologous cancer cells. In the phase III ECOG 5383 trial of patients with CRC treated with surgery with or without vaccine, there was no significant difference in overall or disease-free survival.[53] GVAX is an allogeneic whole-cell vaccine composed of two human pancreatic adenocarcinoma cell lines modified to express granulocyte-macrophage colony-stimulating factor (GM-CSF).[54] Promising early data with CRS-207, a listeria modified to express the common TAA mesothelin,[55] were not borne out in the larger ECLIPSE trial[56] or in combination with checkpoint inhibitors.[57]

DCs are antigen-presenting cells that can activate naïve T cells against various host insults. A MUC1 peptide–loaded DC vaccine was tested in a phase I/II trial in resected pancreatic cancer with some long-term survivors.[58] Many ongoing trials in CRC involve administrating DCs pulsed with autologous tumor lysates. Immune responses to tumor antigens found in CRC and pancreatic cancer can be generated after DC vaccination, but these have not resulted in improved clinical outcomes.[59]

Another class of vaccines use different vaccine vectors, such as peptides, DNA plasmids, viruses, or RNA, to encode specific tumor. Potential challenges include identifying tumor antigens that will be immunogenic in specific patients. In a phase II trial in advanced CRC, a mixture of five HLA-A*24:04–restricted peptides combined with oxaliplatin-based chemotherapy had no significant effect on clinical outcomes.[60] The RAS G12D/R peptide vaccine ELI-002 is currently being examined in patients with ctDNA-positive only pancreatic and other cancer (ClinicalTrials.gov identifier: NCT04853017).[61] Advances in sequencing and manufacturing of vaccine vectors have enabled the design of personalized and off-the-shelf vaccines that can target neoantigens (tumor antigens derived from mutations). As an example, the mRNA-based phase II trial, KEYNOTE-942 trial, showed encouraging activity and possible proof of concept with this approach, reducing recurrence or death by 44% in patients with stage II/IV melanoma.[62] These data support the concept that treating patients earlier in their course of disease may improve the efficacy of vaccine approaches. A phase I study of a prime boost strategy–personalized vaccine study using chimp adenovirus and self-replicating RNA resulted in robust antitumor immune response[63] and is being examined in the first-line colorectal maintenance setting in the phase II/III GRANITE trial (ClinicalTrials.gov identifier: NCT05141721).[64] New vaccine approaches even have the exciting potential to reduce cancer incidence in patients with high-risk premalignant conditions such as Lynch syndrome.[65]

Although several cancer vaccines have shown induction of vaccine-specific responses, these have not resulted in clinical benefits in GI or most other cancers. The quality and quantity of these immune responses, especially with respect to CD8+ and CD4+ T cells, remain incompletely characterized and are an important consideration in evaluating the effectiveness of cancer vaccines. The antigens targeted by vaccines have important implications in the quality of the immune response as one of the primary issues with overexpressed TAAs is that central and peripheral tolerance mechanisms limit the generation of autoreactive B and T cells that strongly recognize these sequences.[66] Vaccines need to overcome this immune tolerance to mount a response without causing autoimmune reactions. There is still much work to be performed to identify which class of tumor antigens delivered by which vaccine vectors results in an optimal immune response. Additional factors include how to combine vaccines with standard-of-care chemotherapy and other immunotherapy drugs and the treatment setting (ie, adjuvant, early *v* late metastatic disease). A successful vaccine approach aims to overcome tolerance, reverse

immunosuppression, cause tumor death, and generate long-lasting memory responses.

OVs IN GI MALIGNANCIES

The benefits of immune herapies seem to be greatest in immunologically hot TMEs.[67] These tumors have high mutational burdens, high levels of tumor-infiltrating lymphocytes (TILs), and increased PD-L1 expression. The lack of presentation and/or expression of TAAs; infiltration by suppressive neutrophils, regulatory T cells, macrophages, myeloid-derived suppressor cells, or NK cells; low density of TILs; and expression of immunosuppressive factors lead to an immunologically cold tumor.[67] OVs are an exciting class of anticancer immunotherapies that exploit viruses' innate ability to preferentially infect, self-amplify, and lyse tumor cells.[68] They hijack and reprogram the host's cellular machinery, expressing both therapeutic and virus transgenes.[69] OVs were initially designed to just kill tumor cells, but more recent data have shown that at least some of the anticancer effects are by infecting a tumor cell and induce apoptosis, triggering an inflammatory reaction.[70] This activates innate and adaptive immune responses by the release of TAAs, pathogen-associated molecular patterns, and danger-associated molecular patterns from lysed tumor cells to act like a cancer vaccine to achieve an abscopal effect.[69] Talimogene laherparepvec (T-VEC), a herpesvirus designed to produce GM-CSF in the tumor to enhance antigen release, presentation, and antitumor immune response, was the first OV approved for use in the United States and Europe.[67] In a phase III trial, intratumoral injection of T-VEC improved durable RR and other clinical outcomes in advanced, nonresectable melanoma, leading to full FDA approval in 2015.[71] Despite initial encouraging results together with pembrolizumab, in a phase III trial, the combination was not superior to pembrolizumab alone.[72,73]

Multiple classes of OVs have been developed. The nonenveloped double-stranded DNA (dsDNA) adenoviruses were some of the first.[69] ONYX-015 is a first-generation *E1B*-55kD gene-deleted replication-selective adenovirus that preferentially replicates in and kills malignant cells. In a phase I/II trial of endoscopic ultrasound injection of locally advanced or metastatic pancreatic cancer in combination with gemcitabine, two of 21 patients had partial regressions of the injected tumor and eight had stable disease.[74] Although not being developed further in GI cancers, a variant, H101, is approved in China for head and neck cancer.[75] TNFerade, an adenovirus encoding tumor necrosis factor alpha, was examined in combination with chemoradiation in locally advanced pancreatic cancer with encouraging phase I/II results, but a phase III trial was negative.[76,77] Other adenoviruses being examined in GI cancers include enadenotucirev (EnAd, ColoAd1) and telomelysin,[78] which are currently being studied in combination with pembrolizumab in a phase II trial for advanced gastroesophageal adenocarcinoma (ClinicalTrials.gov identifier: NCT03921021).[79]

Herpesviruses are characterized by an icosahedral capsid and a dsDNA genome. Oncolytic herpes simplex viruses (HSVs) have been extensively studied because of a large transgene capacity, lack of insertional mutagenesis, and ability to activate innate and adaptive immune responses against tumors.[69] A phase I study using T-VEC in combination with atezolizumab for triple-negative breast cancer and CRC with liver metastases, however, showed limited evidence of antitumor activity.[80] Other HSV derived agents are in development.[81]

Vaccinia virus has a large dsDNA genome[69] and replicates in the cytoplasm, thereby eliminating the risk of insertional mutagenesis. The best studied vaccinia OV is pexastimogene devacirepvec (Pexa-Vec, JX-594), an engineered thymidine kinase–mutant vaccinia virus armed to express GM-CSF and β-galactosidase as transgenes.[69,82,83] It was found to be trafficked to the tumor as evidenced by the viral genome found in tumor biopsies,[84] and there were early hints of anticancer activity.[85] Unfortunately, a randomized phase IIb trial in hepatocellular cancer was negative[86] and a phase I/II trial with durvalumab and tremelimumab in CRC showed modest benefit.[87]

Pelareorep (Reolysin) is an unmodified oncolytic reovirus, delivered intravenously, that can induce a T-cell inflamed phenotype in pancreatic ductal adenocarcinoma. In a phase Ib study in patients who had progressed after first-line treatment, pelareorep, pembrolizumab, and 5-fluorouracil, irinotecan, or gemcitabine[88] did not add significant toxicity and showed encouraging efficacy. Other phase II trials of pelareorep in pancreatic cancer in combination with carboplatin/paclitaxel have showed similar results of good tolerability but mixed responses in terms of RR, PFS, and OS.[89,90]

This is a nonexhaustive survey of OVs in GI cancers. There are many challenges to overcome in the development of effective OVs. The need for intratumoral injection of some OVs, proper spread and penetration of the therapeutic agent, tumor cell targeting, pre-existing immunity to the viruses, and hypoxia are all factors that can inhibit the effectiveness.[82] The site of injection may also affect efficacy. The liver is particularly immunosuppressive with multiple mechanisms including liver metastases siphoning activated CD8+ T cells from systemic circulation and within the liver, leading to acquired immunotherapy resistance.[91] The optimal degree of infectivity and oncolysis is also unknown. Other unknowns in the study of OVs are which patients and tumor types most benefit from this therapy and in which combinations of chemotherapy and immunotherapy. Potential combinations with cytokines, BiTEs, and even chimeric antigen receptor (CAR)-T cells may improve efficacy.[92,93]

IMMUNE CELL THERAPY FOR GI TUMORS

The ability of infused cultured tumor-reactive immune cells to induce the rejection of human cancers has been well demonstrated. Expanding the resident T cells in melanomas (TIL) and infusing them along with systemic interleukin-2 (after preparative lymphodepletion with chemotherapy) can result in an ORR of over 50%, with half of those responding patients apparently cured of metastatic disease.[94] Genetically modifying peripheral blood lymphocytes (PBLs) with a CAR targeting a B-cell antigen, CD19, can cause objective regressions of large B-cell lymphoma in 82% of patients with refractory disease, again with many of them achieving durable complete remissions after a single administration.[95] A third example is the introduction of a tumor-reactive T-cell receptor (TCR; cloned from a T cell specific for the NY-ESO-1 antigen) into the PBL of patients with synovial sarcoma or melanoma, which resulted in a 58% ORR.[96] The major goal at this time is to expand such results to the common epithelial cancers, and this has proven to be difficult. This review will clarify the differences between these three sources of tumor reactive T cells, review their results, and discuss future directions.

PBLs (or in some cases, NK cells) engineered with CAR-T cells have been quite effective in the treatment of several hematopoietic malignancies. The CAR consists of an antigen-binding domain coupled to the T-cell signaling machinery, often with an interposed costimulatory domain. The antigen-binding domain is typically an antibody single-chain variable fragment (scFv), the T-cell signaling moiety usually uses CD3-zeta, and the costimulator is often CD28 or CD134 although innumerable variations on this framework have been devised. The current obstacle to using CAR T cells against solid malignancies has been the identification of safe TAAs. First, these TAAs need to be outer cell membrane structures and then they must be invariant because of the complexities of creating Ag-binding domains and optimizing the CAR. Most have been normal differentiation antigens on disposable tissues. Targeting cell surface B-cell markers such as CD19 and CD22 to destroy both benign and malignant B cells is tolerable because patients can live without B cells. Unfortunately, the organs giving rise to GI cancers are typically not dispensable. Very limited efforts to target solid tumors with CAR-T cells have been pursued. Early efforts to target carcinoembryonic antigen (CEA) either were ineffective or generated normal bowel toxicity.[97] Targeting the GD2 ganglioside on neuroblastoma and some pediatric gliomas has shown some positive results in small studies, but it is not a target on common epithelial cancers.[98] One very interesting phase I trial targeted the tight junction protein Claudin18.2 with a classic CAR consisting of a scFv-binding domain, CD28 costimulation, and CD3 zeta signaling.[99] Cells were administered after cyclophosphamide and fludarabine preconditioning, but no interleukin-2 was administered. An ORR of 49% was reported in patients with predominantly gastric cancer despite administering a relatively low numbers of cells ($\leq 5 \times 10^8$ cells). All responses were partial, and many of short duration; yet, this represents one of the only CAR-T-cell trials relevant to GI cancers with significant objective responses. Another research initiative has been to apply gating strategies to CARs to allow immune attack on cancer, but block activity when the target is encountered on normal tissues.[100] Logic-gated CAR-T cells have shown activity and specificity in preclinical models, and trials are ongoing in GI cancers expressing CEA.[101-103] Alternatively, one can target two structures with imperfect specificity on cancer that do not coexpress on normal tissues to generate better specificity.[104] These promising ideas are poised to enter early clinical trials, and their effectiveness remains unknown. The idea of CAR-T cells for common solid tumors remains attractive because of the circumvention of the major histocompatibility complex (MHC) restriction of normal T cells, expanding the applicability to more patients. There is also a theoretical advantage to a novel synthetic receptor for cancer. As will be described below, tumors under siege by endogenous T cells rapidly develop diverse immune evasion and escape mechanisms. Using a novel non-native receptor to initiate a T-cell attack has the advantage of not encountering a priori escape mechanisms generated before the adoptive transfer. Yet, the main obstacle remains not having suitable and safe target antigens.

The alternative to using CAR-T cells is to use native T cells and TCRs. Their major disadvantage is that TCRs recognize small processed peptide epitopes presented on MHC molecules. Therefore, a TCR is only pertinent to tumors with both the antigen and the presenting MHC allele and a much larger array of receptors is needed to address a population of patientswith cancer. On the other hand, because the epitope is proteolytically processed and exported to the cell surface on the MHC molecule, the TAA can be any protein made in the cytoplasm, not just outer cell membrane proteins. Humans also have nearly 10^{11} premade T-cell specificities in their repertoire, so there is no manufacturing required. Again, the main problem is finding safe and effective TAA. Here, the critical role of tumor-specific mutations comes into play. It has become clear from laboratory work and checkpoint inhibitor therapies that these mutated proteins are the major driver of the immune response of humans to cancer. Their tumor-specific nature also makes them a safe T-cell target. Unfortunately, the array of tumor-specific mutations is highly specific to each patient and their tumor,[105] with a limited number of common, shared mutations. One method of identifying T-cell reactivities to mutated antigens (neoantigens) has been described and extended to clinical trials.[106] A cancer's mutations are defined by whole exomic sequencing, and those mutations are

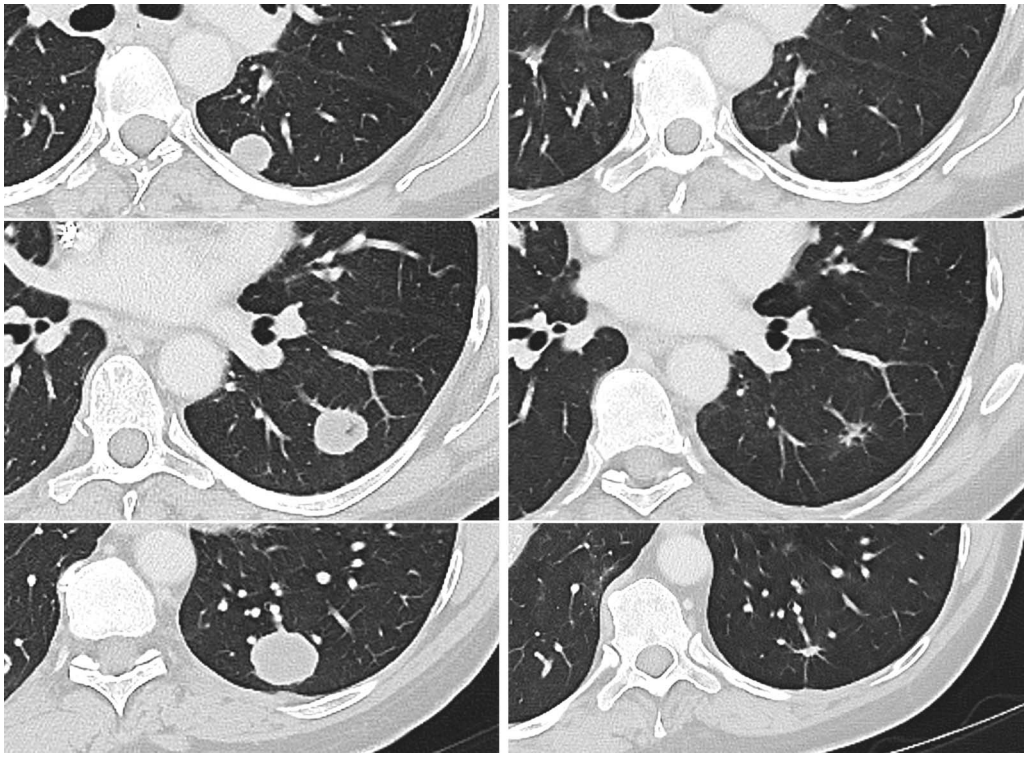

FIG 1. Responses to TIL reactive with neoantigens in colon cancer. Patient with colon cancer metastatic to lungs. Treated with lymphodepletion followed by adoptive transfer of TIL reactive with mutations in *DNMT3A* and *MUC6* and six doses of interleukin-2. The patient had near complete response and had received no other treatment. The left panel is baseline CT scan, and the right is 5-year follow-up showing all residual disease. CT, computed tomography; TIL, tumor-infiltrating lymphocyte.

expressed in autologous DCs by either minigene electroporation or loading synthetic peptides to create an avatar of that cancer's mutanome. This is then cocultured with TILs to identify which TILs are neoantigen-reactive. Patients are infused with subcultures selected for reactivity after undergoing preparative lymphodepletion with chemotherapy, and then systemic IL-2 is coadministered with the cells. The first patient to undergo this had cholangiocarcinoma and had a partial response of liver and lung metastases lasting nearly 3 years. She then relapsed but had persisting TIL from the infusion that expressed PD-1 and reresponded to a short course of pembrolizumab and remains free of disease, now 9 years after cell transfer.[107] Patients with breast cancer,[108] cervical cancer,[109] and colon cancer (Fig 1) have had durable complete responses to TIL reactive with neoantigens. Yet the RR is low despite the proven specificity of the infused TIL. Although this may in part be due to the exhausted phenotype of most TIL,[110] a host of tumor-related evasion mechanisms have been found as well. The simplest is the loss of the neoepitope or the restricting MHC allele. Although the latter was thought to occur from loss of both alleles of β-2 microglobulin (for MHC

TABLE 2. Advantages and Disadvantages of CAR-T Versus Native TCRs

Advantage/Disadvantage	CAR T Cells	T Cells/TCRs
Advantages	No MHC restriction	All proteins can be potential targets
	No previous immune resistance or evasion	Can easily target tumor-specific neoantigens
		Diverse repertoire naturally available
		Thymic tolerance prevents autoimmunity
Disadvantages	Targets essentially limited to shared (self) antigens	MHC restriction requires more TCRs
	Targets must be outer cell membrane structures	Prior selection for resistance occurs
	No thymic protection against autoimmunity	

Abbreviations: CAR, chimeric antigen receptor; MHC, major histocompatibility complex; TCRs, T-cell receptors.

class I), it has become apparent that loss of the single presenting MHC allele (seen as loss of heterozygosity at the MHC locus on chromosome 6) or downregulation[111] is more common and can even occur during the course of treatment.[112] Other evidence from checkpoint inhibitor therapy identified interferon-gamma signaling defects as a cause of tumor resistance to T cells.[113-115] Because the tumor and neoantigen-reactive T cells coexist for years, there is an opportunity for escape mechanisms to evolve; immune pressure leads to immune selection, which can lead to immune escape. Some mechanisms are reversable (such as T-cell inhibition by checkpoint receptors), some are irreversible (tumor MHC loss), some are T-cell–associated, and some are tumor-associated. One drawback of TIL therapy is that there is little control over the T cells that one recovers from a resected tumor. There can be problems with exhausted T cells, a low frequency of reactive cells, and inhibited TIL. One way to address issues with the quality of TIL is to clone the TCRs from neoantigen-reactive TIL and re-express them in fresh autologous PBL for transfer. This can also create an opportunity to target common recurring mutations with off-the-shelf reagents.

Mutations in *KRAS*, TP53, EGFR, BRAF, and PIK3CA, among others, are seen recurrently in many human cancers. Assembling libraries of TCRs specific for these mutations would allow the rapid generation of T cells for transfer by retroviral transduction. This would also allow one to select or genetically engineer optimized T-cell phenotypes to induce tumor rejection. Each mutation would require TCRs with specific MHC restrictions, greatly expanding the TCR libraries required. Yet, less than a 100 TCRs restricted by the most common HLA alleles would apply to the majority of human cancers. Most of the current efforts concentrate on *KRAS* (G12D, G12V mutations)[116,117] and TP53 (high-frequency hot spot mutations),[118] common in GI tumors. These mutations have been shown to be immunogenic, and in some cases, there is evidence that targeting them can be clinically effective.[112,119,120] Preclinical and clinical studies on genetic modifications to improve efficacy have looked at introducing cytokine secretion or orthogonal synthetic cytokine receptors into T cells,[113,121,122] and modifying function instead of just specificity represents the future of T-cell therapy. In summary, the adoptive transfer of tumor reactive T cells can cause curative regressions of some cancers. These T cells can be obtained from the natural repertoire of the patient via TIL or be genetically constructed by introducing either a CAR or a native TCR with tumor specificity. Each of these approaches has their advantages and disadvantages (Table 2). Solving the problems of antigen selection and intrinsic tumor immune evasion will allow advances in the genetic engineering of T-cell fitness to better promote the durable rejection of cancers.

CONCLUSION

Multiple immunotherapeutic approaches are actively being pursued in metastatic GI cancers. Although standard ICIs help some patients for a relatively short time, the immuno-oncology revolution in cancer care has bypassed most of these patients. Novel strategies including new checkpoint inhibitors, cancer vaccines, OVs, and immune cell therapies hold the promise of overcoming barriers to effective treatments. Progress has been slow, but the large number of ongoing studies may lead to improved outcomes.

Update on Emerging Therapies for Advanced Colorectal Cancer

Olatunji B. Alese, MD, FWACS[1]; Christina Wu, MD[2]; William J. Chapin, MD, MSCE[3]; Mark B. Ulanja, MD[4]; Binbin Zheng-Lin, MD, MSc[2]; Millicent Amankwah, MD[5]; and Jennifer Eads, MD[3]

overview

Colorectal cancer (CRC) is the third most common malignancy worldwide. It is projected to increase by 3.2 million new cases and account for 1.6 million deaths by 2040. Mortality is largely due to limited treatment options for patients who present with advanced disease. Thus, the development of effective and tolerable therapies is crucial. Chemotherapy has been the backbone of systemic treatment of advanced CRC, but utility has been limited because of invariable resistance to therapy, narrow mechanisms of action, and unfavorable toxicity profile. Tumors that are mismatch repair-deficient have demonstrated remarkable response to immune checkpoint inhibitor therapy. However, most CRC tumors are mismatch repair-proficient and represent an unmet medical need. Although *ERBB2* amplification occurs only in a few cases, it is associated with left-sided tumors and a higher incidence of brain metastasis. Numerous combinations of *HER2* inhibitors have demonstrated efficacy, and antibody-drug conjugates against *HER2* represent innovative strategies in this area. The *KRAS* protein has been classically considered undruggable. Fortunately, new agents targeting *KRAS G12C* mutation represent a paradigm shift in the management of affected patients and could lead the advancement in drug development for the more common *KRAS* mutations. Furthermore, aberrant DNA damage response is present in 15%-20% of CRCs, and emerging innovative combinations with poly (ADP-ribose) polymerase (PARP) inhibitors could improve the current therapeutic landscape. Multiple novel biomarker-driven approaches in the management of patients with advanced CRC tumors are reviewed in this article.

INTRODUCTION

Colorectal cancer (CRC) is the third most common malignancy worldwide and is projected to increase by 3.2 million new incident cases and account for 1.6 million deaths by 2040.[1] Up to 25% of individuals with CRC present with stage IV disease and approximately 25%-50% who initially present with early-stage CRC go on to develop metastases.[2-4] Stage IV CRC has a 5-year survival of 12.5% in the United States, and thus, the development of safe, effective, and tolerable therapy represents an urgent clinical need.[3,5]

Colorectal cancers are classified on the basis of molecular profile. The most studied classification divides tumors into *RAS* (*KRAS*, *NRAS*, *HRAS*) and *BRAF* mutated or wild-type, which guides the use of epidermal growth factor receptor (EGFR) or the serine/threonine-protein kinase B-Raf inhibitors in this disease. More recently identified are the mismatch repair-deficient (dMMR) CRCs that constitute 15% of CRC neoplasms and are characterized by high microsatellite instability (MSI-H) by polymerase chain reaction (PCR) or lack of mismatch repair (MMR) protein expression by immunohistochemistry.[6] These tumors demonstrate an excellent response to immune checkpoint inhibitor (ICI) therapy,[6,7] but 85% of CRCs that are mismatch repair-proficient (pMMR) represent an unmet medical need. Additional targets such as *HER2* have also led to new molecularly based treatment options (Fig 1), and as our knowledge in the tumor genomic landscape deepens, the therapeutic paradigm of CRC is expanding. Herein, we summarize a novel biomarker-based therapy in patients with advanced CRC tumors.

SPECIFIC MOLECULAR TARGETS

Antiangiogenic Therapy

Angiogenesis plays a significant role in CRC metastasis and growth, and therapies targeting the vascular endothelial growth factor (VEGF) pathway have improved patient survival. There are five antiangiogenic drugs that are US Food and Drug Administration (FDA)–approved: bevacizumab, ramucirumab, ziv-aflibercept, regorafenib, and fruquintinib. Bevacizumab, a monoclonal antibody to VEGF-A, is the only drug approved in the first-line setting in combination with chemotherapy.[8,9] Continuation of bevacizumab in the second line with an alternative chemotherapy backbone also improves overall survival (OS) versus chemotherapy alone.[10,11] The phase III RAISE trial studied ramucirumab, a monoclonal antibody that targets VEGF receptor-2, in

PRACTICAL APPLICATIONS

- Novel biomarker-driven approaches in the management of patients with advanced colorectal cancer are leading to improvements in outcomes.
- New therapeutics targeting DNA repair pathways may play an important role for both early- and late-stage diseases.
- Innovative linker technologies, diverse payloads, higher drug-to-antibody ratios, and novel Fc receptor engineering are being investigated in the development of antibody-drug conjugates as cancer therapeutics.

combination with fluorouracil, leucovorin, and irinotecan (FOLFIRI) in the second-line setting for patients with metastatic CRC (mCRC) and demonstrated an OS improvement when compared with FOLFIRI alone. Similarly, ziv-aflibercept, a recombinant fusion protein that binds VEGF-A, VEGF-B, and placental growth factor, was shown in the VELOUR phase III study to improve survival when given in combination with FOLFIRI versus FOLFIRI alone in the second-line setting.[12] Although none of the antiangiogenic agents have been compared with each other prospectively, a recent retrospective analysis compared aflibercept and FOLFIRI (n = 326) with bevacizumab and FOLFIRI (n = 355) in patients with progressive CRC on first-line chemotherapy plus bevacizumab.[13] Bevacizumab was associated with better median progression-free survival (PFS), median OS, and treatment tolerability.

In patients with refractory mCRC, regorafenib, an oral VEGF inhibitor, demonstrated modest yet statistically significant improvement in disease control rate (DCR), median PFS, and median OS compared with best supportive care in two multicenter randomized trials.[14,15] In the phase III FRESCO-2 trial of patients with heavily treated mCRC, fruquintinib,

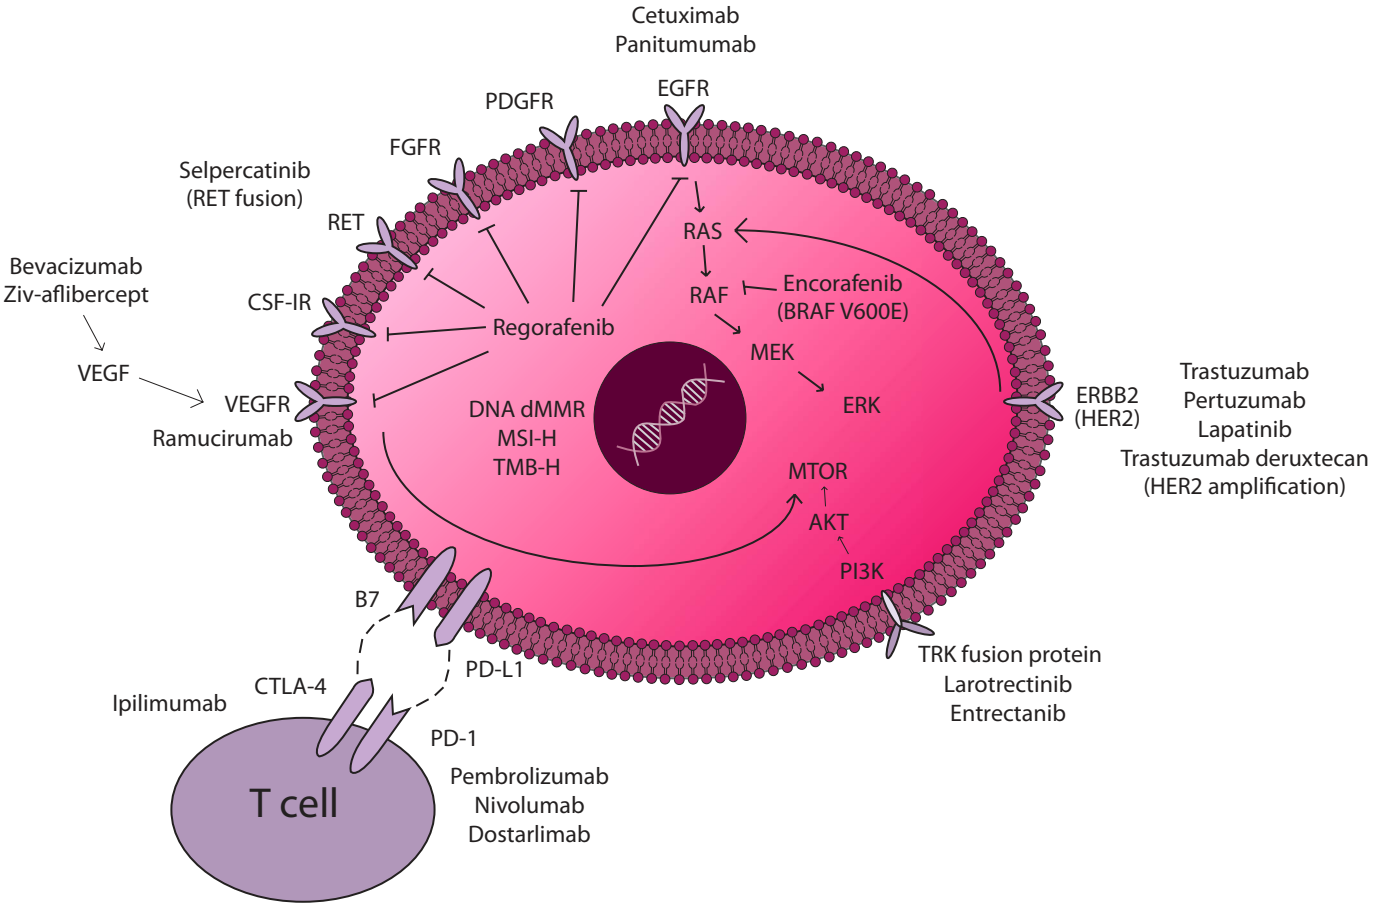

FIG 1. Molecular targets in colorectal cancer. CSF-IR, colony stimulating factor 1 receptor; CTLA-4, cytotoxic T-cell lymphocyte-4; dMMR, mismatch repair deficient; EGFR, epidermal growth factor receptor; HER2, human epidermal growth factor receptor 2; MSI-H, high microsatellite instability; PDGFR, platelet-derived growth factor receptor; TMB-H, tumor mutational burden-high (≥10 mutations/megabase [mut/Mb]); TRK, tropomyosin receptor kinase; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor. Artwork for figure graciously provided by Nyah Yao.

another oral VEGFR inhibitor, showed a superior DCR (55.5% *v* 16%) and median OS (7.4 *v* 4.8 months; hazard ratio [HR], 0.66; 95% CI, 0.55 to 0.80; $P < .001$) compared with placebo.[16] The recent phase III SUNLIGHT study randomly assigned patients with mCRC who had one to two previous lines of therapy to either trifluridine/tipiracil alone or bevacizumab, and there was an improvement in median OS with the addition of bevacizumab (10.8 months *v* 7.5 months; HR, 0.61; 95% CI, 0.49 to 0.77; $P < .001$).[17]

Anti–Human Epidermal Growth Factor Receptor 2 Therapy

ERBB2 amplification or human epidermal growth factor receptor 2 (HER2) overexpression occurs in 2%-3% of patients with CRC and is associated with left-sided tumors and a higher incidence of brain metastasis.[18,19] Clinically, retrospective data show that HER2 overexpression is associated with poorer response to anti-EGFR therapies in *RAS* wild-type metastatic CRC.[20] In addition to fam-trastuzumab deruxtecan discussed later in this chapter, dual HER2 blockade has shown benefit in HER2-overexpressing refractory CRC tumors.

The phase II MOUNTAINEER study with trastuzumab, a monoclonal antibody to HER2, plus tucatinib, an oral selective tyrosine kinase inhibitor (TKI) for HER2, reported an overall response rate (ORR) of 38%, a median PFS of 8.2 months, and an OS of 24 months for patients with HER2-amplified and RAS wild-type mCRC and had two or greater previous lines of therapy.[21] The targeted combination is now FDA-approved for patients with refractory HER2-amplified mCRC, and there is an ongoing phase III MOUNTAINEER-03 study that compares tucatinib and trastuzumab in combination with infusional fluorouracil, leucovorin, and oxaliplatin (FOLFOX) versus FOLFOX alone in the first-line mCRC setting (ClinicalTrials.gov identifier: NCT05253651). In the HERACLES trial, patients with HER2-amplified mCRC were treated with trastuzumab and lapatinib, an oral TKI of HER2 and EGFR. ORR was 30%, including one complete response (CR) and seven partial responses (PRs).[22,23] In the MyPathway and TAPUR studies, treatment with trastuzumab and pertuzumab, a monoclonal antibody that inhibits the dimerization of HER2 with HER3, yielded an ORR of 25% in 84 patients and 25% in 28 patients, respectively.[24,25] The challenge ahead will be to see how to best sequence the targeted combinations and if repeated HER2 amplification testing will be necessary after HER2-targeted treatments.

KRAS-Targeting Strategies

Forty percent of CRC tumors harbor *Kirsten rat sarcoma* (*KRAS*) missense mutations in codons 12, 13, or 61, which leads to constitutive activation of the *KRAS* gene, and this drives signaling in the MAPK pathway and carcinogenesis.[26] Anti-EGFR therapy in combination with chemotherapy is effective for patients with *KRAS*, *NRAS*, and *BRAF* wild-type and left-sided primary CRC tumors in the first-line metastatic setting, as demonstrated by multiple clinical trials.[27-29] The KRAS protein has otherwise been classically considered undruggable[30]; however, approximately 3% of CRCs harbor a $KRAS^{G12C}$ mutation that is inhibited by sotorasib and adagrasib, both small oral inhibitory molecules. When used as monotherapy in the phase II CodeBreak 100 study, sotorasib yielded a low ORR of 9.7% (n = 6) in 62 patients with previously treated $KRAS^{G12C}$-mutant advanced CRC.[31] Increased EGFR signaling appeared to be responsible for treatment-related resistance, which provided the rationale for dual $KRAS^{G12C}$ and EGFR blockade.[32] The phase II CodeBreak 101 trial (ClinicalTrials.gov identifier: NCT04185883) is currently exploring the clinical activity of sotorasib plus panitumumab.[33] The phase I/II KRYSTAL-1 trial compared adagrasib alone (n = 43) or with cetuximab (n = 28) in advanced $KRAS^{G12C}$-altered CRC.[34] Adagrasib alone showed an ORR of 19% (95% CI, 8 to 33) and a median PFS of 5.6 months (95% CI, 4.1 to 8.3). Adding cetuximab resulted in a markedly higher ORR of 46% (95% CI, 28 to 66) and a median PFS of 6.9 months (95% CI, 5.4 to 8.1). Interestingly, the doublet was associated with fewer grade 3/4 treatment-related adverse events (16% *v* 34%) which included diarrhea (3%), acneiform dermatitis (3%), and stomatitis (3%). There is an ongoing phase III study in the second-line setting, randomly assigning patients with $KRAS^{G12C}$-mutant mCRC to adagrasib and cetuximab versus chemotherapy (ClinicalTrials.gov identifier: NCT04793958).

BRAF Mutations

BRAF encodes a downstream GTPase of the RAS protein. $BRAF^{V600E}$ mutations occur in 5%-10% of CRC tumors and predict poor prognosis. In contrast, atypical or non-$BRAF^{V600E}$ mutations represent 2%-3% of CRCs and are associated with earlier age of diagnosis, left-sided tumors, and better survival outcomes.[35-37] Biologically, $BRAF^{V600E}$ mutations (designated as class I) produce a mutant kinase that activates as a monomer in a RAS-independent fashion. Atypical *BRAF* mutations lead to a RAS-independent kinase with intermediate/high activity (class II) or a RAS-dependent kinase with absent/low activity (class III). Clinically, the different *BRAF* classes translate into discordant responses to EGFR blockade.[38,39] *BRAF* class I CRCs display resistance to anti-EGFR therapy, which can be overcome by adding BRAF inhibitors.[40-43] In a retrospective analysis, CRCs with a class II $BRAF^{V600E}$ mutation showed a low ORR of 8% (n = 1) in 12 patients treated with cetuximab- or panitumumab-containing regimens while the class III mutation was associated with a significantly higher ORR of 50% (n = 14 of 28; $P = .02$).[39]

Targeted therapy for patients with mCRC with a $BRAF^{V600E}$ mutation is a combination of encorafenib, a BRAF inhibitor

plus an EGFR inhibitor in the second- or third-line settings on the basis of the phase III BEACON study.[30] There is an ongoing randomized phase II study of encorafenib and cetuximab with or without nivolumab, with the rationale that preclinical models have demonstrated a transient MSI-H phenotype with BRAF and EGFR inhibition (ClinicalTrials.gov identifier: NCT05308446). In addition, BREAKWATER is a randomized phase III study investigating encorafenib and cetuximab with or without doublet chemotherapy in the first-line setting for mCRC patients with a *BRAF*^{V600E} mutation (ClinicalTrials.gov identifier: NCT04607421). In contrast, for patients with atypical *BRAF* alterations, therapy selection and sequencing are undefined due to under-representation in trials. Ulixertinib, an orally available inhibitor of extracellular signal-regulated kinase (ERK) 1 and 2, showed an acceptable safety profile in a dose-finding phase I study with 135 patients with MAPK-mutant advanced solid tumors, which included atypical *BRAF* mCRC.[44] A phase II trial examining the clinical activity of ulixertinib is underway (ClinicalTrials.gov identifier: NCT04488003).

PIK3CA Blockade

Approximately 20%-25% of CRCs harbor an activating mutation of the *PIK3CA* oncogene, which encodes the catalytic subunit of phosphoinositide 3-kinase alpha (PI3Kα) as part of the AKT/mTOR pathway.[45] PI3K/AKT inhibition alone has not demonstrated clinical benefit.[46,47] Despite altered PI3Kα being implicated in resistance to anti-EGFR therapy, data on PI3Kα inhibitor-containing regimens remain scarce.[48,49] In a phase Ib study, 26 patients with *BRAF*-mutant metastatic CRC were treated with encorafenib plus cetuximab while 28 also received the PI3K inhibitor, alpelisib. The triplet did not improve ORR compared with the doublet regimen (18% *v* 19%) and was associated with a higher incidence of all-grade hyperglycemia (39% *v* 8%).[50] Early-phase trials are examining the activity of various oral selective PI3K inhibitors in recurrent mCRC, including MEN1611 combined with cetuximab (ClinicalTrials.gov identifier: NCT04495621), alpelisib plus capecitabine (ClinicalTrials.gov identifier: NCT04753203), and inavolisib plus cetuximab or bevacizumab (ClinicalTrials.gov identifier: NCT04929223). As *PIK3CA* mutations result in tumor dependency on glutamine, a trial with a glutaminase inhibitor, telaglenastat (CB-839), plus capecitabine is currently underway (ClinicalTrials.gov identifier: NCT02861300).[51]

NTRK Fusion-Driven CRC

In 0.5%-1% of CRC tumors, structural rearrangements of *neurotrophic tyrosine kinase receptor* (*NTRK*) genes encode a constitutively activated chimeric tropomyosin receptor kinase (TRK), resulting in cancer cell growth and survival. *NTRK* fusion-driven CRC tumors exhibit high tumor mutational burden and MSI-H and are associated with poor prognosis.[52] In a pooled analysis from three phase I/II studies, 159 patients with *NTRK* fusion-positive tumors received the TRK inhibitor larotrectinib.[53] Eight patients with CRC were included, of whom four had an objective response (ORR 50%, 95% CI, 16 to 84) with a median duration of response (DOR) of 3.7 months (95% CI, 3.7 to not estimable). Similarly, the efficacy of entrectinib was recorded by an integrated analysis from three studies (STARTRK-2, STARTRK-1, and ALKA-372-001) comprising 121 patients with 14 different *NTRK* fusion-positive tumor types.[54] In the CRC-specific cohort with 10 participants, two (20%) had an objective response. The median PFS and OS were 2.8 and 16 months, respectively. At present, studies informing the treatment sequence in this tumor subset are lacking. Both of these agents are approved by the FDA for patients whose disease has progressed on standard therapy and for whom there are no remaining treatment options.[55,56]

RET Inhibitors

Fusions in the *rearranged during transfection* (*RET*) gene have been reported in <1% of patients with CRC and are associated with MSI-H and *RAS*/*RAF* wild-type tumors.[57] Selpercatinib received FDA tumor-agnostic approval for refractory advanced solid tumors with a *RET* gene fusion on the basis of the results from the LIBRETTO-001 trial.[58,59] In this phase I/II, open-label, basket study, 45 patients with advanced *RET* fusion-positive tumors received oral selpercatinib twice daily. A PR was observed in 2 of 10 patients with CRC. The median DOR was 9.4 months. The activity of another oral RET TKI, pralsetinib, was examined in the phase I/II ARROW study. In the efficacy-evaluable cohort of 23 participants, two had CRC and both attained stable disease.[60]

TARGETING DNA REPAIR ABNORMALITIES

An aberrant DNA damage response (DDR) is present in 15%-20% of neoplasms.[61,62] New therapeutics targeting DNA repair pathways may play an important role in the management of mCRC. There are four known DNA repair systems that are implicated in the pathogenesis of CRC—nucleotide excision repair (NER), base excision repair (BER), MMR, and double-strand break repair (DSBR).[63] Each DNA repair system is activated in response to distinct DNA insults. The NER pathway responds when DNA damage occurs in the setting of irradiation, chemotherapeutic agents, or mutagens. The BER system uses DNA polymerases to repair damage from oxidation, alkylation, or methylation.[64,65] Ionizing radiation or DNA fork collapse-related insults are typically repaired by DSBR, which involves homologous recombination repair during the S phase and nonhomologous end joining during the S and G2 phases.[63,66] Herein, we discuss current and future therapies for CRC that target proteins involved in DNA damage response pathways.

Poly (ADP-ribose) Polymerase Inhibition

Poly (ADP-ribose) polymerase (PARP) inhibitors (PARPi) are currently used for the management of breast, ovarian, prostate, and pancreatic cancers with *BRCA1/2* alterations.[67-69] PARP inhibition is thought to accelerate replication fork progression or collapse, resulting in cell death.[70,71] Germline or somatic alterations in homologous recombination genes are present in up to 20% of CRCs; thus, PARPi are currently under investigation for both early- and late-stage diseases.[72-74]

DNA-damaging agents have been combined with PARPi with some encouraging results in clinical trials. In a study of 92 patients with advanced solid tumors, 10 patients with CRC were included in a molecularly unselected patient population. PR was achieved in two of nine patients with CRC receiving veliparib (200 mg twice daily) plus FOLFIRI therapy, with an ORR of 22.2%.[75] The treatment was well-tolerated with the most common side effects being nausea, diarrhea, and neutropenia. Other trials have focused primarily on the safety of PARPi in combination with chemotherapy. Investigators concluded that the recommended phase II dose of olaparib when given with irinotecan was 50 mg twice daily on days 1-5 (Table 1).[79] Veliparib combined with capecitabine and radiotherapy also showed an acceptable toxicity profile in a dose-escalation phase Ib study of 32 molecularly unselected stage II and III patients with locally advanced resectable adenocarcinoma of the recturm.[80] Tumor downstaging was noted in 71% of patients, and 29% achieved a pathological CR. The recommended dose of veliparib was 400 mg twice daily.

Studies assessing the efficacy of PARPi in CRC have showed mixed results. In a single-arm, open-label, phase II study, 75 patients with heavily pretreated CRC without selection on the basis of DDR status received veliparib plus temozolomide. The primary end point was met with a 25% DCR. Additionally, 4% of patients experienced a PR, with a median PFS of 1. 8 months and a median OS of 6.6 months.[81] In another phase II study including 33 patients who experienced disease progression on standard treatment regimens, single-agent olaparib did not demonstrate activity as no patient experienced complete response or PR.[82]

Early-stage studies highlight the need to combine PARPi with either other DNA repair agents or DNA-damaging agents to harness the full clinical effect. Other studies have evaluated PARPi and anti-EGFR therapy in breast cancer, lung cancer, and CRC and have shown synthetic lethality.[83-85] The use of the PARPi, niraparib in combination with the EGFR inhibitor panitumumab, is currently being explored in CRC with promising early efficacy data (ClinicalTrials.gov identifier: NCT03983993).[86] Taken together, the use of PARPi in microsatellite stable (MSS), pMMR CRC appears promising and more preclinical and clinical trials are needed to better understand and explore the clinical opportunities this class of drugs may offer.

ATM Kinase Inhibition

Ataxia telangiectasia-mutated (*ATM*) kinase is a member of the PI3K-related kinases and is involved in homologous recombination and nonhomologous end-joining pathways for double-stranded DNA breaks and is involved in G1/S cellular checkpoint activation.[87] This gene is frequently altered in CRC, and inhibition of ATM has been evaluated preclinically. ATM inhibitors M3541 and M4076 have shown suppression of DSBR, with inhibition of cancer cell growth. Additionally, these agents potentiated the antitumor effect of radiation in mice bearing human tumor xenografts.[88] In CRC cell lines and patient-derived xenografts, the ATM kinase inhibitor, AZD0156, was explored as a single agent and in combination with irinotecan (SN38) and fluorouracil (FU).[89] Increased G2/M arrest and improved growth inhibition were observed in the combination treatment compared with single agent.[89]

In the TAPUR phase II basket study, 30 patients with treatment-refractory CRC harboring ATM mutations were treated with olaparib.[78] One of the patients had a PR (ATM P938fs*11 and RAD50 variant of unknown significance), with a duration of response lasting 18.6 weeks. Three patients had stable disease (SD) at 16 weeks or longer (SD16+: ATM R1875*, splice site 4237-11_4241del16, E522*). The duration of SD was 19.7, 25.3, and 27.0 weeks, respectively. The DCR was 23% (95% CI, 6 to 39), with an ORR of 4% (95% CI, 0.1 to 19). Six of the patients had a BRCA2 coalteration, but none of them achieved OR or SD16+. The study concluded that olaparib monotherapy did not show sufficient antitumor activity in patients with advanced CRC with ATM mutations to warrant further study.

ATR Inhibition

Ataxia telangiectasia and Rad3-related 9 (ATR) plays an important role in maintaining genome integrity, and disruption of the ATR pathway leads to replication stress and promotion of cell killing. ATR kinase appears to be a viable target for anticancer treatment.[90] ATR inhibition also leads to sensitization of cells to radiation and chemotherapy.[91,92] Patients with tumors with unstable replication forks but not exhibiting defects in homologous recombination may benefit from ATR inhibitor (ATRi) therapies.[93-95] The combination of chemosensitizing agents with cytotoxic agents to increase synthetic lethality in MSS CRC is an attractive proposition that may prevent chemoresistance.[96] A study using the ATRi, AZD6738, in combination with FU showed markedly decreased cell proliferation when compared with FU alone. The effect of AZD6738 with FU was further evaluated in p53-deficient CRC cells, and it effectively inhibited cell survival in all cell lines.[97] Other studies have shown similar results in TP53-mutant CRC models.[98] ATRi

TABLE 1. Therapies Targeting DNA Repair—Completed Clinical Trials

Study Identifier	Phase	Patient Population	Mutations	Treatment Arm(s)	Results
Chen[27] NCT00535353	I	Locally advanced or mCRC (n = 25)	Not required	Olaparib-PARPi plus irinotecan	Intermittent olaparib dosing tolerable, RP2D 50 mg twice a day, 9 of 25 had stable disease (3-13 months)
Berlin[76] NCT01123876	II	Advanced solid tumors including mCRC (n = 10)	Not required	Veliparib-PARPi plus FOLFIRI	No MTD was established, RP2D-200 mg twice a day veliparib ORR: 11.1%
Leichman[31] NCT00912743	II	mCRC (n = 33; 20 MSS, 13 MSI-H)	Stratified by MSI status	Olaparib-PARPi	No complete or PRs reported. mPFS for all patients at 1.84 months, no difference in mPFS among MSS and MSI patients
Michael[77] NCT01589419	Ib	Locally advanced rectal cancer (n = 32)	Not required	Veliparib-PARPi plus capecitabine plus radiation	MTD not reached, RP2D-veliparib 400 mg twice a day, 72% (of 32) postsurgery tumor downstaging, 28% pathologic CR, 70% of 30 had sphincter sparing surgery
Gorbunova[32] NCT02305758	II	mCRC (n = 130)	Not required	Veliparib-PARPi (*v* placebo) plus FOLFIRI with or without bevacizumab	mPFS: 12 *v* 11 months mOS: 25 *v* 27 months mDOR: 11 *v* 9 months ORR: 57%
Pishvaian[30] NCT01051596	II	mCRC (n = 75)	Not required	ABT-888 (veliparib)-PARPi plus temozolomide	DCR-24% mPFS: 1.8 months mOS: 6.6 months PTEN and MGMT protein expression were not predictive of DCR
Cohen[78] NCT02906059	Ib	mCRC progressed on first line (n = 7)	KRAS, NRAS, or BRAF	AZD1775 (WEE 1 inhibitor) plus irinotecan	No results reported

Abbreviations: CR, complete response; DCR, disease control rate; FOLFIRI, fluorouracil, leucovorin, and irinotecan; mCRC, metastatic colorectal cancer; mDOR, median duration of response; mOS, median overall survival; mPFS, median progression-free survival; MSI-H, high microsatellite instability; MSS, microsatellite stable; MTD, maximum tolerated dose; ORR, overall response rate; PARP, poly (ADP-ribose) polymerase; PARPi, Poly (ADP-ribose) polymerase inhibitors; PR, partial response; RP2D, recommended phase II dose.

has demonstrated efficacy as monotherapy or in combination. In preclinical models, BAY 1895344, a novel ATRi, showed efficacy in CRC models that have DNA damage repair deficiencies, either as monotherapy or in combination with chemotherapy or external beam radiotherapy, with synergistic antitumor effect.[99]

ATRi has also been studied with other DNA-damaging drugs to explore clinical effects. In a phase I trial, Yap et al[100] used ATRi M6620 (VX-970) as monotherapy and in combination with carboplatin in patients with advanced solid tumors and demonstrated safety and tolerability. Additionally, a patient with mCRC with ATM loss and an ARID1A mutation had complete and maintained response providing rational for future studies with this combination. A preclinical study using pancreatic and colorectal cell lines demonstrated potent synergy between the ATR inhibitor, ceralasertib, and PARPi therapy.[101] ATR inhibition has been studied in cancers other than CRC, including the association of ATM mutations with response. The ATRi elimusertib was evaluated in a phase Ib expansion trial of 143 patients with advanced solid tumors resistant or refractory to standard treatment. The study included patients with CRC, castration-resistant prostate cancer, HER2-negative breast cancer, gynecologic cancers, and advanced cancers with ATM loss by immunohistochemistry (IHC). The elimusertib monotherapy showed clinical effects in patients with DDR defects. Of the five PRs observed, 60% (3 of 5) were in tumors with ATM IHC loss.[102] Other studies have shown good response in pretreated ATM-mutated advanced solid tumors.[103] The results from larger clinical trials are needed to assess the efficacy of ATRi for the treatment of MSS CRC (Table 2).

Checkpoint Kinase Inhibition

Checkpoint kinase 1 (CHK1) is a key mediator of the DNA damage response and regulates the cell cycle.[104] In the presence of replication stress during the S phase of the cell cycle, CHK1 interacts with ATR and promotes replication fork stabilization. CHK1 inhibitors block replication stress signaling in malignant cells that have DNA repair defects[93,105] and induce synthetic lethality.[104] Targeting either MRE11 or RAD51 has shown to increase sensitivity of

TABLE 2. Therapies Targeting DNA Repair—Active Clinical Trials

Study Identifier	Phase	Patient Population	Mutations	Treatment Arm(s)	Primary End Point	Secondary/Exploratory End Point
NCT05201612	II	Refractory mCRC (n = 40)	HRD	Olaparib—PARPi Pembrolizumab	ORR at 10 months	DCR, PFS, OS, DOR at 10 months/HRD score by Myriad MyChoice
NCT05412706	II	mCRC with CR/PR after oxaliplatin induction (n = 46)	Not required	Niraparib-PARPi maintenance	PFS at 36 months	PFS after reintroduction of first-line treatment, OS, ORR, ITEAE
NCT02484404	I/II	Advanced solid tumors including mCRC (n = 386)	Not required (PD-L1 expression)	Olaparib-PARPi Cediranib Durvalumab	Phase I: Recommended phase II dose, safety of doublet therapies Phase II: ORR of durva-O or durva-C in recurrent ovarian cancer	Cohort 4, mCRC: ORR, safety, DOR
NCT03983993	II	Advanced colorectal (n = 40)	RAS wild-type, MSI, MSS	Niraparib-PARPi plus panitumumab	Clinical benefit rate (up to 5 years)	ORR, DOR, PFS, OS (up to 5 years post-treatment)
NCT04644068	I/IIa	Advanced solid tumors including CRC (n = 715)	Not required	AZD5305-PARPi (with or without anticancer agents) Paclitaxel Carboplatin T-Dxd Dato-DXd	Adverse events (approximately 1 year) DLT (up to cycle 1)	Best change in target lesion ORR, DOR, PFS, TTR
NCT03337087	I/II	Metastatic pancreatic, CRC, EGC, or biliary cancer (n = 18)	Not required	Rucaparib-PARPi Fluorouracil liposomal Irinotecan Leucovorin	Phase I: DLT (up to 28 days) Phase Ib: ORR (up to 3 years) Phase II: BRR (at 32 weeks)	DCR, OS, PFS, adverse events
NCT02921256	II	Locally advanced rectal cancer (n = 362)	Not required	Veliparib-PARPi *v* pembrolizumab plus mFOLFOX, radiation and capecitabine	Neoadjuvant rectal score (up to 3 years)	OS, DFS, pCR, sphincter preservation rate (up to 3 years)
NCT04535401	I	Advanced or metastatic gastric, or colorectal cancers (n = 90)	Not required	Elimusertib (BAY 1895344-ATRi Fluorouracil Irinotecan Leucovorin	MTD (up to 28 days)	OvRR, PFS, OS (up to 1 year post-treatment) PBMC gammaH2AX and p-ATM signaling, ATM status
NCT02595931	I	Metastatic solid tumor (n = 66)	Not required	M6620 (VX-970, berzosertib)-ATRi Irinotecan hydrochloride	MTD (up to 28 days) Recommended phase II dose	IAE, OvRR, ISD, PFS (up to 6 months post-treatment) PK/PD parameters

Abbreviations: ATRi, ataxia-telangiectasia mutated and Rad3-related kinase inhibitor; BRR, best response rate; CR, complete response; CRC, colorectal cancer; Dato-DXd, datopotamab deruxtecan; DCR, disease control rate; DLT, dose-limiting toxicity; DOR, duration of response; EGC, esophagogastric cancer; HRD, homologous recombination repair deficiency; IAE, incidence of adverse events; ISD, incidence of stable disease; ITEAE, incidence of treatment-emergent adverse events; mCRC, metastatic colorectal cancer; MFOLFOX, modified infusional fluorouracil, leucovorin, and oxaliplatin; MSI, microsatellite instability; MSS, microsatellite stable; MTD, maximum tolerated dose; ORR, objective response rate; OS, overall survival; OvRR, overall response rate; PARPi, poly (ADP-ribose) polymerase inhibitor; PBMC, peripheral blood mononuclear cell; pCR, pathologic complete response; PD, pharmacodynamic studies; PFS, progression-free survival; PK, pharmacokinetic studies; PR, partial response; T-Dxd, trastuzumab deruxtecan; TTR, time to response.

the CHK1 inhibitor prexasertib in CRC stem cells by inducing mitotic catastrophic events, resulting in caspase-dependent cell death.[106] The effect of the CHK1i, LY2606368, was studied in vivo and in vitro in CRC stem cells isolated from 27 patients. It showed that most CRC stem cells which are TP53-deficient entered catastrophic premature mitosis and apoptosis; this was independent of *KRAS* status.[107] This is promising, as *KRAS* alteration is a negative predictive biomarker for many therapies in CRC and is associated with poor prognosis. These cells display intrinsic genotoxic stress and CHK1 and MK2 activity. It has been shown that simultaneous inhibition of CHK1 and MK2

leads to mitotic lethality in *KRAS*-altered cells in xenograft models and murine cancer cells.[108] These findings require exploration in clinical trials for CRC patients with chemotherapy-resistant tumors.[109,110]

Clinical trials examining the effect of CHK1/2 inhibitors are mostly in the early phases. These have included a phase Ib trial of CHK1i, prexasertib, in combination with chemotherapy or anti-EGFR therapy and a phase I/II dose-escalation trial of CHK1i, SRA737, as monotherapy.[111,112] Although another CHK1i, AZD7762, will not undergo further development because of unacceptable cardiac toxicity, this provides insight into potential toxicities of this class of therapy that will need to be monitored in further studies.[113,114]

WEE1 Kinase Inhibition

WEE1 is a tyrosine kinase that regulates the G2 checkpoint through the inhibition of cyclin-dependent kinase 1 (CDK1) by phosphorylation.[115] WEE1 kinase inhibition may also sensitize TP53-deficient tumor cells to DNA damage. FOCUS4-C, a randomized phase II study,[116] enrolled patients who had both *RAS* and *TP53* mutations who had responded to or been stable on chemotherapy. Sixty-nine patients were enrolled and treated with adavosertib (AZD1775), a selective Wee1 inhibitor (n = 44) or active monitoring (n = 25). Adavosertib was associated with significantly improved PFS versus active monitoring (median 3.61 *v* 1.87 months; HR, 0.35; 95% CI, 0.18 to 0.68; $P = .0022$), but there was no difference in OS. There was also a signal of greater adavosertib activity in left- versus right-sided tumors. The drug was well tolerated with grade 3 toxicities including diarrhea, nausea, and neutropenia. WEE1 kinase inhibitors have demonstrated promising activity in the early-phase clinical trials with tolerable toxicity profile and are also being explored in combination with other agents, especially in patients with treatment-refractory CRC harboring *KRAS, NRAS*, or *BRAF* alterations.

IMMUNOTHERAPY IN MSS CRC

One important molecular classification for choosing systemic therapy in patients with advanced CRC is MMR/MSI status. MMR-deficient/MSI high tumors are defined by absence of expression of MMR proteins by IHC or high variability of standardized microsatellites assessed by PCR. In contrast, MMR-proficient/MSS tumors are defined by normal expression of all MMR proteins by IHC and low variability of standardized microsatellites by PCR. These subgroups have different characteristics in terms of tumor immune microenvironment and are characterized by differing sensitivity to ICI therapy. Although dMMR CRCs have higher tumor mutational burden, $CD8^+$ cytotoxic T and Th1 helper cell infiltration and high levels of HLA proteins,[117,118] pMMR or MSS CRC are associated with an immune cold and immune excluded tumor microenvironment (TME) on the basis of T-cell density in tumor core, inner invasive, and outer invasive margins.[118,119] Of the four consensus molecular subtypes (CMS1, CMS2, CMS3, and CMS4), the CMS2-4 subtypes represent less immunogenic phenotypes with a less immunogenic TME and are largely pMMR CRC.[120] Immune cells such as M2 macrophages, regulatory T cells, and myeloid-derived suppressor cells exert immunosuppressive activity.[121] This biology underlies the resistance of pMMR to ICIs. Extensive research has focused on methods for improving the sensitivity of pMMR/MSS tumors to ICI therapy.

Chemotherapy and radiation therapy induce DNA damage including double-strand breaks, leading to genomic instability, which may trigger an antitumor immune response.[122-124] Because of their ability to induce DNA lesions that may encode immune-stimulating neoantigens, chemotherapy and radiation therapy have been explored in combination with ICIs in patients with pMMR/MSS CRC in hopes of improved efficacy in this patient population.

Chemotherapy has been studied in combination with ICI therapy because of its direct cytotoxic activity with the release of neoantigens into the circulation along with reduction in immunosuppressive Treg activity. Additionally, preclinical data in CRC cell lines have demonstrated that chemotherapy increases PD-L1 expression, potentially sensitizing cells to ICIs.[125] Combining chemotherapy with ICIs has been studied in lung and gastric cancers leading to multiple FDA approvals.[126] This approach has been explored in patients with advanced pMMR/MSS colorectal cancer as well—the multicenter, randomized, open-label, phase II AtezoTRIBE study combined FOLFOXIRI (folinic acid, fluorouracil [5FU], oxaliplatin and irinotecan) and bevacizumab (bev), with or without atezolizumab (atezo) in patients with pMMR or dMMR advanced CRC. The combination arm with atezolizumab was associated with significantly improved PFS (HR, 0.69; $P = .012$). Although the magnitude of benefit was higher in dMMR cancer, efficacy signal was noticed in the pMMR group.[127] Further clinical trials will provide more answers as to the role of ICIs in pMMR CRC and hopefully help shape treatment guidelines. One of those trials is the phase II POCHI trial (ClinicalTrials.gov identifier: NCT04262687), a proof-of-concept study combining pembrolizumab with oxaliplatin and bevacizumab in patients with MSS CRC and high immune infiltrates.

Combining radiation therapy with ICIs to improve response has also been explored.[128] Radiation has a cytocidal effect and may synergistically prime and maintain the immune response when combined with ICIs. The combination of radiation therapy with ICIs also leads to cross-priming of tumor-specific cytotoxic T lymphocytes and helps to neutralize immunosuppressive effects of TMEs.[76] Other studies have shown that ICIs potentiate radiosensitivity of cancer cells by repressing PD-L1/PD1.[77,129] Radiation therapy has also been associated with an abscopal effect, where tumor response is observed in lesions outside of the radiation field because of the immune-stimulating effects of radiation

therapy.[130] A nonrandomized phase II study[131] studied pembrolizumab with radiation therapy or ablation. An interim analysis of 26 patients with pMMR/MSS CRC demonstrated an ORR of 9% in the radiation therapy plus pembrolizumab group, but 0% in the ablation plus pembrolizumab group. Interestingly, one patient achieved a PR after radiation therapy in a nonirradiated lesion suggesting an abscopal effect.[131] Furthermore, a phase II single-arm study[132] combined durvalumab, tremelimumab, and radiation therapy in chemotherapy-refractory pMMR CRC to assess ORR (primary end point) in nonirradiated lesions. The ORR was 8.3%, which did not meet the prespecified end point. However, there was regression in nonirradiated lesions suggesting an abscopal effect. Twenty-five percent of patients in the cohort experienced grade 3-4 adverse events.[132] The combination of radiation therapy plus ICIs is feasible with a manageable side effect profile in pMMR CRC.

VEGF signaling exerts immunosuppressive effects in the TME, and anti-VEGF therapies may promote a less immunosuppressive tumor immune microenvironment.[133,134] In the phase II BACCI trial, the addition of atezolizumab (anti–PD-L1) to capecitabine and bevacizumab in refractory pMMR/MSS CRC was associated with improved PFS, meeting the study's prespecified primary end point, although this was considered to be marginal and not clinically signfiicant.[135] The addition of atezolizumab to maintenance therapy with FU and bevacizumab in patients with pMMR CRC in the MODUL trial did not demonstrate a benefit.[136] The NIVACOR trial combining FOLFOXIRI/bevacizumab in association with an anti–PD-1 antibody, nivolumab, in *RAS*- or *BRAF*-altered CRC, regardless of MMR status, preliminarily showed an acceptable toxicity profile.[137] Other options that have been explored in MSS CRC include ICIs in combination with anti-EGFR therapies[138,139] and in combination with MAPK pathway inhibitors with ICIs.[140-143]

In addition to strategies that alter the tumor immune microenvironment, therapies that target multiple immune checkpoints in combination have been explored with preliminary success in CRC. A phase I study of botensilimab, and Fc-enhanced cytotoxic T-cell lymphocyte-4 inhibitor, and balstilimab, and PD-1 inhibitor, in patients with advanced MSS/pMMR CRC was associated with an ORR of 22% in 58 patients, with a DCR of 73%.[144] The most commonly observed grade 3 or 4 adverse event was immune-mediated colitis in 21% of patients. On the basis of these promising results, a phase II randomized trial in MSS CRC is underway (ClinicalTrials.gov identifier: NCT05608044).

Although ICIs have been effective in patients with dMMR/MSI-H CRC, results have been underwhelming in patients with pMMR/MSS CRC.[145,146] Combination therapies of ICIs with chemotherapy and radiation therapy, combination therapies of ICIs with agents that alter the tumor immune microenvironment, and combinations of agents targeting multiple immune checkpoints have demonstrated promise for enhancing the response of ICIs in patients with pMMR/MSS CRC.

ANTIBODY-DRUG CONJUGATES IN COLORECTAL CANCER

There has been increasing interest in antibody-drug conjugates (ADCs) as cancer therapeutics, leading to 12 active FDA approvals across hematologic malignancies and solid tumors.[147,148] ADCs consist of antibodies that target tumor cell surface molecules, a cytotoxic payload (or a payload with a distinct mechanism of action, including immune-stimulating functions), and a linker molecule, all of which can affect the pharmacokinetic, pharmacodynamic, and safety profiles of the agent.[149,150] The rationale behind the design of ADCs is that they have the potential to improve the therapeutic index of potent cytotoxic therapies by delivering them more selectively to tumor tissues with relative sparing of normal tissues. The primary mechanism of action of ADCs involves antibody binding to the target antigen on tumor cells, internalization of the ADC, cleavage of the linker by various mechanisms, and the payload exhibiting its cytotoxic effect in target cells.[150,151] Additional mechanisms contributing to

TABLE 3. Ongoing Trials of Antibody-Drug Conjugates in Colorectal Cancer

Study Identifier	Agent	Target	Payload	Special Features
NCT04744831	Trastuzumab deruxtecan	HER2	Deruxtecan (topoisomerase I inhibitor)	
NCT05464030	M9140	CEACAM5	Exatecan (topoisomerase I inhibitor)	
NCT05493683	Disitamab vedotin	HER2	Monomethyl auristatin E (microtubule inhibitor)	In combination with immune checkpoint inhibitor, tislelizumab
NCT05489211	Datopotamab deruxtecan	Trop2	Exatecan (topoisomerase I inhibitor)	
NCT04410224	ASN004	5T4	Auristatin F hydroxypropylamide (microtubule inhibitor)	Single-chain Fv-Fc antibody
NCT03602079	A166	HER2	Duo-5 (microtubule inhibitor)	
NCT04460456	SBT6050	HER2	TLR8 agonist	Immune stimulatory payload; monotherapy and in combination with PD-1 inhibitor

Abbreviation: Fv-Fc, fragment variable, fragment crystallizable.

efficacy include antibody-dependent cytotoxicity of target cells and the bystander effect by which free cytotoxic payload affects target negative adjacent cells.[152,153]

Numerous ADCs have been evaluated in patients with advanced colorectal cancer (CRC), although only one to date is supported in guidelines for use, and none have yet garnered FDA approval in this patient population.[30] Here, we review the existing data and highlight ongoing studies involving the use of ADCs as a treatment of CRC (Table 3).

Trastuzumab Deruxtecan

The HER2 (ERBB2) receptor is part of the family of receptor tyrosine kinases that include EGFR/ERBB1, ERBB3, and ERBB4. All these receptors have an extracellular ligand-binding region, a membrane-spanning region, and a cytoplasmic receptor tyrosine kinase domain. Binding of ligands to the HER2 receptor promotes dimerization and activation of the intrinsic kinase domain, which activates intracellular signaling pathways that contribute to tumorigenesis and progression.[154] HER2 overexpression is present in up to 20% of breast and gastric cancers but is also overexpressed in 2%-3% of CRCs.[155-157] The HER2-targeting monoclonal antibodies trastuzumab and pertuzumab are approved in combination with chemotherapy for the first-line treatment of metastatic HER2-overexpressing breast cancer, and trastuzumab is approved in combination with chemotherapy (with or without immunotherapy) for the first-line treatment of advanced HER2-overexpressing gastroesophageal cancer.[158-160] In patients with HER2-overexpressing CRC who had previously been treated with standard-of-care therapies, HER2-targeted therapies including trastuzumab plus lapatinib, trastuzumab plus pertuzumab, and trastuzumab plus tucatinib demonstrated ORRs of 30%-38%, supporting continued investigations of HER2-targeted therapies in this patient population.[23,161,162]

Trastuzumab deruxtecan is an ADC with a humanized anti-HER2 antibody, a cleavable, peptide-based linker, and a potent topoisomerase I inhibitor payload.[163,164] Preclinical work demonstrated that the cytotoxic payload is highly membrane permeable and exhibits a strong bystander effect on adjacent HER2-negative cells.[153] Trastuzumab deruxtecan was evaluated in a phase I dose escalation and expansion trial in patients with tumors harboring HER2 overexpression or mutation, including 20 patients with CRC.[163] Among these patients, 45% (9 of 20) had tumors with HER2 IHC 3+, 10% (2 of 20) with HER2 IHC 2+ (one of these tumors was HER2 FISH positive), 10% with HER2 IHC 1+, and 30% (6 of 20) with HER2 mutations. The confirmed ORR was 15% by investigator review, but only 5% by confirmed central review with a DCR of 80%.[163] On the basis of these results, a single-arm phase II trial of trastuzumab deruxtecan was performed in patients with advanced CRC with HER2 expression who had experienced disease progression on at least two previous therapies (DESTINY CRC 01).[165] Notably, patients could enroll if they had previously received treatment with other HER2-directed therapies. Three cohorts were enrolled on the basis of tumor HER2 expression by IHC and FISH: (A) HER2 IHC 3+ or HER2 IHC 2+ with positive FISH, (B) HER2 IHC 2+ with negative FISH, or (C) HER2 IHC 1+. The primary objective was ORR in cohort A which was 45.3% (95% CI, 31.6 to 59.6) among 53 patients with a DCR of 83% (95% CI, 70.2 to 91.9). There were no responses in cohorts B and C suggesting that, in contrast to breast cancer with low HER2 expression, there does not appear to be a signal for efficacy for patients with CRC and low HER2 expression.[165,166]

Regarding toxicity, trastuzumab deruxtecan has been associated with pneumonitis and interstitial lung disease. In DESTINY CRC 01, 6.41% of patients experienced pneumonitis or interstitial lung disease, with 3.8% of patients experiencing grade 3 or higher pneumonitis, including two patients with grade 5 events.[165] Overall, this is consistent with estimates across studies of trastuzumab deruxtecan in advanced solid tumors which demonstrated rates of any grade pneumonitis or interstitial lung disease of 11.40%.[167] On the basis of these findings, trastuzumab deruxtecan is recommended in the second line and beyond for patients with advanced CRC with HER2 amplification or overexpression that are *KRAS*, *NRAS*, and *BRAF* wild-type but does not hold an official FDA approval for this indication. DESTINY-CRC 02 (ClinicalTrials.gov identifier: NCT04744831) is an ongoing study investigating different dose levels of trastuzumab deruxtecan in patients with HER2-overexpressing CRC (Table 3).

ADCs Without Clear Signals for Efficacy and/or Safety in Colorectal Cancer

Although recent success across solid tumors has demonstrated the promise of ADCs, there have been many examples that appeared promising in preclinical development but were found to be too toxic or with insufficient activity in clinical trials. There are many reasons for this discrepancy, including normal tissue target antigen expression in animal models that differs from humans, linker chemistry that leads to free cytotoxic drug and off-target toxicity, and choice of payload to which CRC is not intrinsically sensitive at pharmacokinetically achievable doses.[151] We discuss the following examples to highlight lessons that can be learned from this valuable previous work.

Trastuzumab emtansine (anti-HER2 ADC). Trastuzumab emtansine is a an ADC consisting of trastuzumab linked through a thioether uncleavable linker to a microtubule inhibitor (DM1) with a drug-to-antibody ratio of 3.5:1 that is approved for HER2-positive breast cancer in multiple

disease settings.[168] Before the development of trastuzumab deruxtecan, trastuzumab emtansine was evaluated in patients with advanced CRC with HER2 overexpression. Results were underwhelming as ORR was 0% in 11 patients with CRC treated with trastuzumab emtansine monotherapy and was 9.7% in patients with CRC treated with pertuzumab plus trastuzumab emtansine.[169,170] Despite sharing a common target (HER2) and monoclonal antibody (trastuzumab), trastuzumab deruxtecan demonstrated an ORR of 45% in a similar setting highlighting the importance of the linker technology and the choice of cytotoxic payload in the development of an ADC. Future development of ADCs in CRC should prioritize classes of cytotoxic payloads to which CRC is known to be sensitive.

Labetuzumab govitecan (anti-CEACAM5 ADC). Labetuzumab govitecan is an ADC targeting carcinoembryonic antigen-related cell adhesion molecule 5 (CEACAM5) or CEA that is expressed in >80% of CRCs.[171] The cytotoxic payload is SN-38, an active metabolite of irinotecan.[172] Preclinical models demonstrated enhanced delivery of SN-38 to tumor and less to normal tissues compared with irinotecan.[173] A phase I/II trial evaluated labetuzumab govitecan in patients with advanced CRC with serum CEA levels > 5 ng/mL but <1,000 ng/mL who experienced disease progression on previous therapies, including irinotecan.[174] Eighty-six patients received labetuzumab govitecan two times per week on weeks 1 and 2 of 3-week repeated cycles at 4 mg/kg or 6 mg/kg or once weekly at 8 mg/kg or 10 mg/kg. Of 72 evaluable patients, one experienced a PR and 42 experienced stable disease (ORR of 1.4%). The clinical benefit rate (PR + SD for 4 months or longer) was 29% (25 of 86 patients).[174] Grade 3 or higher neutropenia occurred in 16% of patients while grade 3 or higher diarrhea occurred in 7%, overall favorable compared with irinotecan.[174] Although this study demonstrated modest activity in a heavily pretreated population (with previous treatment including irinotecan) with a favorable toxicity profile, no further studies have evaluated labetuzumab govitecan in a different setting or as part of combination therapy.

Sacituzumab govitecan (anti-Trop2 ADC). Sacituzumab govitecan is an ADC-targeting trophoblast cell surface antigen-2 (Trop2) that is overexpressed in CRC compared with normal colon and has been associated with disease progression but is also highly expressed on normal human tissues including cervix, skin, esophagus, breast, kidney, bile duct epithelium, pancreas, prostate, and uterus.[175,176] The cytotoxic payload for this agent is similarly SN-38. Sacituzumab govitecan was evaluated in patients with advanced solid tumors that had progressed on at least one standard therapeutic regimen.[177] In the overall cohort, notable grade 3 or higher adverse events included diarrhea (7.9%), nausea (3.6%), neutropenia (42.4%), febrile neutropenia (5.3%), and anemia (10.3%). Of 31 patients with CRC treated at doses of 8 or 10 mg/kg on days 1 and 8 of 21-day cycles, one patient experienced a PR. The ORR was 3.2% (95% CI, 0.1 to 16.7), and 51.6% of patients experienced stable disease. Notably, the majority of the patients had received previous irinotecan-containing therapy.[177] Combined with the experience with labetuzumab govitecan, these two studies suggest that SN-38 delivery to the tumor via these ADCs is not sufficient to overcome acquired resistance to irinotecan and its active metabolite, SN-38. Notably, sacituzumab govitecan demonstrated significant activity against relapsed or refractory triple-negative breast cancer and improved OS compared with standard-of-care chemotherapy, resulting in an FDA approval for this indication.[178]

MRG003 (anti-EGFR ADC). MRG003 is an ADC-targeting EGFR and carries a monomethyl auristatin E payload, a potent microtubule inhibitor.[179] A phase Ia/Ib trial evaluated MRG003 in patients with advanced cancers refractory to standard therapies, including a cohort of patients with CRC. In the overall cohort, the most frequently observed adverse events included rash (39% any grade) and AST increase (39% any grade), with the most frequent grade 3 or higher adverse events being hyponatremia (8%), leukopenia (7%), and neutropenia (5%). The ORR for patients with CRC in phase Ib was 0%, with a DCR of 33%. This was compared with ORRs of 50% and 50% for squamous cell carcinoma of the head and neck and nasopharyngeal carcinoma, respectively.[179] Patients were screened for EGFR expression with IHC before phase Ib enrollment, and all but one of the patients with CRC was positive. The lack of efficacy in the CRC cohort is likely due to its lack of intrinsic sensitivity to microtubule inhibitors rather than poor target expression, highlighting the importance of choosing a cytotoxic payload to which the cancer of interest is sensitive.[151]

Additional previously investigated ADCs. Several additional ADCs have failed to demonstrate safety and/or efficacy in CRC. Aprutumab ixadotin (anti-FGFR2 ADC with auristatin W derivative payload) and ABBV-176 (anti-prolactin receptor ADC with pyrrolobenzodiazepine payload) were each studied in phase I trials, but development was stopped on the basis of maximum tolerated dose being below a preclinically determined therapeutic threshold and late and cumulative toxicities, respectively.[180,181] TAK-264 (antiguanylyl cyclase C ADC with monomethyl auristatin E payload) and cantuzumab mertansine (anti-CanAg ADC with maytansinoid payload) were studied in phase I trials with an ORR of 0% among patients with CRC.[182,183] These two studies further highlight that conjugating a cytotoxic agent to a tumor antigen-targeting antibody appears to be insufficient to overcome a lack of sensitivity of colorectal cancer to the cytotoxic agent.[151]

Ongoing Trials of ADCs in Colorectal Cancer

Ongoing trials of ADCs in CRC are primarily targeting previously investigated antigens that are overexpressed in tumors compared with normal tissues (Table 3). Although many of these agents target previously studied antigens, novel linker technologies, diverse payloads, higher drug-to-antibody ratios, and novel Fc receptor engineering are being investigated. In particular, ongoing work should select classes of cytotoxic payloads to which CRC is sensitive, should focus on payloads that optimize the bystander effect while minimizing systemic toxicity, should investigate novel payloads including immune stimulating payloads, and should revisit promising antigen targets for which earlier generation ADCs were unsuccessful.

Therapy Sequencing in Patients With Advanced Neuroendocrine Neoplasms

Rachel P. Riechelmann, MD, PhD[1]; Rodrigo G. Taboada, MD, MSc[1]; Victor Hugo F. de Jesus, MD, MSc[2]; Michael Iglesia, MD[3]; and Nikolaos A. Trikalinos, MD[3]

overview

Neuroendocrine neoplasms (NENs) comprise a beautifully complicated, exciting landscape of histologies and clinical behaviors. However, the nuanced complexity of low- and high-grade variants can easily overwhelm both patients and providers. In this chapter, we review the ever-expanding literature on both functioning and nonfunctioning small bowel and pancreatic NENs, touching on somatostatin analogs, hepatic-directed therapies, small molecules, radiopharmaceuticals, immunotherapy, cytotoxic chemotherapy, and new promising agents. Furthermore, we suggest some strategies to address the most challenging scenarios seen in clinical practice, including sequencing of agents, treatment of carcinoid syndrome, and options for well-differentiated high-grade disease.

INTRODUCTION

Neuroendocrine neoplasms (NENs) comprise a rare and heterogeneous group of cancers. Patients with NENs may present variable symptomatology and clinical course, making disease management challenging. Histologically, NENs are epithelial cancers with immunohistochemistry expression of neuroendocrine markers and most commonly originate from the lungs or the gastroenteropancreatic (GEP) tract. Nearly half of patients present synchronous metastatic disease.[1] The therapeutic approach is based on precise diagnosis and staging, and clinical evaluation of NEN-related genetic and/or hormonal syndromes. Such complexity reinforces the need of multidisciplinary discussion teams (MDTs) of NEN specialists to propose the best treatment plans.

Although the number of therapeutic options for advanced NENs is evolving because of their rarity and often more indolent course, randomized clinical trials of NENs may take time to reach their targeted number of events and thus be underpowered to provide precise results. Consequently, there are few randomized trials of NENs, and robust evidence to guide treatment sequencing for NENs is limited. Therefore, clinical decision making should consider patient characteristics, NEN-related features, and treatment toxicities (Table 1). The 2022 WHO classification of GEP NENs (Table 2) provides prognostic information, and Table 3 summarizes trial-level criteria for choosing treatments.[28] In this chapter, we will discuss the scientific evidence along with expert opinions to guide treatment sequencing for patients with advanced sporadic GEP NENs.

INITIAL APPROACH TO GASTROENTEROPANCREATIC NEN

Imaging Tests

Conventional imaging with abdominal and thoracic computed tomography or magnetic resonance are standard methods for clinical staging, response evaluation, and surveillance of GEP NENs.[29] The frequency of monitoring can vary greatly and should be individualized: Slow growing disease on surveillance or treatment can be monitored every 6-12 months while patients with more aggressive tumors could have scans performed every 3-6 months. Additionally, functional imaging with somatostatin receptor imaging (SRI) such as positron emission tomography (PET)/computed tomography or PET/magnetic resonance imaging is recommended in patients with well-differentiated (WD) NENs to improve staging accuracy, to identify the primary NEN site in metastatic disease, and to document expression of somatostatin receptors in the tumor (SSTR).[30] The latter provides prognostic information and utility for treatment planning with radiopharmaceuticals (discussed later). 18-fluorodeoxyglucose-PET (FDG-PET) is usually of little value in patients with slow-growing tumors, such as G1 GEP NENs, but should be considered to clinically stage more aggressive NENs, for instance, G3 tumors.[31,32] Intensity of uptake on FDG-PET is inversely associated with prognosis, with simultaneous higher FDG uptake and low SSTR-PET uptake being linked to inferior survival.[33] Importantly, at this point, SRI is not recommended for response evaluation because fluctuations in NEN uptake do not necessarily reflect tumor progression; conventional imaging is the preferred method to measure tumor response.

PRACTICAL APPLICATIONS

- Treatments for patients with gastroenteropancreatic neuroendocrine neoplasms (GEP NENs) have to be individualized with regard to grade, disease burden, origin, and functional status.
- Observation or somatostatin analogs (SSAs) are reasonable options for low-burden, oligoprogressive, nonfunctioning, advanced GEP NENs while SSAs can help most patients with functioning NENs. Patients with high-grade disease derive most benefit from chemotherapy.
- The evidence on treatment sequencing for patients with both low- and high-grade GEP NENs is limited. However, there is evolving, high-quality knowledge on the usefulness of liver-directed therapy, chemotherapy, peptide-receptor radionuclide, and tumor agnostic agents.
- Ongoing clinical trials will help answer that question, and patient participation in those trials is strongly encouraged.

Molecular Testing

Next-generation sequencing (NGS) does not have an established role in the initial evaluation of WD-NENs as they typically present with low mutational burden and rarely demonstrate actionable genomic alterations to guide therapy.[34-36] In contrast, molecular profiling should be performed in neuroendocrine carcinomas (NECs) where genomic alterations such as mismatch repair deficiency, *NTRK* fusions, or *BRAF V600E* mutations can guide the use of successful targeted therapy (see ahead Extrapulmonary Neuroendocrine Carcinoma). The authors believe that patients with advanced NEN progressing through most standard treatments could consider NGS to determine mismatch repair deficiency or eligibility for clinical trials/tumor agnostic treatments.

LOCOREGIONAL THERAPIES FOR ADVANCED G1-2 NONFUNCTIONING GASTROENTEROPANCREATIC NEN

Locoregional (nonsystemic) treatments can be used at any point during a patient's disease course.

Surgery

Surgery has the potential to cure select patients with N0M0 disease regardless of the grade and is often the first option considered on a new diagnosis. However, selected patients with node-positive or oligometastatic low-grade disease and good *performance status*, properly staged with SRI, could be considered for R0 resection.[37,38] Some patients require surgery for symptomatic tumor bulk, hormone hypersecretion, or threatening of critical structures. The timing of surgery and expected outcomes vary between providers and institutions and should be individualized. For example, one study reported a 10-year overall survival (OS) rate of 50.4% after hepatic metastasectomy while in a series of 339 patients who underwent surgical management, disease recurred in 95% of patients at 5 years.[39,40] At this point, metastasectomy for NENs is often a line of therapy, with most patients eventually experiencing tumor recurrence.[41]

As of now, there are no data supporting adjuvant treatment for patients with WD NENs whose tumors have been completely resected. The ongoing (ClinicalTrials.gov identifier: NCT05040360) study is assessing the efficacy of adjuvant capecitabine and temozolomide (CAPTEM) in patients with high-risk pancreatic NEN (PanNEN) after curative-intent surgery.

Liver transplantation remains investigational but can be considered, after MDT deliberation, in selected properly staged cases (age younger than 60 years, unresectable liver metastases, Ki-67 <10%, primary tumor removed, <50% involvement of the liver parenchyma, and a minimum of disease stabilization of 6 months).[42] In this highly selected group, 5-year OS >60% has been described,[43,44] but the data are not mature for further recommendations.

Liver-Directed Therapies

Nonsurgical liver-directed therapies (eg, radiofrequency ablation, thermal ablation, microwave, bland hepatic arterial embolization, chemoembolization, and radiation therapy) for patients with oligoprogressive liver-predominant disease can lead to symptom and tumor control for a median of 16-22 months.[45,46] They can be performed in second or later lines of treatment and repeated in patients who experienced benefit and maintain good hepatic function. They can also be indicated in patients with metastatic disease but focal progression, with retrospective series reporting a median time to new systemic treatments of 32 months.[47]

Radioembolization with yttrium-90 microspheres delivered intrahepatically has been effective in patients with NENs in uncontrolled studies, particularly those at risk of carcinoid crisis and/or with colonized biliary system.[48,49] Optimized tumor radiation dosimetry is important to improve therapeutical response and minimize toxicity to the normal liver parenchyma. Indeed, studies have reported delayed severe hepatic toxicity after liver radioembolization in nearly 30% of patients with NENs.[50] Therefore, the risks of long-term liver injury after radioembolization, especially when used sequentially with peptide receptor radionuclide therapy (PRRT) or after extensive liver resection, should be considered in the treatment sequencing for patients with NENs.[49]

TABLE 1. Checklist of Important Factors for Treatment Strategies in Patients With Advanced NENs

Factor	Aims
Tumor-related factors	
Histopathological diagnosis	Accurate grading by the 2022 WHO classification to inform prognosis and evaluate grade-specific treatments
Radiological staging	Evaluation of tumor burden and surgical resectability
Functioning images[a]	Evaluate SSTR-2 tumor expression and staging 18-FDG-PET: optional for more aggressive tumors
Identify primary tumor	Evaluate clinical behavior and guide site-specific therapies and hormone secretion
Evaluate tumor functional status (clinically and biochemically) and related symptoms	Specific treatments of NEN-related hormone syndromes
Assess criteria for genetic syndrome	Diagnose hereditary syndromes (genetic counseling for patients and relatives) Evaluate impact on treatment strategy
Assess tumor aggressiveness and behavior	Evaluate tumor burden, constitutional symptoms, and, if possible, tumor growth rate on the basis of clinical history and/or previous images to plan treatment strategy according to tumor aggressiveness
Patient-centered evaluation	
Assess clinical condition	Evaluate performance status, comorbid illnesses, and concurrent medications
Assess patient's preferences	Understand patient's perception of therapy-related toxicities, efficacy, convenience, and access

Abbreviations: PET, positron emission tomography; SSTR, somatostatin receptors in the tumor.
[a]18-FDG PET and SSTR-PET.

FIRST-LINE SYSTEMIC TREATMENTS IN ADVANCED G1-2 NONFUNCTIONING GASTROENTEROPANCREATIC NENs

First Line

Observation. Although not a treatment per se, some patients with asymptomatic, low tumor burden, and nonfunctioning (and biochemically inactive) NENs from most organs, including the GEP tract, can be observed with surveillance imaging to determine the rate of clinically significant growth and development of symptoms. Disease stabilization from 6 to 18 months was observed in the placebo arms of randomized trials of patients with WD GEP NENs.[4,5,51,52] Serial imaging can be performed every 3-6 months depending on the disease growth rate and patient preference.

There are no randomized data to guide earlier versus delayed initiation of somatostatin analogs (SSAs; the next usual treatment) for newly diagnosed patients. A cost-benefit analysis on the basis of data from the CLARINET study showed that active surveillance was most cost-effective as initial therapy for newly diagnosed patients at the current lanreotide cost.[53]

Somatostatin analogs. For patients with advanced inoperable G1-2 GEP NENs, disease stability is an acceptable

TABLE 2. WHO Classification and Grading Criteria for Gastroenteropancreatic NENs[2]

Terminology	Differentiation	Grade	Mitotic Count Mitoses/2 mm²[a]	Ki-67 Index[b]
G1 NET	Well differentiated	Low	<2	<3%
G2 NET		Intermediate	2-20	3%-20%
G3 NET		High	>20	>20%
Small-cell NEC	Poorly differentiated	High	>20	>20%
Large cell NEC			>20	>20%
MiNEN	Well or poorly differentiated	Variable	Variable	Variable

Abbreviations: G, grade; MiNEN, mixed neuroendocrine-non-neuroendocrine neoplasm; NEC, neuroendocrine carcinoma; NET, neuroendocrine tumor.
[a]Mitotic counts are to be expressed as the number of mitoses/2 mm² (equaling 10 high-power fields) at 40× magnification evaluated in areas of highest mitotic density.
[b]The Ki-67 proliferation index value is determined by counting at least 500 cells in hot spots.

RETNET[77] (NCT02724540)	II	Randomized, open-label	120, progressive or symptomatic unresectable NEN liver metastases	Hepatic PFS	Bland embolization	Lipiodol chemoembolization

Abbreviations: CAPTEM, capecitabine and temozolomide; FOLFOX, infusional fluorouracil, leucovorin, and oxaliplatin; G, grade; GEP-NET, gastroenteropancreatic neuroendocrine tumor; LAR, long-acting release; NENs, neuroendocrine neoplasm; NET, neuroendocrine tumor; PFS, progression-free survival; SSA, somatostatin analog; SSTR, somatostatin receptors in the tumor.

disease outcome. In this setting, SSAs are usually the preferred treatment. The randomized PROMID trial showed that long-acting octreotide (30 mg intramuscular injection once monthly) delayed tumor progression by 8.3 months (hazard ratio [HR], 0.34; 95% CI, 0.20 to 0.59; $P = .000072$) in 85 patients with G1-2 progressive small bowel (SB) NEN.[4] The phase III CLARINET trial evaluated an alternative long-acting SSA, lanreotide (120 mg s.c. injection once monthly), in 204 patients with nonfunctioning nonprogressive SRI-positive GEP NEN with Ki-67 index <10%, demonstrating a progression-free survival (PFS) benefit (HR, 0.47; 95% CI, 0.30 to 0.73; $P < .001$).[5] Both SSAs yielded negligible tumor responses (2%) and are usually well tolerated, with most common adverse events being abdominal pain, injection site reaction, diarrhea, hyperglycemia, and cholelithiasis.

SECOND AND FURTHER LINES OF SYSTEMIC TREATMENTS IN ADVANCED G1-2 NONFUNCTIONING GASTROENTEROPANCREATIC NENs

WD Small Bowel NEN

Somatostatin analogs. There are no data on the direct comparative efficacy of SSAs, so we do not suggest switching from one SSA to another in patients whose tumors progress. Because lanreotide is administered subcutaneously, it is preferred over octreotide (which is administered intramuscularly) in obese patients. There are limited data on higher dose or more frequent administration of SSAs. In the phase II trial CLARINET FORTE, 99 patients with G1-2 GEP NENs and disease progression on standard dose SSA received lanreotide 120 mg subcutaneously once every 14 days. The median PFS was 8.6 in the SB cohort. In the NETTER-1 phase III trial (discussed below), the control arm received octreotide long-acting release (LAR) 60 mg once monthly with a median PFS of 8 months for patients with progressive G1-2 SB-NENs.[9]

Peptide receptor radionuclide therapy. PRRT consists of combining a SSA with a radioactive atom, most commonly the beta emitter lutetium^{177}, forming ^{177}-lutetium-DOTATATE. For patients with SSTR-positive G1-2 GEP NENs experiencing unequivocal disease progression on first-line SSA, PRRT is an acceptable second-line option. In the phase III NETTER-1 trial, 229 patients with progressive SRI-positive G1-2 SB-NENs were randomly assigned to second-line treatment with four infusions of lutetium^{177} every 8 weeks along with 30 mg of octreotide LAR once every 28 days or octreotide LAR 60 mg once every 28 days until progression.[9] At a median follow-up of 76 months, the median PFS was 28 months for lutetium^{177} and 8 months for octreotide (HR, 0.18; 95% CI, 0.11 to 0.29; $P < .0001$), with a median OS of 48 and 36 months (HR, 0.84; 95% CI, 0.60 to 1.17; $P = .3$), respectively.[10] Approximately 27% of patients from the control arm were treated with lutetium^{177} on progression, with a median PFS2, that is, the time from random assignment to second investigator-assessed NEN progression, being 45 months for lutetium^{177} and 23.2 months for the control arm (HR, 0.42; $P < .0001$).[54] Serious but rare adverse events included irreversible myelotoxicity, myelodysplastic syndrome (2%), and leukemia (0.5%). Acute common (mostly mild) adverse events are nausea and renal and hepatic toxicity.

A multicenter retrospective study with 508 patients with GEP G1-3 NENs with tumor progression after SSA reported longer PFS with PRRT (HR, 0.37; $P < .001$) when compared with chemotherapy or targeted agents after

adjustment for prognostic factors (tumor functionality, primary site, and tumor grade).[55]

Everolimus. Everolimus, an oral inhibitor of the mammalian target of rapamycin, is an effective therapy in second or further lines for patients with GI NENs, lung NENs, or PanNENs. Everolimus 10 mg once daily led to longer median PFS (11.0 *v* 3.9 months; HR, 0.48; $P < .00001$) in the RADIANT-4 placebo-controlled phase III trial for patients with pretreated progressive, nonfunctional lung or GI G1-2 NENs.[8] Previous systemic therapies included SSAs (53%), chemotherapy (26%), and PRRT (22%). OS numerically favored everolimus (HR, 0.73; $P = .071$).[56] Post hoc subgroup analyses confirmed the efficacy of everolimus regardless of type of previous therapies.[57] Everolimus was also evaluated in another placebo-controlled trial for patients with functioning GI or lung G1-2 NEN pretreated with SSAs (80%) and/or chemotherapy (35%); numerical albeit not statistically significant improvement in median PFS was reported with everolimus.[58] Objective responses with everolimus were seen in <5% of cases. Clinically relevant drug-related adverse events occur in 40%-50% of patients, including stomatitis, rash, fatigue, diarrhea, pneumonitis (severe in <2%), and metabolic abnormalities (eg, hyperglycemia, dyslipidemia).[59] Oral mucositis is often a dose-limiting toxicity, and a randomized study found that the incidence or severity of stomatitis improved with therapeutic dexamethasone mouthwash.[60] A real-world retrospective Latin American study found that 21.6% of patients with NENs treated with everolimus 10 mg once daily had grade 3-4 infections, with 3.6% related deaths.[61] Therefore, everolimus should ideally not be administered in patients with uncontrolled diabetes, moderate/severe preexistent pulmonary disease, or systemic infections and used cautiously in those with uncontrolled dyslipidemia.

Tyrosine kinase inhibitors. NENs are highly vascularized tumors with multiple tyrosine kinase pathways involved in angiogenesis and tumor progression.[62] Currently, only sunitinib has received US Food and Drug Administration (FDA) approval for PanNENs. However, other tyrosine kinase inhibitors (TKIs) targeting vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), and fibroblast growth factor receptor have been tested after failure on standard treatments, showing encouraging results.

Lenvatinib 24 mg once daily yielded an objective response rate (ORR) of 16% and a median PFS of 15.7 months in a phase II trial of heavily pretreated patients with SB and other GI NENs.[63] In the AXINET phase III placebo-controlled trial, third-line axitinib 5 mg twice daily combined with SSA for patients with G1-G2 extrapancreatic NENs offered response rate in 13.2% of cases, and a blinded independent radiological evaluation observed a median PFS of 16.6 months (*v* 9.9 months for placebo; $P = .01$).[64] An uncontrolled phase II trial with cabozantinib 60 mg once daily demonstrated a median PFS of 31 months in patients with progressive and heavily pretreated G1-2 GI-NENs,[65] and a large placebo-controlled trial (ClinicalTrials.gov identifier: NCT03375320) is currently underway. Sunitinib has shown modest efficacy in G1-2 SB-NENs.[66]

Chemotherapy. Overall, indolent G1-2 SB-NENs are less responsive to chemotherapy. The combinations tried in the past include fluorouracil (FU) with streptozotocin or doxorubicin, dacarbazine monotherapy, capecitabine and oxaliplaitn (CAPOX)/infusional fluorouracil, leucovorin, and oxaliplatin (FOLFOX), or CAPTEM, with all providing radiological objective responses in <10% of patients.[67-71]

WD PANCREATIC NENs

SSAs

Similar to G1-2 SB-NENs, oligoprogressive WD PanNENs can be managed by increasing standard SSA dosage. In the phase II trial CLARINET FORTE, the median PFS was 8 months in the PanNEN cohort with Ki67 ≤10%.[72]

PRRT

Retrospective analyses have shown that PRRT is effective in G1-2 PanNENs, with response rates as high as 60%.[73,74] In the phase II OCLURANDOM trial, 84 patients with SRI-positive advanced G1-2 PanNENs treated with at least one previous line of therapy were randomly assigned to receive ^{177}Lu-DOTATATE or sunitinib 37.5 mg once daily.[11] Both 12-month PFS rates (80 *v* 42%) and median PFS (20.7 *v* 11.0 months) favored ^{177}Lu-DOTATATE. Yet, phase III trials are required to determine whether PRRT, targeted therapy (everolimus, sunitinib), or CAPTEM is the preferred second-line option for patients with G1-2 PanNENs (Table 4). Importantly, the sequential use of CAPTEM and PRRT is associated with increased risk of myelodysplastic syndrome and acute myeloid leukemia (8%-10%) in retrospective series.[78]

Everolimus

The placebo-controlled phase III RADIANT-3 trial evaluated everolimus 10 mg once daily in 410 patients with pretreated progressive G1-G2 PanNENs, demonstrating a significant gain in PFS (median, 11.0 *v* 4.6 months; HR, 0.35; $P < .001$).[6] Objective responses were seen in only 2% of patients, and no difference in OS was observed.[7] In subanalyses, antitumor activity was not affected by previous use of chemotherapy (50%) or SSA (49%).[79]

Tyrosine Kinase Inhibitors

Sunitinib. PanNENs are particularly responsive to TKIs. Sunitinib is an FDA-approved oral multitargeted TKI that inhibits PDGFRα/β, VEGFR1-3, fetal liver kinase-3, colony-stimulating factor 1 receptor and RET signaling. Sunitinib at 37.5 mg once daily was tested in 171 patients with

advanced G1-2 PanNENs in a placebo-controlled phase III trial.[12] Prolonged PFS (median, 11.4 *v* 5.5 months; HR, 0.42; $P < .001$) and higher response rate (9.3% *v* 0%; $P = .007$) favored sunitinib. A post hoc analysis adjusted for crossover suggested sunitinib increased OS.[13] The most frequent adverse events of any grade are diarrhea, fatigue, stomatitis, hypertension, and epistaxis; grade 3 or 4 toxicities were neutropenia (12%), hypertension (10%), and palmar-plantar erythrodysesthesia (6%). Given that median PFS times of everolimus and sunitinib seem similar, the choice between these two drugs should be based on their toxicity profiles. Each sequential administration provided similar disease control rates in retrospective series.[80]

Other TKIs. Lenvatinib 24 mg once daily provided a median PFS of 15.6 months and ORR of 44.2% in a phase II trial in patients with PanNENs previously treated with SSA (100%), everolimus (69%), sunitinib (29%), or chemotherapy (32.7%).[63] In the Spanish PAZONET trial, pazopanib 800 mg once daily in patients with progressive G1-G2 lung or GEP NENs provided a median PFS of 10 months for the GI cohort.[81] The ongoing phase III CABINET trial (ClinicalTrials.gov identifier: NCT03375320) compares cabozantinib 60 mg once daily with placebo in patients with GEP NENs previously treated with PRRT or everolimus. Consistent with other indications, TKIs should not be delivered to patients with symptomatic heart failure, uncontrolled hypertension, and high risk of bleeding.

Chemotherapy

For patients requiring tumor shrinkage, chemotherapy with CAPTEM is the preferable therapy. The ACRIN-ECOG 2211 phase II trial randomly assigned 144 patients with G1-2 PanNENs to receive CAPTEM or single-agent temozolomide. About two-thirds had been pretreated with SSA.[14] Despite similar response rate (39.7 *v* 33.7%) and OS (median: 59.7 *v* 53.8 months; $P = .42$), the combination led to improved PFS (median: 22.7 *v* 14.4 months; HR, 0.58; $P = .022$). Forty-five percent of patients experienced grade 3-4 adverse events, with the most frequent ones being myelotoxicity, nausea, and diarrhea.

Nonrandomized trials have also demonstrated that FOLFOX/CAPOX can offer tumor response in approximately 30% of patients with G1-2 PanNENs, with a median PFS in the range of 12 months, including those previously treated with temozolomide-based chemotherapy.[70,82,83] Several studies have also demonstrated the activity of streptozocin-based regimens in advanced PanNENs, with response rates from 10% to 40% and the median PFS of 10-18 months in randomized trials.[84] Yet, the SEQTOR randomized trial failed to show improvement in PFS (median 21.5 *v* 23.8 months; $P = .35$) with streptozocin plus FU when compared with everolimus 10 mg once daily administered in second line; streptozocin led to higher response rate (30% *v* 11%; $P = .014$) and everolimus to more infections (15% *v* 5%).[15]

Immunotherapy

Patients with advanced, mismatch repair deficient NENs should receive immune checkpoint inhibitors at some point in their treatment. Yet, WD GEP NENs are mostly microsatellite stable and harbor low mutational burden, what explains why available immune checkpoint inhibitors targeting programmed cell death receptors have been ineffective in these cases. Rare cases of tumor transformation to hypermutated NENs, with rapidly progressive disease, following treatment with alkylating chemotherapy have been reported. Whether immune checkpoint inhibitors can be used in this setting, similar to de novo high-grade disease, is currently unknown.[85]

TREATMENT SEQUENCING FOR GASTROENTEROPANCREATIC ADVANCED G1-2 NENs

Figure 1 provides overall therapeutic sequencing strategies for patients with advanced nonfunctioning G1-2 GEP NENs. For most patients, either SSA or observation is a good first-line strategy. After tumor progression, decision on second line is based on tumor aggressiveness, disease burden, and expected treatment-related toxicities. Targeted therapies, PRRT, and locoregional therapies can be used in second or later lines. Chemotherapy is mostly reserved for more aggressive disease, particularly for patients with PanNENs. Table 4 depicts the ongoing randomized trials in advanced G1-3 NENs.

TREATMENT SEQUENCING FOR ADVANCED G1-2 FUNCTIONING GEP NENs

NENs which secrete peptide hormones that trigger symptoms are deemed functioning.

Functioning NENs are typically WD, with the most common being carcinoid syndrome (CS). PanNENs are generally nonfunctioning, although approximately 20% present hormone-specific syndromes. It is recommended to have a NEN endocrinologist specialist involved in the care of patients with functioning PanNENs. In Figure 2, we propose a summarized treatment sequencing for patients with functioning NENs.

General Treatments

SSAs. Since the majority of NENs overexpress SSTR, SSAs are the preferred first-line treatment for patients with functioning NENs and should be kept throughout the disease course, even when there is tumor progression. SSAs offer pronounced symptom control in nearly 70% of patients with CS.[86] For patients with functioning PanNENs (except for insulinomas and gastrinomas), SSAs are also the standard first-line therapy.

Liver-directed locoregional therapies. Liver-directed therapies can be performed at any moment of disease course. Tumor debulking with surgical or locoregional treatments

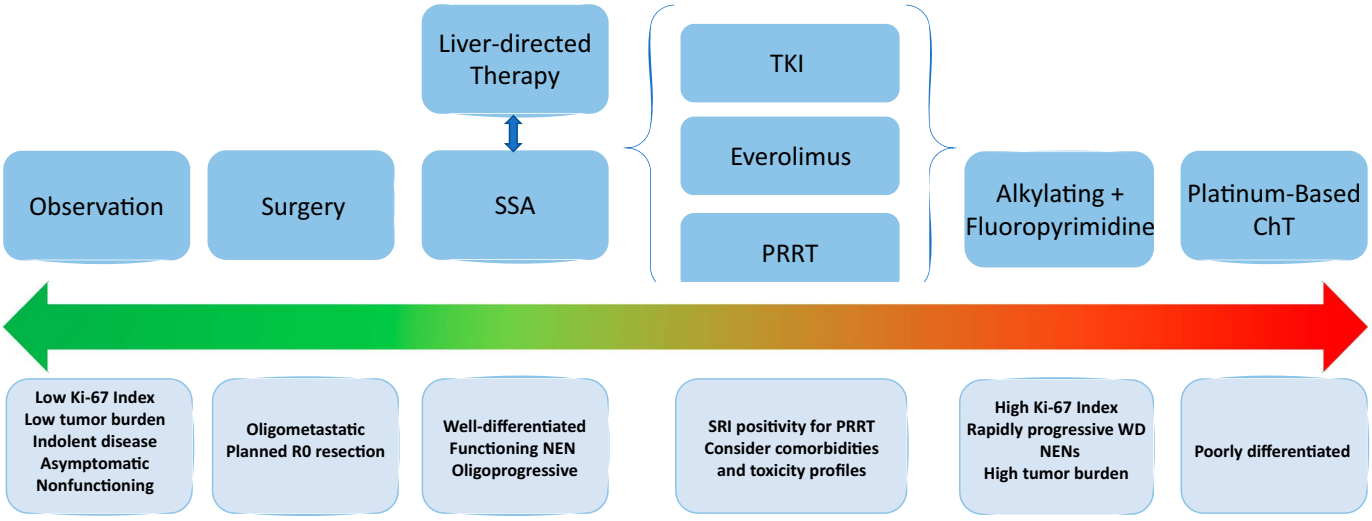

FIG 1. ChT, chemotherapy; NEN, neuroendocrine neoplasm; PPRT, peptide receptor radionuclide therapy; SRI, somatostatin receptor imaging; SSA, somatostatin analogs; TKI, tyrosine kinase inhibitor; WD, well-differentiated.

can offer symptom control, with symptom relief and some degree of biochemical response reported in 80% and 63% of patients with CS, respectively.[86] R2 surgical debulking of large tumors areas can also be performed in selected cases as uncontrolled studies have reported symptom relief in up to 90% of cases, with a median duration of CS control of up to 45 months.[87] Although liver-directed therapies can be repeated if there is good hepatic function, it is not recommended for patients with moderate/severe carcinoid heart disease—for these patients,

Therapy line	Carcinoid syndrome		Functioning Pancreatic NEN	
	Indolent tumors	Aggressive tumors[a]	Indolent tumors	Aggressive tumors[a]
First	SSA[b]	SSA[b]	SSA[c]	SSA[c] + chemotherapy (eg, CAPTEM)
Second	Increase SSA dose and/or shorten injections intervals	Increase SSA dose and/or shorten injections intervals + Hepatic embolization[d] +/- telotristat ethyl[e]	Everolimus, sunitinib or Hepatic embolization[d]	Switch chemotherapy (eg, to oxaliplatin-based)
Later lines	Add telotristat ethyl[e] or Hepatic embolization[d] or Lutetium^{177}	Lutetium^{177d}	Lutetium^{177} or CAPTEM	Palliative surgical debulking or Hepatic embolization[d]
Other options	Everolimus or Alpha-interferon	Chemotherapy	Palliative surgical debulking	Everolimus or Sunitinib

FIG 2. Therapeutic sequencing strategies for patients with advanced functioning GEP NENs. Clinical trials preferred. Surgery can be considered at any therapy line. CAPTEM, capecitabine and temozolomide; NEN, neuroendocrine neoplasm; SSA, somatostatin analog. [a]High tumor and symptom burden, rapidly progressive, complications from hormonal syndrome (eg, carcinoid heart disease, Cushing syndrome). [b]Maintain SSA throughout treatment sequencing. [c]SSA used cautiously in insulinoma. [d]Consider retreatment if prior prolonged benefit. [e]If available.

surgical valve replacement should be performed before these procedures.[88]

Specific Hypersecretion Syndromes

Patients with insulinoma should be treated cautiously with SSAs because these drugs may worsen hypoglycemia by inhibiting the release of counter-regulatory hormones. Therefore, other treatments should be prioritized before resorting to SSA use while actively monitoring glycemia. Everolimus is particularly effective in insulinomas, both for glycemia normalization and tumor control, and should be used in first line.[6]

Gastrinomas should be firstly managed by high dose of proton-pump inhibitors. Patients with VIPomas should receive intravenous fluids and electrolytes. Table 5 summarizes the characteristics and treatment particularities of the most frequent functioning NENs.

Treatments for Patients With Resistant Hormone Hypersecretion Syndromes

Despite the effectiveness of SSAs in recommended doses to control NEN hormonal syndromes, symptomatic and biochemical progression ultimately occurs.

Refractory carcinoid syndrome. Ruling out other causes of diarrhea such as problems with injection administration, infections, or SSA-induced exocrine pancreatic insufficiency is important in patients with CS whose symptoms worsen despite SSA label dosage.

When there is radiologically stable or slow-growing disease and worsening CS, increasing SSA dose and/or shortening the intervals of injections can sometimes alleviate symptomatology.[89] Few trials have been conducted in this setting, with only two randomized trials being conducted to guide treatment sequencing in patients with refractory CS. A double-blind phase III trial compared the symptomatic response of pasireotide LAR, a new SSA with broader affinity to SSTR-5, with octreotide LAR 40 mg. The study was closed prematurely because of futility.[90]

Telotristat ethyl is an oral inhibitor of tryptophane hydroxylase, the enzyme responsible for 5HT synthesis. In a double-blind phase III trial at two different doses (250 mg or 500 mg three times a day), telotristat ethyl significantly reduced diarrhea in patients with refractory CS. With a predefined response of reduction $\geq$30% in the frequency of bowel movements lasting for $\geq$50% during 12 weeks, nearly 40% had a response versus 20% of those on placebo.[91] Another placebo-controlled trial confirmed these results.[92] Telotristat ethyl is approved for CS-associated diarrhea insufficiently controlled by SSAs in few countries, including the United States, at a dose of 250 mg three times a day in combination with SSAs.

In the NETTER-1 trial, diarrhea improved in nearly half of patients with SB-NENs treated with ^{177}-lutetium-DOTATATE combined with octreotide LAR 30 mg once monthly, although similar improvement occurred in patients in the octreotide LAR 60-mg once monthly arm, yet time to deterioration of diarrhea (HR, 0.39), social functioning (HR, 0.63), and pain (HR, 0.62) significantly favored ^{177}-lutetium-DOTATATE.[93] Flushing also improved with ^{177}-lutetium-DOTATATE.[93]

Refractory CS can also be treated with everolimus 10 mg once daily and interferon alpha (IFN-α).[94] Uncontrolled studies have reported CS relief in up to 75% of patients treated with IFN-α (3-5 million UI s.c. three times weekly), although randomized trials failed to prove its clinical benefit in comparison with SSA alone.[87] Given its undesirable toxicity profile, IFN-α can be used in later lines as an add-on to SSAs.

For aggressive CS (high tumor and/or symptom burden, rapidly radiological progressive disease, or presence of carcinoid heart disease), therapies providing higher probability of tumor response are recommended.

Resistant hormone hypersecretion syndromes in PanNEN. Classic systemic treatments for nonfunctioning PanNENs can provide not only growth but also symptom control in functioning counterparts. This includes PRRT, everolimus, and chemotherapy.

PRRT can control hypoglycemia in patients with metastatic insulinomas and ectopic Cushing syndrome in patients with adrenocorticotropic hormone-secreting PanNEN.[6,95,96]

Tyrosine kinase inhibitors are not effective to treat hormonal symptoms but can be used in combination with SSA for tumor control in more indolent functioning PanNENs. Chemotherapy has limited activity in SB-NENs but offers response rate in the range of 30% in PanNENs, consequently improving hormonal symptoms.

TREATMENTS FOR PATIENTS WITH METASTATIC GRADE 3 GASTROENTEROPANCREATIC NEN

Grade 3 (G3) NENs comprise a rare group of WD, high-grade NENs, most commonly of pancreatic origin.[28] G3 NENs are biologically and molecularly distinct from NECs, which reflects in their lower aggressiveness: high-uptake on PET-Ga,[85] low FDG uptake, often with Ki-67 $\leq$30%, and generally slower tumor growth rate compared with NEC, and patients are often oligosymptomatic.[35,97] Although G3 NENs can secrete hormones, NECs are generally nonfunctioning.

More indolent G3 NENs are managed similarly to G2 NENs, for example, with targeted agents, locoregional therapies, and PRRT. There are limited data on the use of either everolimus or sunitinib in G3 GEP NENs, but these are acceptable first-line options in patients with more indolent behaving neoplasms. In highly selected nonfunctioning oligoprogressive cases with SSTR-positive tumors, SSAs can provide a median PFS of 6-7 months.[98] PRRT has demonstrated promising activity in pretreated selected patients with SSTR-positive WD G3 NENs, with an objective response achieved by 42%, a median PFS of 19 months, and a median OS of 44 months.[99]

TABLE 5. Characteristics of Functioning NENs

NEN	Laboratory Marker and Clinical Syndrome	Peptide Hormone Secreted	Site(s) of Origin	Therapy for Hormonal Syndrome
Well-differentiated NENs	24-hour urinary 5-HIAA Carcinoid syndrome: Facial flushing, diarrhea, fibrotic complications (carcinoid heart disease and mesenteric fibrosis)	Serotonin and several vasoactive peptides	Small bowel, lung, thymus, ovary, metastatic unknown primary NEN	Long-acting SSA Add short-acting SSA before, during, and after invasive procedures to prevent carcinoid crises
Glucagonoma	Serum glucagon Diabetes mellitus, necrolytic migratory erythema, dementia/ depression, thromboembolism	Glucagon	Pancreas	Long-acting SSA
Insulinoma	Elevated fasting serum insulin and C-peptide; in doubtful cases, a 72-hour fasting test is performed during hospitalization Symptoms of hypoglycaemia	Insulin	Pancreas	Consider hospitalization for IV glycose, frequent feeding, diazoxide, steroids, calcium-channel blockers, beta-blockers, phenytoin. Everolimus 10 mg once daily SSA: Start with short-acting SSA while monitoring glycose. Unknown benefit of long-acting SSA
Gastrinoma	Fasting serum gastrin >1,000 pg/mL If <1,000 pg/mL, secretin test is indicated Recurrent peptic ulcer, dyspepsia, esophageal reflux, steatorrhea	Gastrin	Pancreas (85%) Duodenum (15%)	High-dose proton-pump inhibitors Long-acting SSA (for steatorrhea and tumor control)
VIPoma	Serum VIP Severe secretory and watery diarrhea, dehydration, hypokalaemia, achlorhydria Hypercalcaemia (if PTH-rp is cosecreted)	VIP with or without concurrent PTH-rP	Pancreas	Long-acting SSA Intravenous electrolytes and fluid administration For hypercalcemia: see PTH-rPoma
ACTHoma	Elevated ACTH and/or CRH, 24-hour urinary free cortisol; Cushing syndrome	ACTH	Pancreas, lung, metastatic unknown primary NEN	Steroidogenesis inhibitors (bilateral adrenalectomy in severe cases) Long-acting SSA Add other NEN-directed therapies only when Cushing syndrome is under control
Somatostatinoma	Serum somatostatin Diabetes mellitus, cholelelithiasis, steatorrhea, hypochloridria	Somatostatin	Pancreas Duodenum (neurofibromatosis I)	Long-acting SSA
PTH-rPoma	Hypercalcemia Elevated serum PTH-rp and low PTH	PTH-rP	Pancreas	Long-acting SSA Therapies for cancer-associated hypercalcemia (intravenous fluids, bisphosphonates/ denosumab, furosemide)

Abbreviations: ACTH, adrenocorticotropin hormone; CRH, corticotrophin-releasing hormone; IM, intramuscularly; IV, intravenously; NEN, neuroendocrine neoplasm; PTH-rP, parathyroid hormone (PTH)–related peptide; SSA, somatostatin analogs (long-acting octreotide 30 mg IM monthly or lanreotide autogel 120 mg SC monthly; short-acting octreotide 100-200 mcg IV); SC, subcutaneously; VIP, vasoactive intestinal peptide.

Importantly, patients with tumors with heterogeneous uptake on SRI and higher ^{18}FDG-PET uptake seem to benefit less from PRRT, although no specific uptake thresholds have been established so far.[100]

In contrast, those with more aggressive features (low uptake on PET-Ga,[85] high FDG uptake, symptomatic patients, Ki-67 >30%, and high metastatic burden) can be treated with CAPTEM or oxaliplatin-doublet chemotherapy.[98] CAPTEM offers objective response in nearly 40%, a median PFS of up to 20 months, and 5-year OS rate ranging from 20% to 68%.[98] FOLFOX is another effective chemotherapy option with objective responses being reported in nearly half of patients and median PFS in the range of 9 months.[101] Differently from NECs, cisplatin and etoposide/irinotecan are not routinely recommended for patients with G3 NENs because they provide inferior disease control when compared with CAPTEM or oxaliplatin-based regimens.[98]

TREATMENTS FOR PATIENTS WITH METASTATIC GASTROENTEROPANCREATIC NECs

Advanced Extrapulmonary NECs

Extrapulmonary NEC is an aggressive disease that, like the more common entity of small-cell lung cancer (SCLC), is characterized by rapid development of chemoresistance and early metastatic spread. Thus, curative-intent resection should be used whenever possible for potentially resectable disease. Specific approaches vary with disease site, but strategies including neoadjuvant or adjuvant chemotherapy with or without radiation have been used, without strong evidence to support one approach over the other.

Platinum-based regimens. First-line systemic therapy for extrapulmonary NEC was initially adopted from regimens used for SCLC. Similar to SCLC, extrapulmonary NEC is associated with high response rate to platinum-based chemotherapy, even compared with WD G3 NENs.[16] Several retrospective studies have evaluated cisplatin or carboplatin in combination with etoposide, with response rates of 31%-67% and a median OS ranging from 11 to 19 months.[16,17,102,103] Cisplatin with irinotecan has shown similar results in the first-line setting.[18,19,104]

FU-based regimens. There is no established second-line regimen for advanced extrapulmonary NEC supported by robust evidence. Particularly for GEP NEC, there is a rationale for using FU-based regimens including FOLFOX, fluorouracil, leucovorin, and irinotecan (FOLFIRI), or fluorouracil, leucovorin, oxaliplatin and irinotecan (FOLFIRINOX). A retrospective analysis of 20 patients with G3 NEC (16 extrathoracic or unknown primary site) treated with FOLFOX after failure of platinum and etoposide showed a median OS of 9.9 months.[20] The PRODIGE 41-BEVANEC trial of FOLFIRI with or without bevacizumab after failure of first-line platinum and etoposide showed a 6-month OS of 60% in the FOLFIRI group, with no improvement in outcome from the addition of bevacizumab.[21] A retrospective study of 37 patients with GEP NEC treated with FOLFIRINOX showed an ORR of 46% and a median OS of 17.8 months.[22] Although there is evidence for FU-based regimens in the second line, it is not clear whether, or in which case, these regimens may be appropriate as first-line therapy.

CAPTEM. A Polish retrospective analysis of CAPTEM in 32 patients with G3 NENs, of whom 12 had NEC, yielded a median OS of only 4.6 months, consistent with the aggressive nature of this disease.[23] The ECOG-ACRIN EA2142 trial randomly assigned patients with G3 GEP NENs (including NEC) to CAPTEM or platinum and etoposide in first line.[24] Although this study was terminated early for low accrual, interim analyses suggested similar outcomes between the two regimens. Although this trial suggests that CAPTEM may be used in the first-line setting, indications of more aggressive disease biology (eg, higher Ki-67 or small cell histology) are generally regarded as indicators favoring platinum and etoposide.

Immune checkpoint blockade. Immune checkpoint blockade has been explored alone or in combination with chemotherapy in extrapulmonary NEC. The phase II DART SWOG 1609 trial enrolled 32 patients with nonpancreatic NENs, of whom 26 had extrapulmonary disease and 18 had high-grade disease. These patients received ipilimumab and nivolumab in the second line or later, with an overall response rate of 44% among patients with high-grade disease. Although dual checkpoint blockade was successful in this population, the addition of immunotherapy to chemotherapy showed lackluster results. In a trial of pembrolizumab plus chemotherapy (irinotecan or paclitaxel) in extrapulmonary NEC, the response rate was only 9% with a median PFS of 2 months and a median OS of 4 months.[27] The ongoing SWOG S2012 trial (ClinicalTrials.gov identifier: NCT05058651) evaluates the potential role of atezolizumab in combination with first-line platinum and etoposide, which is standard for SCLC.

Targeted therapy. Given the overall poor outcomes of advanced NEC, these tumors should be evaluated by molecular profiling for genomic indications for targeted therapy. Although no NEC-specific targeted therapies have been identified, therapeutic targets evaluated across multiple tumor types are present in extrapulmonary NEC to varying degrees. Therapeutic targets with evidence of efficacy in extrapulmonary NEC include microsatellite instability or mismatch repair deficiency (pembrolizumab), high tumor mutational burden (TMB; pembrolizumab), *NTRK* fusions (entrectinib or larotrectinib), *RET* alterations (selpercatinib), and *BRAF V600E* mutations (dabrafenib and trametinib).

Microsatellite instability varies in abundance by tissue, with prevalence in pancreatic and ampullary NEC estimated at 5%-8% and up to 12.4% in gastric and enteric NEC.[105-107]

Similar to other MSI-high carcinomas, microsatellite instability is associated with improved prognosis in NEC.[105,107] High TMB is another tissue-agnostic approval for pembrolizumab, and relatively sparse data support its use in TMB-high NEC.[108,109] *NTRK* fusions were identified in 0.3% of all NENs in a study of 2,147 patients with NEN; five of six identified cases were found in NEC (four extrapulmonary).[110] *RET* gene fusions are best known in medullary thyroid cancer and the association with multiple endocrine neoplasia types 2A and 2B. Although *RET* alterations are rare in extrapulmonary NEC, *RET* status should be evaluated as part of panel testing in NEC because of its overall importance in neuroendocrine tumor development and the tumor agnostic approval of selpercatinib for *RET* fusion–positive tumors. Finally, subprotocol H of the NCI-MATCH trial, which evaluated dabrafenib and trametinib in patients with *BRAF V600E* mutations, included two patients with colon NECs and two mixed ductal/NECs of the pancreas. The *BRAF V600E* mutation is relatively common in colorectal NEC, similar to colorectal adenocarcinoma, with one study estimating a prevalence of about 20%.[111]

Sequencing therapy. At this point, there is no optimal sequencing treatment for patients with high-grade NECs. The totality of evidence favors a platinum and etoposide regimen as a first-line option for eligible patients with poorly differentiated or small cell histology and for most patients with a Ki-67 of >55%. Alternative chemotherapies can be considered for patients with poor performance status, less aggressive tumors, and WD histology as mentioned above. Targeted therapy and immunotherapy could be reserved for later lines of treatment. All patients should consider enrolling in a clinical trial whenever possible.

CONCLUSIONS

NENs are a very complex and heterogeneous group of neoplasms. Although several clinical trials have been conducted in patients with advanced NENs of different origins in the past decade, the scientific evidence for treatment sequencing is still limited. In this regard, MDTs are of prime importance to provide the best approach to individual patients. Future ongoing trials (Table 4) will hopefully better define therapeutical sequencing strategies for patients with NEN.

Advancements in Systemic Therapy for Pancreatic Cancer

Timothy J. Brown, MD[1,2]; Kim A. Reiss, MD[1,2]; and Mark H. O'Hara, MD[1,2]

overview

Outcomes for patients with advanced pancreatic cancer have improved in the past 12 years, mainly because of progress made in systemic therapies. New treatment strategies for advanced pancreatic cancer include switch maintenance with cytotoxic therapies, induction maintenance, and the utilization of targeted agents for patients with actionable variants, as well as ongoing development of cytotoxic regimens, such as NALIRIFOX. The activity of immunotherapy has been disappointing to date, but novel combinations and identifying appropriate patient populations may further unlock its potential.

ADVANCEMENTS IN SYSTEMIC THERAPY FOR PANCREATIC CANCER

Progress with systemic therapy for patients with advanced pancreatic cancer has historically been slow. However, therapeutic advances in the past 12 years have resulted in modest yet tangible improvements for patients. The cornerstone of these improvements has been in the continuous development of cytotoxic chemotherapy combinations, including oxaliplatin, irinotecan, fluorouracil, and leucovorin (FOLFIRINOX; 2011)[1]; gemcitabine plus nab-paclitaxel (2013)[2]; fluorouracil (FU)/nanoliposomal irinotecan (2016)[3]; and NALIRIFOX (2023).[4] In addition, for a select population—namely, those with *BRCA* or *PALB2* variants who have stable or improved disease on frontline platinum-based therapy—induction/maintenance has emerged as an option that lengthens time off cytotoxic agents.[5] Although this strategy has not yet been shown to improve survival, it offers patients a less-toxic, chemotherapy-free treatment option. Another major breakthrough has been the progressive expansion of targeted agents for patients with pancreatic cancer. Although the population of patients eligible for targeted treatment remains small, the ongoing development of KRAS inhibitors offers hope that we soon might be able to offer precision therapies to a large number of our patients. Finally, although immunotherapy has historically yielded disappointing results, novel combinations and the use of immunotherapy in novel settings may unlock its potential.

CURRENT STANDARD-OF-CARE APPROACH

Currently, the standard-of-care approach for most patients with metastatic pancreatic adenocarcinoma is perpetual cytotoxic chemotherapy with either FOLFIRINOX or gemcitabine and nanoparticle albumin–bound (nab-) paclitaxel on the basis of the PRODIGE-4/ACCORD-11[1] trial and the MPACT trial, respectively.[2]

Although both these regimens have improved outcomes over the previous generation of gemcitabine monotherapy as first-line therapy, FOLFIRINOX and gemcitabine-nab-paclitaxel have never been compared head-to-head in a prospective clinical trial. However, FOLFIRINOX is generally preferred for first-line treatment of advanced pancreatic cancer in patients who are healthy enough to tolerate it and is endorsed in the ASCO guidelines, with gemcitabine-nab-paclitaxel reserved for the second-line treatment or in the first-line treatment for patients with medical comorbidities.[6] Indirect evidence from the recently reported NAPOLI-3 trial of NALIRIFOX versus gemcitabine-nab-paclitaxel lends further support to this approach and is discussed in more detail later in this review.[4] In clinical practice, FOLFIRINOX is often modified from its original dosing schema with a lower dose of irinotecan (150 mg/m^2 once every two weeks) and elimination of the FU bolus to improve the adverse event profile without reducing the efficacy.[7]

NEW DEVELOPMENTS IN CYTOTOXIC CHEMOTHERAPY FOR ADVANCED PANCREATIC CANCER

NALIRIFOX

Combination of 5-FU, leucovorin, and liposomal irinotecan was previously approved for metastatic pancreatic cancer after progression with a gemcitabine-based regimen on the basis of the global, randomized, phase III NAPOLI-1 trial.[3] In practice, this combination has been historically limited to the second- or third-line setting in patients with progressive disease (PD) who remain candidates for therapy. The combination of NALIRIFOX (liposomal irinotecan 50 mg/m^2, FU 2400 mg/m^2, leucovorin 400 mg/m^2, and oxaliplatin 60 mg/m^2) once daily on days 1 and 15 of a

PRACTICAL APPLICATIONS

- The cornerstone of systemic therapy for advanced or metastatic pancreatic cancer remains cytotoxic chemotherapy.
- NALIRIFOX is a possible option for frontline therapy on the basis of NAPOLI-3 clinical trial.
- All patients with incurable pancreatic cancer should undergo germline and somatic next-generation sequencing to identify possible actionable variants.
- Noncytotoxic maintenance therapy after a period of chemotherapy induction is an option for patients with *BRCA* or *PALB2* variants. Maintenance treatment is actively being explored for a broader population.
- Progress is being made in identifying candidate combinations to enhance the effects of immunotherapy in pancreatic cancer.

28-day cycle was evaluated in a phase I/II study and demonstrated manageable toxicity and a median overall survival (OS) of 12.6 months, generating preliminary data for testing this combination in a phase III trial.[8]

The global, open-label, phase III NAPOLI-3 trial compared NALIRIFOX given on days 1 and 15 of a 28-day cycle with gemcitabine and nab-paclitaxel given on days 1, 8, and 15 of a 28-day cycle in previously untreated patients with metastatic pancreatic cancer.[4] This trial randomly assigned 770 patients (n = 383 NALIRIFOX, n = 387 gemcitabine and nab-paclitaxel) and had a primary end point of OS. After a median follow-up of 16.1 months, the median OS in the NALIRIFOX arm was 11.1 months compared with 9.2 months in the gemcitabine and nab-paclitaxel arm (hazard ratio [HR], 0.84; 95% CI, 0.71 to 0.99; P = .04). Similarly, median progression-free survival (PFS) was significantly improved with NALIRIFOX versus gemcitabine/nab-paclitaxel (7.4 months *v* 5.6 months; HR, 0.70; 95% CI, 0.59 to 0.84; P = .0001). Objective response rates (ORRs) slightly favored NALRIFOX (ORR, 41.8%; 95% CI, 36.8 to 6.9 *v* 36.2%; 95% CI, 31.4 to 41.2). Furthermore, grade ≥3 treatment-related adverse events, serious treatment-related adverse events, and treatment-related adverse events (TRAEs) that led to death were similar between NALIRIFOX and gemcitabine/nab-paclitaxel. Diarrhea, nausea, vomiting, and hypokalemia were the most common grade ≥3 TRAEs in the NALIRIFOX arm.

Although NALIRIFOX has not been directly evaluated against FOLFIRINOX and cross-trial comparisons are challenging and subject to bias across patient populations, the findings from the NALIRIFOX arm in NAPOLI-3 are strikingly similar to the outcomes of the FOLFIRINOX arm of PRODIGE-4/ACCORD-11,[1] whereas gemcitabine and nab-paclitaxel in NAPOLI-3 led to slightly longer OS and higher ORR compared with MPACT.[2] Without direct head-to-head comparisons of FOLFIRINOX and NALIRIFOX and while we await the publication of the NAPOLI-3 trial, it is expected both regimens will be acceptable for frontline standard of care for otherwise healthy patients with advanced pancreatic cancer. Moreover, the results of the gemcitabine and nab-paclitaxel arm lend support to either NALIRIFOX or FOLFIRINOX as the preferred frontline option for patients who are candidates for this intensive therapy.

TARGETED THERAPY IN PANCREATIC CANCER

For patients with metastatic pancreatic cancer, both germline and somatic sequencing should be performed in an expeditious manner as up to a quarter of patients with advanced pancreatic cancer might have a potentially actionable mutation and may be eligible for biomarker-directed therapies or clinical trials.[9-11] The results of such testing can influence the approach to first-line therapy in the case of *BRCA*-mutated pancreatic cancer,[12] inform risk of developing hereditary cancers in family members, identify potentially actionable variants, and facilitate enrollment into clinical trials that may not otherwise be available. Until recently, there were very few druggable targets available, aside from the tissue-agnostic approvals. However, progress is being made in identifying and exploiting potentially targetable mutations.

RET

RET fusions or alterations are uncommon in pancreatic cancer, representing 0.6% of all patients and 1.35% of those with *KRAS* WT disease, but are targetable by selpercatinib.[13,14] LIBRETTO-001 was an open-label phase I/II basket trial designed to assess the ORR of patients with *RET* fusion–containing malignancies treated with selpercatinib.[15] In total, 12 of 45 patients enrolled on this trial had refractory advanced pancreatic adenocarcinoma (27%), of whom 11 were evaluable for a response. The ORR in these patients with pancreatic cancer was 54.5% (95% CI, 23.4 to 83.3).[15] On the basis of these results, the US Food and Drug Administration (FDA) granted selpercatinib an accelerated tissue-agnostic approval for patients with solid tumors harboring a *RET* fusion, offering a potential option for a small population of patients with *RET* fusion–positive advanced pancreatic cancer.[16]

NTRK Fusions

NTRK fusions are extremely rare in pancreatic cancer, reported to be present in up to 0.56% of patients with

pancreatic adenocarcinoma.[17,18] However, there is a tumor-agnostic approval for either larotrectinib or entrectinib in patients with tumors harboring *NTRK* fusions and case reports documenting response to these targeted therapies in patients with refractory pancreatic cancer driven by NTRK fusions.[19,20] It is reasonable to consider evaluation for the presence of *NTRK* fusions in patients with advanced pancreatic cancer to identify patients who are candidates for these targeted therapies.

Targeting KRAS

KRAS is one of the most commonly mutated genes in pancreatic cancer, mutated in over 90% of pancreatic cancers and almost exclusively in the G12 codon, although, up until recently, it has been challenging to target.[14,21,22] Sotorasib is a small molecule that specifically inhibits *KRAS* G12C through an interaction with the P2 pocket of the mutated protein, locking it into an inactive form. Sotorasib was approved for use by the US FDA in late 2022 for non–small-cell lung cancer harboring a *KRAS* G12C mutation.[23-25] In advanced pancreatic cancer, however, G12C is a relatively uncommon mutation, representing only 1%-2% of all patients with pancreatic cancer.[26] The initial report of the phase I CodeBreaK 100 trial testing sotorasib in advanced solid tumors enrolled 12 patients with pancreatic cancer, of whom one experienced a partial response.[27] This led to expansion and investigation specifically into patients with *KRAS* G12C–mutated pancreatic cancer. Thirty-eight patients with pancreatic cancer harboring a pathogenic *KRAS* G12C mutation were enrolled and received sotorasib 960 mg orally once daily. No patient discontinued sotorasib because of toxicity, and the most common treatment-related adverse events were diarrhea and fatigue (5% each). Eight patients (21%) had a confirmed partial response, and 24 (63%) had stable disease as their best response. The median PFS in the trial was 4.0 months (95% CI, 2.8 to 5.6), and the median OS was 6.9 months (95% CI, 5.0 to 9.1). The follow-up CodeBreaK 101 trial investigating sotorasib combinations is currently underway (ClinicalTrials.gov identifier: NCT04185883).

Although the majority of patients will not benefit from *KRAS* G12C inhibition, we have cautious optimism for targeting *KRAS* mutations in pancreatic cancer as a number of novel KRAS inhibitors are just starting to enter the clinic by way of clinical trial. ASP3082 (ClinicalTrials.gov identifier: NCT05382559) and MRTX1133 (ClinicalTrials.gov identifier: NCT05737706) are two drugs with open phase I trials targeting KRAS G12D, a mutation that is found in about 35% of pancreatic cancers, and still many other companies have KRAS G12D inhibitors in various phases of development. In addition, pan-KRAS inhibitors such as RMC-6236 (ClinicalTrials.gov identifier: NCT05379985) are also in development, opening a potential avenue to treat a majority of patients with *KRAS*-mutated pancreatic cancer.[28-31] Furthermore, the conserved mutational profile of *KRAS* in pancreatic cancer and the previous identification of T-cell receptors specific to the mutant KRAS protein in tumor-infiltrating lymphocytes make this a potential avenue for adoptive T-cell therapies in the future,[21,32-34] and this is further discussed later in this review.

CDK

Loss of function of the *CDKN2A* tumor suppressor gene through promoter hypermethylation or deletion is a key event in the tumorigenesis in pancreatic cancer and leads to the loss of the P16 inhibitory signal to CDK4 and CDK6.[35,36] Despite this key interaction, early-phase clinical trials aimed at inhibiting CDK4/6 and its associated pathways have been disappointing, with both a trial of abemaciclib with or without a PI3K inhibitor and a trial of ribociclib with everolimus failing to improve outcomes for these patients.[35]

Ulixertinib is a novel ERK1/2 inhibitor that has shown promising results in preclinical xenograft models.[37] A phase I trial testing the combination of ulixertinib and palbociclib (ClinicalTrials.gov identifier: NCT03454035) reached its maximum tolerated dose of ulixertinib 450 mg PO twice daily and palbociclib 125 mg PO once daily and was reported at the ASCO 2021 Annual Meeting.[38] Three of 16 evaluable patients had stable disease as their best response.[38] An expansion cohort of patients with metastatic pancreatic cancer is currently enrolling. A similar trial of palbociclib and the PI3K inhibitor gedatolisib is also ongoing (ClinicalTrials.gov identifier: NCT03065062).

NRG1

Neuregulin-1 (*NRG1*) fusions are rare but enriched in the *KRAS* wild-type (WT) population of patients with pancreatic cancer, representing only 0.6% of all cases of pancreatic cancer but up to 17% of patients with *KRAS* WT pancreatic cancer.[39,40] These fusions lead to near-constitutive activation of human epidermal growth factor receptor (HER) 3, promoting overactivation of the MAPK and PI3K pathways. Patients with pancreatic cancer driven by these fusions have been successfully treated with agents targeting this pathway, such as afatinib, erlotinib, and pertuzumab.[39]

Seribantumab, a fully human anti-HER3 IgG2 antibody, was also evaluated in the phase II CRESTONE trial, showing promising clinical activity and acceptable toxicity.[41] This study has completed accrual and is expected to report in the summer of 2023. A case report of a patient with *NRG1* fusion who was treated off trial with seribantumab for refractory pancreatic adenocarcinoma informed by preliminary results of this trial exhibited a partial response and disease control for more than 6 months at the time of publication.[40]

In addition, the ongoing phase II study eNRGy is testing whether zenocutuzumab, a bispecific antibody targeting the

HER3 pathway, has clinical activity in patients with treatment-refractory solid tumors (including pancreatic cancer) harboring an *NRG1* fusion (ClinicalTrials.gov identifier: NCT02912949).[42] This study is expected to be completed in late 2024 and may provide another treatment option for these patients.

Trophoblast Cell Surface Antigen-2

Trophoblast cell surface antigen-2 (Trop-2) is a transmembrane calcium signal transducer that is expressed in normal human epithelia and at high levels in many cancers.[43] Its expression has been associated with an increase in cancer growth and the development of metastases although activating mutations have not been described.[44,45] Sacituzumab govitecan is an antibody-drug conjugate that consists of hRS7, an IgG1 anti-Trop2 humanized monoclonal antibody, linked to SN-38, the active camptothecin metabolite of irinotecan.[46] In the first-in-human study, sacituzumab govitecan had an acceptable safety profile and resulted in stable disease in five of five evaluable patients with refractory metastatic pancreatic cancer.[47] In the follow-on basket study IMMU-132-01, 16 patients with refractory metastatic pancreatic cancer were enrolled, of whom seven experienced stable disease as best response, whereas the remainder had PD.[48] The low response rate in pancreatic cancer was partially attributed to previous irinotecan exposure; it is unclear if this compound will be investigated further for pancreatic cancer.[48]

MAINTENANCE THERAPY FOR PANCREATIC CANCER

The standard approach to treatment in pancreatic cancer is continuous cytotoxic combination chemotherapy until either adverse events or progression of disease leads to a change in therapy. Other strategies of evaluating alternative therapies after a period of induction cytotoxic therapy, an approach that has historically albeit admittedly poorly termed maintenance therapy, are being explored. While some of these strategies are truly meant to maintain the response or stable disease achieved by upfront induction chemotherapy in an effort to minimize toxicity, other strategies aim to potentially deepen the response induction chemotherapy achieved.

Maintenance FU

PANOPTIMOX-PRODIGE-35 was a three-arm phase II trial in previously untreated patients with metastatic pancreatic cancer that compared 6 months (12 cycles) of FOLFIRINOX with either the sequence of FOLFIRINOX for eight cycles followed by FU/leucovorin maintenance (an oxaliplatin stop-and-go strategy, LV5FU2) or FIRGEM, a sequential treatment strategy consisting of fluorouracil, leucovorin, and irinotecan (FOLFIRI.3) for four cycles and gemcitabine for two cycles in a previously untreated population of patients with pancreatic cancer.[49] The primary end point of interest was a noncomparative landmark 6-month PFS to select the best regimen to test in a phase III trial. The 6-month PFS for FOLFIRINOX in the study was 41%; for LV5FU2, it was 42.9% (95% CI, 34.3 to 51.4); and for FIRGEM, it was 34.1% (95% CI, 25.7 to 43.3). The median OS, a secondary objective, was 10.1 months (95% CI, 8.5 to 12.2) with FOLFIRINOX, 11.2 months (95% CI, 9.0 to 13.1) with LV5FU2, and 7.3 months (95% CI, 5.7 to 9.5) with FIRGEM. Despite eliminating oxaliplatin after eight cycles of FOLFIRINOX, LV5FU2 had similar rates of grade 3 or 4 neurotoxicity compared with perpetual FOLFIRINOX within the first 6 months of therapy (LV5FU2 11.0%, FOLFIRINOX 10.2%), which, however, were higher overall in the LV5FU2 arm (19.8%) compared with FOLFIRINOX (10.2%) at study completion.[49] This unexpected finding is hypothesized to be due to higher cumulative oxaliplatin dose in the LV5FU2 arm since oxaliplatin was restarted after progression on maintenance therapy in more than a third of patients.[49] Regardless, this study provided support for a maintenance approach for patients with pancreatic cancer that is controlled after induction FOLFIRINOX although this specific strategy does not clearly reduce chemotherapy-induced neurotoxicity.[50]

Cytotoxic Switch Maintenance

The results of the SEQUENCE trial were presented at the ASCO 2022 Annual Meeting, developing an alternative maintenance management concept compared with PANOPTIMOX.[49,51] This was a phase I/II trial exploring a switch maintenance strategy in which untreated patients with metastatic pancreatic cancer were randomly assigned to receive standard gemcitabine plus nab-paclitaxel versus alternating gemcitabine-nab-paclitaxel and modified FOLFOX.[51] The schedule and dosing of the experimental arm were as follows: gemcitabine and nab-paclitaxel on days 1, 8, and 15, followed by modified FOLFOX-6 on day 29 of a 6-week cycle. Safety data from this approach had been previously published, demonstrating acceptable tolerability with few dose delays.[52] This strategy resulted in improved landmark 12-month survival (55.3%; 95% CI, 44.2 to 66.5 *v* 35.4%; 95% CI, 24.9 to 46.0; $P = .016$), 24-month survival (22.4%; 95% CI, 13.0 to 31.8 *v* 7.6%; 95% CI, 1.8 to 13.4; $P = .012$), and median OS (13.2 months; 95% CI, 10.1 to 16.2 *v* 9.7 months; 95% CI, 7.5 to 12.0; HR, 0.676; 95% CI, 0.483 to 0.947; $P = .023$) with the switch maintenance strategy compared with gemcitabine and nab-paclitaxel.[51] Although intriguing, this strategy may complicate further sequencing after progression, particularly with regard to postprogression treatments. Further prospective study is warranted.

Induction/Maintenance Therapy—A New Paradigm for Patients With Unique Biology

Select subgroups of patients with advanced or metastatic pancreatic cancer exhibit durable responses to chemotherapy, correlating with increased OS for some of these

patients.[53] Rather than treating all patients with perpetual chemotherapy, fueling cumulative toxicity, eventual therapeutic resistance, and degradation of quality of life, interest has been growing in identifying patients who may be appropriate for a new paradigm: using chemotherapy as an induction therapy and then switching to noncytotoxic maintenance treatment. Under this paradigm which has been pioneered in other cancer types, select patients with pancreatic cancer who possess unique biology (such as homologous recombination repair deficiency) are treated for a fixed period of time with cytotoxic chemotherapies (induction) to chemically debulk their cancers.[54] After a period of stability on these treatments, the cytotoxic chemotherapies are electively discontinued and the patient is started on the maintenance agent, with a goal of continuing the ongoing response to therapy while avoiding the cumulative effects of cytotoxic chemotherapies.[53] The development of poly (ADP-ribose) polymerase (PARP) inhibitors (PARPi) best illustrates this approach in practice in patients with pancreatic cancer.

PARP inhibitors for BRCA- or PALB2-mutated pancreatic cancer. Patients with locally advanced or metastatic pancreatic cancer with a germline or somatic pathogenic variant in *BRCA1*, *BRCA2*, or *PALB2* that has not progressed after at least 16 weeks of platinum-based combination chemotherapy are candidates for PARPi, rucaparib, or olaparib. For these patients, PARPi is an effective, nonchemotherapy maintenance treatment option.[55] For patients with either germline or somatic mutations in *BRCA1/2* or *PALB2*, PARPi maintenance therapy is capable of producing deep and long-lasting responses without chemotherapy.[56,57]

POLO is the only randomized, phase III clinical trial that evaluated maintenance PARPi in pancreatic cancer.[5] This study, which randomly assigned patients with germline *BRCA* variants and at least stable disease after 4 months or more of platinum chemotherapy to either olaparib or placebo, demonstrated a significant improvement in PFS in the experimental arm compared with the control (7.4 months *v* 3.8 months; HR for disease progression or death, 0.53; 95% CI, 0.35 to 0.82; $P = .004$).[5] Although OS was not different between the arms, results from this trial led to the approval of maintenance olaparib for this population by the US FDA in December 2019.

RUCAPANC2 was a single-arm phase II study investigating maintenance rucaparib in patients with platinum-sensitive, advanced pancreatic cancer with germline or somatic pathogenic variants in *BRCA* or *PALB2*.[58] A total of 42 patients without evidence of platinum resistance after at least 16 weeks of platinum-based cytotoxic chemotherapies were enrolled to receive rucaparib 600 mg PO twice daily until unacceptable toxicity or progression. The median PFS on the study was 13.1 months (95% CI, 4.4 to 21.8), and the median OS was 23.5 months (95% CI, 20.0 to 27.0), both of which compare favorably with historical controls. Remarkably, the ORR of 36 evaluable patients on this study was 41.7%, including three complete responses, highlighting the sensitivity of these patients to noncytotoxic treatment and the potential to deepen responses with a maintenance strategy. As a result of this study, rucaparib is now endorsed by the National Comprehensive Cancer Center guidelines as a category 2A recommendation for patients with metastatic pancreatic cancer and germline or somatic *BRCA1/2* or *PALB2* mutations without evidence of progression on previous platinum-based chemotherapy.[59]

Active areas of investigation include developing a better understanding of mechanisms of PARPi resistance, developing clinical models that can more accurately predict homologous recombination deficiency phenotypes, and identifying optimal post-PARPi therapeutic regimens.[60,61] Evaluating patients treated on RUCAPANC2 with rucaparib, we have previously found that reversion mutations that restore *BRCA* or *PALB2* functionality via restoration of the open reading frame were a rare event but were independently associated with short OS and PFS compared with patients whose tumors did not develop reversion mutations.[61] In the post-PARPi progression setting, cytotoxic chemotherapy continues to retain activity for patients who remain fit for intense therapy although the optimal therapy is unknown and should be investigated in the future.[60] Furthermore, expanding the use of PARPi beyond *BRCA* and *PALB2* remains under investigation and will rely on the development of assays that can accurately predict loss of homologous recombination repair phenotype from mutations in noncanonical homologous recombination repair genes.[62] Finally, post-PARPi therapy remains an active area of investigation, with several ongoing trials testing novel agents for patients with HRD and pancreatic cancer who have PD on PARPi (Table 1).

Capitalizing on the success of PARP inhibitors in the advanced pancreatic cancer setting, olaparib is now being tested in the adjuvant setting for patients with early-stage, *BRCA*- or *PALB2*-related pancreatic cancer. The ECOG/ACRIN APOLLO trial (EA2192) is a randomized, phase II, double-blind study of olaparib versus placebo after curative-intent therapy in patients with resected pancreatic cancer harboring a pathogenic *BRCA1*, *BRCA2*, or *PALB2* variant (ClinicalTrials.gov identifier: NCT04858334).[63] Eligible patients are required to have undergone curative-intent surgery and have received at least 3 months and up to 6 months of perioperative chemotherapy (delivered as neoadjuvant, adjuvant, or a combination of both). After this, patients are randomly assigned 2:1 to receive olaparib 300 mg PO twice daily in 28-day cycles for up to 12 cycles (1 year). The study seeks to improve relapse-free survival

TABLE 1. Selection of Trials in Patients With HRD Who Have Progressive Disease

Trial Name	Molecule(s)	Relevant Clinical Setting	Phase/NCT
A trial of AMXI-5001 in advanced malignancies	AMXI-5001 (small molecule; PARPi plus taxane)	Solid tumors with *BRCA* or *PALB2* and PD after PARPi	I/II NCT04503265
A study of ART4215 in advanced or metastatic solid tumors	ART4215 (DNA Polθ inhibitor) Talazoparib	Solid tumors with g/s *BRCA* mutations and PD after PARPi	I/II NCT04991480
NUV-868 as monotherapy and in combination with olaparib or enzalutamide in solid tumors	NUV-868-01 (BETi) Olaparib	Breast, ovarian, pancreatic cancers with *BRCA* mutations and PD after PARPi	I/II NCT05252390
CX-5461 in solid tumors with *BRCA*, *PALB2*, or other HRD	CX-5461 (G4 stabilizer)	Breast, ovarian, pancreatic, prostate cancers with *BRCA* or *PALB2*; platinum-resistant and/or PARPi-resistant	Ib NCT04890613
Lurbinectedin in patients with advanced solid tumors	Lurbinectedin (transcription inhibitor)	Endometrial, biliary, urothelial, breast, pancreatic, or gastric cancer with g/s HRD+, after other tx	II NCT05126433

Abbreviations: BETi, BET inhibitor; g/s, germline/somatic; HRD, homologous recombination deficiency; PARPi, poly (ADP-ribose) polymerase inhibitor; PD, progressive disease; tx, treatment.

from an expected 22 months in the control arm to 44 months with olaparib. This trial is actively recruiting.

PARPVAX (PARP inhibitor plus checkpoint inhibitor). The treatment of pancreatic cancer with PARPi is recognized to increase cytosolic DNA, activate the immune inflammatory stimulator of interferon genes (STING) pathway, and result in an increase in PD-L1 expression in both *BRCA*-mutated and WT tumors.[64] Furthermore, there are preclinical evidence to suggest synergy between PARPi and cytotoxic T-cell lymphocyte-4 (CTLA-4) blockade and evidence that CTLA-4 may be upregulated in HRD tumors.[65,66] The phase Ib/II PARPVAX trial sought to exploit this unique biology.[67] Patients on this trial with advanced pancreatic cancer without evidence of progression after at least 16 weeks of platinum-based chemotherapy (with or without a germline *BRCA1*, *BRCA2*, or *PALB2* mutation) were randomly assigned to receive niraparib 200 mg PO once daily plus either nivolumab (continuous dosing every 2 weeks or every 4 weeks) or ipilimumab (every 3 weeks for four doses) with a primary end point of assessing safety and PFS at 6 months and a null hypothesis of meaningful 6-month PFS of 44%, doubling the PFS observed in the only other published trial of maintenance therapy in pancreatic cancer.[68]

Although the niraparib and ipilimumab arm had a grade 3 or worse treatment-related adverse event rate of 50%, the 6-month PFS was 59.6% (95% CI, 44.3 to 74.9; $P = .045$ compared with the null hypothesis of 44%). While the niraparib and nivolumab arm had fewer grade 3 adverse events (22%), this arm failed to meet the landmark 6-month PFS end point (20.6%; 95% CI, 8.3 to 32.9; $P = .0002$ *v* the null hypothesis of 44%). These results were unchanged when patients with recognized HRD were removed from the analysis. Overall, this study provided important information regarding the feasibility of a noncytotoxic maintenance regimen and data for the potential efficacy of niraparib with ipilimumab in this population. Further study is needed in this area.

Other ongoing maintenance trials of PARPi with immunotherapy include SWOG2001 and POLAR. SWOG2001 randomly assigns patients with metastatic pancreatic cancer and germline *BRCA1* and *BRCA2* mutations without evidence of platinum resistance after 4-6 months of chemotherapy to olaparib with or without pembrolizumab. The primary objective of this study is to improve the median PFS of the experimental arm from 7 months to 11.7 months with a goal of recruiting 78 patients, which is estimated to complete enrollment in mid-2025 (ClinicalTrials.gov identifier: NCT04548752).[69] POLAR is a phase II trial evaluating the safety and efficacy of pembrolizumab and olaparib in patients with metastatic pancreatic adenocarcinoma and either a known gene mutation that results in HRD or response to platinum-based chemotherapy. This trial contains three cohorts of patients—cohort A with core homologous recombination deficiency (recognized pathogenic mutations in *BRCA1/2* or *PALB2*), cohort B with noncore HRD (pathogenic mutations in *ATM*, *BAP1*, *BARD1*, *BLM*, *BRIP1*, *CHEK2*, *FAM175A*, *FANCA*, *FANCC*, *NBN*, *RAD50*, *RAD51*, *RAD51C*, *RTEL1*), and cohort C with platinum-sensitive disease (no HRD mutations qualifying for cohort A or B with either a partial or complete response to platinum-based therapies). This trial is also assessing the primary end point of PFS and is expected to complete accrual in mid-2025 (ClinicalTrials.gov identifier: NCT04666740).[70]

IMMUNOTHERAPY IN PANCREATIC CANCER

Although development of immunotherapy for other cancers has greatly improved prognoses and fundamentally altered the approach to treatment, immunotherapy in pancreatic cancer has been notoriously disappointing. Clinical trials of

single-agent immunotherapy, doublet immunotherapy combinations, and immunotherapy with chemotherapy have all failed to demonstrate clinical efficacy in patients with pancreatic cancer.[71-78] This is, in part, related to the immunosuppressive myeloid infiltration and low T-cell infiltration within the tumor microenvironment, intrinsic low tumor mutational burden, immune privilege.[79] Despite disappointing efficacy with immunotherapy in pancreatic cancer to date, potential novel immunotherapies and novel biomarker selection will be key to future immunologic treatment strategies in this disease.

Immunotherapy Biomarkers in Pancreatic Cancer

Markers that predict response to immunotherapy in other cancers are not effective in pancreatic cancer. For example, PD-L1 expression as assessed combined positive score or tumor proportion score is a biomarker for potential response to PD-1 and PD-L1 inhibitor in malignancies, such as non–small-cell lung cancer, head and neck squamous cell cancer, gastroesophageal cancer, and cervical cancer. PD-L1 expression within pancreatic cancer, however, does not predict response to PD-1 inhibition, noting a 0% response rate to pembrolizumab in PD-L1–expressing pancreatic cancers in KEYNOTE-028.[80] A lack of response to PD-1 inhibition was also noted in the rare population of patients with pancreatic cancer with high tumor mutational burden (TMB $\geq$10 mutations per megabase),[81] despite FDA approval for pembrolizumab for tumors with TMB, regardless of histology. Similarly, although pembrolizumab is approved for use in microsatellite unstable (MSI-high) cancers regardless of histology,[82] the ORR in patients with MSI-high pancreatic cancer treated with pembrolizumab was only 18.2%, at least 50% lower than other MSI-high cancer types.[83] Data are limited on the role of dual checkpoint inhibition in MSI-high pancreatic cancer although it is noteworthy that the isolated response to durvalumab and tremelimumab in metastatic pancreatic adenocarcinoma occurred in an MSI-high patient.[74] Although PD-1 inhibition remains a potential option in the rare population of patients with pancreatic cancer that is MSI-high or has a high TMB, we would recommend consideration of an immunotherapy clinical trial for these patients given limited efficacy to monotherapy PD-1 inhibitors to date.

Ongoing studies in immunotherapy in pancreatic cancer may help to elucidate patient populations who may benefit from therapeutic immune approaches (Table 2). In a retrospective analysis of ipilimumab and nivolumab in patients with chemotherapy-refractory pancreatic adenocarcinoma harboring a pathogenic germline variant in homologous recombination genes, 20% of patients had a complete response, 10% had a partial response, and 20% had stable disease.[84] Pancreatic cancers with homologous recombination deficiencies have increased genomic instability and an associated elevated tumor mutational burden and so may theoretically be more responsive to immunotherapy. As evidenced by the aforementioned studies[81] and the fact that those patients who responded in this retrospective study had a TMB of <10 mutations/MB,[84] tumor mutational burden alone does not explain the responsiveness of this group to immunotherapy. Further analysis is needed, and clinical trials evaluating immunotherapy in homologous recombination-deficient pancreatic cancers are ongoing (ClinicalTrials.gov identifiers: NCT05659914, NCT04548752, NCT04493060).

CD40 agonist has been evaluated in pancreatic cancer in several clinical trials on the basis of preclinical evidence suggesting that treatment with CD40 agonists can change resident tumor immunosuppressive macrophages into tumoricidal macrophages and deplete the tissue stroma, potentially restoring adequate immunosurveillance.[85,86] The PRINCE trial was a phase Ib/II trial evaluating the combination of gemcitabine and nab-paclitaxel with or without the CD40 agonist sotigalimab with or without nivolumab in previously untreated patients with pancreatic adenocarcinoma.[87,88] Although this study was limited by the lack of a chemotherapy-only control arm, the combination of gemcitabine, nab-paclitaxel, and nivolumab was the only arm to meet the primary end point of improved 1-year OS compared with the historical control, which is contrary to previous publications of this combination.[78] Despite the lack of significant efficacy of these chemoimmunotherapy combinations in this unselected population, there did appear to be some patients who benefited in each arm. Moreover, specific tumoral and plasma immune signatures were detected at baseline in patients who benefited from the combination of gemcitabine, nab-paclitaxel, and nivolumab, and this signature was distinct from the signature noted in patients who benefitted from gemcitabine, nab-paclitaxel, and sotigalimab (Padron). These findings are being further evaluated to determine if a novel immune biomarker may be used to select patients for treatment with these chemoimmunotherapy combinations in future clinical trials.

Cell Therapy in Pancreatic Cancer

Although adoptive cell therapy has revolutionized the management of liquid tumors, their role in solid cancers, including pancreatic cancer, has been limited. Chimeric antigen receptor (CAR) T-cell therapy has been ineffective in managing pancreatic cancer to date,[89-92] limited by target selection, CAR manufacturing feasibility, trafficking of CAR T cells to the tumor, and immunosuppressive microenvironment within the pancreatic tumors.[93] Trials evaluating novel targets (ClinicalTrials.gov identifier: NCT04404595) and combination approaches (ClinicalTrials.gov identifier: NCT05057715) are

TABLE 2. Select Ongoing Trials of Immunotherapies in Pancreatic Cancer

Study Title	Setting	Design	Primary End Point	Estimated Completion Date	NCT
Multi-agent Low Dose Chemotherapy GAX-CI Followed by Olaparib and Pembro in Metastatic Pancreatic Ductal Cancer	First-line maintenance olaparib and pembrolizumab after gemcitabine, nab-paclitaxel, capecitabine, and irinotecan	Single-arm, open-label	6-Month PFS	December 2025	NCT04753879
Lenvatinib and Pembrolizumab Maintenance Therapy for the Treatment of Patients of Advanced Unresectable Pancreatic Cancer	Maintenance after at least 16 weeks of first- or second-line chemotherapy without evidence of progression	Single-arm open-label phase 2	4-Month PFS	December 2023	NCT04887805
A Study to Evaluate the Safety and Tolerability of SX-682 in Combination With Nivolumab as a Maintenance Therapy in Patients With Metastatic Pancreatic Ductal Adenocarcinoma	Maintenance therapy after at least 16 weeks of first-line chemotherapy without evidence of PD	Open-label phase 1	Maximum tolerable dose of SX-682 in combination with nivolumab	December 2024	NCT04477343
Niraparib and Dostarlimab for the Treatment of Germline or Somatic BRCA1/2 and PALB2 Mutated Metastatic Pancreatic Cancer	After one or two lines of systemic therapy with at least one line containing platinum chemotherapies	Open-label single-arm phase 2	Disease control rate at 12 weeks	December 2023	NCT04493060
A P1b Study of Odetiglucan With a CD40 (CDX-1140) Agonist	Maintenance after 16-24 weeks of first-line chemotherapy without evidence of PD	Open-label phase 1	Maximum tolerated dose of odetiglucan with CDX-1140	March 2026	NCT05484011
Testing the Addition of Pembrolizumab, an Immunotherapy Cancer Drug to Olaparib Alone as Therapy for Patients With Pancreatic Cancer That Has Spread With Inherited BRCA Mutations	Maintenance therapy after first-line platinum-based chemotherapy without PD	Two-arm randomized phase 2 trial	PFS	March 2025	NCT04548752
A Study of Pembrolizumab and Olaparib for People With Metastatic Pancreatic Ductal Adenocarcinoma and Homologous Recombination Deficiency or Exceptional Treatment Response to Platinum-Based Therapy (POLAR)	Maintenance after first- or second-line platinum-based therapies without evidence of platinum resistance. Three cohorts: (1) core HR mutations, (2) noncore HR mutations, (3) platinum responders without HR mutations	Single-arm, open-label, nonrandomized	6-Month PFS	January 2024	NCT04666740

Abbreviations: HR, homologous recombination; PD, progressive disease; PFS, progression-free survival.

underway to potentially circumvent these barriers to potentially enhance efficacy of this cellular therapeutic approach.

More promising results have been published using T-cell receptor (TCR) therapy in pancreatic cancer. A case report of autologous T-cell therapy expressing HLA-C*08:02–restricted TCRs targeting KRAS G12D showed signs of efficacy.[94] This case report outlines two chemotherapy-refractory patients treated with this therapy in conjunction with tocilizumab and cyclophosphamide preconditioning and high-dose interleukin-2 postinfusion, and although both patients had an initial clinical benefit, only one of these patients had a durable partial response lasting more than 6 months. Although only a single patient response is not a proof of concept and TCR therapy is limited by the specific KRAS mutation and an associated HLA type, the durability of efficacy in this patient is intriguing and is driving ongoing clinical trials evaluating KRAS-directed TCR (ClinicalTrials.gov identifiers: NCT03190941, NCT03745326).

FUTURE DIRECTIONS AND CONCLUSIONS

Progress with systemic therapy for patients with pancreatic cancer has been slow, but the development of novel approaches is improving the prognosis for patients with select biomarkers. Effective cytotoxic chemotherapies with the emerging success of immunotherapies and targeted therapies have proven to be beneficial. Novel approaches to delivering effective therapies such as induction/maintenance and further development of biomarkers may provide additional benefit to selected patients to exploit molecular and immunogenic characteristics of their tumors.

State of the Art: Multidisciplinary Management of Oligometastatic Renal Cell Carcinoma

Shawn Dason, MD[1]; Kristine Lacuna, MD[2]; Raquibul Hannan, MD, PhD[3]; Eric A. Singer, MD, MA, MS, FACS, FASCO[1]; and Karie Runcie, MD[2]

overview

Oligometastatic renal cell carcinoma (OM-RCC) refers to patients who have limited (typically up to 5) metastatic lesions. Although management principles may overlap, OM-RCC is distinguishable from oligoprogressive RCC, which describes progression of disease to a limited number of sites while receiving systemic therapy. Cytoreductive nephrectomy and metastasectomy are common surgical considerations in OM-RCC, and indications are discussed in this review. It is evident that stereotactic ablative radiotherapy is effective in RCC and is being applied increasingly in the oligometastatic setting. Finally, we will review advances in systemic therapy and the role of active surveillance before the initiation of systemic therapy.

INTRODUCTION

Kidney cancer is one of the 10 most common cancers in the United States with an estimated 81,800 cases and 14,890 attributable deaths in 2023.[1] Most kidney cancers are renal cell carcinomas (RCCs) in which 15% of patients will have metastases at presentation and an additional 20% will develop metastatic disease after the treatment of localized disease.[2]

Metastatic RCC (mRCC) represents a wide spectrum of disease aggressiveness as evident from the risk stratification by International Metastatic Database Consortium (IMDC) where poor-risk patients have survival of less than 1 year, whereas those with favorable-risk disease might have a smoldering progression over many years.[3,4] Patients with oligometastatic RCC (OM-RCC) have a limited number of detectable metastatic lesions at presentation, typically 5 or less.[5] Although commonly encountered, limited direct data are available on the incidence of OM-RCC.

Although some of these patients may be truly oligometastatic where the detectable lesions are the only metastases they have, the assumption is that the majority of these patients likely have sites of undetectable micrometastatic disease. Therefore, depending on the rate of progression of the metastatic sites, many patients may benefit from local therapy alone or a combination of local therapy with systemic therapy. Although not evaluated specifically, IMDC risk stratification should be applied to OM-RCC and divided into subcategories on the basis of the risk of distant micrometastasis and the rate of disease progression. This can help inform the probability of future progression at distant sites, thereby ascertaining the likely duration of disease control and potential benefit from local therapy versus the need for a combination of local and systemic therapies. Those on the slowest end of the progression spectrum may even be candidates for careful surveillance. OM-RCC is distinct from oligoprogressive disease, which describes patients with RCC with any number of metastases but progressing only in a limited number of sites in response to ongoing systemic therapy. Both oligometastatic and oligoprogressive diseases have overlapping multimodality management principles.

There have been significant advances in the surgical, radiation, and medical management of RCC in the past decade. This review summarizes the contemporary multidisciplinary management of OM-RCC.

CYTOREDUCTIVE NEPHRECTOMY

Cytoreductive nephrectomy (CN) refers to surgical removal of the kidney and primary tumor in a patient with synchronous metastatic disease and is often one of the first considerations at initial diagnosis of mRCC.[6,7] In the following sections, we discuss the rationale for CN to delay systemic therapy, as an adjunct to systemic therapy, or for symptom palliation.

Contemporary indications for CN include the following:

1. Limited metastatic disease that would be amenable to active surveillance (AS) after CN[8]
2. Limited metastatic disease that can be controlled completely with metastasis-directed therapy (MDT) after CN
3. One IMDC risk factor with the majority of tumor burden located in the kidney[8]
4. Oligoprogressive disease within the kidney after upfront systemic therapy

PRACTICAL APPLICATIONS

- Patients with oligometastatic renal cell carcinoma (OM-RCC) have a limited number of (typically up to 5) metastatic lesions at presentation.
- Cytoreductive nephrectomy is commonly performed in OM-RCC, and indications should be informed by recent clinical trials.
- Stereotactic ablative radiotherapy is effective in RCC and can be used for both the primary tumor and metastatic lesions.
- Active surveillance or metastasis-directed therapy (metastasectomy or stereotactic ablative radiotherapy) can delay systemic therapy, which may improve quality of life.
- Significant advances in systemic therapy have occurred in the past decade that improved survival in metastatic RCC and has implications for OM-RCC.

5. Significant local symptoms, particularly those that require hospitalization and prevent the receipt of systemic therapy

Relative indications for up-front systemic therapy rather than up-front CN include the following:

1. Significant extrarenal disease
2. Excessive surgical morbidity
3. Poor performance status and/or multiple IMDC risk factors

CN to Delay Systemic Therapy

CN followed by AS. CN may allow for delay of systemic therapy if the extrarenal disease is amenable to AS.[8] AS is a common management strategy, being used in about 32% of patients according to an observational mRCC cohort.[9]

Prospective data for AS originate from a phase II study in which 52 patients with treatment-naïve, asymptomatic, mRCC underwent AS with serial imaging at baseline, every 3 months for year 1, every 4 months for year 2, and every 6 months thereafter.[4] The study allowed previous surgery (nephrectomy or metastasectomy) and radiotherapy (including radiation for CNS metastases). The primary end point was the time to initiation of systemic therapy. Most patients (75%) were in the IMDC intermediate-risk category. Patients had metastases most commonly located in the lung (71%), lymph nodes (25%), and bone (21%) with an overall average tumor burden of 3.2 cm at baseline. With a median follow-up of 38.1 months, the median time on AS was 14.9 months.[4] Patients with IMDC poor-risk disease and a higher number of metastatic sites were associated with a shorter surveillance period. After disease progression on surveillance, patients were usually started on systemic therapy. Subsequent genomic analysis of this cohort has identified TP53 and SMARCA4 mutations as biomarkers for a shorter period of AS.[10]

CN is conventionally performed before AS in mRCC as this is often the site of bulky and or symptomatic disease. Several studies have reported on the feasibility of AS in mRCC to delay the toxicity of systemic therapy and thereby improve quality of life.[4,9,11-13]

CN combined with MDT. Up-front CN and complete MDT may delay systemic therapy for a median time of 1 year, with 20%-30% of patients achieving long-term disease control without systemic therapy.[14-17] Although case series on this approach have been published, CN and complete MDT have not been prospectively compared with either surveillance or systemic therapy. MDT is discussed further in the following sections.

CN as an Adjunct to Systemic Therapy

Complete response in the primary tumor is exceedingly unlikely with systemic therapy alone, and the majority of patients in the landmark systemic therapy trials have received previous nephrectomy.[18-22]

The role of CN in mRCC originated from the cytokine era where SWOG-8949 and EORTC-30947 demonstrated a 5.8-month median survival benefit for those patients randomly assigned to receive CN before interferon alfa-2b compared with interferon alfa-2b alone.[23-26] In the era of targeted therapy, 30%-40% of patients received CN and retrospective data suggested that CN improved survival.[27,28]

Previous enthusiasm for up-front CN has been tempered with the more recent publication of the CARMENA and SURTIME studies.[29-31] Although these studies have a number of limitations, predominantly their use of historic systemic therapy (sunitinib), they have shaped our current CN paradigm.[8]

The CARMENA study randomly assigned 450 patients with mRCC to CN followed by sunitinib versus sunitinib alone.[29,30] Sunitinib alone was noninferior to CN and sunitinib in both the initial study and a subsequent abstract with longer follow-up. In a post hoc analysis, it was noted that patients with one IMDC risk factor had a slight benefit in overall survival (OS) in the CN group (30.5 *v* 25.2 months, nonsignificant), whereas those with two or more IMDC risk factors had a shorter survival in the CN group (16.6 *v* 31.2 months; $P = .015$). This informs current ASCO guideline recommendations that CN be considered in patients with one IMDC risk factor and the majority of their disease in the kidney.[8]

The SURTIME study randomly assigned 99 patients to up-front CN versus deferred CN in patients receiving sunitinib.[31] Although the study was stopped early for poor accrual, findings again demonstrated a lower OS in the group receiving up-front CN (15.0 *v* 32.4 months). A higher proportion of patients in the deferred group were able to receive sunitinib (98% *v* 80%).

These data support the paradigm that patients with a lower number of IMDC risk factors are more likely to benefit from CN and that deferring CN to follow a period of systemic therapy is beneficial. The benefit of this paradigm is likely derived from the increased receipt of systemic therapy in patients with rapidly progressive disease and a poor prognosis. Observational studies with current systemic therapy regimens continue to strongly support the better prognosis of patients who undergo CN but are limited by selection bias.[32,33] Prospective randomized studies are ongoing (Table 1), which will inform us on the role of CN in the current era of systemic therapy.

CN for Symptom Palliation

Large renal masses may result in pain, hematuria, and other local symptoms. Patients with inferior vena cava tumor thrombus might also have specific sequelae from venous obstruction or embolization.[41] Symptomatic disease remains an important indication for CN, particularly for those who are hospitalized for their symptoms and unable to receive systemic therapy.[42] In a patient who is not otherwise a good candidate for CN, there are alternative effective methods for symptom palliation including angioembolization, SBRT, and systemic therapy.

MDT

MDT refers to a treatment focused on control of one or more specific metastatic lesions. MDT was conventionally performed with surgical metastasectomy but is increasingly performed with ablative techniques like SBRT.[8] The oligometastatic patient best considered for up-front MDT is the one who is rendered free of disease by MDT in combination with previous nephrectomy.

The goal of MDT is to improve survival while preserving quality of life by delaying both systemic therapy and the sequelae of metastatic disease. In highly selected cohorts, 20%-30% of patients might have long-term disease control with MDT without systemic therapy.[14-17] MDT also plays an essential role in the palliation of a symptomatic lesion where awaiting systemic therapy response may be detrimental (eg, symptomatic bone or brain disease)—but this indication is not the focus of the following discussion.[42]

The conventional MDT approach outlined above is undergoing a paradigm shift because of (1) increasing utilization of ablative techniques like stereotactic body radiotherapy, (2) recognition of the role of AS in mRCC, and (3) integration with more effective systemic therapy regimens.[43] When integrated with systemic therapy, MDT can be performed up-front followed by adjuvant therapy or used for sites of oligoprogression.[43-45] Oligometastatic patients being considered for MDT benefit from multidisciplinary discussion to see if surveillance or systemic therapy may be more appropriate and whether MDT is best accomplished by surgery or ablative techniques.

Most of the published data for MDT are related to surgical metastasectomy.[46] A recent multi-institutional series of 740 metastasectomies in 522 patients provide contemporary data on surgical outcomes.[47] In this study, 8% of patients experienced a major complication of metastasectomy, with 1% experiencing a perioperative death. Age, multiple sites of resection, and pancreatic resection were associated with major complications.[47]

The oncologic outcomes for metastasectomy originate from retrospective data and have been summarized in recent systematic reviews.[15,17] Complete metastasectomy (to render free from disease) is the goal, and the carefully selected patients who can undergo complete metastasectomy have a favorable prognosis. Two series from the Mayo Clinic illustrate the value of this prognostic factor. For patients treated between 1976 and 2006, 14% of the 887 patients who had undergone nephrectomy had multiple metastases and were able to receive complete metastasectomy.[48] In this population, the 5-year cancer-specific survival was 49.4% with complete metastasectomy as opposed to 13.9% without. An updated Mayo Clinic series including only patients after TKI approval revealed that 27% of patients who had undergone nephrectomy could undergo complete metastasectomy. Those who had a complete metastasectomy had a 2-year OS of 84% compared with 54% in those who had not.[49]

Additional prognostic factors include the number of metastatic sites and disease-free interval since nephrectomy.[15] The prognostic implications of metastatic organ sites are less established—lung metastases are most commonly considered for metastasectomy and appear to have better prognosis.[48] Favorable outcomes have also been described in series of metastasectomy for pancreatic, adrenal, and thyroid locations. Highly selected patients with other organ metastases also had long-term survival (liver, bone, brain, lymph node).

Stereotactic Ablative Radiotherapy

In the wide spectrum of disease aggressiveness for patients with OM-RCC, stereotactic ablative radiation (SAbR) may be applicable to a few subgroups. The first subcategory comprises patients who present with metachronous metastases that develop multiple years after resection of the primary kidney tumor. This suggests that the patient's disease is indolent and portends the best prognosis. A

TABLE 1. Selected Prospective Clinical Trials Relevant to CN

Study	Status	Design	Outcome	Relevance
Reported				
SWOG-8949[34]	Published in 2001	mRCC randomly assigned to CN + ifn alfa-2b *v* ifn alfa-2b alone	Improved survival with CN	Original support for the role of CN in mRCC
EORTC-30947[25]	Published in 2001	mRCC randomly assigned to CN + ifn alfa-2b *v* ifn alfa-2b alone	Improved survival with CN	Original support for the role of CN in mRCC
CARMENA[29]	Published in 2018	Clear cell mRCC randomly assigned to CN + sunitinib *v* sunitinib alone	Noninferiority of sunitinib alone compared with CN + sunitinib. Shorter survival with CN + sunitinib when two or more IMDC risk factors are present (SS). Longer survival with CN + sunitinib when one IMDC risk factor is present (NSS)	Questions dogma supporting CN in mRCC and suggests that patient selection on the basis of IMDC risk is important
SURTIME[31]	Published in 2019	Clear cell mRCC randomly assigned to immediate CN + sunitinib *v* sunitinib for 12 weeks + deferred CN in the absence of progression	Longer OS and higher proportion of patients receiving sunitinib treatment with up-front sunitinib and deferred CN	Supports the concept of deferring CN to follow a period of systemic therapy
NAXIVA[35]	Published in 2022	Resectable ccRCC with venous tumor thrombus treated with 8 weeks of axitinib, single-arm, M0, or mRCC	No patients had an increase in tumor thrombus level	Supports safety of deferring CN in patients with IVC tumor thrombus
Ongoing				
NCT04370509[36]	Recruiting, estimated completion in 2025	ccRCC treated with pembrolizumab with or without axitinib for 9 weeks before nephrectomy or metastasectomy, M0, or mRCC	Primarily the impact of pembrolizumab on composition, phenotype, and function of tumor-infiltrating immune cells Secondarily efficacy, safety, and tolerability of preoperative pembrolizumab	Immunologic impact of pembrolizumab on RCC Efficacy and safety of neoadjuvant pembrolizumab with or without axitinib before CN or metastasectomy
NCT05319015[37]	Recruiting, estimated completion in 2025	RCC with IVC tumor thrombus treated with lenvatinib + pembrolizumab before nephrectomy and IVC thrombectomy, M0, or mRCC	Primarily disease control rate, local and metastatic progression rate, postoperative complications	Efficacy and safety of neoadjuvant lenvatinib + pembrolizumab in patients with RCC with IVC thrombus, many of whom will have mRCC
NORDIC-SUN[38]	Recruiting, estimated completion in 2026	mRCC receiving doublet systemic therapy, randomly assigned to CN *v* no CN if resectable and 3 or less IMDC risk factors are present after 3 months of ST; reassessed for random assignment after 6 months of ST if not eligible at 3 months	Primarily OS	Assess the role for CN in mRCC with contemporary ST regimens
CYTO-KIK[39]	Recruiting, estimated completion in 2027	Clear cell mRCC receives cabozantinib and nivolumab for 12 weeks before nephrectomy	Primarily complete response rate Secondarily median size reduction of primary tumor, PFS, response rate, OS, surgical outcomes	Oncologic and perioperative outcome data after neoadjuvant treatment with cabozantinib + nivolumab
PROBE[40]	Recruiting, estimated completion in 2033	mRCC receiving doublet systemic therapy, randomly assigned to nephrectomy *v* no nephrectomy in the absence of progression at 12 weeks	Primarily OS	Assess the role for CN in mRCC with contemporary ST regimens

Abbreviations: ccRCC, clear cell RCC; CN, cytoreductive nephrectomy; ifn, interferon; IMDC, International mRCC Database Consortium; IVC, inferior vena cava; mRCC, metastatic RCC; M0, nonmetastatic; NSS, not statistically significant; OS, overall survival; PFS, progression-free survival; RCC, renal cell carcinoma; SS, statistically significant; ST, systemic therapy.

subgroup of these patients may represent the true oligometastatic state and can potentially be cured with local therapy. For these patients, Although treatment options include AS, metastasectomy, SAbR, or systemic therapy, local therapy with SAbR should be preferred.[4,16,50-53] The second subcategory includes patients with favorable or intermediate IMDC risk. This represents a heterogeneous patient population that will eventually need systemic therapy; however, carefully selected patients can be treated with up-front sequential SAbR that can preserve health-related quality of life and available systemic therapy options. Both retrospective and prospective studies have shown disease control in excess of 15 months for these patients treated with sequential SAbR.[50-53] The benefit of SAbR may be particularly pronounced in delaying the initiation of systemic therapy for patients who have glandular metastasis that is known to be associated with a more indolent RCC biology.[54] The third subcategory involves patients with a high chance of distant micrometastatic disease, including those with IMDC poor risk, grade 4 histology, or sarcomatoid component histology. Despite having oligometastatic disease, this group of patients generally requires up-front systemic therapy. However, there may still be a role for consolidation with SAbR to the bulky therapy-resistant metastatic sites particularly if taking advantage of a potential synergy between SAbR and checkpoint inhibitors as shown in the subgroup analysis of two studies.[43,55] Data are lacking for the application of SAbR for this subgroup of patients with IMDC poor-risk OM-RCC. Nevertheless, these patient scenarios provide a framework in which SAbR may be considered as part of the treatment plan for patients with OM-RCC.

SAbR is a promising treatment option for patients with mRCC with favorable local control and toxicity rates. Reviewing the literature, SAbR's success in treating mRCC is evident, with local control rates ranging from 82% to 98% with minimal acute or late grade 3 or higher toxicities.[50,56-66] Any adverse events that did occur were typically acute and resolved with either no intervention or the use of medication (grade 1 to 2). A recent meta-analysis (SABR ORCA) of pooled data from 28 studies evaluated the use of SAbR for mRCC and reported a 1-year local control rate of 89.1% and a 1-year OS rate of 86.8%, which is comparable with retrospective surgical series.[16,48,67] Overall, the studies support the use of 40 Gy in five fractions, 36 Gy in three fractions, or 25 Gy in a single fraction for optimal local control of treatment-naïve mRCC metastasis. Evidence further supports the need for SAbR dose escalation in the setting of multiple previous systemic therapies that may make RCC metastasis more radioresistant.[68] Although these studies included patients with mRCC, they did not necessarily limit patient inclusion to oligometastatic patients.

Once local control and safety of SAbR for mRCC are established, the next relevant question is whether SAbR can be applied for overall disease control, progression-free survival (PFS), and OS in patients with OM-RCC. Moreover, this strategy can be used sequentially in the setting of additional oligometastatic lesions, thus providing durable disease control. This approach was first described in a retrospective study of 47 patients where 30% of patients received two or more courses of sequential SAbR to sites of metastatic disease, leading to a median PFS of 15.2 months.[50] This strategy was further evaluated in prospective studies, including a multi-institutional registry study that included 143 patients with OM-RCC in the midst of other primary sites and supported the efficacy and safety of this approach with SAbR.[69] A phase II version of this study confirmed that sequential SAbR in patients with systemic therapy–naïve OM-RCC can confer 1 year freedom from systemic therapy in 91.3% of patients.[52,53] This phase II trial also demonstrated a preservation of patient's quality of life using pre- and post-treatment patient-reported quality-of-life questionnaires. In another prospective feasibility study by Tang et al that allowed pretreatment with systemic therapy, SAbR alone showed a median PFS of 22.7 months and a 1-year PFS of 64% with acceptable toxicity.[51] A phase III noninferiority trial (EA 8211, SOAR) randomly assigning patients with OM-RCC to be treated with sequential SAbR followed by systemic therapy at progression versus up-front systemic therapy is currently being designed and expected to open for enrollment in 2023.

The application of SAbR for cytoreduction in the setting of mRCC and OM-RCC has limited prospective data.[70] Given the demonstrated promising local control and safety of SAbR for primary RCC, it would be reasonable to consider SAbR for the treatment of primary RCC for patients with oligometastatic RCC.[71,72]

In summary, SAbR, particularly sequential SAbR, appears to be a promising strategy for the overall disease control that is supported by retrospective and early-phase prospective trials for a subgroup of patients with OM-RCC that includes (1) metachronous metastasis when the metastasis appeared >1 year after addressing the primary, (2) patients with indolent biology, and (3) IMDC favorable- and intermediate-risk patients. Prospective randomized evidence is currently lacking for the application of SAbR for any of the described subgroups of patients with patients OM-RCC.

Systemic Therapy

Patients with oligometastatic disease may be offered systemic therapy in the perioperative setting, frontline metastatic setting, and oligoprogressive setting. The role of systemic therapy in these clinical scenarios is detailed below.

Perioperative systemic therapy. Up until 2021, adjuvant systemic therapy after curative metastasectomy showed no clear benefit in advanced clear cell RCC (ccRCC). In the cytokine therapy era, the efficacy of one course of high-dose bolus interleukin-2 (IL-2) versus observation was tested postoperatively in a high-risk population (T3b-4 or N1-3, or M1 resected to no evidence of disease [NED]). Sixty-nine patients were enrolled in the study and randomly assigned within 12 weeks of surgery, of which 25 were M1 NED. Despite complete accrual, an interim analysis led to early termination of the trial after it failed to meet its primary end point of 30% improvement in 2-year disease-free survival (DFS).[73] Similarly, a pilot study using subcutaneous IL-2 was conducted in the same high-risk patient population with the goal of testing toxicity and tolerability. The study showed that subcutaneous administration of IL-2 improved tolerability, but there was no significant difference in DFS or 3-year survival between the treatment arms.[74] Retrospective data evaluating the role of IL-2 followed by metastasectomy also failed to demonstrate a survival benefit.[75]

After case reports of complete remission of mRCC achieved with targeted kinase inhibition followed by metastasectomy, perioperative strategies using targeted kinase inhibition in combination with metastasectomy were explored.[76] The randomized, phase III ECOG-ACRIN Cancer Research Group (ECOG-ACRIN) E2810 study of pazopanib versus placebo in patients with mRCC after curative metastasectomy demonstrated no difference in DFS between the treatment and placebo group (hazard ratio [HR], 0.85; 95% CI, 0.55 to 1.31; $P = .47$ in favor of pazopanib). In addition, there was a trend toward worse OS for patients who received pazopanib.[77] The phase II RESORT study, which randomly assigned 132 patients with mRCC to sorafenib versus observation after metastasectomy, also showed no difference in relapse-free survival (RFS) between the treatment and observation group (sorafenib: 27 months; 95% CI, 11 to not applicable [NA] *v* observation: 37 months; 95% CI, 20 to NA; $P = .404$).[78]

Over the past decade, the treatment landscape of mRCC has changed dramatically, with immunotherapy-based therapy becoming the standard of care. Concordant with this, the benefit of immunotherapy has been investigated in the adjuvant setting in several clinical trials including IMmotion101, PROSPER, and KEYNOTE-564.[44,79,80] Although most of the patients enrolled to these studies had high-risk nonmetastatic (M0) disease, the aforementioned trials allowed for an M1 population that underwent metastasectomy with NED at study entry. In the phase III IMmotion010 study, the M1 NED category included patients with synchronous metastases to the adrenal gland or lung or metachronous metastatic disease to the lung, lymph node, or soft tissue with recurrence more than 12 months after initial nephrectomy who underwent nephrectomy with metastasectomy within 12 weeks of random assignment. Seven hundred seventy-eight patients were randomly assigned to receive 16 cycles or 1 year of atezolizumab versus placebo, and the median DFS was 57.2 versus 49.5 months, respectively (HR, 0.93; 95% CI, 0.75 to 1.15; $P = .50$), demonstrating no improved clinical outcomes with adjuvant therapy.[79] Similarly, in the randomized phase III PROSPER RCC study evaluating RFS in high-risk patients receiving perioperative nivolumab compared with observation after nephrectomy, RFS was similar between treatment groups (HR, 0.97; 95% CI, 0.74 to 1.28; $P = .43$).[80,81] Patients with $\leq$3 metastases were included if they were planned to undergo local treatment of metastases (metastasectomy, thermal ablation, or stereotactic radiation) within 12 weeks of nephrectomy. Of note, patients with any liver, bone, or brain metastases were excluded because of poor prognosis.

KEYNOTE-564 is currently the only phase III randomized controlled trial demonstrating a benefit of adjuvant immunotherapy in patients who received nephrectomy with metastasectomy.[44] In this double-blind study, 496 patients with ccRCC at high risk for recurrence postnephrectomy were randomly assigned to adjuvant pembrolizumab versus placebo for up to 17 cycles or 1 year. Patients with synchronous M1 disease with metastases completely resected at the time of nephrectomy or within 1 year after nephrectomy were included, except for patients with bone or brain metastases. Pembrolizumab was shown to be associated with significantly longer DFS versus placebo (DFS at 24 months: 77.3% *v* 68.1%; HR, 0.68; 95% CI, 0.53 to 0.87; $P = .002$) in the study population. The subgroup analysis showed that the M1 NED cohort from the trial population derived the greatest benefit from adjuvant pembrolizumab (M1 NED: HR, 0.29; 95% CI, 0.12 to 0.69; M0: HR, 0.74; 95% CI, 0.57 to 0.96). Although the OS data are immature, these results suggest that patients who undergo nephrectomy with metastasectomy and complete resection of disease should be considered for adjuvant pembrolizumab.[44] The RAMPART Trial, a phase III multiarm multistage platform trial evaluating the benefit of perioperative durvalumab and tremelimumab in patients with advanced-stage RCC at intermediate or high risk for relapse, is ongoing (ClinicalTrials.gov identifier: NCT03288532).

Frontline systemic therapy. Frontline systemic therapy may be offered to patients with OM-RCC who are not candidates for AS and have disease that is not amenable to local intervention. This includes patients who are unable to receive local therapy to primary and oligometastatic sites. Patients with mRCC who are likely to benefit from local therapy to primary and oligometastatic sites include IMDC favorable-risk patients with low-volume, asynchronous metastases (particularly limited to the lung), with a prolonged disease-free interval of $\geq$12 months.[15,29,31,82,83] Consequently, up-front systemic therapy is selected for patients with unfavorable IMDC, faster-growing, multiple synchronous metastases, especially when local therapy to all sites is not feasible. These patients are

essentially left with residual, incurable disease, which requires systemic intervention. In this scenario, treatment regimens for oligometastatic and diffuse mRCC are identical.

Preferred first-line systemic therapy for mRCC is dependent on histology, for which the majority encompass ccRCC (Fig 1). For patients with ccRCC across all IMDC risk categories, treatment consists of immune checkpoint blockade (ICB) + vascular endothelial growth factor receptor-tyrosine kinase inhibition (VEGFR-TKI) such as axitinib + pembrolizumab, cabozantinib + nivolumab, and/or lenvatinib + pembrolizumab, on the basis of the phase 3 trials KEYNOTE-426, CheckMate 9ER, and CLEAR, respectively.[19,21,22] For patients with IMDC poor- or intermediate-risk metastatic ccRCC, preferred first-line systemic treatment also includes dual ICB (ipilimumab + nivolumab) or single-agent VEGFR-TKI (cabozantinib), on the basis of the phase 3 CheckMate-214 trial and the phase 2 CABOSUN trial, respectively.[20,84,85] For patients with metastatic non-ccRCC, preferred first-line systemic treatment is nuanced on the basis of individual histology.

Despite several available first-line systemic therapy regimens, 10% of patients treated with ICB-TKI combinations and 15%-25% of patients treated with first-line TKI or combination ICB experience progression.[20,22,86] For patients who develop diffuse recurrence that is no longer considered oligometastatic (>5 metastases), later-line systemic therapies are offered. However, the treatment of oligoprogressive disease is more complex and continues to consider a multimodal approach of local and systemic therapies, as detailed below.

Systemic therapy for oligoprogressive mRCC. As previously defined, oligoprogression represents acquired resistance to systemic therapy in a limited number of sites, whereas the remaining metastasis remains controlled or continues to respond.[87,88] Choosing a particular therapeutic strategy considers several factors including previous treatments or lines of therapy, sites of disease, and patient characteristics.

An important consideration for patients with oligoprogressive disease is whether to continue the current systemic regimen or switch to another later-line treatment. There is some evidence supporting the maintenance of current systemic therapy in progressive disease. In a subgroup analysis of a randomized, phase 2 study of nivolumab in patients previously treated with anti-angiogenic therapy, 36 patients were treated beyond progression and 25 (69%) experienced reduction or stabilization in tumor size.[89] Similarly, in subgroup analysis of the phase 3 CheckMate-025 study of nivolumab in previously treated patients, 153 patients were treated beyond progression, among whom 13% (20 of 153) had ≥30% tumor burden reduction.[90]

Management of oligoprogressive disease in the setting of ongoing systemic therapy has also been investigated in the

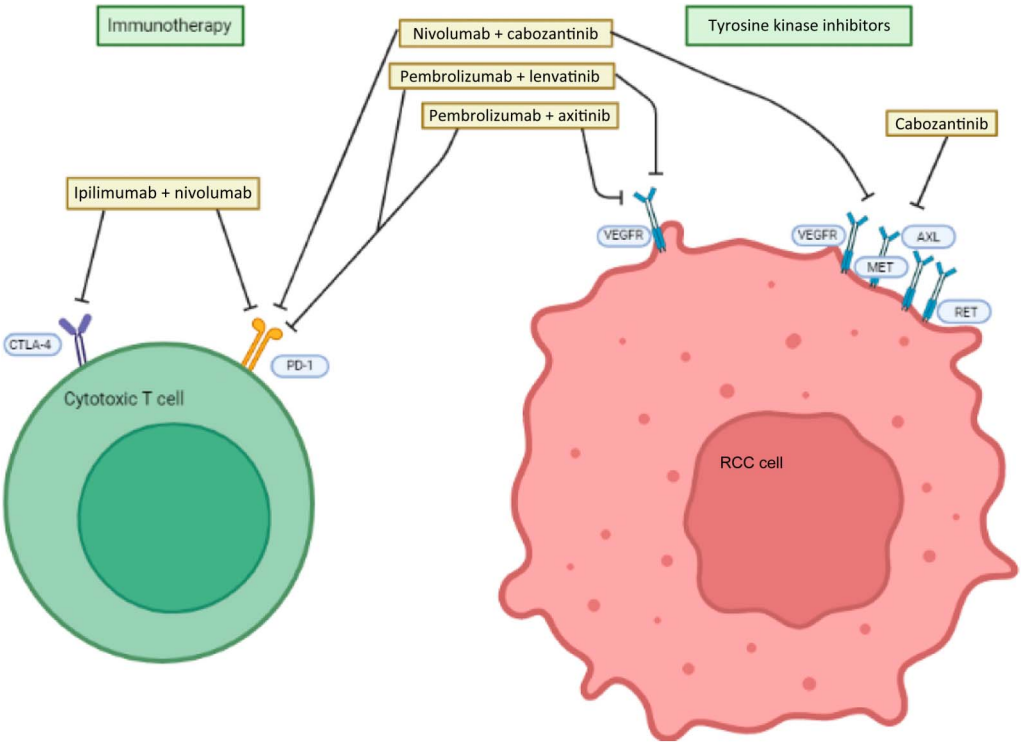

FIG 1. Current frontline systemic therapies for mRCC. AXL, AXL receptor tyrosine kinase; MET, mesenchymal-epithelial transition factor; mRCC, metastatic RCC; RCC, renal cell carcinoma; RET, RET proto-oncogene; VEGFR, vascular endothelial growth factor receptor.

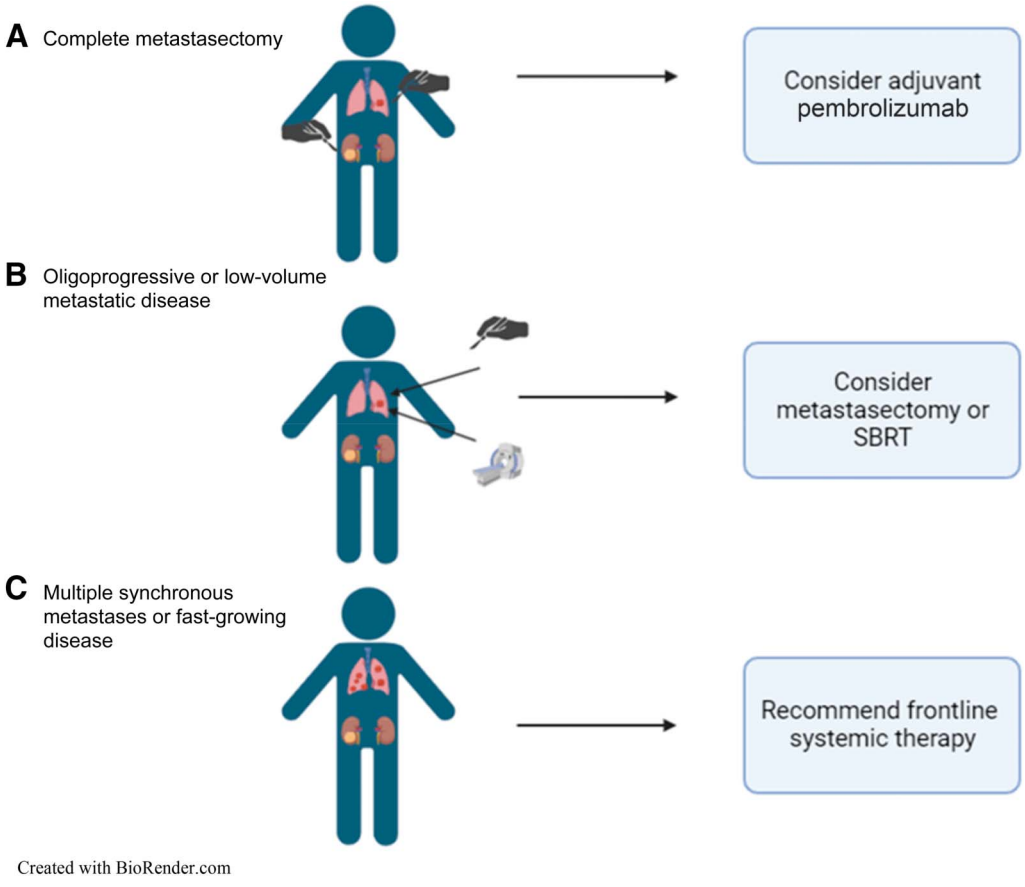

FIG 2. Multimodal treatment strategies for oligometastatic or oligoprogressive RCC. RCC, renal cell carcinoma; SBRT, stereotactic body radiotherapy.

setting of adding local intervention. The rationale is that resistant disease may be amenable to local treatment, whereas other sites remain sensitive to the same systemic therapy.[43,91,92] There are retrospective and prospective data supporting the use of SAbR while maintaining treatment with systemic therapy.[43,55,93-97] Interestingly, when the systemic therapy is checkpoint inhibitor, there appears to be a synergistic effect on the use of SAbR for oligoprogressive RCC.[43,55] We eagerly await the results of the prospective trials of SAbR for oligoprogressive RCC in the setting of checkpoint inhibitors (ClinicalTrials.gov identifier: NCT04974671, NCT04299646), which will provide further insight into whether the addition of SAbR in oligoprogressive disease will support continuation of newer systemic therapies, such as immunotherapy. Further prospective investigation is needed to elucidate the optimal management, especially in the changing treatment landscape of mRCC.

CONCLUSION

OM-RCC represents a heterogenous disease group that requires an individualized treatment approach. Treatment strategies include AS, local interventions (surgery or SAbR), and systemic therapy. There is no definitive treatment algorithm for these patients, and management will often involve a multimodal strategy (Fig 2).

Patient selection is key, and the available data show that patients with oligometastatic disease with IMDC favorable- or intermediate-risk classification, good performance status, metachronous metastases, and no evidence of hepatic, brain, or bone metastases are most likely to benefit from local therapy to the primary tumor and metastatic sites. After complete local control of the disease, patients with clear cell histology are recommended for adjuvant immunotherapy. For patients who are unable to proceed with upfront local therapy, frontline systemic therapy for mRCC is recommended.

In patients with indolent or oligoprogressive mRCC, treatment also involves a multimodal approach. On the basis of the available data, most clinicians proceed with locoregional intervention such as SAbR, while continuing current systemic therapy, allowing for the delay of systemic treatment escalation.

Future management of OM-RCC is contingent on a greater understanding of the tumor biology driving this disease. The

development of prognostic and predictive biomarkers may change the roles for surgery, radiation, and systemic therapy. Furthermore, management of this disease will continue to shift alongside the rapidly changing landscape of systemic therapy. Regardless, treatment of oligometastatic disease will continue to require a multidisciplinary team and ongoing prospective studies are investigating the optimal approach to this disease.

Triplet Strategies in Metastatic Clear Cell Renal Cell Carcinoma: A Worthy Option in the First-Line Setting?

Catherine C. Fahey, MD, PhD[1,2]; Jeffrey W. Shevach, MD[3]; Ronan Flippot, MD[4]; Laurence Albiges, MD, PhD[4]; Naomi B. Haas, MD[3]; and Kathryn E. Beckermann, MD, PhD[1,2]

Overview

Significant strides have been made in the frontline treatment of patients with advanced clear cell renal cell carcinoma (ccRCC). There are multiple standard-of-care doublet regimens consisting of either the combined dual immune checkpoint inhibitors, ipilimumab and nivolumab, or combinations of a vascular endothelial growth factor receptor tyrosine kinase inhibitor and an immune checkpoint inhibitor. Currently, there is an emergence of clinical trials examining triplet combinations. In COSMIC-313, a randomized phase III trial for patients with untreated advanced ccRCC, the triplet combination of ipilimumab, nivolumab, and cabozantinib was compared with a contemporary control arm of ipilimumab and nivolumab. While patients receiving the triplet regimen demonstrated improved progression-free survival, these patients also experienced greater toxicity and the overall survival data are still maturing. In this article, we discuss the role of doublet therapy as standard of care, the current data available for the promise of triplet therapy, the rationale to continue pursuing trials with triplet combinations, and factors for clinicians and patients to consider when choosing among frontline treatments. We present ongoing trials with an adaptive design that may serve as alternative methods for escalating from doublet to triplet regimens in the frontline setting and explore clinical factors and emerging predictive biomarkers (both baseline and dynamic) that may guide future trial design and frontline treatment for patients with advanced ccRCC.

INTRODUCTION

The advent of immune oncology (IO) and checkpoint inhibitors has dramatically changed the practice of oncology and outcomes for our patients. Clear cell renal cell carcinoma (ccRCC) is a poster child for the success of IO and shows how immunotherapy can be combined with vascular endothelial growth factor receptor tyrosine kinases (VEGFR-TKI) to improve outcomes. With four doublet combinations showing overall survival (OS) advantages, the clinical questions are now how to improve on this new standard of care or make the right decision for an individual patient. In this chapter, we will present current evidence supporting the use of doublet therapy (VEGFR-TKI/IO or dual IO/IO), the rationale for and evidence supporting triplet therapy (VEGFR-TKI plus dual IO/IO), and discuss strategies to select between these therapy plans.

DOUBLET THERAPY AS AN ESTABLISHED STANDARD OF CARE

The combinations of VEGFR-TKI plus IO or dual IO/IO with progressive disease (PD)1 and CTLA4 blockade have become the preferred approach in patients with advanced ccRCC International Metastatic Renal Cell Carcinoma Database Consortium (IMDC) intermediate or poor risk groups.[1,2] The IMDC risk groups were initially developed during the VEGFR-TKI monotherapy era; however, they continue to be used to risk stratify patients in combination therapy trials.[1] The move from single agent to combination therapies is largely based on the results of the randomized phase III trials listed in Table 1. All five trials demonstrated statistically significant improvements in progression-free survival (PFS) of the following doublet combinations versus sunitinib: ipilimumab plus nivolumab, axitinib plus pembrolizumab, axitinib plus avelumab, cabozantinib plus nivolumab, and lenvatinib plus pembrolizumab (*v* lenvatinib plus everolimus).[3-7] With the exception of JAVELIN Renal 101 (axitinib plus avelumab *v* sunitinib), each combination has shown an improvement in OS that has proven durable with subsequent follow-ups.[8-10]

The debate continues as to whether dual IO/IO or VEGFR-TKI plus IO combinations are more relevant approaches in subsets of patients. Specific patterns of response observed with dual IO/IO or VEGFR-TKI plus IO may help clinical decision making. The CheckMate 214 trial of nivolumab plus ipilimumab had high rates of complete response (CR) versus sunitinib (9% *v* 1%), and also impressively, more than 80% of patients who

PRACTICAL APPLICATIONS

- Combination therapy with dual immune checkpoint inhibitors or with a vascular endothelial growth factor receptor tyrosine kinase inhibitor and immune checkpoint inhibitor is the standard of care in the frontline setting for patients with advanced clear cell renal cell carcinoma (ccRCC).
- A triplet regimen consisting of ipilimumab, nivolumab, and cabozantinib demonstrated improved progression-free survival when compared with a doublet of ipilimumab and nivolumab at the cost of excess toxicity with unknown overall survival.
- Strategies to personalize therapy for ccRCC in the frontline setting, including response-adaptive treatment strategies and the use of biomarkers such as gene expression analysis to guide initial therapy, are under study.

achieved a CR did not relapse after 3 years of median follow-up, even in the context of treatment discontinuation.[11] On the other hand, combinations involving VEGFR-TKI with IO allow for swift activity provided by the targeted therapy with more frequent disease control (89%-95% *v* 81% with ipilimumab/nivolumab) and a numerically higher objective response rate (56%-71% *v* 42%). Additional disease features may also affect outcomes on treatment. In the CheckMate 214 trial comparing IO/IO with sunitinib, a subgroup analysis of patients with sarcomatoid features showed a higher overall response rate (ORR) of 61% versus 42% and CR of 19% versus 9% for the entire population.[12] In this trial, an exploratory analysis of favorable risk patients showed a higher ORR for patients in the sunitinib arm at 52%, compared with 29% in the IO/IO arm. As an additional consideration, the VEGF-TKI cabozantinib has shown compelling data in patients with brain metastases.[13-15] In a retrospective study of 88 patients with brain metastases who were treated with cabozantinib, the intracranial response rate among patients who did not receive brain-directed therapy was 55% and the rate among patients who received concomitant brain-directed therapy was 47%.[14,16] Subset analysis of the CLEAR trial while not statistically powered to study these subgroups suggested that despite having difficult-to-treat bone and liver metastasis, these patients still experienced improved trends in PFS hazard ratio (HR) 0.33 and 0.43, respectively, compared with sunitinib. Thus, expert clinical decision takes into consideration IMDC criteria, patient presentation, and requirement for quick response, as well as the aforementioned disease characteristics. There are no approved biomarkers to help with treatment selection in renal cell carcinoma (RCC).

TRIPLET THERAPY AS A NEW FRONTIER

As we continue to make strides in our management of advanced ccRCC, the question of whether less is more remains uncertain. We have several examples across oncology where additional therapies and associated toxicities were accepted due to improved outcomes for patients.[17-20] Within genitourinary oncology, the prostate cancer PEACE-1[19] and ARASENS[20] trials examined both triplet regimens comparing androgen deprivation therapy (ADT) and docetaxel alone versus ADT/docetaxel with abiraterone (PEACE-1) or darolutamide (ARASENS). Both trials had positive outcomes, with improved OS in PEACE-1 and decreased risk of death in ARASENS.

The success of such combination strategies relies on targeting distinct mechanisms of tumor growth and limiting

TABLE 1. Phase 3 Trials of Doublet Therapy

Identifier	Arms of Therapy	Primary Outcome Measure	No. of Patients	OS	PFS	ORR
CheckMate 214[3] NCT02231749	Ipilimumab + nivolumab *v* sunitinib	Coprimary OS, PFS, and ORR in intermediate and poor risk IMDC patients	1,096	HR, 0.63; $P < .001$	HR, 0.82; $P = .03$	42% *v* 27%
KEYNOTE 426[4] NCT02853331	Axitinib + pembrolizumab *v* sunitinib	OS and PFS	861	HR, 0.53; $P < .0001$	HR, 0.69; $P < .001$	59% *v* 36%
Javelin Renal 101[5] NCT02684006	Axitinib + avelumab *v* sunitinib	OS and PFS in patients with PD-L1+ tumors	886	HR, 0.83 (immature)	HR, 0.61; $P < .001$	55% *v* 26%
CheckMate 9ER[6] NCT03141177	Cabozantinib + nivolumab *v* sunitinib	PFS	651	HR, 0.60; $P = .001$	HR, 0.51; $P < .001$	56% *v* 27%
CLEAR[7] NCT02811861	Lenvatinib + pembrolizumab *v* lenvatinib + everolimus *v* sunitinib	PFS	1,069	HR, 0.66; $P = .005$ for lenvatinib + pembrolizumab *v* sunitinib	HR, 0.65; $P < .001$ for lenvatinib + pembrolizumab *v* sunitinib	71% *v* 36%

Abbreviations: HR, hazard ratio; IMDC, International Metastatic Renal Cell Carcinoma Database Consortium; ORR, overall response rate; OS, overall survival; PFS, progression-free survival.

primary resistance to therapy. In patients with ccRCC, the VEGF pathway is targeted due to the near ubiquitous loss of von Hippel-Lindau (VHL) function[21] and remains an important biologic mechanism of ccRCC growth. Combining VEGFR-TKI inhibition to dual IO/IO immune checkpoint blockade is a logical step to attempt to increase cure rates and decrease the 20% primary progressive disease rate seen with dual IO/IO therapy alone.[3] As there is no currently validated biomarker to individualize treatment decisions, the field has embarked upon triplet regimens.[22]

A phase I trial conducted across genitourinary malignancies studied different escalating regimens of cabozantinib (40 or 60 mg daily), nivolumab (1 or 3 mg/kg every 3 weeks), and ipilimumab (1 or 3 mg/kg every 3 weeks).[23] The randomized phase 2 dose was determined to be cabozantinib 40 mg oral daily, nivolumab 3 mg/kg and ipilimumab 1 mg/kg every 3 weeks. Across diverse tumor biology, the ORR was 30.6% and grade 3/4 treatment-related adverse events occurred in 87% of patients treated with the triplet combination. The triplet regimen also showed higher rates of immune-related adverse events requiring treatment with corticosteroids at 29% of patients treated with the randomized phase 2 dose compared with 17% of patients treated with the equivalent dosing doublet regimen.

Additional RCC-specific triplet data next came from the CheckMate 9ER trial. Arm 3 received nivolumab 3 mg/kg and ipilimumab 1 mg/kg every 3 weeks with cabozantinib 40 mg daily for four cycles, followed by nivolumab 240 mg every 2 weeks with cabozantinib 40 mg daily. Random assignment was stratified by IMDC prognostic risk score, PD-L1 expression, and geographic region. Eligible patients were those with locally advanced or metastatic RCC with a clear cell component, no previous systemic therapy, Karnofsky performance status score $\geq$70, and RECIST measurable disease. All IMDC prognostic risk categories were included. The primary end point was PFS. Shortly after the initiation of this trial in 2017, the CheckMate 214 trial showed improved OS for dual IO/IO combination with nivolumab and ipilimumab compared with sunitinib.[3] Owing to this new evidence for an immediate role for the use of ipilimumab with nivolumab in the management of advanced ccRCC as standard of care, the triplet arm of CheckMate 9ER was discontinued via protocol amendment in late 2017.[24] Given early discontinuation of the study arm, the results were not compared with the other arms of CheckMate 9ER.

An exploratory analysis of the 50 patients randomly assigned to the triplet arm was reported in 2022. In this cohort, 11 patients had IMDC favorable risk, 31 had intermediate risk, and eight had poor risk. With a median follow-up of 39.1 months, ORR was 44% and CR rate was 8%. The median PFS (mPFS) by blinded independent central review was 9.9 months (5.7-16.8), and median overall survival 37.0 months (31.8-not reached). Forty-eight (96%) patients had treatment-related adverse events. The most common adverse events were diarrhea, increased alanine aminotransferase, increased aspartate aminotransferase, and hand-foot syndrome. In total, 84% of patients had a grade 3 or 4 event, and 46% of patients had treatment discontinuation of at least one study drug due to adverse events. Treatment was complicated by toxicity requiring dose delays, with 39 patients delaying at least one nivolumab dose, 19 delaying at least one ipilimumab dose, 43 delaying at least one cabozantinib dose, and 33 of 50 patients requiring dose reduction of cabozantinib. Twenty-four patients discontinued treatment for disease progression, and 11 patients discontinued treatment because of drug toxicity. Overall, these results show that there is clinical efficacy of a triplet regimen, but this is complicated by high rates of toxicity.

The COSMIC-313 study is the first phase 3 trial evaluating triplet therapy with cabozantinib, nivolumab, and ipilimumab compared with a contemporary standard-of-care ipilimumab and nivolumab (ClinicalTrials.gov identifier: NCT03937219).[25] Patients received triple therapy with cabozantinib 40 mg daily, nivolumab 3 mg/kg, and ipilimumab 1 mg/kg every 3 weeks for four cycles, followed by cabozantinib 40 mg daily with nivolumab 480 mg every 4 weeks versus standard dosing of ipilimumab 1 mg/kg and nivolumab 3 mg/kg dosing and nivolumab maintenance 480 mg every 4 weeks with placebo. Random assignment was stratified by region and IMDC risk category. Patients were previously untreated advanced ccRCC, with intermediate or poor risk IMDC. The primary end point was PFS. In the triplet therapy arm, the mPFS was not reached compared with 11.3 months in the dual IO/IO group (HR, 0.73; 95% CI, 0.57 to 0.94). Surprisingly, the mPFS in patients with poor risk disease was lower with triplet therapy at 9.5 months versus 11.2 months in the dual IO/IO group. Triplet therapy had a higher rate of disease control at 86% versus 72% in the dual IO/IO arm, including the ORR of 43% versus 36%. Both arms had low rates of CR at 3%, possibly because of the higher number of patients without previous nephrectomy. OS results are pending ongoing follow-up.

As in the CheckMate 9ER triplet arm, there was a high rate of adverse events with 90% of patients in the COSMIC-313 triplet arm requiring a dose hold of at least one therapy because of adverse events, compared with 70% in the dual IO/IO arm. In the triplet arm, 12% of patients had to discontinue all treatment components because of adverse event versus 5% in the dual IO/IO arm. Fewer patients in the triplet arm were able to complete four doses of ipilimumab (58% *v* 73%). In the triplet arm, 54% of patients had to dose reduce cabozantinib versus 20% of patients reducing placebo dose. As in the CheckMate 214 study,

transaminase elevations were the most commonly observed adverse events in the triplet arm. A higher percentage of patients (58%) in the triplet required treatment with corticosteroids, compared with 35% seen in the dual IO/IO arm.

Maturation of survival data from COSMIC-313 will aid in our ability to understand the broader implication for the use of cabozantinib, ipilimumab, and nivolumab in frontline treatment of advanced ccRCC given the above challenges with toxicity and dosing. Limiting the ability to make cross-comparison studies, it should be noted that COSMIC-313 had higher rates of IMDC poor risk patients (25%) compared with any standard-of-care IO/IO or IO/VEGFR-TKI doublet study (9%-19%), had more patients with primary kidney tumors in place, and did not include any favorable risk patients.

Further studies are needed to find the optimal treatments for patients with advanced ccRCC including the role of triplet therapy. Many ongoing studies will further address this need, evaluating novel agents such as hypoxia-inducible factor (HIF) or AXL inhibitors (Table 2). The rationale of many of these trials is similar to the objective stated above: adding therapies in combination to target a different biologic susceptibility of the tumor as a way to increase cure, decrease resistance, and not worsen toxicity. Several of these trials are taking a similar triplet approach as COSMIC-313 but varying the specific checkpoint inhibitor or VEGFR-TKI. In study 516-008, ipilimumab and nivolumab are combined with sitravatinib a to provide unique targeting and safety profile (ClinicalTrials.gov identifier: NCT04518046). One arm of MK6482-012 combines pembrolizumab (PD1), quavonlimab (CTLA4), and lenvatinib (VEGF-TKI; ClinicalTrials.gov identifier: NCT04736706) using different drugs to combine for IO/IO/VEGFR-TKI triplet. This trial is also looking at pembrolizumab, lenvatinib, and oral HIF inhibition with belzutifan. HIF inhibition is an exciting avenue in ccRCC, as the aforementioned ubiquitous loss of VHL results in upregulation of HIF and downstream cellular proliferation and angiogenesis. The trial adding belzutifan will answer if targeting HIF directly may enhance efficacy. New methods of dual targeting PD1 and CTLA4 with a monovalent bispecific antibody using MEDI5752 are being tested in combination with increasing doses of axitinib or lenvatinib (ClinicalTrials.gov identifier: NCT04522323).

Completely novel mechanisms of action to fight kidney cancer are also being conducted in frontline triplets. In a single-center study of 30 patients, CBM588, a bifidogenic live bacterial product suggested to enhance immune responsiveness, was tested in combination with dual IO/IO ipilimumab and nivolumab with a promising safety profile and an early suggestion of efficacy with ORR of the triplet at 58% versus 20% in the dual IO/IO (ClinicalTrials.gov identifier: NCT03829111).[26] Batiraxcept is a novel decoy protein that binds GAS6 and inhibits activation of AXL being studied in combination with cabozantinib and nivolumab to increase efficacy, decrease resistance mechanisms that may result from upregulation of AXL, and aim for a tolerable and sustainable safety profile (ClinicalTrials.gov identifier: NCT04300140). A number of patients with RCC have dysregulation of the cell cycle, and the APART trial is testing

TABLE 2. Ongoing Clinical Trials to Evaluate Triplet Therapy in the Management of Advanced RCC

Identifier	Arms of Therapy	Primary Outcome Measure	Phase	Status	Estimated Completion Date
MK6482-012 NCT04736706	Pembrolizumab + belzutifan + lenvatinib Pembrolizumab/quavonlimab + lenvatinib Pembrolizumab + lenvatinib	PFS	3	Recruiting	October 2026
APART NCT05176288	Axitinib + avelumab + palbociclib	ORR	2	Not yet recruiting	May 2024
INC NCT05501054	Ciforadenant + ipilimumab + nivolumab	Safety/tolerability Depth of response	1b/2	Recruiting	November 2026
NCT04522323	MEDI5752 + axitinib or lenvatinib	Adverse events Dose limiting toxicity	1b	Recruiting	March 2025
NCT04300140	Batiraxcept + cabozantinib + nivolumab	Adverse events Combination dosing Antitumor activity	1b	Active, not recruiting	December 2024

NCT03829111	CBM588 + ipilimumab + nivolumab	Effect of CBM588 on gut microbiome	1	Active, not recruiting	June 2023

Abbreviations: ORR, overall response rate; PFS, progression-free survival; RCC, renal cell carcinoma.

if the use of palbociclib, which blocks cyclin-dependent kinases 4 and 6 in combination with axitinib (VEGFR-TKI) and avelumab (PD-L1), will enhance efficacy while not having overlapping toxicities (ClinicalTrials.gov identifier: NCT05176288). The INC trial (ClinicalTrials.gov identifier: NCT05501054) is targeting the metabolic vulnerabilities of kidney cancer by combining ipilimumab and nivolumab with ciforadenant, an oral adenosine A2A receptor inhibitor. Adenosine is elevated in the RCC tumor microenvironment, and its inhibition in preclinical models has shown tumor regression and activation of immune effector T and NK cells.[27]

CHOOSING BETWEEN DOUBLET AND TRIPLET REGIMENS

While COSMIC-313 met its primary end point of improved PFS, it remains to be seen whether the addition of up-front cabozantinib to ipilimumab and nivolumab translates to improved OS. It is imperative to consider factors beyond PFS when choosing between therapies for patients with advanced ccRCC. These factors include toxicities of treatment, health-related quality of life (HRQoL), secondary measures of clinical efficacy (including response rates and primary progressive disease rates), and clinicopathologic factors or biomarkers that might enrich response to treatment.

The expected and potential toxicities of IO and VEGFR-TKI are well known and described, and may inform frontline therapy decisions. Toxicities of IO include, but are not limited to, rash, arthralgias and arthritis, colitis, fatigue, endocrinopathies, hepatotoxicity, and pneumonitis.[1] These side effects are more common and severe in patients receiving ipilimumab and nivolumab versus nivolumab alone.[28] There is overlap in toxicities between IO and VEGFR-TKI, the latter of which has adverse effects such as mucositis, diarrhea, rash, palmar-plantar erythrodysesthesia, fatigue, and hepatotoxicity and hypertension.[29] Choosing the appropriate treatment regimen depends on patients and their comorbid conditions. For instance, those with a history of autoimmunity—but still deemed candidates to receive IO—may be better suited for a regimen without ipilimumab, while those with uncontrolled hypertension or heart failure may be better served avoiding a VEGFR-TKI containing regimen. Frailer patients or those with borderline performance status are unlikely to tolerate a triplet regimen. Patients enrolled in the triplet arm of COSMIC-313, all with Karnofsky performance status of 70 or higher, had difficulty tolerating the triplet regimen, as evidenced by the relatively high frequency of dose reductions and treatment delays.[25]

Given the significant toxicity caused by the addition of cabozantinib to ipilimumab and nivolumab in COSMIC-313, justification to use this regimen requires clinically impactful benefits. The addition of cabozantinib to ipilimumab and nivolumab improved PFS and decreased the proportion of patients with primary progressive disease (8% *v* 20%) when compared with ipilimumab and nivolumab alone. However, ORR was not much higher in the triplet arm (43%) than in the dual IO/IO (36%) arm, and CR rates were identical (3% in each; Table 3). One possible reason for the lack of deep responses theoretically expected in the triplet arm is that the excess toxicity seen in the triplet arm prevented adequate treatment exposure, thereby limiting the benefit in the overall population.[30] The overlap in toxicities, especially hepatic toxicity, can make it challenging to determine which agent to dose modify and can force the interruption of both the VEGFR-TKI and the dual IO/IO.

In addition to picking frontline treatments on the basis of efficacy and toxicity, it may also be helpful to make use of clinical predictive markers. This is exemplified by the case of COSMIC-313, in which one unexpected predictive clinical parameter was the IMDC risk criteria.[25] Much of the PFS benefit derived in the intention-to-treat population was reserved for the intermediate risk group (HR, 0.63; 95% CI, 0.47 to 0.85), whereas the addition of cabozantinib did not meaningfully improve PFS in the poor risk group (HR, 1.04; 95% CI, 0.65 to 1.69). Similarly, triplet therapy conferred a 10% improvement in ORR in the intermediate risk group (45% *v* 35%), but the results in the poor risk group were similar between treatment arms (37% *v* 38%). As mechanisms underlying these allegedly distinct outcomes are yet to be explored, bolstering the development of robust predictive biomarkers is a key need.

CLINICAL BIOMARKERS: DEPTH OF RESPONSE AND QUALITY OF LIFE

Clinical parameters may predict long-term benefit from combination strategies and inform adaptative treatment strategies. Among those, depth of response (DepOR) is a clinical marker predictive of long-term outcomes, which can be defined as the percentage of tumor shrinkage and is correlated with clinical outcome in a number of solid tumors.[31-33] In an exploratory analysis of DepOR in the CheckMate 214 trial, the median time to a DepOR of >50% was 4 months for the dual IO/IO arm, compared with 5.6 months in the sunitinib arm.[34] Additionally, 42% of dual IO/IO-treated patients obtained a DepOR of >50%, compared with 26% of sunitinib-treated patients. Powles et al evaluated DepOR in a post hoc analysis of KEYNOTE-426—which randomly assigned patients to receive axitinib plus pembrolizumab versus sunitinib for metastatic ccRCC—and found that increasing DepOR, particularly in the axitinib and pembrolizumab arm, was associated with increased OS.[35] Similarly, in an exploratory 6-month landmark analysis of CheckMate 9ER, Suarez et al analyzed the relationship of DepOR to clinical outcomes of PFS and OS in patients with treatment-naïve metastatic ccRCC treated with either cabozantinib and nivolumab or sunitinib.[36] The DepOR was based on percent tumor reduction measured

TABLE 3. Comparison of Response and Toxicities Between Doublet and Triplet Trials

	Phase 1 Safety Trial[23]		CheckMate 9ER[24,30]			COSMIC-313[25]		CheckMate 214[3,9]
	Nivolumab/ Cabozantinib	Ipilimumab/ Nivolumab/ Cabozantinib	Sunitinib	Nivolumab/ Cabozantinib	Ipilimumab/ Nivolumab/ Cabozantinib	Ipilimumab/ Nivolumab	Ipilimumab/ Nivolumab/ Cabozantinib	Ipilimumab/ Nivolumab
Phase of trial	1		3			3		3

NOTE. Bolded text highlights the triplet arm for each study and associated results.
Abbreviations: CR, complete response; ORR, overall response rate; OS, overall survival; PD, progressive disease; PFS, progression-free survival.

using RECIST and broken into six response levels. Deeper responses were associated with improved mPFS in the nivolumab with cabozantinib arm and in both arms suggested better OS outcomes. There was no clear relationship between DepOR and baseline IMDC risk groups, nor with occurrence of treatment-related adverse events. These analyses by themselves are not practice changing due to their post hoc nature and lack of prospective validation. Nonetheless, these data suggest that DepOR may itself be a mediator of improved OS in ccRCC. If that is the case, an adaptive trial design aimed at improving DepOR may represent an ideal strategy to address the question of whether doublet or triplet therapy is advantageous to select groups of patients.

An important question regarding the development of adaptative strategies relies on the choice of the starting therapy. OMNIVORE was an adaptive study for patients with metastatic ccRCC without previous immunotherapy. Patients received up to 6 months of nivolumab monotherapy, and if they did not achieve at least a partial response (PR), they received two doses of ipilimumab.[37] In total, 16.9% of patients achieved a PR, with no patients achieving a CR. These relatively poor results—in comparison with CheckMate 214—suggest that patients cannot be salvaged with delayed ipilimumab following monotherapy with PD-1 inhibition, and the synergy seen with combined PD-1/CTLA-4 inhibition requires contemporaneous treatment initiation with both agents. Similar results were seen in the HCRN trial evaluating the role of salvage ipilimumab/nivolumab in patients with metastatic ccRCC who achieved PD or stable disease (SD) as best response with nivolumab alone.[38] Therefore, adaptive trials aimed at escalating from doublet to triplet therapy should not focus on escalating from IO/VEGFR-TKI but rather should investigate the use of a dual ICI backbone with possible escalation to a dual IO/IO/VEGFR-TKI triplet, such as the currently enrolling PDIGREE (Alliance A031704) trial (ClinicalTrials.gov identifier: NCT03793166).[39] PDIGREE includes patients with treatment-naïve metastatic ccRCC of intermediate or poor IMDC risk. All patients in PDIGREE start treatment with induction ipilimumab and nivolumab for four cycles. At 3 months, patients undergo repeat imaging and are randomly assigned based on their radiographic response: (1) Patients with CR undergo maintenance nivolumab, (2) patients with SD or PR are randomly assigned to maintenance nivolumab or nivolumab plus cabozantinib, and (3) patients with PD are switched to cabozantinib monotherapy. Among patients with SD or PR, PDIGREE will answer whether DepOR can be augmented using this adaptive approach and if achieving higher DepOR after adaptive change in treatment course will be associated with improved survival outcomes.

There is also evidence in ccRCC that changes in—or maintenance of—HRQoL can serve as an additional predictive clinical marker. CheckMate 214 studied the impact of the change in HRQoL on survival outcomes.[40] HRQoL was measured using the FKSI-19 total scores and disease-related symptom score. FKSI-19 includes the following domains: physical disease-related symptoms, emotional

disease-related symptoms, treatment side effects, and function well-being. Measurements were obtained at baseline, 4 weeks, and longitudinally every 6 weeks for the duration of the study until disease progression. A landmark analysis of the change in HRQoL from baseline to 6 months and association with OS was also performed. Those deemed responders had either no change or an improved score, whereas the nonresponders had worsening score of at least five points from baseline. There was a longer OS (HR, 0.48; 95% CI, 0.39 to 0.59) in those patients who had maintained or improved QoL compared with nonresponders, and it was notable that longitudinal assessment was more predictive of benefit than baseline assessment. Similar to DepOR, a change in HRQOL could be applied in an adaptive design to determine intensification or de-escalation of therapy between doublet and triplet.

EMERGING BIOMARKERS

Current tools provide limited insights at an individual level regarding the biology driving tumorigenesis. Created as a tool to assess outcomes in the era of patients receiving VEGFR-TKI monotherapy, the IMDC criteria as such may be potentially limited in its ability to define patient cohorts for immunotherapy trials. Efforts to validate IMDC in patients on pure immunotherapy are underway, and this biomarker remains the most robust tool available in assessing metastatic renal cell carcinoma. However, several molecular and clinical tools are of interest. The use of simple biomarkers such as PD-L1 remains of limited value in ccRCC.[41] Novel avenues on the basis of molecular tools for patient selection are now undergoing evaluation.

A promising potential biomarker approach is the use of tissue-based transcriptome analysis to characterize tumor cells and the surrounding microenvironment. Such an approach allowed for identification of distinct biological clusters (angiogenesis, immune, cell cycle, metabolism, and stromal programs) in over 800 patients with ccRCC[42] who participated in a randomized phase III trial of sunitinib versus bevacizumab and atezolizumab therapy (IMmotion 151).[43] These cluster panels correlated with potential sensitivity or resistance of metastatic RCC to immune checkpoint inhibitor or antiangiogenic therapy.[42] Transcriptomics in other large trials have identified similar signatures with variable results when applied to other clinical trial samples.[3] These approaches need prospective validation and could be used to assign patients to distinct treatment strategies. The feasibility of such trials has been already demonstrated in the BIONIKK program,[44] and contemporary efforts are now underway with the OPTIC RCC study (ClinicalTrials.gov identifier: NCT05361720). Efforts to bring more easily accessible dynamic biomarkers in metastatic ccRCC may also rely on circulating immune factors, which could accurately reflect the broader immune contexture and individual susceptibility to checkpoint blockade.[45]

Liquid biopsies (including circulating tumor DNA [ctDNA], cell-free DNA [cfDNA], and circulating noncoding RNA) using a variety of commercial assays have been successfully used to define treatment options for patients with solid tumors (GI, lung, breast, and urothelial).[46-48] CtDNA, which detects mutated DNA in the blood (usually plasma to avoid contamination from leukocytes), can be collected longitudinally and sequenced to follow further genomic aberrations. The potential for ctDNA, determining sensitivity to drugs or in detecting the emergence of resistant clones and therefore new directions in therapy, has been demonstrated in other solid tumors, including colorectal, non–small-cell lung, and urothelial cancers. In the SWOG1314 trial of dose dense chemotherapy regimen including methotrexate, vinblastine, Adriamycin, and cisplatin before radical cystectomy for muscle invasive urothelial cancer, response of cfDNA methylation and quantitative bladder cfDNA correlated independently with the pathologic response.[49] A strength of this approach is that concordance of ctDNA mutation to tumor mutation is high.[50] CtDNA can detect longitudinal evolution of genomic aberrations in metastatic RCC.[51]

The yield of ctDNA in metastatic RCC in some analyses is lower than in other solid tumors,[50,51] but exploiting fragment lengths of circulating DNA can improve sensitivity.[52] A more promising approach is the quantification of cfDNA, extracellular DNA shed in plasma, with further sensitivity by the use of methylated DNA immunoprecipitation.[53] Methylated cfDNA is measurable in all stages of ccRCC,[54,55] and ongoing studies are correlating increases or decreases in cfDNA to response to or progression on therapies, as measured using imaging.[55] Future application of cfDNA could be imagined in several ways: First, as both transcriptomic and cfDNA technology evolve, concordance between the two could be used to direct patients to triplet or doublet combinations. Second, and more practically, validating the concordance of cfDNA decrease with imaging response might identify in advance of imaging and toxicity, which patients are benefiting from triplet or doublet therapy or potentially who should continue on current therapy to enhance response, de-escalate, or intensify therapy.

CONCLUSIONS

In summary, standard-of-care frontline treatment remains doublet IO/IO or IO/VEGFR-TKI therapy. There is a growing body of evidence assessing efficacy and safety of treatment with triplet therapy in advanced ccRCC. Triplet therapy has shown improved PFS, but OS outcomes are still maturing. However, a PFS benefit with triplet therapy comes at the expense of significant toxicity. Patient selection will be

crucial in finding those in whom the risk-benefit ratio favors aggressive therapy. Ongoing efforts to develop tools that will allow individualized treatment decisions range from clinical HRQoL and DepOR to biologic transcriptomics and liquid biopsies. Finally, efforts to move the field forward with novel targeting agents and mechanisms to increase cure while not adding to toxicity in triplet therapy are ongoing. We eagerly await the full results of the above trials to better inform therapy selection for our patients with ccRCC.

Metastatic Hormone-Sensitive Prostate Cancer: Toward an Era of Adaptive and Personalized Treatment

Anis A. Hamid, MBBS[1,2]; Nicolas Sayegh, MD[3]; Bertrand Tombal, MD[4]; Maha Hussain, MD[5]; Christopher J. Sweeney, MBBS[6,7]; Julie N. Graff, MD[8]; and Neeraj Agarwal, MD[3]

Overview

The advent of more effective treatment combinations for metastatic hormone-sensitive prostate cancer (mHSPC) has been built on successes in therapy development for metastatic, castration-resistant prostate cancer (mCRPC). Both disease phases hold similar challenges and questions. Is there an optimal therapy sequence to maximize disease control and balance treatment burden? Are there clinical and biologically based subgroups that inform personalized and/or adaptive strategies? How can clinicians interpret data from clinical trials in the context of rapidly evolving technologies? Herein, we review the contemporary landscape of treatment for mHSPC, including disease subgroups informing both intensification and potential deintensification strategies. Furthermore, we provide current insights into the complex biology of mHSPC and discuss the potential clinical application of biomarkers to guide therapy selection and the development of novel personalized approaches.

INTRODUCTION

Prostate cancer is among the most common solid malignancies in men, accounting for a significant proportion of the global burden of cancer morbidity and mortality.[1] The diagnosis and clinical presentation of prostate cancer may be influenced by sociodemographic, geographic, economic, and biological factors. Most men in developed nations are diagnosed when cancer is confined to the prostate gland, and this has stemmed, historically, from the advent and widespread use of prostate-specific antigen (PSA) screening.[2] Despite variation in the mode and stage of diagnosis, the spectrum of disease can be consistently divided by two key clinical factors: (1) the presence or absence of metastasis on conventional imaging modalities and (2) sensitivity or resistance to gonadal testosterone suppression (TS). The former is determined by clinical and radiographic evaluation and remains an area of rapid evolution in recent times with the adoption of novel diagnostic imaging techniques, such as magnetic resonance imaging and positron emission tomography (PET). The latter provides a phenotypic label in relation to response to androgen deprivation therapy (ADT)—the backbone of systemic therapy for metastatic prostate cancer—and has a formalized definition, most notably by the Prostate Cancer Working Group.[3]

The incidence of mHSPC is increasing.[4,5] US-based studies point to shifts in stage of diagnosis, which parallel changes in PSA screening recommendations by the US Preventative Services Task Force.[6] Although not inferring direct causality, the rising incidence of metastatic prostate cancer is considered a high priority because of the incurable nature of advanced disease associated with inevitable therapy resistance and worse survival. Treatment for mHSPC has evolved considerably over the past decade because of successive large, randomized, phase III clinical trials demonstrating improvements in overall survival (OS) and quality of life (QoL) with combination therapy above the historical standard of ADT alone (Table 1). Many of the novel strategies for mHSPC have arisen from therapies proven successful in mCRPC (Fig 1). We have been ushered into a new era of mHSPC, which has led to intense questioning of how we can both balance and improve the benefit, burden, and precision of treatment for patients.

TREATMENT OF mHSPC

Inhibition of the androgen receptor (AR) remains the mainstay of treatment for mHSPC, owing to seminal experiments published in 1941, which proved that prostate cancer is an androgen-driven and androgen-dependent disease that responds to testosterone deprivation.[17] These discoveries led to Charles Huggins receiving the Nobel Prize in Physiology or Medicine in 1966. Indeed, androgen signaling is central in driving growth and survival of prostate cancer even in treatment-resistant states.[18] TS was

PRACTICAL APPLICATIONS

- The landscape of treatment for metastatic hormone-sensitive prostate cancer (mHSPC) continues to evolve, with a shift to combination systemic therapy being established as the backbone of contemporary treatment.
- Clinical factors, including disease volume and presentation, demonstrate prognostic associations and have been studied in the context of predicting the benefit of combination strategies, including triplet systemic therapy.
- The role of treatment intensity modulation is of high interest, given that modern trials in mHSPC have demonstrated that a subset of patients have favorable long-term outcomes. De-intensification strategies guided by prostate-specific antigen response aim to balance both the benefits and long-term risks and burden of treatment.
- Biomarker development in mHSPC is leveraging the rapid accumulation of knowledge from biological profiling of both localized prostate cancer and metastatic, castration-resistant prostate cancer.
- In the era of precision cancer care, targeted novel therapies are being tested in ongoing clinical trials to further personalize therapy for mHSPC.

originally instituted by surgical castration (bilateral orchiectomy), followed by diethylstilbestrol and subsequent development of luteinizing hormone-releasing hormone (LHRH) agonists and antagonists built on the elucidation of hypothalamic pituitary control of gonadal testosterone production. Labrie et al[19] initially hypothesized that the concomitant administration of an antiandrogen to ADT, or complete androgen blockade, eliminates the activity of testicular and adrenal androgens. Early-generation AR inhibitors, such as flutamide, bicalutamide, nilutamide, and cyproterone acetate, are generally not used as monotherapy and instead are more often combined with TS (termed combined ADT) for prevention of flare responses due to initial agonistic (positive feedback) effects of LHRH agonist therapy. An individual patient data (IPD) meta-analysis of 8,275 men from 27 randomized trials comparing TS alone versus combined ADT[20] showed that 5-year OS was improved with nonsteroidal antiandrogens (absolute benefit 3%; two-sided $P = .005$) and possibly worse with cyproterone acetate (absolute reduction 3%; two-sided $P = .04$), compared with TS alone. These data have laid the basis of combined ADT of TS plus weak, early-generation AR inhibitors as a potential control arm in clinical trials of mHSPC. However, real-world practice remains heterogeneous.

ADT Plus Docetaxel or Novel AR Signaling Inhibitor: Doublet Systemic Therapy

ADT plus docetaxel. From the early 1940s to 2015, TS alone with or without an AR inhibitor was a standard treatment for mHSPC before development of castration resistance. In 2004, the TAX 327 and SWOG9916 trials demonstrated a significant improvement in OS for men with mCRPC treated with ADT plus docetaxel/prednisone (or docetaxel plus estramustine in SWOG9916), compared with ADT plus mitoxantrone/prednisone.[21,22] These findings led to an immediate shift in the treatment paradigm of mCRPC. The combination of hormonal therapy and cytotoxic therapy also reflected a strong scientific rationale as clonal populations in advanced and resistant prostate cancer are diverse (both within and between metastases) and may be differentially driven by AR-dependent and non–AR-dependent mechanisms.[23]

Therapy intensification with ADT plus docetaxel in frontline management of mHSPC was tested in three key phase III trials. GETUG-AFU 15 randomly assigned 385 men to either ADT plus docetaxel once every 3 weeks (up to nine cycles, without prednisone) or ADT alone. At a median follow-up of 50 months, OS was not significantly different between the groups (hazard ratio [HR], 1.01; 95% CI, 0.75 to 1.36).[24] Long-term follow-up, at a median of 83.9 months, again failed to show a significant difference in OS; however, post hoc analysis by volume of metastatic disease demonstrated a trend to benefit in the high-volume subgroup (HR, 0.78; 95% CI, 0.56 to 1.09), which did not meet statistical significance and was notably underpowered.[25] The CHAARTED trial was the first to report a significant OS improvement with ADT plus docetaxel for mHSPC—also the first of any combination strategy.[26] In total, 790 men were randomly assigned to ADT alone or ADT plus docetaxel (for six cycles), with a primary end point of OS. The trial had several prespecified stratification factors including disease volume (high versus low), where high-volume was defined as the presence of any visceral metastases, or four or more bone lesions with at least one beyond the vertebral bodies and pelvis. After a median follow-up of 28.9 months, chemohormonal therapy was associated with significantly prolonged OS (57.6 months *v* 44 months, HR, 0.61; 95% CI, 0.47 to 0.80; $P < .001$), as well as improvements in secondary end points including time to CRPC and the proportion of patients with suppressed PSA (<0.2 ng/mL) at 12 months. The effect of docetaxel was particularly pronounced in the high-volume subgroup (65% of cohort). In long-term follow-up, the median OS for patients with high-volume disease was 51.2 months versus 34.4 months (HR, 0.63; 95% CI, 0.50 to 0.79; $P < .001$) for ADT plus

docetaxel versus ADT alone, respectively.[7] Notably, no significant OS benefit was observed for patients with low-volume disease (HR, 1.04; 95% CI, 0.70 to 1.55; $P = .86$), suggesting marked heterogeneity of effect. Subsequent meta-analysis of aggregate data from GETUG-AFU 15 and CHAARTED with harmonized disease volume definitions confirmed heterogeneity in effect sizes between volume subgroups, with significant OS advantage from docetaxel demonstrated in high-volume disease (synchronous and metachronous), modest OS benefit in synchronous low-volume disease, and no OS benefit in metachronous, low-volume disease.[27] The multiarm, multistage STAMPEDE trial also showed a significant benefit for addition of docetaxel to ADT for mHSPC.[28] In a trial population of 2,962 men, which also included patients with high-risk localized disease (39%), arm C (ADT plus docetaxel) and arm E (ADT plus docetaxel plus zoledronic acid) demonstrated improved OS compared with ADT alone (HR, 0.78; 95% CI, 0.66 to 0.93; $P = .006$ and HR, 0.82; 95% CI, 0.69 to 0.97; $P = .022$, respectively). Subgroup analysis showed this effect clearly in men with metastatic disease. Updated analysis of this subgroup at a median follow-up of 78.2 months failed to show heterogeneity of docetaxel effect on OS by retrospectively evaluated metastatic burden (per CHAARTED definition).[8] Notably, 95% of the patients in the STAMPEDE-M1 cohort had synchronous disease. The latter clearly differed to the patient mix of CHAARTED and GETUG-15, which had 17% of patients with metachronous, low-volume disease. An IPD meta-analysis of 2,261 men from GETUG-AFU 15, CHAARTED, and STAMPEDE by the STOPCAP group demonstrated a gradient effect of OS benefit for the addition of docetaxel to ADT, with the most pronounced effect in the synchronous, high-volume subgroup. A modest effect was noted in the metachronous, high-volume subgroup and synchronous, low-volume subgroup. No effect was seen in metachronous, low-volume disease, which is associated with a more favorable prognosis with TS alone.[29] It should also be noted that not all patients are fit for docetaxel, often because of comorbid conditions. Radiation to the prostate also has an

OS benefit with a more favorable adverse event profile than docetaxel for men with synchronous, low-volume mHSPC.[30]

The role of prostate RT. Treatment of the primary tumor in the face of metastatic disease is an enticing concept with the rationale of eliminating a significant source of lethal metastatic seeding. Between 2013 and 2016, STAMPEDE addressed this strategy in mHSPC, randomly assigning 2,061 men to the standard care arm (ADT, with concurrent docetaxel permitted from late 2015) or standard care plus prostate radiotherapy (RT) delivered over 4-6 weeks.[31] Fifty-four percent of men had high metastatic burden, and 18% received up-front docetaxel. The addition of prostate RT significantly improved failure-free survival, but not OS (HR, 0.92; 95% CI, 0.80 to 1.06; $P = .226$) in the overall cohort. However, there was a pronounced OS benefit in patients with low metastatic burden (HR, 0.68; 95% CI, 0.52 to 0.90; $P = .007$), which was not evident in high-burden disease (interaction $P = .01$). This differential effect was again observed in long-term follow-up, and there was no evidence of deterioration in global QoL and long-term high-grade urinary toxicity.[32] When combined with data from the smaller HORRAD trial, meta-analysis by the number of bone metastases demonstrated significant benefit for patients with <5 bone lesions and not higher burden disease.[30] On the basis of these data, prostate RT is an established standard for synchronous, low-burden/volume mHSPC; however, questions remain regarding its role with combination systemic therapy. The proportion of patients treated with docetaxel in the STAMPEDE radiation cohort does not allow for clear conclusions to be drawn from the subset of patients with low-burden disease treated with chemohormonal therapy. PEACE-1 has similar subgroups that may be pooled for analysis and will also define the role of prostate RT combined with ADT plus abiraterone (with or without docetaxel).

ADT plus AR signaling inhibitor. After the proven OS-prolonging benefit of AR signaling inhibitors (ARSIs) in CRPC, several phase III, randomized trials have cemented the role of intense ADT, with a combination of TS plus ARSI, for mHSPC.

Abiraterone acetate, which decreases androgen synthesis by inhibiting CYP17A1, has been evaluated in the STAMPEDE, LATITUDE, and PEACE-1 trials. STAMPEDE assigned men with HSPC 1:1 to either ADT plus abiraterone plus prednisolone (arm G) or ADT alone.[9] Fifty-two percent of men had metastatic disease. At a median follow-up of 40 months, a significant improvement in the primary end point of OS was noted, with a magnitude of effect in the metastatic subgroup, again 95% with synchronous disease, strikingly similar to the aforementioned docetaxel trials (HR, 0.61; 95% CI, 0.49 to 0.75). The clinically meaningful secondary end point of time to symptomatic skeletal events was also significantly improved with combination therapy. LATITUDE randomly assigned 1,199 men to analogous treatment arms; however, the cohort of patients with mHSPC were selected specifically for poor prognostic features—all patients had synchronous metastatic disease and at least two of Gleason score ≥8, ≥3 bone lesions, and presence of visceral metastasis.[33] ADT plus abiraterone significantly improved OS at a planned interim analysis (HR, 0.62; 95% CI, 0.51 to 0.76; $P < .0001$). Time to pain progression, initiation of chemotherapy, and symptomatic skeletal events were all in favor of the abiraterone arm. At the final analysis after a median follow-up of 51.8 months, survival benefit remained (median 53.5 months *v* 36.5 months, HR, 0.66; 95% CI, 0.56 to 0.78; $P < .0001$).[10]

Three next-generation AR inhibitors (enzalutamide, apalutamide, and darolutamide) have established efficacy in mHSPC. ENZAMET[34] and ARCHES[35] tested the addition of enzalutamide to ADT, with the notable difference that the control arm of ENZAMET required patients to receive ADT plus a nonsteroidal antiandrogen. In ENZAMET, concurrent use of up-front docetaxel (maximum six cycles) was permitted after a protocol amendment early in accrual. A total of 1,125 men were randomly assigned, and after a median follow-up of 34 months, clear OS prolongation with enzalutamide was observed (HR, 0.67; 95% CI, 0.52 to 0.86, $P = .002$). Benefit was observed across stratified subgroups, including disease volume (high/low) and metastatic timing (synchronous/metachronous). The primary end point of ARCHES was radiographic progression-free survival (rPFS), and the study design allowed for previous lead-in docetaxel. The enzalutamide arm had significantly longer rPFS (HR, 0.39; 95% CI, 0.30 to 0.50; $P < .001$). In the final analysis after a median follow-up of 44.6 months, a significant OS benefit for ADT plus enzalutamide (HR, 0.66; 95% CI, 0.53 to 0.81; $P < .001$) was confirmed[11]—similar to effect size in ENZAMET. Apalutamide was evaluated in the TITAN trial, which compared ADT plus apalutamide with ADT alone with coprimary end points of radiographic PFS and OS.[36] High-volume disease comprised 62.7% of the cohort, and a small proportion of patients had received previous docetaxel (10.7%). At the first interim analysis, OS was superior in the apalutamide arm (HR, 0.67; 95% CI, 0.51 to 0.89; $P = .005$), and the frequency of high-grade adverse events was similar between treatment arms. Benefit was observed across subgroups, irrespective of timing or volume of metastatic disease. On the basis of these results, the study cohort was unblinded and crossover permitted. Despite 40% of placebo-treated men crossing over to apalutamide, the effect on OS persisted in long-term follow-up.[12]

ADT Plus Docetaxel Plus ARSI: Triplet Systemic Therapy

Identification of patients who benefit from highly intensified up-front systemic therapy is critical. This group of patients is hypothesized to be at risk of greatest symptom burden,

quicker progression to castration resistance, and early death. Moreover, curtailing potential toxicities (including personal financial and economic burden) of multiple therapies in patients unlikely to benefit from this approach is of high priority. There is ongoing debate regarding the role of so-called triplet systemic therapy (ADT plus docetaxel plus ARSI) for mHSPC, given the expanse of different agents in varying combination across the trials reported to date. There are several informative data sets to highlight (Table 1).

First, the role of darolutamide for mHSPC was tested in the ARASENS trial.[13] This randomized, phase III trial assigned 1,306 patients to darolutamide or placebo, both with a mandated backbone of ADT plus docetaxel for all—unique among reported mHSPC studies. Notably, disease volume was not a stratification factor, and most patients (86%) had synchronous metastatic disease. Addition of darolutamide led to significant improvement in OS (HR, 0.68; 95% CI, 0.57 to 0.80; $P < .001$) and similar benefits in prolonging time to pain progression, symptomatic skeletal events, and initiation of chemotherapy, compared with those receiving ADT plus docetaxel. In a post hoc analysis, adding darolutamide to docetaxel and TS clearly improved OS in patients with the high- but not low-volume disease (as defined by CHAARTED criteria) and clear evidence of benefit was seen in patients with high- and low-risk disease (as defined by LATITUDE criteria).[14]

Second, the European PEACE-1 trial evaluated the efficacy of adding abiraterone plus prednisone to ADT, with or without RT, for synchronous mHSPC using a 2 × 2 factorial design.[15] In a pooled analysis (because of noted noninteraction between abiraterone and RT), men who received abiraterone had significantly longer OS (HR, 0.82; 95.1% CI, 0.69 to 0.98; $P = .03$) compared with ADT control. Across all studies, the rate of high-grade adverse events was higher in abiraterone arms, with common toxicities of hypertension, hypokalemia, and mild transaminase rise.[15] A planned subgroup analysis of PEACE-1 showed significant prolongation of OS with abiraterone among 710 men who received ADT plus docetaxel (HR, 0.75; 95.1% CI, 0.59 to 0.95; $P = .017$). This effect was significant among men with high-volume disease within this subgroup (median OS: 5.14 years *v* 3.47 years, HR, 0.72; 95.1% CI, 0.55 to 0.95; $P = .019$); OS is immature for the low-volume comparison.[15]

Third, ENZAMET allowed for concurrent docetaxel (planned for 45% of patients at investigator discretion), and 85% of patients in the control arm received any subsequent therapy, including 76% who received abiraterone or enzalutamide on progression. A prespecified analysis showed evidence of a difference in OS favoring the enzalutamide arm in the subset of 362 men with synchronous metastatic disease planned for docetaxel (5-year OS: 60% *v* 52%, HR, 0.73; 95% CI, 0.55 to 0.99).[16] This was not evident in patients with metachronous disease planned for docetaxel (HR, 1.10; 95% CI, 0.65 to 186). Within the synchronous population planned for docetaxel, OS point estimates favored enzalutamide in both high- and low-volume subgroups. Curiously, examination of survival curves revealed higher OS rates in the first 30 months for participants receiving enzalutamide plus docetaxel plus TS versus those contemporaneously accrued to enzalutamide plus TS in the highest-risk subgroup (synchronous, high-volume), suggesting the need for early chemotherapy in rapidly lethal disease.

In summary, the collective data support the role of adding an ARSI to those initiating ADT plus docetaxel, particularly for patients with synchronous, high-volume metastatic disease. Further follow-up may more clearly elucidate the role of ADT plus docetaxel therapy in other clinical subgroups. Specifically, the benefit of adding docetaxel to a backbone of ADT plus ARSI is yet unknown; to our knowledge, no randomized trials have reported the outcomes of patients treated with ADT plus ARSI with or without docetaxel. However, exploratory analysis of ENZAMET does highlight the potential of this approach in high-risk subgroups who were chosen for docetaxel and have worse prostate cancer–specific survival.

Baseline Clinical Prognostic Factors

Clinical features at mHSPC diagnosis that associate with survival have largely centered on timing of metastatic disease and volume of disease. In the CHAARTED trial, men with metachronous and low-volume disease had the best prognosis, with a median OS of nearly 70 months with TS and TS plus docetaxel. This contrasted strongly with the synchronous, high-volume subgroup (median OS: 33-48 months) and those with one risk factor falling between those extremes[7]—a stratification also observed in a retrospective registry cohort with aligned definitions.[37] Post hoc analysis of the STAMPEDE-Docetaxel metastatic cohort confirmed the clear prognostic effect of disease volume.[8] IPD meta-analysis of GETUG-AFU 15, STAMPEDE-Docetaxel, and CHAARTED has highlighted, in aggregate, the favorable long-term outcomes of men with metachronous, low-volume disease (5-year OS: 73%) and no evidence of benefit in this group with the best prognosis.[29] The same subgroup has exceptional outcomes on ADT plus ARSIs as observed in the long-term follow-up of ENZAMET (ADT plus enzalutamide, 5-year OS: approximately 85%) versus 65% with TS plus weak NSAA.[16] An update of the STAMPEDE-Abiraterone M1 comparison by disease risk per LATITUDE criteria revealed that the low-risk subgroup (43% of patients) had an estimated 5-year OS of 72% when treated with ADT plus abiraterone.[38] Noting that 95% of participants in STAMPEDE and all patients on LATITUDE have synchronous metastasis, it is reasonable to expect similar outcomes for men with metachronous, low- and high-volume disease treated with abiraterone,[39] as those seen with novel AR inhibitors. This notion was demonstrated one

step earlier in the HSPC continuum in men with high-risk, lymph node–positive M0 prostate cancer treated with RT adjuvant TS plus abiraterone associated with improved OS compared with RT plus TS alone.[40]

DEINTENSIFICATION AND ADAPTIVE APPROACHES

Intermittent and Response-Adjusted Therapy

Many clinicians will have made the observation that there is a subset of patients receiving modern combination therapy, or even ADT alone, that achieve prolonged disease control. Their clinical course is marked by stability of disease symptoms and an undetectable PSA for years. The potential adverse impact of prolonged exposure to these ARSIs remains to be defined, but we do know that abiraterone can exacerbate heart failure and that enzalutamide and apalutamide should not be used with patients at risk for seizure and have been associated with increased falls in the elderly.[41] Indeed, the emergence of treatment-related toxicities may become the dominant clinical priority over time. How do we identify patients suitable for therapy deintensification?

Before the era of combination therapies for mHSPC, deintensification of ADT held a number of proposed benefits. First, progression to castration resistance is adaptive, and replacing androgen levels may therefore prolong the duration of androgen dependence and disease control with AR-directed therapy. Second, intermittent therapy could ameliorate QoL by minimizing adverse symptoms and insidious health effects of continuous castration. SWOG 9346 was a large phase III trial that randomly assigned men with mHSPC to continuous versus intermittent ADT if PSA <4 ng/mL was achieved after 7 months with coprimary end points of difference in QoL at 3 months and OS noninferiority between the arms.[42] After a median follow-up of nearly 10 years, intermittent therapy was not proven to be noninferior for OS, and survival was numerically longer in the continuous arm. Although intermittent therapy resulted in modest improvements in QoL, the lack of definitive OS noninferiority has scuttled widespread adoption of intermittent combined ADT, and clinical practice remains heterogeneous.

Given the apparent stratification of outcomes by baseline clinical factors, there has been increasing interest in identifying response-based end points that may guide not only prognosis but also the development of deintensification strategies for patients with favorable long-term outcomes. PSA is the most thoroughly investigated response end point in this context. SWOG 9346 demonstrated a stratification of outcomes by the level of absolute PSA (PSA ≤0.2 ng/mL, 0.2 ng/mL <PSA ≤4 ng/mL, or PSA >4 ng/mL) after 6-7 months of ADT alone, and a prolonged time to nadir has been associated with even shorter survival in mHSPC.[43-46] Similar stratification of OS by PSA ≤0.2 ng/mL at 7 months was seen in CHAARTED, and this effect remained significant in multivariable analysis adjusting for docetaxel exposure and disease volume.[47] Addition of docetaxel increased the likelihood of PSA suppression (achieved by 37% overall and in a predominately poor prognosis patient population). These data consequently suggest a role for therapy intensification for patients not reaching this PSA milestone on ADT plus docetaxel alone. Similar analyses have been performed in LATITUDE, with 40% of men receiving ADT plus abiraterone who achieved PSA ≤0.1 ng/mL compared with 6.5% on ADT alone.[48] PSA suppression at 6 months correlated with improved rPFS and OS. A preplanned analysis of PEACE-1 showed similar association of rPFS and OS with PSA value measured at 8 months.[49] In ARASENS, addition of darolutamide to ADT plus docetaxel led to a more than doubling of the proportion of patients achieving an undetectable PSA at 24 weeks and 36 weeks, and this correlated with improved OS using either time landmark.[50] In the TITAN trial, achievement of a PSA level of ≤0.2 ng/mL at landmark 3 months of apalutamide therapy was associated with a significantly longer OS (HR, 0.35; 95% CI, 0.25 to 0.48).[51]

Trials combining ADT with ARSIs have a continuous treatment paradigm, which holds several implications. Treatment-related toxicities, effects on health-related QoL, and long-term financial impact need to be considered carefully for all and weighed against efficacy of ARSIs across clinical subgroups—especially in low-volume, metachronous disease where a 90% 5-year prostate cancer–specific survival was noted with TS plus enzalutamide.[16] Moreover, the median OS of control arms across major phase III trials has been consistently improving in the past decade. The SWOG 1216 trial showed a median OS of 70 months in patients treated with ADT plus bicalutamide, twice the value reported in earlier SWOG trials for mHSPC with a similar proportion of patients with extensive disease (visceral metastases and/or presence of at least one bone metastasis beyond the vertebral bodies and pelvis).[52]

Landmark PSA response and other biomarkers may guide treatment de-escalation. The Alliance-sponsored A-DREAM trial (ClinicalTrials.gov identifier: NCT05241860) is a phase II adaptive study where patients receiving ADT plus an ARSI for mHSPC will undergo treatment interruption if PSA <0.2 ng/mL after 18-24 months. Recommencement of therapy will occur on PSA (≥5 ng/mL), radiographic, or clinical progression. The primary end point of the trial is the proportion of men who experience 18-month treatment-free interval (with eugonadal testosterone level) after treatment interruption. EORTC-2238 GUCG (De-Escalate) is a randomized pragmatic trial, sponsored by EORTC, in collaboration with the European Prostate Cancer patient coalition, Europa Uomo, revisiting the concept of intermittent ADT in patients achieving a PSA ≤0.2 ng/mL after 6-12 months of ADT and one of the ARSIs. The study end points include OS, time to next OS-prolonging treatment, health-related QoL,

and resource utilization. In the phase III LIBERTAS trial, men with mHSPC being treated with ADT plus apalutamide and achieving a PSA nadir of ≤0.2 ng/mL within the first 7 months of starting apalutamide will be randomly assigned to continuation of ADT plus apalutamide versus intermittent ADT plus apalutamide. End points include radiographic event-free rate and hot flash severity score and frequency. Novel antiandrogen monotherapy has been tested in an earlier disease setting—for example, enzalutamide without TS in the EMBARK trial (ClinicalTrials.gov identifier: NCT02319837) of biochemically recurrent prostate cancer. Historical data from antiandrogen monotherapy trials suggest lower rates of survival compared with TS.[53] The role of modern noncastrating therapies alone, however, remains undefined.

NOVEL BIOMARKERS AND PRECISION-INFORMED TREATMENT

The answer to guide a new era of therapy modulation and personalization in mHSPC may lie in biology and biomarkers. Much of our knowledge of the biology of mHSPC is derived from deep interrogation of the clinical bookend settings of prostate cancer—localized disease and mCRPC, respectively—over the past 30 years. Large-scale efforts, such as the Cancer Genome Atlas and Stand Up 2 Cancer-Prostate Cancer Foundation program, have provided insights into the genetic, genomic, and transcriptomic landscape of prostate cancer.[54-56]

Although there is a paucity of data to characterize mHSPC specifically, particularly for clinical correlation, recent genomic profiling studies have spurred the need for further investigation. Progression from localized prostate cancer to mCRPC is marked by enrichment of deleterious genomic alterations in the latter disease state. Tumor suppressor genes such *PTEN*, *TP53*, and *RB1* are frequently altered in mCRPC, so too genes that effect DNA damage and repair (*BRCA2*, *BRCA1*, *ATM*, and *FANCA*), PI3K signaling (*PIK3CA* and *AKT1*), chromatin remodeling (*KMT2C* and *KMT2D*), and, most frequently, the *AR*.[57-59] Retrospective data sets reveal that the frequency of such alterations appears to lie between localized prostate cancer and mCRPC, suggesting acquisition of deleterious alterations over time that confers cancer advantage in survival and treatment resistance.[60,61] Interestingly, significant enrichment of such tumor suppressor and *AR* alterations is observed in mCRPC relative to mHSPC (and not mHSPC relative to localized disease). Previous studies have further characterized the mHSPC genomic landscape by clinically relevant groups. High-volume mHSPC has evidence of greater genomic instability measured by global copy number burden and more frequent NOTCH pathway, cell cycle, and Wnt signaling alterations relative to low-volume disease, but no significant differences at an individual gene level.[62,63] Genomic alterations hold prognostic and predictive strength in mHSPC. Tumor sequencing from the STAMPEDE trial has demonstrated a relationship with increasing copy number burden and risk of progression and death in high- and low-volume disease.[64] Time to castration resistance is shorter with alterations in *AR*, *TP53*, *PTEN*, *RB1*, cell cycle, and *MYC* pathways.[61,65] *AR* aberrations detected in circulating tumor DNA (ctDNA) at baseline have been associated with shorter OS.[66] Conversely, *SPOP* mutations are associated with prolonged time to progression and death in patients treated with ARSIs (but not docetaxel) for mHSPC.[67,68]

Prognostic transcriptomic biomarkers are established in localized prostate cancer to the point of clinical implementation.[69,70] The role of such assays in advanced disease is not well-defined; however, recent RNA profiling of mHSPC suggests strong biomarker potential. Profiling of 160 patients from CHAARTED using the Decipher microarray platform was the first to comprehensively map the transcriptomic landscape of mHSPC.[71] Applying discrete signatures, marked differences were noted compared with localized prostate cancer with predominance of luminal B and basal subtypes (and <5% with luminal A), lower AR activity, and enrichment for high Decipher risk. When translated to outcomes, luminal B subtype was associated with poorer prognosis on ADT but significantly benefited from addition of docetaxel (and no significant benefit for docetaxel was seen in the basal subtype). Higher Decipher risk and lower AR activity were associated with shorter OS, and this effect remained significant despite adjusting for disease volume and metastatic timing. These data propose both prognostic and predictive roles for transcriptional subtyping in mHSPC. Comparative data from TITAN demonstrated similar enrichment of adverse-risk subtypes and their association with shorter rPFS. However, there was evidence of benefit for adding apalutamide to ADT across molecular subtypes.[72] Similar findings support the prognostic role of Decipher risk as reported in a STAMPEDE cohort treated with ADT with or without abiraterone.[73] The beneficial effect of abiraterone was noted across subtypes, mirroring the benefit of ARSIs across clinical subgroups (in contrast to docetaxel). Put together, transcriptomic profiling of mHSPC has revealed a molecular landscape skewed toward known aggressive and poor prognosis subtypes. Evidently transcriptomic subtyping can provide prognostic information independent of clinical factors. Its role as a predictive biomarker requires further development, validation, and aggregate analysis across data sets.

We are now getting closer to testing the potential benefits of biomarker-informed clinical trials of precision therapy for mHSPC (Table 2). The expansion of understanding personalized and targeted treatments in mCRPC is ripe for investigation in mHSPC, promising greater balance in the

TABLE 2. Selected Registration Phase III Trials in the Metastatic Hormone-Sensitive Prostate Cancer Setting

Trial	Phase	Target Enrollment	Inclusion Criteria	Previous Docetaxel Therapy in the Metastatic Hormone-Sensitive Setting	Intervention Arm	Control Arm	Primary End Point
PSMAddition (NCT04720157)	III	1,126	PSMA-positive disease on a ^{68}Ga-PSMA-11 PET/CT scan Treatment-naïve or up to 45 days of ADT before inclusion or up to 45 days of ARSI	Not allowed	^{177}Lu-PSMA-617 intravenously once every 6 weeks for six cycles plus standard of care (ADT plus ARSI)	Standard of care (ADT plus ARSI)	rPFS
AMPLITUDE (NCT04497844)	III	788	Positive for deleterious germline or somatic homologous recombination repair gene mutations Ongoing ADT Radiation with curative intent or previous treatment with PARPi not allowed Up to 6 months of ADT or 45 days of abiraterone acetate and prednisone allowed before random assignment	Allowed	Niraparib 200 mg orally once daily plus abiraterone acetate 1,000 mg orally once daily plus prednisone 5 mg orally once daily	Placebo plus abiraterone acetate 1,000 mg once daily plus prednisone 5 mg once daily	rPFS
TALAPRO-3 (NCT04821622)	III	550	Positive for deleterious germline or somatic homologous recombination repair gene mutations Ongoing ADT Previous docetaxel for mHSPC or previous treatment with a PARPi not allowed ≤3 months of ADT with or without ARSI for mHSPC allowed before random assignment	Not allowed	Talazoparib 0.5 mg orally once daily plus open-label enzalutamide 160 mg orally once daily	Placebo plus open-label enzalutamide 160 mg orally once daily	rPFS
CAPItello-281 (NCT04493853)	III	1,000	Synchronous mHSPC PTEN deficiency on tissue immunohistochemistry Ongoing ADT Previous surgery or radiation with curative intent not allowed	Not allowed within 3 weeks of first dose of study treatment	Capivasertib 400 mg orally twice daily (intermittent weekly dosing schedule) plus abiraterone acetate 1,000 mg orally once daily	Placebo plus abiraterone acetate 1,000 mg orally once daily	rPFS
CYCLONE-03 (NCT05288166)	III	900	High-risk mHSPC (≥4 bone metastases and/or ≥1 visceral metastasis) Ongoing ADT Previous systemic treatment for metastatic prostate cancer not allowed except ADT with or without ARSI up to 3 months before random assignment	Allowed	Abemaciclib plus abiraterone acetate plus prednisone	Placebo plus abiraterone acetate plus prednisone	rPFS
KEYNOTE-991 (NCT04191096)	III	1,232	Previous treatment with an ARSI or immune checkpoint inhibitor not allowed Ongoing ADT Up to six previous cycles of docetaxel allowed without evidence of progression Absence of a superscan bone scan	Allowed	Pembrolizumab 200 mg intravenously once every 3 weeks plus enzalutamide 160 mg orally once daily	Placebo plus enzalutamide 160 mg orally once daily	rPFS OS

Abbreviations: ADT, androgen deprivation therapy; ARSI, androgen receptor signaling inhibitor; mHSPC, metastatic hormone-sensitive prostate cancer; OS, overall survival; PARP, poly (ADP-ribose) polymerase; PARPi, poly (ADP-ribose) polymerase inhibitor; PET, positron emission tomography; PTEN, phosphatase and tensin homolog; rPFS, radiographic progression-free survival.

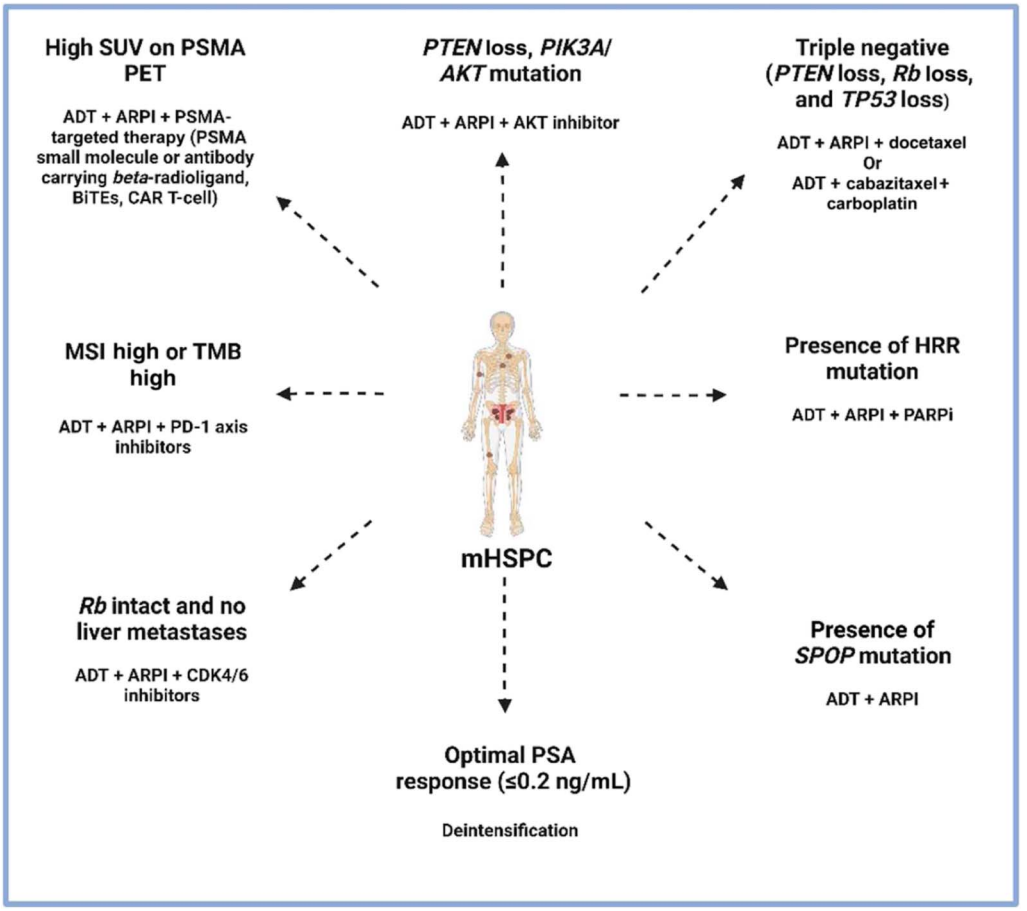

FIG 2. Potential precision therapy approaches in mHSPC. ADT, androgen deprivation therapy; ARPI, androgen receptor pathway inhibitor; BiTEs, bispecific T-cell engager; CAR T cell, chimeric antigen receptor T cell; CDK4/6, cyclin D Kinase 4/6; HRR, homologous recombination repair; mHSPC, metastatic hormone-sensitive prostate cancer; MSI, microsatellite instability; PARPi, poly (ADP-ribose) polymerase inhibitor; PD-1, programmed cell death protein 1; PSA, prostate-specific antigen; PSMA, prostate-specific membrane antigen; TMB, tumor mutational burden.

benefit to burden ratio of systemic therapies (Fig 2). The frequency of germline and somatic BRCA1/2 and homologous recombination–associated gene alterations in metastatic prostate cancer and the success of poly (ADP-ribose) polymerase (PARP) inhibitors in this context[74] have led to the development of numerous trials or PARP inhibitor combinations in mHSPC. Targeting frequent PI3K-Akt pathway alterations and cell cycle dysregulation in mCRPC[75,76] has spurred study in the hormone-sensitive setting, combining AKT inhibitors and CDK4/6 inhibitors with hormonal therapy, respectively. ^{177}Lu-PSMA-617 has received FDA approval for the treatment of mCRPC on the basis of significant activity[77] and OS improvement.[78] As a form of molecular-targeted therapy using novel PET imaging, ^{177}Lu-PSMA-617 holds promise in mHSPC because of the widespread expression of PSMA in hormone-sensitive disease. Trials combining ^{177}Lu-PSMA-617 with chemotherapy (eg, UpFrontPSMA, NCT04343885) or ARSI (eg, PSMAddition, NCT04720157) are ongoing. The rapid development of predictive biomarkers is directly influencing the design of future multiarm umbrella trials in mHSPC, guided by baseline and on-treatment molecular, PSA, and imaging characterization and other levels of individual data to define treatment strategies.

CONCLUSIONS

Rapid shifts in the paradigm and complexity of therapy for mHSPC in recent years have led to significant improvement in OS, especially notable for those with synchronous, high-volume disease associated with worse prognosis, converting mHSPC from imminently deadly to a disease with the ultimate goal of durable control. Contemporary data from mHSPC clinical trials highlight notable improvements in the prognosis of patients across the spectrum of risk, and these need to be adopted and realized in the real world. However, many unanswered questions remain. Men are living longer with metastatic prostate cancer, and it remains imperative that new treatment approaches promote personalization to increase patient benefit and decrease the unbalanced burden.

Management of Prostate Cancer in Older Adults

Laura S. Graham, MD[1]; John K. Lin, MD, MSHP[2]; Daniel E. Lage, MD[3]; Elizabeth R. Kessler, MD[1]; Ravi B. Parikh, MD, MPP[4,5]; and Alicia K. Morgans, MD, MPH[6]

Overview

The majority of men with prostate cancer are diagnosed when they are older than 65 years; however, clinical trial participants are disproportionately younger and more fit than the real-world population treated in typical clinical practices. It is, therefore, unknown whether the optimal approach to prostate cancer treatment is the same for older men as it is for younger and/or more fit men. Short screening tools can be used to efficiently assess frailty, functional status, life expectancy, and treatment toxicity risk. These risk assessment tools allow for targeted interventions to increase a patient's reserve and improve treatment tolerance, potentially allowing more men to experience the benefit of the significant recent treatment advances in prostate cancer. Treatment plans should also take into consideration each patient's individual goals and values considered within their overall health and social context to reduce barriers to care. In this review, we will discuss evidence-based risk assessment and decision tools for older men with prostate cancer, highlight intervention strategies to improve treatment tolerance, and contextualize these tools within the current treatment landscape for prostate cancer.

INTRODUCTION

Prostate cancer predominantly affects older men. The median age of diagnosis is 66 years, and 60% of patients are diagnosed in men older than 65 years, with 20% being diagnosed in men older than 75 years.[1,2] Older patients and those with more comorbidities are not proportionally represented in clinical trials.[3-5] Therefore, despite the incidence of prostate cancer peaking in older age, it is not known whether older men derive the same benefit from the treatment strategies used in younger men. Given that older patients tend to have more medical comorbidities and less physical functional reserve (ie, the difference between a person's maximum physical capacity and the minimum necessary to perform daily functioning), they may benefit from tailored approaches to treatment.[6,7]

The first step in developing a tailored approach is to assess a patient's overall health status including a frailty assessment to most appropriately align treatment recommendations with each patient's goals and ability to tolerate treatment. Frailty is a state of vulnerability to external stressors, leading to poor health outcomes. Phenotypically, frail patients experience declines in multiple physiologic systems, resulting in decreased mobility, muscle strength, bone density, balance, motor processing, cognition, endurance, and physical activity. The biology of frailty is complex, with mechanisms spanning inflammation, loss of stem-cell regeneration, DNA damage, metabolic decline, hormone dysregulation, epigenetic changes, and loss of proteostasis.[8] The prevalence of frailty in patients with cancer is high—more than half of older patients with cancer are estimated to have either prefrailty or frailty.[9] One important contributor to frailty is a decrease in testosterone. An estimated 50%-80% of men older than 80 years have hypogonadism, which is associated with decreased muscle mass and bone density, as well as increased falls.[10] This is especially relevant to men with prostate cancer because treatment of advanced and metastatic disease is reliant on androgen deprivation therapy (ADT), which depletes testosterone and can accelerate frailty. In one cohort of prostate cancer survivors, those who had current or previous exposure to ADT were more than twice as likely to be classified as prefrail or frail (40%-43%) compared with those never exposed to ADT (15%).[11] Even short courses of ADT can result in sarcopenia, muscle weakness, declines in bone mineral density (BMD), fatigue, reduced activity levels, and falls.[10]

Identifying frailty or prefrailty in men with prostate cancer can allow the clinician to make decisions around whether to offer prostate cancer–directed therapy and to identify interventions that improve the patient's physical reserve. In the first part of this review, we discuss risk assessment and decision-making tools that can be used in the management of older men with prostate cancer. In conjunction with implementing these assessment tools in the oncology clinic, it is paramount to also have a plan in place for addressing the potential deficits identified. Studies have demonstrated the importance of having an intervention plan and have also shown the significant variation in the rate of interventions after completing a geriatric assessment (GA).[12] The second part of this review will discuss specific interventions that can reduce frailty and improve treatment tolerance in

PRACTICAL APPLICATIONS

- Geriatric assessments allow for a standardized approach to the evaluation of older adults with the goal of improving informed decision making, acting on intervenable areas, and improving the ability to receive maximally tolerated cancer therapy.
- Clinicians should consider estimating non-cancer–related life expectancy for patients older than 65 years and consider performing geriatric screening with a brief geriatric screening tool, cognitive screening, and an estimate of chemotherapy toxicity with validated tools in patients planned to undergo cytotoxic chemotherapy.
- Before initiation of treatment for older men with prostate cancer, targeted interventions to reduce reversible aspects of frailty should be implemented.
- Universal bone health screening with dual-energy x-ray absorptiometry and selective use of bone antiresorptive therapies is critical in older patients beginning and continuing long-term androgen deprivation therapy.
- Decision making for older patients with prostate cancer should mirror other populations by incorporating patient's goals and values for care and quality of life and may need additional consideration of financial toxicity, social domains, and barriers to care because of the potential vulnerability in older age.

men with prostate cancer, highlighting evidence from prospective studies of interventions that may comprehensively address frailty among men with prostate cancer. The final section will discuss how to synthesize the use of assessment tools and interventions with recent treatment advances in prostate cancer while also considering the social determinants of health at play for each individual (Fig 1).

RISK ASSESSMENT AND DECISION TOOLS FOR OLDER MEN WITH PROSTATE CANCER

Relying on traditional indicators, such as the Eastern Cooperative Oncology Group performance status or Karnofsky performance status (KPS), to predict risk of adverse outcomes with cancer treatment is inadequate in an older adult population. Several studies have shown that these traditional tools are inaccurate assessments of functional status in older adults with cancer.[13-15] GAs provide a standardized approach to the evaluation of older adults to enable informed discussions with patients and caregivers. They also serve to identify reversible areas of frailty that may be intervened upon to improve a patient's ability to tolerate therapy. These assessment tools are not interventions in and of themselves, but rather can point the clinician to appropriate interventions. Understanding non-cancer–based life expectancy, screening for geriatric syndromes, and estimating toxicity associated with specific therapies, including chemotherapy, can improve outcomes for older adults with prostate cancer by ensuring that patients get the optimal balance of disease-directed treatment and support.

Life Expectancy Calculators

Life expectancy calculators are used to estimate non-cancer–based life span. This estimate can inform discussions around the expected risks and benefits of cancer treatment in relation to natural life expectancy. Given the significant heterogeneity in life expectancy among older adults, a validated life expectancy calculator that considers patient-specific factors may mitigate the risk of both over and undertreatment.

The Social Security Administration (SSA) releases actuarial life tables for the US population solely on the basis of age, which can be used to generate a rough life expectancy estimate on the basis of population statistics but does not include specific individual patient characteristics. In a study of 39,191 patients with localized prostate cancer, SSA life tables underestimated survival in patients undergoing brachytherapy, those with D'Amico low-risk disease, and those undergoing radical prostatectomy.[16] In a subset analysis of patients older than 75 years, the difference was even more pronounced.[16]

Other tools may give a more accurate estimate, although they have not been investigated specifically in the prostate cancer setting. Both the Lee Index and the Schonberg Index are well-validated tools for community-dwelling older adults that were created and validated from separate large US-based populations.[15,17-20] The website ePrognosis, produced by the University of California, San Francisco, contains an online calculator that synthesizes the inputs for both indices and produces separate estimates for each (ePrognosis[21]). These calculators account for age, sex, comorbid conditions, functional status, and lifestyle factors. In indices that have a variable for the presence of cancer, answering "no" will allow for an estimate of non-cancer–related life expectancy, which is relevant when trying to understand the overall benefit of cancer therapy. Machine learning–based prognostic calculators are being developed that may provide more accurate prognostic assessments using variables commonly found in the electronic health record.[22]

Geriatric Assessment

GA refers to assessing domains where older patients frequently have needs to characterize overall health status.

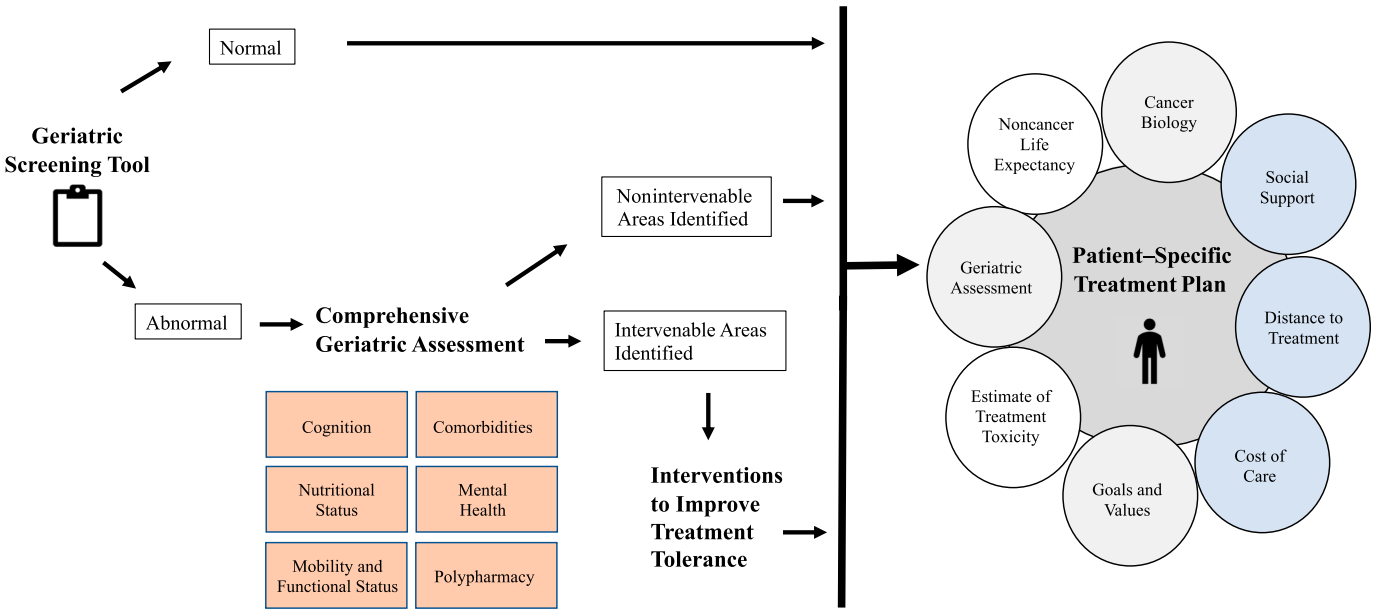

FIG 1. Patient-centered approach to the care of older men with prostate cancer.

The domains of the GA are functional status, mobility, cognition, nutritional status, mental health, comorbidities, polypharmacy, and social support.[23] The use of GA may improve outcomes of patients with prostate cancer by unearthing conditions that may affect cancer treatment tolerance, estimating frailty and resilience, and guiding the clinician by identifying areas in which interventions may be applied to maintain or improve function and quality of life by decreasing cancer treatment toxicity, increasing resilience, and improving communication.[15,23-26]

The areas of the GA can be assessed in several ways, including objective physical performance measures, validated instruments, and detailed history taking. No singular method has been shown to be superior to others, and the choice of how to obtain a GA should be based on the resources and structure of the specific clinical setting that they are being obtained.[23]

Several shorter screening tools are available that can be used to screen patients for those most likely to benefit from a complete GA. The use of a screening tool is more easily implemented than a comprehensive GA and can then focus resources on those in need of further in-depth assessment. The Geriatric 8 (G8) screening tool is validated and highly referenced in geriatric oncology.[27] This screening tool encompasses eight questions that take 4-5 minutes to complete and covers screening for food intake, weight loss, mobility, neuropsychological conditions, body mass index, polypharmacy, self-assessed health status, and age.[28] The G8 ranges from 0 to 17, with lower numbers associated with increasing frailty. In patients with cancer, scoring below 14 has an 85% sensitivity and 64% specificity for detecting frailty.[27] An alternative screening tool, the Vulnerable Elders Survey-13, has a higher specificity (70%-100%) but a lower sensitivity (20%-72%).[29] Either of these tools can be used to screen patients and refer those who are at risk of having an impairment for a complete GA. In one single-center prospective study of the G8 screening tool in 540 patients with localized and metastatic prostate cancer, G8 scores of $\leq$14 were observed in 70% of patients with metastatic disease, 36% of patients with localized disease undergoing radical prostatectomy, 57% of patients with localized disease being treated with radiotherapy, and 91% of patients with localized disease treated with ADT alone. In the metastatic population in that study, OS was significantly different between patients with G8 scores $\leq$13 and >13 (hormone-sensitive disease; P = .049) and between patients with G8 scores $\leq$12 and >12 (castrate-resistant disease; P = .022).[30] This suggests that G8 screening is feasible to administer and may have prognostic value in the prostate cancer population, as it does in other populations.[23]

The Mini-Cog is a validated assessment tool to screen for cognitive impairment. While the G8 contains a question about the presence or absence of dementia, the Mini-Cog provides an objective screen that encompasses three assessments and takes less than 3 minutes to complete. Patients are asked to register three words, then asked to draw a clock, and finally asked to recall the three words in step 1. In a large (nononcologic) population-based sample, the Mini-Cog had a 76% sensitivity and 89% specificity for

dementia.[31] The Mini-Cog is scored out of 5, and a score of 3 or less has been validated for dementia screening. A score of ≤3 suggests the need for a referral for more complete testing. The Mini-Cog is more sensitive and equally as specific for the detection of dementia and mild cognitive impairment as other dementia screening tools, including the Mini-Mental State Examination, which takes longer and is more affected by education level.[32,33] Identifying baseline cognitive impairment in men with prostate cancer allows clinicians to screen for reversible factors of decline (eg, nutritional deficiencies, alcohol use, mood disorders, and medication adverse effects) and enables an informed discussion of treatments risks, many of which have been associated with cognitive decline.[34] Cognitive impairment may also affect a patient's ability to understand treatment options and manage side effects and may prompt the clinician to increase the involvement of caregivers in treatment decisions and use other patient-specific tailored strategies to improve treatment tolerability.

Predicting Chemotherapy Toxicity

Specific tools have been developed to identify older patients at increased risk of chemotherapy toxicity and to quantify the risk of chemotherapy in these patients. This is relevant for older patients with prostate cancer, as docetaxel and cabazitaxel are cytotoxic chemotherapy agents that are frequently used in the treatment of metastatic prostate cancer.[35-37] The Cancer and Aging Research Group (CARG) toxicity tool uses 11 items, of which five are GA items. This tool has been shown to perform better at predicting chemotherapy toxicity than the KPS.[14,38] It is available for free online and takes approximately 5 minutes to complete (Cancer and Aging Research Group[39]).[15] Because it has predominantly been evaluated in terms of chemotherapy toxicity, future work defining the utility of the CARG toxicity tool in terms of predicting risks related to poly(ADP-ribose) polymerase (PARP) inhibitors, radiopharmaceuticals, and other novel approaches to treatment is necessary.

The chemotherapy risk assessment scale for high-age patients (CRASH) tool can also be used to predict chemotherapy toxicity. It has been validated for patients 70 years and older.[40] The CRASH tool takes longer than the CARG tool to complete, but can be considered a GA in and of itself.[15] The CRASH tool estimates the risk of grade 3 or higher hematologic toxicity as well as the risk of grade 3 or higher nonhematologic toxicity. The CRASH score is also available for free online (Senior Adult Oncology Program Tools[41]).

KNOWN AND NOVEL INTERVENTION STRATEGIES FOR OPTIMIZING TREATMENT TOLERANCE

Reducing Frailty in the Perioperative Setting

Radical prostatectomy has an important role in curative-intent treatment for men with localized prostate cancer. Numerous studies have shown that frailty is associated with increased risk of major postoperative complications for patients undergoing a wide range of surgical procedures. This holds true for frail patients treated with radical prostatectomy, who have higher rates of complications, longer length of stay, and higher rates of non-home discharge compared with their less frail counterparts.[42]

Two strategies have been used to mitigate frailty perioperatively: (1) prehabilitation to increase the patient's physiologic reserve preoperatively and (2) coupling formal frailty assessments with multidisciplinary management to tailor intraoperative and postoperative management. Prehabilitation, or enhancing a frail patient's physiologic reserve through physical therapy and nutritional optimization, has been shown to improve outcomes before some surgeries. In a systematic review of eight randomized controlled trials with 856 patients undergoing cardiac surgery, preoperative physical therapy reduced postoperative atelectasis, pneumonia, and length of hospital stay.[43] Unfortunately, to date, prehabilitation studies have not demonstrated similar clinical benefit in patients undergoing cancer surgery generally or urologic oncology surgeries specifically.[44,45] Further investigations are needed to define methods that optimize prehabilitation programs for patients undergoing radical prostatectomy.

Preoperative assessments of frailty predict postoperative outcomes and should be used in addition to surgical risk-assessment tools in risk-stratifying patients before surgery.[46] A growing body of evidence suggests that coupling formal frailty assessments with multidisciplinary management may improve mortality when used to guide intraoperative care. Hall et al evaluated 9,153 patients undergoing elective non-cardiac surgery who participated in a preoperative frailty screening initiative.[47] If a patient was identified as frail by Risk Analysis Index score ≥21 and confirmed on review from the chief of surgery or designee, clinicians from surgery, anesthesia, critical care, and palliative care were notified to potentially modify perioperative plans if indicated. One goal was to use shared decision making to clarify goals and expectations for the surgery and postoperative recovery. For instance, a diagnosis of frailty could change the decision to operate, the surgical approach, or the anesthetic plan. Palliative care consultation, when appropriate, could enhance discussions around ventilator dependence, dialysis, and do-not-resuscitate or do-not-intubate status. After implementation of this frailty screening initiative, among frail patients, 30-day mortality significantly improved (12.2% before implementation to 3.8% after implementation), as did 6-month mortality (24% to 7.7%) and 1-year mortality (34.5% to 11.7%). Further studies are warranted to understand whether a similar approach is beneficial for patients undergoing prostatectomy.

Reducing Frailty in Patients Receiving ADT

The primary definitive alternative to radical prostatectomy is radiotherapy, often administered with a prescribed course of

ADT. In the metastatic disease setting, ADT is generally administered continuously. ADT carries risks regardless of whether it is given for a finite period or indefinitely. In one study, prostate cancer survivors with a history of ADT exposure experienced nearly double the risk of falls.[11] Notably, this elevated fall risk was also seen in patients no longer receiving ADT, suggesting that even after cessation, the effects of ADT on frailty do not completely reverse. This may in part be explained by the link between ADT and sarcopenia—as lean body mass is lost, it may be difficult to rebuild after cessation of ADT.

More work is needed to develop interventions that reduce falls in patients receiving ADT. Nutritional optimization, exercise, and physical therapy are hypothesized to reduce the risk of falls, but as of now, there are no high-quality prospective trials. In a systematic review and meta-analysis of 33 randomized controlled trials of exercise interventions in patients with prostate cancer, exercise had a moderate-to-large effect on cardiovascular fitness and lower body strength; however, these trials did not specifically evaluate patients who were frail.[48] Ongoing trials, such as GET FIT Prostate, are specifically enrolling frail patients with prostate cancer who have either fallen in the past year or are at high risk of falling and assessing the use of supervised programs, such as strength training or Tai Ji Quan training.[49] If second generation androgen signaling inhibitor intensification is being considered in frail patients with high fall risk, abiraterone or daralutamide can be considered in lieu of apalutamide and enzalutamide. The latter two ARSIs cross the blood-brain barrier and are associated with elevated risk of fall and fracture.[50]

ADT can also result in obesity, impaired insulin sensitivity, and cardiovascular complications. Although specific guidelines have not yet been developed, all patients should be counseled on these complications and encouraged to maintain an active lifestyle and heart-healthy diet. In patients at especially high risk of atherosclerotic cardiovascular disease, luteinizing hormone-releasing hormone (LHRH) antagonists can be considered in lieu of LHRH agonists. The LHRH antagonists are hypothesized to have plaque-stabilizing effects, but the precise mechanism of the possible decreased risk of cardiovascular events compared with LHRH agonists has yet to be defined. In the phase 3 HERO trial, patients who received oral relugolix had a lower incidence of major adverse cardiovascular events at 2.9% in comparison with 6.2% in those treated with leuprolide (hazard ratio, 0.46; 95% CI, 0.24 to 0.88).[51]

Optimizing Bone Health in Older Patients Receiving ADT

In a study of 618 men with newly diagnosed prostate cancer, before ADT initiation, 41% met criteria for osteoporosis, 39% for osteopenia, and only 20% had normal BMD.[52] The presence of low BMD is associated with increased fragility fracture risk, which can contribute to decreased mobility, isolation, and loss of independence, particularly in an older adult population. This high prevalence of abnormal bone density at baseline is exacerbated by ADT use. Within the first year of ADT treatment, BMD decreases by approximately 2% at the hip and 3% at the lumbar spine and is associated with a 10%-20% risk of significant fracture at 5 years.[53,54] Pathologic and nonpathologic fractures are a major source of morbidity in men with prostate cancer and are correlated with poor survival outcomes.[55,56]

For men initiating ADT, bone health management with universal dual-energy X-ray absorptiometry (DXA) screening, adequate calcium (1,000-1,200 mg daily from food and supplements) and vitamin D3 (400-1,000 international units daily) intake, and selective administration of antiresorptive therapy should be implemented to reduce future fractures (Table 1).[57] In men with metastatic castrate-sensitive prostate cancer (mCSPC), guidelines recommend that bone antiresorptive therapy (denosumab, zoledronic acid, or alendronate) be reserved for men with either a history of fracture or high risk of future fracture. To define that risk, before receiving ADT, men with mCSPC should be screened with bone DXA scans to evaluate their BMD. Men with osteoporosis (BMD T-score ≤ -2.5) or high-risk osteopenia (BMD T-score between –1.0 and –2.5 and 10-year probability by fracture risk assessment tool of either hip fracture $\geq 3\%$ or major osteoporosis-related fracture $\geq 20\%$) are considered high-risk and should receive bone antiresorptive therapy.

Randomized trials have failed to show reductions in skeletal-related events (ie, pathologic fracture, palliative radiation to the bone, spinal cord compression, or surgery to the bone) when proactively administering antiresorptive therapy (eg, bisphosphonates or denosumab) to all men with mCSPC.[58-60] Even when analyses were restricted to patients who presented with bone metastases, zoledronic acid did not reduce skeletal-related events.[58] Overuse of antiresorptive therapy in mCSPC has been prevalent in recent years. In one real-world study, 18% of Medicare patients with mCSPC but without evidence of increased fracture risk received antiresorptive therapy, which confers a risk of side effects (eg, gastrointestinal irritation, hypocalcemia, or rarely, osteonecrosis of the jaw) and financial burden in a population that is unlikely to experience improved clinical outcomes.[57] Unfortunately, real-world use of DXA screening is also low—only 8% of Medicare patients with mHSPC initiating ADT receive baseline DXA screening.[61] Emerging technologies, such as biomechanical computed tomography (CT), a radiomic technique that measures BMD and bone strength from routine CT scans, may be used in the future to assess fracture risk without the need for DXA.[62] This approach would enable clinicians to define risk of fracture in all older adult patients who were staged by CT scans, allowing improved rates of bone density screening in a high-risk population without the burden of additional testing.

TABLE 1. Summary of Recommendations

Clinical Setting	Tools	Management Recommendations
All patients older than 75 years, consider for patients older than 65 years	Cancer-based assessment of prognosis Non-cancer–related life expectancy Social Security Administration life table Lee Index Schonberg Index ePrognosis GA screening Geriatric-8 screening tool (4-5 minutes) Vulnerable Elders Survey-13 (4-5 minutes)	Referral for comprehensive GA if any deficiencies seen on screening. Identify resources and targeted interventions needed to maintain independence Assess patient goals and values for care and quality of life Communicate options in the context of these factors
	Cognitive impairment assessment Mini-Cog (3 minutes)	Neuropsychiatric testing if possible dementia identified
	Financial toxicity assessment Financial screening question	Involve financial services if support is needed
Surgical resection	Frailty assessment Risk Analysis Index Score	Used to identify whether surgery is appropriate, and if so, what perioperative considerations should be made. Consider prehabilitation (physical therapy and nutritional optimization)
ADT	Bone health management DXA scan on initiation of ADT FRAX calculator	Indications for bone antiresorptive therapy along with vitamin D/calcium mCSPC and previous fracture, osteoporosis (BMD T-score ≤ -2.5), or high-risk osteopenia (BMD T-score between –1.0 and –2.5 and 10-year probability by FRAX of either hip fracture $\geq 3\%$ or major osteoporosis-related fracture $\geq 20\%$) mCRPC and bone metastasis
	Fall risk	Consider physical therapy referral and/or strength training Consider abiraterone or darolutamide in lieu of apalutamide or enzalutamide
	Cardiovascular health	Cardiovascular risk factor optimization Maintain an active lifestyle Heart-healthy diet Consider relugolix in lieu of LHRH agonists
Chemotherapy	Estimate chemotherapy toxicity CARG toxicity CRASH tool	Consider whether to use chemotherapy, adjust doses, and/or monitor more carefully

Abbreviations: ADT, androgen deprivation therapy; BMD, bone mineral density; CARG, Cancer and Aging Research Group; CRASH, chemotherapy risk assessment scale for high-age patients; DXA, dual-energy X-ray absorptiometry; FRAX, fracture risk assessment tool; GA, geriatric assessment; LHRH, luteinizing hormone-releasing hormone; mCRPC, metastatic castration-resistant prostate cancer; mCSPC, metastatic castrate-sensitive prostate cancer.

Improving Tolerance to Chemotherapy

In older patients for whom systemic chemotherapy is being considered, formal GA and multidisciplinary management should be used before initiation of therapy. The GAP70+ cluster randomized controlled trial included patients with cancer who were older than 70 years. Participants who had at least one impaired GA domain who received a tailored GA summary with management recommendations had lower rates of grade 3-5 adverse events (51% *v* 71%; relative risk [RR], 0.74; $P = .0001$) and fewer falls over 3 months compared with those with impairment who did not receive a tailored GA summary (12% *v* 21%; RR, 0.58; $P = .0035$).[63] Similarly, in the GAIN randomized controlled trial, patients who received a GA and multidisciplinary intervention had fewer grade ≥ 3 adverse events compared with participants who received GA alone (51% *v* 61%; $P = .02$).[24] In contrast, the 5C trial was a recent trial that failed to show the benefit of GA and management in patients older than 70 years receiving chemotherapy for cancer.[64] The authors speculated that this could have been because the intervention was conducted after chemotherapy was initiated (and thus was less likely to trigger changes in the plan) and the population was unselected (one-third of patients did not have any impaired frailty domain).

INTEGRATING ASSESSMENTS AND INTERVENTIONS FOR OLDER MEN WITH PROSTATE CANCER IN THE SETTING OF RECENT TREATMENT ADVANCES

Treatment of prostate cancer, particularly advanced prostate cancer, has dramatically changed in the past 10 years,

with more men receiving intensified treatment earlier in their disease course.[65] While these additional treatments significantly improve overall survival, they also have the potential for added toxicity over longer periods of time. Among the most relevant recent developments is the advent of earlier treatment intensification for mCSPC, with agents such as docetaxel chemotherapy with or without secondary hormonal agents as well as secondary hormonal agents alone.[65-71] In trials of secondary hormonal agents, the proportion of men who were 75 years or older ranged from 20% to 25%, and in the CHAARTED trial of early docetaxel chemotherapy, 22% of men were 70 years or older.[66-68,72] In addition, in certain patients with mCSPC, treatment of the primary tumor with definitive radiation can also improve overall survival.[73] In the metastatic castration-resistant prostate cancer (mCRPC) setting, multiple novel treatment strategies with unique side effect profiles are now used. PARP inhibitors are increasingly used alone or potentially in combination with secondary hormonal agents in patients with homologous recombination repair (HRR) mutations.[34,74] In addition, the prostate specific membrane antigen (PSMA)-targeted radionuclide therapy, ^{177}lutetium PSMA-617, has been approved for use in patients with PSMA positron emission tomography–positive disease, with ongoing trials looking at moving it earlier in the disease course.[75,76] Finally, trials continue exploring the role of additional agents in the curative setting, building on the evidence of the benefits of abiraterone/prednisone in addition to radiation therapy and ADT in men with very high-risk localized prostate cancer.[77]

Particularly for older men, clinicians must carefully weigh the benefits of treatment with systemic agents alone or in combination with the trade-offs in terms of side effects, functional status, and quality of life.[65,78,79] Careful attention to the points raised in this article will help clinicians navigate these clinical decisions and conversations with patients. In this section, we will describe specific clinical contexts in which geriatric approaches to evaluation and management can help support optimal clinical care for older men with prostate cancer.

Treatment Decision Making in the Context of Advanced Age

A key concept in the care of older men with prostate cancer is finding the optimal balance between overtreatment and undertreatment, particularly given competing risks of death from cardiovascular and other comorbidities, as well as overall frailty. On the other hand, for older men with prostate cancer in robust health, intensive treatment strategies may be warranted. In this setting, a GA may protect against age-related bias against treatment. Whether the question is that of overtreatment or undertreatment, the main goal for the clinician is to develop a holistic assessment of the patient's clinical and functional status beyond their chronologic age and understand how cancer therapy fits within that context and the patients' goals and values.

On the basis of the information presented in previous sections, we suggest a five-step approach to assessing older men with prostate cancer as they begin treatment.

1. Cancer-based assessment of prognosis (traditional cancer staging and treatment decision making).
2. Aging-based prognosis separate from cancer-based prognosis (ie, life expectancy calculators and geriatric screening tools).
3. Identification of resources needed to maintain independence using GA and targeted interventions.
4. Assessment of patients' goals and values for care and quality of life.
5. Communication about options with the patient and caregivers in the context of the above factors.

To illustrate decision making using this approach, several examples follow.

Metastatic Hormone-Sensitive Prostate Cancer: Early Intensification of Therapy

Case 1. A 72-year-old man with a history of coronary artery disease and coronary artery bypass grafting 2 years before presentation and insulin-dependent diabetes presented to the emergency department with severe back pain. Before his presentation, he was ambulatory and independent in all activities of daily living. Imaging demonstrated diffuse spinal metastatic disease and concern for cord compression. Prostate-specific antigen (PSA) was 1,500, and he was started on a LHRH antagonist in the hospital with significant symptomatic relief. He presented 1 month later for his first outpatient follow-up visit to discuss further treatment recommendations. He is no longer on pain medications and has recovered to his baseline level of functioning, and his PSA is 180 with castrate levels of testosterone.

On considering this patient's cancer-based assessment, he had high-volume metastatic disease, and in addition to being maintained on ADT, treatment intensification was warranted. With the advent of docetaxel chemotherapy and secondary hormonal agents in the mCSPC setting, doublet therapy is now the standard of care.[72,80] Recent data from the ARASENS and PEACE-1 trials suggest that clinicians should consider triplet therapy with ADT as well as both docetaxel and a second-generation androgen signaling inhibitor in patients with de novo and high-volume mCSPC. On the basis of cancer considerations alone, this patient merits consideration of the most aggressive treatment course possible given his dramatic presentation.[70,81]

However, assessment of this patient should consider his other comorbidities and functional status as well as his evolving health in the setting of already-initiated cancer treatment (ie, his dramatic improvement in symptoms and functional status with ADT alone). A post hoc analysis of the PEACE-1 trial demonstrates the importance of this. On

average, older (≥70 years) men derived less benefit from triplet therapy than younger (<70 years) men. However, older men who were fit enough to receive triplet therapy derived similar benefit compared with younger patients.[82]

His history of coronary artery disease and diabetes placed him at higher risk of treatment-related side effects both from chemotherapy and hormonal therapy. If chemotherapy is given, close attention to neuropathy, hyperglycemia (with steroid premedication), cytopenias, and infectious complications will help mitigate complications related to chemotherapy.

Geriatric screening and assessment may also identify other areas of need to help improve tolerance to this intense treatment strategy. Additional supports offered through oncology practices could include physical therapy and nutrition consultation. Social work resources and involvement of caregivers can ensure adequate resources at home, including food and transportation to treatment and follow-up visits. For patients with complex support symptoms or a poor prognosis requiring more intensive management, palliative care consultation is recommended.[83]

Unlike the paradigm for geriatric oncology in other cancer types, the possibility of durable, long-term response and preserved quality of life in older men with mCSPC make the discussion of the risks and benefits of treatment more complex. A focus on supporting patients through optimal treatment rather than avoiding treatments perceived as too toxic for older patients could be an important shift in mindset. In patients with less than 5-year survival for reasons other than their prostate cancer, an approach of ADT alone in the mCSPC setting can be reasonable and appropriate, particularly if patients are asymptomatic from their cancer and have lower volume disease. However, given evidence from multiple trials and real-world data sets of the relative tolerability of novel mCSPC treatment regimens, the population ineligible for intensification beyond ADT is expected to be extremely small.[65,84,85]

Essential to the management of patients is close monitoring for the side effects of ADT and secondary hormonal agents. Studies focused on other cancer types have shown the benefits of proactive symptom monitoring in patients with cancer receiving chemotherapy, and a reasonable degree of monitoring for toxicities of treatment is merited.[86,87] As discussed earlier, attention to bone density, obesity, sarcopenia, metabolic syndrome, and cognitive toxicities because of treatment is essential to ensuring good clinical outcomes for this population.[53,88,89]

Metastatic Castration-Resistant Prostate Cancer: The Promise of Targeted Therapy Balanced With Potential Toxicities

Case 2. An 86-year-old man with a history of chronic obstructive pulmonary disease and Gleason 8 prostate adenocarcinoma was treated 6 years ago with external beam radiotherapy and 2 years of ADT. Two years ago, he experienced a metastatic, asymptomatic recurrence to the pelvis and spine and was placed on continuous ADT intensified with apalutamide. His PSA nadir was nearly undetectable. Recently, he presented with a sharply rising PSA and innumerable new bone lesions throughout the axial and appendicular skeleton. He remains asymptomatic from his metastases, and he requires assistance for some activities of daily living because of arthritis and sarcopenia. He presents for initial treatment planning for mCRPC.

Primary treatment options for first-line mCRPC include docetaxel chemotherapy, sipuleucel-T, radium-223, and targeted treatments, such as PARP inhibitors and pembrolizumab. It is important to recognize that a subset of men with pathogenic mutations in HRR genes may benefit from PARP inhibitors, making germline and somatic genetic testing critical parts of understanding treatment options in mCRPC. Deciding between these options is dependent on the presence/absence of symptoms, likelihood of treatment toxicity, and overall assessment of the patient's ability to tolerate treatment. Men with mCRPC and osseous metastases should also receive bone antiresorptive therapy.

Frailty and performance status in mCRPC are challenging to assess because functional deficits could be related to age and comorbidities but also because of symptoms of cancer itself (eg, bone pain) or previous treatment toxicities (eg, neuropathy from previous docetaxel). In particular, in the mCRPC setting, patients are more likely to be symptomatic from their disease and experience more toxicities from treatment than patients with mCSPC. The conversation with patients about treatment options should balance estimates of life expectancy, expected toxicities, and patient goals and values. For instance, a conversation with this patient about his goals with therapy should focus on the potential trade-offs between length of life, quality of life, and prevention of symptomatic skeletal events, among other toxicities.

Addressing Social Determinants of Health

Health care disparities. There are well-documented health care disparities in men with prostate cancer from underrepresented minority backgrounds, including Black and Latino men. Differences exist in access and use of diagnostic, therapeutic, and supportive cancer care as well as differential cancer outcomes.[90-92] Persistent disparities in prostate cancer incidence and mortality have profound implications for ethnic minorities, with Black men, in particular, having almost a 50% higher incidence of prostate cancer compared with White men.[90-93] Although ADT and other novel therapies are effective treatments of prostate cancer, racial/ethnic minorities are still at increased risk of

prostate cancer-specific mortality.[92] Furthermore, Black and Hispanic/Latino men on ADT reported significantly lower quality of life (QOL) than White men, with about 20% lower uptake of health behaviors such as exercise accounting in part for up to 40% of this QOL difference.[33] However, there are more limited data on the outcomes of older men with minority backgrounds, and further studies on interventions to support this population are urgently needed.

Financial toxicity. Furthermore, discussions of intensification of therapy in older adults with prostate cancer need to incorporate an understanding of the financial costs of this additional therapy. Traditionally, ADT with leuprolide or other injectable medications is covered for most older adults through Medicare's Part A benefit. However, oral drugs are covered under Medicare's Part D prescription drug benefit. Patient financial responsibility for Part D medications is typically much higher than that for Part A medications.[94,95] While many oral medications for mCSPC and mCRPC have or will have patents expired and thus allow the production of cheaper generic versions, many of these drugs are exceedingly costly, to the tune of 10,000 dollars or more per month with patient access programs dwindling and discounted prices less and less available.[96] Asking patients about their cost concerns and involving financial services to support with more specific financial questions can help ensure that patients have access to and stay on optimal treatment.

CONCLUSION

Robust evidence suggests that the use of GA and other assessment tools can improve prognostication and risk stratification, can improve patient-centered and caregiver-centered communication, and can improve tailoring of care to an individual treatment to both avoid undertreatment but also excess toxicity.[23] Although guidelines vary on the age threshold to define an older adult, we suggest that for patients older than 65 years, the following assessments may be considered: (1) estimate of non-cancer–related life expectancy, (2) geriatric screening such as G8 or Vulnerable Elders-13 with referral for complete GA if possible deficits are identified, (3) Mini-Cog with referral for neuropsychiatric testing if possible dementia is identified, and (4) estimate of chemotherapy toxicity with either the CARG or CRASH tools in patients who are planned for cytotoxic chemotherapy. Older adults with prostate cancer have many integrated domains that may require consideration or intervention when treating a cancer. Special attention should be paid to optimizing bone health and reducing frailty to increase tolerance to both ADT and chemotherapy. In addition, this patient population is quite heterogeneous and may require a combination of consideration of their health data and social determinants of health. Many older adults have fixed income, have transportation barriers, require social support for clinic visits, and thus may need a socially conscious approach to their care inclusive of many of the tools we have listed above.

Genetic and Genomic Testing for Prostate Cancer: Beyond DNA Repair

Cameron Herberts, BSc[1]; Alexander W. Wyatt, PhD[1,2]; Paul L. Nguyen, MD, MBA[3]; and Heather H. Cheng, MD, PhD[4]

overview

Significant progress has been made in genetic and genomic testing for prostate cancer across the disease spectrum. Molecular profiling is increasingly relevant for routine clinical management, fueled in part by advancements in testing technology and integration of biomarkers into clinical trials. In metastatic prostate cancer, defects in DNA damage response genes are now established predictors of benefit to US Food and Drug Administration–approved poly (ADP-ribose) polymerase inhibitors and immune checkpoint inhibitors, and trials are actively investigating these and other targeted treatment strategies in earlier disease states. Excitingly, opportunities for molecularly informed management beyond DNA damage response genes are also maturing. Germline genetic variants (eg, *BRCA2* or *MSH2/6*) and polygenic germline risk scores are being investigated to inform cancer screening and active surveillance in at-risk carriers. RNA expression tests have recently gained traction in localized prostate cancer, enabling patient risk stratification and tailored treatment intensification via radiotherapy and/or androgen deprivation therapy for localized or salvage treatment. Finally, emerging minimally invasive circulating tumor DNA technology promises to enhance biomarker testing in advanced disease pending additional methodological and clinical validation. Collectively, genetic and genomic tests are rapidly becoming indispensable tools for informing the optimal clinical management of prostate cancer.

INTRODUCTION

Prostate cancer management has undergone substantial transformation within the past decade. Genetic and genomic testing has rapidly matured from a research tool to standard practice across multiple clinical settings, with importance reinforced via inclusion in key practice guidelines. Opportunities for genomic testing in routine practice are continually being refined and expanded, cultivating excitement about precision oncology among patients and prostate cancer health care providers. However, this sea change also emphasizes the importance of having a solid foundational understanding of the data to support clinical practice changes. End users must be aware of testing nuances and potential pitfalls, which transect not only clinical decision making but also patient education and medical resource stewardship. Here, we review key updates in genetic and genomic testing for prostate cancer, including clinical implications of testing for advanced disease, the role of RNA expression tests with emphasis on localized and recurrent disease, and emerging opportunities for minimally invasive plasma circulating tumor DNA (ctDNA) technology to affect the clinical management of advanced prostate cancer.

CLINICAL AND THERAPEUTIC IMPLICATIONS OF GENETIC AND GENOMIC TESTING IN PROSTATE CANCER

Implications of germline genetic testing (ie, testing for inherited alterations) and genomic testing (ie, testing a tumor for somatic and germline alterations) have precipitated major practice changes in the care of patients with prostate cancer, particularly in advanced disease. These changes were heralded by a series of key discoveries beginning in 2015. First, The Cancer Genome Atlas Research Network evaluated 333 primary prostate cancers and found that 19% harbored mutations in DNA repair genes.[1] This was followed up by a Stand Up to Cancer/Prostate Cancer Foundation/American Association for Cancer Research–lead effort sequencing 150 metastatic tissue biopsies collected from patients with castration-resistant disease, revealing that 23% had alterations in DNA repair pathway genes—most commonly within genes *BRCA2*, *ATM*, and *BRCA1*.[2] Shortly thereafter, another pioneering study reported that approximately one in 10 patients with metastatic prostate cancer carried a heritable (ie, germline) mutation in a DNA repair gene.[3] These and subsequent confirmatory studies[4-8] have demonstrated that the DNA damage response pathways—particularly homologous recombination repair (HRR) and mismatch repair—are recurrently altered in a large subset of patients and can drive aggressive prostate cancer biology. Clinically, DNA damage response alterations can confer therapeutic sensitivity to novel targeted agents and potentially constitute life-saving information in the context of navigating familial cancer risk.

DNA Damage Response Defects as Prognostic Biomarkers

Patients with prostate cancer who carry germline *BRCA* mutations are more likely to have poor clinical

PRACTICAL APPLICATIONS

- Defects in DNA damage response genes (eg, *BRCA1/2*, *ATM*, *MSH2/6*) are prevalent in approximately 15%-25% of patients with metastatic prostate cancer and confer treatment candidacy for poly (ADP-ribose) polymerase inhibitors and immune checkpoint inhibitors.
- Germline *BRCA2* pathogenic variants are linked to elevated risk of prostate cancer and have implications for intensified early cancer screening and familial risk management. Polygenic risk scores are poised to improve risk evaluation in future.
- RNA expression tests (using prostate tissue) can help inform treatment options for patients with localized disease, including decisions surrounding definitive local treatment and salvage therapy.
- Minimally invasive circulating tumor DNA (ctDNA) tests are used to identify treatment-predictive and prognostic biomarkers in advanced prostate cancer. Newer generations of tests are rapidly augmenting the biological resolution that can be gleaned from ctDNA but require further clinical validation.

outcomes, intraductal and cribriform morphology, and higher Gleason grades compared with their non-*BRCA* carrying counterparts.[9,10] Moreover, evidence suggests that *BRCA2*-defective localized prostate cancers have singularly aggressive biology resembling treatment-refractory metastatic disease. This is evidenced by greater genomic instability and increased (epi)genomic dysregulation of the WNT-pathway mediator complex (ie, *MED12L*/*MED12*) in *BRCA2*-defective localized disease, which are common molecular hallmarks of castration-resistant prostate cancer.[11]

The link between germline *BRCA1/2*-defective disease and clinical aggression is also supported by studies from Castro et al, who observed that germline *BRCA1/2* mutation carriers were more likely to have Gleason score $\geq$8 (P = .00003), T3/T4 stage (P = .003), nodal involvement (P = .00005), and metastases at initial prostate cancer diagnosis (P = .005). Germline *BRCA1/2* carriers also had shorter prostate cancer–specific survival (CSS)[12] and metastasis-free survival (MFS) after curative intent therapy: *BRCA1/2* carriers (n = 67) had 3-, 5-, and 10-year MFS rates of 90%, 72%, and 50%, compared with 90%, 94%, and 84% for non-*BRCA1/2* patients ($P < .001$), respectively.[13] Multivariable analysis incorporating standard clinical risk metrics for localized disease demonstrated that *BRCA1/2* mutations were independently prognostic for MFS (hazard ratio [HR], 2.36; 95% CI, 1.38 to 4.03; P = .002) and CSS (HR, 2.17; 95% CI, 1.16 to 4.07; P = .016).[13] Finally, a retrospective analysis of the Consortium of Investigators of Modifiers of BRCA1/2 cohort of 6,902 men reported an elevated prostate cancer risk for patients with germline pathogenic variants in *BRCA1/2*, affirming the relevance of germline *BRCA1/2* status for familial risk management.[14]

DNA Damage Response Defects as Biomarkers for Response to Poly (ADP-ribose) Polymerase Inhibitors

Recognition of DNA damage response defects as a core molecular driver of metastatic prostate cancer led to multiple clinical trials therapeutically exploiting these defects. Poly (ADP-ribose) polymerase inhibitors (PARPi) are a key targeted drug class developed initially in the context of breast and ovarian cancer. One of the first trials of PARPi in metastatic prostate cancer was the single-arm, phase II, TOPARP-A study, where patients with alterations in DNA damage response genes *BRCA2*, *ATM*, and *BRCA1* achieved significantly higher response rates to olaparib than biomarker-negative patients.[15] This observation fueled several important PARPi studies culminating in US Food and Drug Administration (FDA) approvals for patients with metastatic castration-resistant prostate cancer (mCRPC). The phase III PROfound study enrolled patients with mCRPC harboring DNA repair alterations who had progressed on at least one AR-pathway inhibitor (ARPI) and randomly assigned them to olaparib versus a second ARPI.[16] Patients in the olaparib arm had improved progression-free survival and overall survival,[16,17] leading to olaparib being the first FDA-approved PARPi for prostate cancer in 2020. The strongest signal was seen in patients with *BRCA1*, *BRCA2*, and *ATM* mutations, although rarer DNA repair gene alterations in *BRIP1*, *BARD1*, *CDK12*, *CHEK1*, *CHEK2*, *FANCL*, *PALB2*, *RAD51B*, *RAD51C*, *RAD51D*, and *RAD54L* are also included within the approval label. In the same year, the phase II TRITON2 study of rucaparib showed a 51% radiographic response rate for docetaxel-refractory patients with *BRCA1/2*-altered mCRPC,[18] leading to FDA-accelerated approval. Recently, multiple phase III studies have investigated the combination of PARPi plus ARPI for mCRPC,[19-21] consistently showing the greatest magnitude of PARPi benefit in patients whose tumors have germline or somatic DNA damage response defects. Several clinical-genomic registries are underway exploring novel biomarkers of PARPi response, including the PROMISE germline-focused registry (NCT04995198)[22] and the PRECISION PARPi-focused registry.[23]

Germline (ie, Inherited) DNA Damage Response Defects as Cancer Risk Genes

Given the relatively high prevalence of germline cancer risk genes and their growing significance in both familial and

therapeutic contexts, the National Comprehensive Cancer Network (NCCN) Prostate Cancer and American Urological Association/American Society for Therapeutic Radiology and Oncology/Society of Urologic Oncology Advanced Prostate Cancer guidelines advise genetic counseling and genetic testing for patients with metastatic or high-risk localized prostate cancer.[24-26] Identification of germline cancer risk genes in patients enables blood relatives to learn if they share the same cancer risk gene and could potentially benefit from cancer screening and/or risk-reducing and prevention options.

There are recognized and established early detection and risk-reducing options to mitigate breast and ovarian cancer risk, but the implications for male carriers of *BRCA1/2* and other prostate cancer risk genes are less widely recognized. On the basis of the associations of increased prostate cancer risk and aggressiveness overviewed above—as well as findings from the ongoing international United Kingdom–led Identification of Men with a Genetic Predisposition to Prostate Cancer study—there is a strong rationale for offering men with germline *BRCA2*, *BRCA1*, *MSH2*, and *MSH6* mutations intensified prostate cancer screening.[27,28] NCCN Prostate Cancer early detection guidelines currently recommend consideration of family history, Black ancestry and familial cancer risk genes (such as *BRCA2*) in prostate cancer screening decisions, and advise initiating screening at age 40 years for *BRCA2* carriers. Additional trials exploring screening and early detection are ongoing at the National Cancer Institute (ClinicalTrials.gov identifier: NCT03805919), Yale (ClinicalTrials.gov identifier: NCT02154672), University of Michigan, Israel (ClinicalTrials.gov identifier: NCT02053805), Sunnybrook (ClinicalTrials.gov identifier: NCT01990521), and University of Washington/Fred Hutch (ClinicalTrials.gov identifier: NCT04472338) and are expected to help clarify screening/interventional strategies for at-risk carriers.

In the foreseeable future, it is likely that further incorporation of genetic risk into screening optimization will occur across at least two domains. The first domain is refining risk prediction beyond the rare variants in genes such as *BRCA2*, *BRCA1*, *MSH2*, *MSH6*, and *HOXB13*. This combined approach involves simultaneously evaluating rare but higher penetrance genes (eg, *BRCA2*) together with more common but lower-risk variants (so-called polygenic risk scores), as recently reported.[29,30] This combined approach is promising due to its potentially broader applicability but will require additional study and validation in larger diverse populations.[31] The second domain is improving cancer early detection methods beyond prostate-specific antigen (PSA) and current imaging modalities. Excitingly, early cancer detection is a highly active research area precipitating advancements in novel DNA, transcription, methylation, and other genomic profiling technologies. These methodological developments will be reviewed (mostly in the context of biomarker profiling for advanced disease) in the section on ctDNA technology below. Overall, enhanced genetic risk prediction together with increasingly sensitive prostate cancer screening tools is positioned to help reduce prostate cancer–related mortality and morbidity.

Implementation of Germline Genetic Testing

Recommendations for germline genetic testing have recently expanded across the prostate cancer continuum. Testing is now standard practice for all patients with metastatic prostate cancer plus a significant fraction of patients with localized disease (eg, those with high-risk features and/or family history). An important challenge in prostate cancer management is determining how to optimally integrate cancer genetics care, which has been reviewed in a previous ASCO Education session.[32-34] However, broader implementation challenges exist, and consensus recommendations have been made to guide further development.[35] Increasing demand for genetic counseling and testing—coupled to existing accessibility barriers (eg, geographic constraints on in-person services)—has led to bottlenecks in testing, treatment decision making, and familial risk planning. Deficiencies in timely and accessible genetic testing have incentivized a number of experimental practical alternatives to traditional testing models. Efforts to broaden access and alleviate overburdened genetic specialists include the use of online patient video education, as well as reallocating responsibilities of consenting, testing, and/or counseling to oncology professionals (ie, "mainstreaming").[36] These and other novel germline genetic testing paradigms are being investigated prospectively (eg, GENTLeMEN,[37] ProGen,[38] and TARGET studies[39]). Nevertheless at present, collaboration with genetic experts remains crucial when a cancer risk gene is discovered, ensuring that patients and their families receive appropriate education[35] and access to relevant cancer prevention and screening services.

WHAT PROVIDERS NEED TO KNOW ABOUT PROSTATE CANCER RNA EXPRESSION AND HOW IT INFLUENCES MANAGEMENT DECISIONS

The D'Amico/NCCN Risk groups remain the dominant strategy to risk-stratify clinically localized prostate cancer. However, over the past several years, information about prostate cancer RNA expression has substantially augmented our ability to predict patient outcomes and has become an important tool in decision making for many patients with prostate cancer.

Most published literature focuses on the Decipher Genomic Classifier (GC). The Decipher GC uses the Affymetrix Human Exome 1.0st array and is based on a locked model of 22 genes, including genes relevant to cell proliferation, cell motility, cell differentiation, androgen receptor signaling, and immune modulation. This model was originally

developed to determine the risk of distant metastasis from radical prostatectomy (RP) specimens, and subsequently, a biopsy version of the test has been demonstrated to be prognostic after surveillance, surgery, or radiation.[40] Two other commonly used tests are the Myriad Prolaris test, based on 31 cell-cycle progression (CCP) genes,[41] and the Oncotype DX Genomic Prostate Score (GPS) that evaluates 17 genes including 12 cancer-related genes (androgen signaling, cellular organization, stromal response, and cellular proliferation) and five housekeeping genes.[42] Here, we review the clinical utility of these RNA expression-based GCs in different prostate cancer disease states.

Selecting Patients for Active Surveillance Versus Treatment

Each of the three GCs has shown some utility in identifying low-risk or favorable intermediate-risk patients at risk of progression while on active surveillance or patients who may harbor occult high-grade or stage disease. Therefore, these classifiers are useful for patients who may be borderline between definitive treatment and active surveillance as candidate management options.

Herlemann et al[43] reviewed 220 patients with favorable intermediate-risk prostate cancer who underwent RP and found that the Decipher GC independently predicted adverse pathology (defined as Gleason Grade Group 3-5, pT3b or higher, or N+ disease) with an odds ratio of 1.34 per 0.1 unit increased GC ($P = .002$). Interestingly, patients with GC low or intermediate (ie, <0.6) did not have an increased odds of adverse pathology compared with a population with exclusively very low- or low-risk prostate cancer, suggesting that patients with GC low/intermediate may be reasonable candidates for active surveillance.

Cuzick et al[44] showed in a cohort of 349 patients diagnosed by needle biopsy and managed conservatively that the Prolaris CCP score was the strongest independent predictor of death from prostate cancer (HR per one unit increase, 1.65 [CI, 1.31 to 2.09]; $P = .00003$). The 17-Gene Oncotype DX GPS score was shown to predict adverse pathology and increased risk of biochemical recurrence after RP among men who were initially on active surveillance.[45] Conversely, Lin et al[46] notably evaluated the performance of the GPS score in the Canary Prostate Cancer Active Surveillance Study cohort and did not find a significant independent association of higher GPS score with adverse pathology. In addition, there was no identified association between higher GPS score and subsequent biopsy upgrading in surveilled patients with low-risk prostate cancer who subsequently underwent prostatectomy.

Use of Androgen Deprivation Therapy with Radiation for Intermediate-Risk Prostate Cancer

All three classifiers can potentially help decide if patients with intermediate-risk prostate cancer should receive definitive radiation alone or with androgen deprivation therapy (ADT). Berlin et al[47] found that among a cohort of both favorable and unfavorable intermediate-risk patients managed with radiation alone, the Decipher GC predicted biochemical recurrence and metastasis, whereas the NCCN risk group was not predictive. This suggested that patients with high GC scores may warrant consideration for the addition of ADT to definitive radiation. This approach is being tested prospectively in the NRG-GU-010 trial (ClinicalTrials.gov identifier: NCT05050084) that aims to either intensify or deintensify therapy based on the Decipher GC score.

Tward et al[48] found among 741 patients treated with radiation that the Cell-Cycle Risk score (comprised by combining the Myriad CCP score with the UCSF CAPRA score) identified patients who benefited from ADT (ie, if they scored above the multimodality threshold of 2.112) versus had no benefit from ADT (ie, if they scored below the threshold of 2.112, where the 10-year risk of metastasis was 3.7%, regardless of ADT use). In a small study of 30 patients with Gleason 3 + 4 prostate cancer, GPS was associated with a higher percentage of Gleason pattern 4 at surgery, leading the authors to conclude that GPS may help inform the addition of ADT to radiation.[49]

Prognostication in High-Risk Disease

The role of GCs in changing treatment decisions for high-risk prostate cancer is less firmly established but can still offer prognostic information. A recent example is the Decipher GC was found to be prognostic for outcomes in three RTOG phase III trials.[50] This finding forms the basis for the NRG-GU-009/PREDICT-RT randomized trial that aims to determine whether the Decipher GC can identify patients whose ADT duration can be reduced from 24 to 12 months versus patients who may benefit from up-front treatment intensification with 24 months of ADT plus apalutamide (ClinicalTrials.gov identifier: NCT04513717).

Postprostatectomy Setting: Salvage Radiotherapy Alone Versus Salvage Radiotherapy + ADT

One of the most commonly used classifiers in the postoperative setting is the Decipher GC, which may inform whether to offer ADT with salvage radiation. While gonadotropin-releasing hormone agonists have been shown to improve metastasis-free survival when added to salvage radiation in both the GETUG-16[51] and RADICALS-HD trials,[52] the RTOG 96-01 trial[53] remains particularly influential because it showed that radiotherapy (RT) plus 2 years of ADT in the form of bicalutamide monotherapy 150 mg daily improved overall survival. A post hoc analysis of the RTOG 96-01 trial found that all the survival benefit of ADT was driven by patients with PSA $\geq$ 0.7, while patients with a PSA $<$ 0.7 did not benefit, causing reluctance among some providers to offer ADT with salvage radiation for patients with PSA $<$ 0.7.[54] However, in a reanalysis of the RTOG 96-01 trial, Feng et al[55] leveraged the

GC score to provide practical guidance on whether to add ADT to RT for patients with PSA < 0.7. This study showed that among patients with PSA < 0.7, those with a low GC score (<0.45) had worse overall survival with bicalutamide. However, patients with intermediate (≥0.45) or high (>0.6) GC score had better outcomes with bicalutamide, including less distant metastasis, reduced prostate cancer mortality, and better overall survival. Consequently, the Decipher GC score may help identify which patients with PSA < 0.7 (for whom salvage radiation is planned) would benefit from concomitant ADT.

Another GC that has shown promise in the post-prostatectomy setting is the PAM-50 classifier, which was adapted from breast cancer and recreated in a cohort of patients with prostate cancer who had the Decipher GC test. Prostate cancer samples can be classified into luminal and basal subtypes using the same Affymetrix Human Exome 1.0st array as the Decipher GC. Zhao et al[56] found that patients with tumors classified as luminal B benefited more from the addition of postoperative ADT than patients with nonluminal B tumor subtypes. The PAM-50 classifier is being tested prospectively in the NRG-GU-006 randomized trial of salvage radiation plus apalutamide or placebo for patients with rising postoperative PSA (ClinicalTrials.gov identifier: NCT03371719).

Androgen Signaling Inhibitor Benefit in Castrate-Resistant Prostate Cancer

The same PAM-50 classifier may also help prioritize choice of systemic treatment for patients with castration-resistant disease. Feng et al[57] observed that patients with non-metastatic castration-resistant disease and luminal tumor subtype are more likely to benefit from ADT plus apalutamide than ADT alone. In the mCRPC setting, Aggarwal et al[58] demonstrated a link between luminal subtype and biological features suggesting heightened androgen signaling, translating clinically to greater ARPI benefit for patients with luminal tumors versus other subtypes. Ultimately, PAM-50 classification may inform on the degree of tumor androgen reliance and facilitate appropriately tailored treatment.

In summary, RNA expression profiling for genomic classification has enhanced prostate cancer risk stratification in early disease, further broadening the repertoire of genomically informed management strategies across the prostate cancer continuum.

HOW CAN TECHNOLOGY HELP US? NEW AND EMERGING USES FOR ctDNA IN PROSTATE CANCER

As aforementioned, genomic biomarkers are increasingly used for clinical decision making in mCRPC, but challenges of tissue analysis impede integration of biomarkers into routine practice. Routine metastatic tissue biopsy is hampered by financial and health toxicity and high failure rates (16%-40%), especially for bone lesions.[59-61] In addition, archival tissues can be difficult to retrieve, exhausted by previous molecular profiling,[59,62] and may ultimately no longer molecularly reflect contemporaneous mCRPC shaped by often years of previous systemic therapy.[2,4]

Plasma ctDNA is an established minimally invasive source of predictive and prognostic biomarkers, overcoming many of the limitations of tissue-only testing.[63] High concordance of genomic alterations between metastatic tissue and ctDNA[64] plus comparative ease of collection has spurred incorporation of ctDNA profiling into mCRPC clinical trials, including recent pivotal trials of PARPi,[16,19,20,65] PI3K inhibitors,[66,67] and umbrella/platform trials that leverage profiling results for treatment arm assignment.[68-71] Finally, ctDNA testing can democratize access to precision oncology since blood samples can be drawn outside specialized cancer centers and mailed for centralized testing.[72]

Applications for ctDNA testing can be broadly categorized into quantification (ie, detection of ctDNA) or characterization (ie, identifying molecular biomarkers in ctDNA). Detection of ctDNA in mCRPC has prognostic implications across clinical scenarios. For example, high pretreatment ctDNA fraction (ie, the proportion of total cell-free DNA [cfDNA] that is tumor-derived rather than from other sources) is linked to poor treatment response, shorter progression-free survival, and abbreviated overall survival across multiple therapeutic contexts and independent of other established clinical prognostic markers.[73-81] The dynamics of the ctDNA fraction during treatment is a potential surrogate for treatment response, with the magnitude of ctDNA decline (relative to pretreatment levels) associating with time to progression on both taxanes and ARPIs.[74,76] Strikingly, changes in ctDNA fraction may be more informative than on-treatment PSA changes as an early metric of tumor response.

Characterization-based applications include using ctDNA to detect clinically relevant biomarkers, such as truncating defects in *BRCA2* that predict vulnerability to PARPi, as well as mutations in *TP53*, *RB1*, *SPOP*, *PTEN*, and *AR* that may inform prognosis and/or androgen dependency.[78,82] *AR* alterations are an acquired resistance mechanism to AR/androgen-axis drugs with prognostic and potentially predictive relevance but can only be detected in treatment-exposed ctDNA or metastatic tissue (ie, are not present in primary tissue).[1,80,83]

Importantly, ctDNA fraction largely determines which classes of alteration are amenable to de novo detection. Copy number variants (CNVs) require severalfold higher ctDNA fraction compared with mutations and in general detection sensitivity (for all alteration classes) scales with ctDNA fraction.[84] Low ctDNA fraction can therefore lead to

false-negative results, especially for deletions such as homozygous *BRCA2* or *PTEN* loss. Importantly, some testing platforms do not analyze matched white blood cell controls, potentially resulting in incomplete filtration of clonal hematopoietic variants which can manifest as false-positive ctDNA mutations.[85] It is therefore ideal to perform synchronous tissue and ctDNA testing to mitigate the limitations of each approach.

Beyond Targeted Panel Sequencing: The Promise of Broader DNA Profiling From Liquid Biopsies

Presently, clinical ctDNA tests typically use targeted panel sequencing: profiling of dozens to hundreds of cancer-related genes in parallel. Most ctDNA tests only capture coding exons, although some tests include introns implicated in recurrent oncogenic fusions. Targeted panel sequencing assays have high sensitivity for single-nucleotide variants (SNVs) and small insertions/deletions (InDels), moderate sensitivity for gene-level copy number changes (eg, *PTEN* deletions), and low sensitivity for complex structural rearrangements and large aneuploidies. Cost feasibility forces a practical tradeoff between sequencing depth (ie, redundant read coverage across target regions) and breadth (ie, number of genes or regions examined). However, diminishing sequencing costs are enabling broader sequencing methods such as whole-exome sequencing (WES) and whole-genome sequencing (WGS) to become cost permissive and clinically feasible at scale.

In contrast to targeted panel sequencing, WES enables detection of SNVs, InDels, and gene-level copy number changes across approximately 20,000 genes, while WGS extends detection to noncoding territory (eg, introns, enhancers, intergenic regions, and other types of regions). Growing data indicate that tumor defects in noncoding areas can drive aggressive cancer biology. Notable examples include *AR* enhancer copy gains[86,87] and genomic rearrangements with intronic breakpoints in *RB1*, *PTEN*, *BRCA2*, and *MSH2/6*.[5,7,88-91] Current clinical assays typically cannot detect these biologically relevant truncating rearrangements (due to not profiling introns), but newer iterations of broader tests will enable their detection in future. Finally, a key advantage of WES/WGS is enhanced resolution for whole-genome doubling (WGD). In prostate cancer, WGD is potentially linked to poorer prognosis and can confound accurate discrimination of homozygous from heterozygous deletions (in key genes such as *PTEN* and *BRCA2*).[92,93]

Tumor cell characteristics and clinical phenotypes are shaped by the totality of somatic and germline defects across the genome. Intriguingly, alterations in genes such as *BRCA2* and *MSH2/6* are associated with genome-wide scars whose quantification may be an alternative biomarker measuring the biological consequences of the gene alteration. WES and WGS enable synthesis of second-order information from all mutations, deletions, and structural rearrangements analyzed in aggregate, overcoming many challenges of detecting alterations within individual genes. These challenges include imperfect detection (eg, poor sensitivity for CNVs in low ctDNA fraction), difficulty of predicting alteration pathogenicity and/or likelihood of sensitization to targeted drugs, and inability to characterize nonsequence mechanisms of gene (in)activation (eg, epigenomic alterations).

Higher-order genomic readouts of emerging clinical relevance in mCRPC include tumor mutation burden, microsatellite instability, and CDK12-associated tandem duplications as predictors of immunotherapy response[91,94,95]; indices of overall genomic instability (eg, large-scale transitions, telomeric imbalance, genomic loss of heterozygosity) suggestive of HRR deficiency and PARPi candidacy[5,96-98]; and mutational signatures that reveal mutation etiologies (eg, tobacco exposure).[99] Sophisticated machine learning techniques (eg, gradient tree boosting) can optimally combine many higher-order genomic features for even more accurate identification of patients likely to benefit from targeted therapy.[100-103] These tools promise to help discover new single-gene and combinatorial genomic mediators of HRR/mismatch-repair deficiency, as well as characterize rare HRR gene defects (eg, *ATM*, *BARD1*, *RAD51* family genes) whose biomarker utility is currently uncertain.

Emerging Techniques for Tumor Phenotyping Using ctDNA

DNA alterations are the blueprint for cell phenotype, but regulation of the epigenome, transcriptome, and proteome also affect tumor behavior. New omic techniques are rapidly expanding the phenotype information that can be measured from ctDNA.

Neuroendocrine prostate cancer (NEPC) is a key clinically relevant phenotype in mCRPC but can be difficult to diagnose. Clinical presentation of NEPC can be heterogeneous, and classical NEPC features are often nonspecific (eg, low PSA),[104] metastatic tissue biopsies for definitive histopathological diagnosis are not always feasible and may not generalize to bulk disease, and known genomic correlates of NEPC (eg, *TP53*/*RB1* loss) are also nonspecific[105,106] and technically challenging to detect.[7,88] Treatment-related NEPC transdifferentiation is an increasingly prevalent clinical trajectory in mCRPC, ostensibly because of the growing cumulative exposure to AR-axis drugs across the spectrum of disease (eg, ARPI for castration-sensitive prostate cancer).[107-114] Therefore, there is mounting urgency to develop more accurate tools to detect treatment-induced NEPC and facilitate timely clinical intervention.

Epigenomic markers (eg, 5-methylcytosine and 5-hydroxymethylcytosine) are promising tools for tumor phenotyping.[115] ctDNA methylation assays can augment

biomarker characterization and classify samples according to global epigenomic features. Methylation assays can distinguish AR-driven mCRPC from NEPC, outperforming traditional DNA-sequencing approaches even in low ctDNA fraction.[116-119] Clinically, ctDNA methylation assays may assess tumor AR dependence, informing timing of treatment change as well as treatment choice (eg, ARPIs versus taxanes or platinum chemotherapy in tumors with low AR signaling). Methylation-based phenotypic subgroups beyond classical NEPC (AR–/neuroendocrine [NE]+)—such as amphicrine (NE+/AR+) and double-negative (NE–/AR–) states[120]—may also be linked to potential therapeutic vulnerabilities (eg, WNT-pathway activation).[106,114,121] Currently, methylation assays are only commercially available for early cancer detection.[122] Standardization and prospective validation are needed to define the role of methylation tests in the management of advanced prostate cancer.

Dying tumor cells release chromatin into the bloodstream as fragmented cfDNA and nucleosomes, which can be analyzed to gain insight into tumor transcriptional activity, gene regulation, and transcription factor binding patterns.[123-129] Fragmentomics is a promising new area that exploits the physical properties of ctDNA to inform tissue of origin and tumor phenotype. In mCRPC, fragmentomic features have been correlated with patient-matched metastatic tissue RNA abundance,[125] as well as AR- and NE-associated transcription factor activity.[123] In a recent article by De Sarkar et al, global fragment features were used to generate a model that classifies prostate cancers along a spectrum of AR- versus NE-driven disease, achieving 90.4% sensitivity (for predicting NEPC) and 97.5% specificity (for predicting AR-driven mCRPC).[128,129] Analogous to methylation-based assays, fragmentomic approaches are being investigated for early cancer detection.[130,131] Chromatin immunoprecipitation and sequencing of cell-free nucleosomes (cfChIP-seq) is another new method that retrieves DNA linked to epigenetically decorated nucleosomes, enabling multiplexed insight into gene regulation and global cell identity.[127] Overall, these experimental techniques are poised to augment the repertoire of ctDNA phenotyping approaches, with methylation techniques most analytically mature for potential clinical use in mCRPC.

Plasma cfDNA includes both DNA from tumor (ctDNA) and from noncancerous normal cells, yet this normal fraction is not currently used for oncology applications. Intriguingly, methylation sequencing and cfChIP-seq can potentially reveal clinically relevant information from normal cfDNA. Normal cfDNA primarily comes from hematopoietic cells, raising the possibility of characterizing immune activity and/or immune-related adverse events.[132] Other cell types can release cfDNA during specific host states, potentially offering measures of organ-specific treatment toxicities (eg, gastrointestinal adverse events) as well as noncancer comorbidities (eg, cardiac dysfunction) that complicate optimal oncological care.[127]

Ultimately, new sequencing and computational techniques that integrate genotype and phenotype are facilitating increasingly multimodal clinical profiling.

CONCLUSIONS

Over the past decade, detailed molecular dissection of thousands of prostate cancer specimens has ushered in a new era of genomics-informed personalized clinical management. DNA biomarkers have become critical tools for informing routine clinical practice, particularly in metastatic disease where FDA-approved PARPi and immune checkpoint inhibitors are available for patients with DNA damage response defects. Genetic and genomic testing is also transforming management for early-stage prostate cancer. Applications include leveraging genetic risk scores for cancer prevention and family risk management and RNA expression tests for navigating options for definitive local therapy and salvage treatment for localized disease. Finally, ctDNA testing has become a recognized minimally invasive tool for biomarker profiling in advanced prostate cancer, and technological advancements for ctDNA tumor phenotyping are continuing to broaden its potential clinical applicability.

A perennial challenge for biomarker-informed care will be balancing clinical pragmatism (eg, dichotomizing patients into easily actionable subgroups) against the risk of oversimplifying complex tumor biology. In the future, multimodal genomic profiling approaches (eg, incorporating DNA, RNA, methylation, and histone markers) will offer increasingly nuanced biological insight, while new machine learning techniques are poised to harmonize this information and streamline clinical decision making. Ongoing education of healthcare practitioners on genomic tools (and their limitations), shifting management practices, and clinical evidence to support decision making will be increasingly critical to ensure caregivers are informed on how to incorporate molecular testing into their daily practice.

Developing Sustainable Cancer and Aging Programs

Tina Hsu, MD[1]; Rawad Elias, MD[2,3]; Kristine Swartz, MD[4]; and Andrew Chapman, MD[4]

overview

Geriatric assessment (GA) has been shown to decrease toxicity from systemic therapy, improve completion of chemotherapy, and reduce hospitalizations in older adults with cancer. Given the aging of the cancer population, this has the potential to have a positive impact on the care of a large swath of patients seen. Despite endorsement by several international societies, including the American Society of Clinical Oncology, uptake of GA has been low. Lack of knowledge, time, and resources has been cited as reasons for this. Although challenges to developing and implementing a cancer and aging program vary depending on the health care context, GA is adaptable to every health care context from low- to high-resource settings, as well as those in which geriatric oncology is a well-established or just emerging field. We provide an approach for clinicians and administrators to develop, implement, and sustain aging and cancer programs in a doable and sustainable way.

INTRODUCTION

Older adults comprise an ever increasing proportion of those diagnosed with cancer, with aging constituting a driving force for the expected rise in cancer incidence.[1] Demographic shifts because of aging of the American and global populations[2,3] and an increase in the survivorship of older adults with cancer because of more effective therapeutics[4] have led to a dramatic increase in the need for resources and education to meet the needs of this group. The unique challenges that older adults may face when diagnosed with cancer, such as digital literacy and social isolation that were exacerbated by the COVID pandemic, have heightened the health care community's awareness of these special needs.

Management of older adults with cancer is more complex than in their younger counterparts. Older adults become more heterogeneous with aging, with differences in overall health, function, social circumstances, and values and preferences.[5,6] The impact of treatment toxicity for older patients can also be more significant. Although older adults on clinical studies tolerate treatments similarly to their younger counterparts,[7,8] overall older adults are underrepresented in clinical studies, and those included in clinical studies tend to be fitter with less comorbidities than those seen in clinical practice.[9-13] This leads to uncertainty about how best to manage older patients with cancer and results in older adults being less likely to be offered systemic therapy because of concerns about their ability to tolerate treatment.[14,15] Although studies targeting older, and particularly less fit, patients should ideally be conducted to help clinicians and patients make better decisions, geriatric assessment (GA) can help better characterize the health of older adults, predict for treatment toxicity, and improve treatment tolerance.

GA is a multidimensional process including a detailed assessment of an older adult, including physical, functional, and psychosocial aspects of health, to help better determine an older adult's fitness, identify and address impairments, and help improve decision making and management.[16] Domains of a GA include comorbidities, medications, functional status, cognition, nutrition, psychological status, and social supports. A number of randomized clinical studies have shown that GA-directed care can improve outcomes for older adults receiving systemic therapy including decreasing the rates of moderate-to-severe toxicity from chemotherapy and improving completion of chemotherapy.[17-19]

The 2018 American Society of Clinical Oncology (ASCO) Guideline recommends a GA for all adults older than 65 years who are being considered for chemotherapy[20] to assure that shared decision-making conversations are taking place to meet the needs of the individual patient and caregiver. Despite endorsement by multiple international societies, including ASCO, it remains underutilized. Among the respondents to a survey by the ASCO Older Adults Taskforce, who were mostly US academic-based oncologists, only 21% reported using a multidimensional GA as part of the standard care of the older patient with cancer.[21] Similarly, among a group of community-based oncologists, 13% reported using a GA for all their older patients with only 7% using it to inform chemotherapy dose.[22] Most older adults with cancer receiving

PRACTICAL APPLICATIONS

- Geriatric assessment (GA) can help better characterize a patient's overall health, identify impairments, help decision making, and improve patient tolerance of systemic therapy
- GA is adaptable to a variety of health care contexts. Several different models exist to deliver geriatric oncology care (primary geriatric oncologist, consultative, and embedded with oncologic team), and the ideal model depends on local resources.
- Steps in developing a proposal for a cancer and aging program include engaging and making a case to stakeholders, choosing a model of delivery of geriatric oncology care, and making a business case. Messaging should align with priorities of stakeholders, including clinicians, leadership, and administrators.

systemic therapy and surgery, therefore, do not benefit from the known benefits of GA.

Challenges to implementation of GA include lack of knowledge about the assessment and lack of time and resources.[21] Although initiatives to educate health care providers about GA are ongoing, a key step in translating knowledge gained from research into improvement in clinical care is tackling implementation. This includes understanding both logistics of running a clinic but also developing effective strategies to acquire the resources needed to support the running of a geriatric oncology clinic. Developing a business plan and model to persuade stakeholders, particularly those in charge of monies and resources, is not a skill most health care providers are well trained to do. This article seeks to provide health care providers with the tools to develop a business proposal to support the development and ongoing sustainability of a geriatric oncology service.

BENEFITS OF GERIATRIC ASSESSMENT IN THE ONCOLOGIC SETTING

Although the value of GA has long been accepted by geriatricians, its benefits in the oncologic setting have more recently been demonstrated by multiple randomized clinical trials (Table 1). In patients receiving systemic therapy, GA and management have been shown to decrease moderate-to-severe toxicity,[18,19] increase the likelihood of completing chemotherapy,[17] and decrease hospitalizations[25] compared with usual oncologic care. GA and management may also result in improved quality of life (QOL) for patients.[17,25] In patients undergoing surgery, one study of patients older than 65 years treated for gastrointestinal malignancies suggested a decrease in hospital stay and admission to intensive care in patients who received GA and management.[27] No differences in postoperative mortality, rehospitalization rates, postoperative QOL, or function, however, were seen.[27,28] The rationale for building programs specifically to address the needs of older adults with cancer is thus based on well-established and validated data.

MODELS OF CARE

There are many different methods in which care for older adults with cancer can be delivered. Depending on resources, GA can be adapted to each health care context. There are three main models in which geriatric oncology care can be delivered: primary geriatric oncologist centered, consultative models, and embedded models of care.[29,30]

In the primary geriatric oncologist model of care, older adults with cancer are seen by a physician trained in both oncology and geriatrics. The geriatric oncologist is typically supported by a multidisciplinary team including nurses, pharmacists, dieticians, and physiotherapists. In this model of care, the geriatric oncologist develops a management plan for the older patient, taking into account both oncologic factors and data from the GA. This plan includes both an oncologic plan and management of impairments identified by the GA. Advantages of this model include patient recommendations on the basis of a thorough synthesis of both oncologic and geriatric data. Furthermore, the care is managed by one physician and team so that care delivery is seamless. Unfortunately, the number of dually trained geriatric oncologists is low, particularly relative to the ever-growing population of older adults with cancer, limiting the deployment of this model in most centers.

A consultative model is a common method of delivering care to older adults with cancer. In this model, patients are cared for by the primary oncologic team and referred to the geriatrics or geriatric oncology team for further assessment and management. The consultative team assesses and makes recommendations to the primary oncology team and/or primary care provider. These recommendations can range from management of identified impairments from the GA to suggestions about oncologic management (such as up-front dose reduction, dose escalation, and best supportive care). A consultative model may be more feasible for some centers, particularly if it can use existing geriatric-based services. Compared with a primary geriatric oncology model, a consultative model is also able to see and affect significantly more patients. Disadvantages of a consultative model include potential delays in decision making particularly if there is significant demand for the consultative services. In some cases, the GA may have limited impact on the oncologic decision making, if patients are not seen by the consultative team in a timely manner.[31]

TABLE 1. Randomized Studies on GA in Older Adults With Cancer

Study	Population/Setting	Intervention	Outcomes
Systemic therapy studies			
ESOGIA study[24] N = 494	Age: 70+ years ECOG PS: 0-2 Stage IV NSCLC First-line chemotherapy	All patients had a GA (no specific interventions mandated) Allocation of treatment (doublet, single agent, or BSC) either on the basis of combination of age/PS (standard arm) or results of GA	Standard arm: 35.1% carboplatin doublet 64.9% docetaxel GA arm: 45.7% carboplatin doublet 31.3% docetaxel 23% BSC No difference in treatment failure-free survival (3.2 *v* 3.1 months, $P = .32$) or PFS (3.7 *v* 3.4 months, $P = .59$) More frequent treatment discontinuation because of toxicity in the standard arm (11.8% *v* 4.8%, $P = .007$) No difference in OS (6.4 *v* 6.1 months, $P = .87$) Adverse effects higher in the standard arm (93.4% *v* 85.6%, $P = .015$), but no difference in grade 3+ adverse effects QOL in GA arm was higher but only significant at 36 weeks
GAP-70[19] N = 718	Age: 70+ years At least 1 impairment in GA (excluding polypharmacy) Stage III/IV cancer Starting a new chemotherapy regimen Community oncology practices	GA performed in all patients Randomly assigned to summary of GA-based recommendations *v* no summary	Decreased grade 3+ chemotherapy toxicity (50% *v* 71%, $P < .01$) in the GA-directed arm *v* usual care No difference in 6-month OS (71% *v* 74%, $P = .33$)
GAIN[18] N = 600	Age: 65+ years Solid tumor Starting chemotherapy	GA performed in all patients GA-directed care and implementation of interventions *v* summary provided but no interventions offered	Decreased grade 3+ chemotherapy toxicity in the GA-directed arm *v* usual care (50.5% *v* 60.4%, $P = .02$)
INTEGERATE[25] N = 154	Age: 70+ years Solid tumor or DLBCL New line of therapy (any systemic therapy including targeted or immunotherapy)	GA-directed care and follow-up *v* usual care	Improved QOL at 12, 18, and 24 weeks Decreased hospitalizations (incidence rate ratio 0.59, $P < .001$) and ER visits (incidence rate ratio 0.61, $P = .007$) *v* usual care No difference in 6-month OS
GERICO study[17] N = 142	Age: 70+ years Colorectal cancer Adjuvant chemotherapy or first-line palliative chemotherapy	GA-based intervention *v* usual care	Increased rates of chemotherapy completion (45% *v* 28%, $P = .04$) in the GA arm *v* control No difference in severe chemotherapy toxicities (28% *v* 29%, $P = .16$) No difference in rates of chemotherapy discontinuation because of toxicity (20% *v* 30%, $P = .17$) Improved QOL in domains of mobility and burden of illness No difference in rates of hospitalization (30% *v* 32%, $P = .86$)

(Continued on following page)

TABLE 1. Randomized Studies on GA in Older Adults With Cancer (Continued)

Study	Population/Setting	Intervention	Outcomes
5C study[26] N = 350	Age: 70+ years New line of systemic treatment (first or second line, included targeted and immunotherapy) Estimated life expectancy of at least 6 months, ECOG PS: 0-2	Baseline GA plus monthly phone calls × 6 months *v* usual care	No difference in QOL between arms No difference in function (as measured by IADL dependence)
Surgical studies			
Qian study[27] N = 160	Age: 65+ years Surgery for gastrointestinal malignancy	GA and interventions with preoperative and in-hospital involvement of geriatric team *v* usual care	Per-protocol analysis: Shorter hospital stay (5.9 *v* 8.2 days, $P = .02$) Less ICU admission (13.3% *v* 32.4%, $P = .049$) No difference in readmissions at 90 days (16.7% *v* 25%, $P = .36$) No differences in intention-to-treat analyses seen No differences in patient-reported QOL or depression 60 days postoperative. Slightly less moderate to severe symptoms reported in the GA arm.
Hempenius study[28] N = 260	Age: 65+ years Elective surgery for solid tumor Groningen Frailty Indicator score of 3+ (frail)	Preoperative GA, individualized treatment plan, and daily visits during hospital stay *v* usual care	No difference in mortality No difference in rehospitalization No difference at 3 months posthospital discharge in function (as measured by ADL), return to independent living situation, use of supportive care, cognitive functioning No difference in QOL 3 months postdischarge

NOTE. Reprinted with permission.[23]

Abbreviations: BSC, best supportive care; DLBCL, diffuse large B-cell lymphoma; ECOG, Eastern Cooperative Oncology Group; ER, emergency room; GA, geriatric assessment; ICU, intensive care unit; NSCLC, non–small-cell lung cancer; OS, overall survival; PFS, progression-free survival; PS, performance status; QOL, quality of life.

Finally, some models of care use a geriatrician, nurse practitioner, or physician assistant, with expertise in geriatrics or geriatric oncology, who works within the primary oncologic team. This person will often administer and summarize the results of the GA making recommendations to the treating oncologist. An embedded model of care allows the integration of GA directly into the oncology treatment plan. This person has expertise in geriatrics and an understanding of oncology principles facilitating oncology-specific communication.

The composition of the geriatric oncology care team can vary widely depending on local resources. Some teams consist of a single clinician who performs the GA while others include multiple health care providers from several disciplines, such as nursing, physiotherapy, occupational therapy, social work, pharmacy, navigation, and nutrition. In a recent survey of 19 geriatric oncology programs in Canada and the United States, 10 have a primary geriatric oncologist model, seven have both a geriatrician and an oncologist involved, while the remaining were run by either a geriatrician or an oncologist.[32] The majority of clinics have nurses (68.4%) and pharmacists (63.2%), but less than half have physiotherapists and nutritionists involved. Two clinics did not have any support from Allied health. Although the ideal delivery of geriatric oncology may include assessment and input by a multidisciplinary team, the delivery of geriatric oncology models of care is very adaptable to locally available resources and context.

CHALLENGES IN DEVELOPING CANCER AND AGING PROGRAMS

The development of a successful geriatric oncology implementation strategy begins with identifying barriers and understanding which challenge, when overcome, can help achieve the intended goal.

Major barriers to the implementation of GA include (1) lack of knowledge and training, (2) uncertainty about tools to use, (3) lack of resources, and (4) time to carry out the assessments in a busy oncology clinic.[21] Additionally, geriatric expertise is scarce and therefore cannot form the basis of a wide-scale implementation.[33,34] Geriatric education among oncology providers can improve the dissemination of cancer and aging practices in daily cancer care. Multiple efforts are ongoing to address this; however, education on its own is unlikely to propel the implementation of clinical cancer and aging practices without additional tangible resources. The ASCO Older Adults Taskforce survey showed that although those who were aware of the ASCO geriatric oncology guidelines were twice as likely to perform specialized assessment of older patients, they still faced significant challenges.[21] In fact, the implementation of the GA in clinical practice is seen by most providers as a complex procedure that requires time, skills, and a level of resources that are not available in most routine cancer care settings.[21,22,35] Therefore, a comprehensive approach that addresses all these barriers is essential in the design of successful implementation strategies and certainly a critical part in the efforts to take the clinical practice of geriatric oncology beyond select high-resource settings.

Given the time intense nature of GA, a modified form is one strategy to make the assessment more feasible and accessible to the larger community. A modified GA has been developed using a set of multidimensional screening tools.[20,36-38] This GA is mostly based on patient-reported information and requires limited involvement by health care providers, usually only to complete physical performance and cognitive assessments.[39] More importantly, because of its simplified aspect, health care providers of any background can be trained to perform this GA format which allows the dissemination of geriatric evaluations in the oncology practice in a scalable fashion that is not directly dependent on the presence of local geriatric expertise.[39-42] This strategy is most successful when the implementation of the GA is done using an electronic platform and particularly if incorporated into the electronic medical record system, which allows an automated processing of the data that facilitates the identification of the geriatric impairments and proposes targeted interventions.[37,43,44]
